Severe sepsis is a medical emergency. The first priority should be to assess and address abnormalities in the "A,B,Cs": airway, breathing, and circulation. In many instances, the clinical assessment of tissue perfusion and response to therapy can be aided by monitoring devices and laboratory measurements (Table 46-4). Once immediate stabilization has been accomplished, the source of the infection should be established and controlled, and specific antimicrobial agents should be administered. After stabilization, source control, initiation of appropriate antimicrobial agents, and further support for dysfunctional organs, disease-specific interventions should be considered. The Surviving Sepsis Campaign is a collaborative effort by the SCCM, European Society of Intensive Care Medicine, and the International Sepsis Forum. The group's primary aim is to decrease the relative mortality rate of sepsis by 25% over a 5-year period. To reach this objective, the group has a number of goals. One of these is to improve the therapy of patients with severe sepsis. To achieve this, they reviewed published literature and achieved consensus on a number of management issues for patients with severe sepsis. These are described in the published Surviving Sepsis Campaign Practice Guidelines and listed in Table 46-5 and Figure 46-6.

TABLE 46-4 Clinical, Hemodynamic, and Ventilatory Goals for the Treatment of Patients with Severe Sepsis

Clinical goals
Alert and oriented
Normal skin color, warmth, perfusion and capillary refill
Able to breathe spontaneously
Vasopressor free
Hemodynamic goals
Adequate perfusion pressure (MAP > 65 mm Hg)
Cardiac index ≥ 2.5 L/min per square meter
Urinary output ≥ 1.0 mL/kg per hour
Lowest filling pressure and vasoactive drug dose necessary to achieve the above
Ventilatory goals
PF ratio ≥300
Sa_{O_2} >88%
FI_{O_2} <0.4 to 0.5
PEEP ≤5 cm H_2O
RR: Vt ≤ 105 breaths/min per liter

ABBREVIATIONS: FI_{O_2}, fraction inspired O_2; MAP, mean arterial pressure; PEEP, positive end-expiratory pressure; PF, partial pressure of O_2 to fraction inspired O_2; RR, respiratory rate; Sa_{o_2}, arterial oxygen saturation; Vt, tidal volume.

Initial Resuscitation

The initial therapeutic intervention in patients with severe sepsis is to reverse organ hypoperfusion. Patients with severe sepsis often have a relative intravascular hypovolemia. As a consequence, initial therapy often consists of the rapid administration of large amounts of fluids.

FLUID RESUSCITATION

Large amounts of fluids may be required to restore tissue perfusion and oxygen delivery. In some instances, correction of large fluid deficits may require at least 6 to 10 L of crystalloids.[96] Fluid resuscitation is often titrated by the responses of clinical end points of heart rate, BP, and urine output.[97] Appropriate amounts of fluid will improve the cardiac index by 25% to 40%. In approximately 50% of patients with severe sepsis who present with hypotension, fluid resuscitation alone will normalize BP and restore hemodynamic stability. Hemodynamic monitoring should be considered for patients who do not respond rapidly to the initial fluid challenge and those with a history of coronary heart disease.

CHOICE OF FLUIDS

There has been an ongoing debate as to whether fluid resuscitation is best accomplished with crystalloids or colloids. Choi et al conducted an evaluation of randomized clinical trials of crystalloids versus colloids in adult patients requiring fluid resuscitation.[98] They reported that there were no apparent differences in the incidences of pulmonary edema, mortality rate, or length of stay in patients who received crystalloid or colloid fluid resuscitation. In contrast, Schierhout et al compared crystalloid with colloid resuscitation in 26 clinical trials using stringent selection criteria.[99] They reported that resuscitation with colloids was accompanied by an increased absolute risk of mortality of 4% (95% confidence interval = 0% to 8%). Because colloids were not associated with improved survival rate and are significantly more expensive

TABLE 46-5 Synopsis of Major Surviving Sepsis Campaign Practice Guidelines

Intervention	Guidelines/Recommendations
Initial resuscitation	1. Resuscitate within 60 min to achieve MAP ≥65 mm Hg, urine output ≥0.5 mL/kg per hour, and CVP of 8–12 mm Hg (12–15 mm Hg in mechanically ventilated patients) 2. Packed red blood cells or dobutamine to achieve Scv_{O_2} ≥70%
Fluids	1. Crystalloids or colloids 2. Packed red blood cells to achieve a target Hb of 7–9 g/dL
Source control and antibiotics	1. The site of infection should be rapidly identified and appropriate source control measures instituted 2. When the specific infecting organism is unknown, empiric antibiotics should be administered within the first hour of treatment
Mechanical ventilation	1. 6 mL/kg tidal volume (ideal body weight) for patients with ALI/ARDS 2. Avoid increased VT plus increased PP, maintain end-expiratory PP <30 cm H_2O 3. PEEP should be used to avoid oxygen toxicity in patients treated with high $F_{I_{O_2}}$ 4. Consider prone positioning in patients with dangerous $F_{I_{O_2}}$ levels
Drotrecogin alfa (activated)	1. Indicated for patients at high risk of death 2. No absolute contraindication 3. Administer as soon as possible after "high-risk of death" identified
Steroids	1. Indicated for patients with vasodepressor-dependent shock despite fluids 2. Administer 200–300 mg/d × 7 d by continuous intravenous infusion or in divided doses at 6-h intervals 3. The following steroid-related issues remain unresolved: ACTH stimulation test, weaning, mineralocorticoids, need to discontinue after resolution of shock
Glycemia control	1. Maintain blood glucose <150 mg/dL with insulin and glucose[a] 2. Monitor glucose concentrations at the bedside
Sedation	1. Intermittent as required 2. Continuous with daily interruption

[a] The Surviving Sepsis Campaign group expressed concerns that an initial recommendation for strict glycemic management (80 to 110 mg/dL) might be so stringent that it would not be adopted.
ABBREVIATIONS: ACTH, corticotropin; ALI, acute lung injury; ARDS; acute respiratory distress syndrome; CVP, central venous pressure; $F_{I_{O_2}}$, fraction inspired O_2; Hb, hemoglobin; MAP, mean arterial pressure; PP, plateau pressure; Scv_{O_2}, O_2 saturation of blood in the superior vena cava or right atrium; VT, tidal volume.

than crystalloids, they concluded that the evidence does not support the continued use of colloids for volume replacement in the critically ill. The crystalloid versus colloid controversy continues.[100] However, in the presence of normal oncotic pressure, most patients are managed with crystalloids; patients requiring osmotic support can also be treated with colloids such as 25% albumin.[100]

Pyruvate is a potent antioxidant and free radical scavenger.[101] Although it is unstable in aqueous solution, its ethyl derivative has greater stability. Ringer ethyl pyruvate has been evaluated in different preclinical models and has been shown to improve survival rate and decrease inflammatory markers in acute endotoxemia, acute bacterial peritonitis, hemorrhagic shock, and mesenteric ischemia/reperfusion injury.[102] There is some basic science and clinical evidence that suggests that infusions of small amounts of hypertonic saline may have some future role in the resuscitation of patients with severe sepsis. In 1980, Velasco et al reported that administration of a hypertonic solution of 7.5% saline had beneficial effects in a canine model of hemorrhagic shock.[103] Experimental studies in models of severe sepsis confirmed beneficial effects similar to those originally reported. Small clinical studies have also reported beneficial effects on cardiac indices, SVR, and oxygen transport.[104,105] Although it was initially proposed that the beneficial effect of this intervention was on cardiac preload, increasing evidence suggests that its effects extend far beyond the osmotic properties of hypertonic saline. Hypertonic saline also appears to improve myocardial contractility, reduce endothelial and interstitial edema, improve microcirculatory blood flow, and exert immunomodulatory activity.[106] Its effects on endothelial cell function and microvascular blood flow are particularly interesting in light of the growing evidence of endothelial cell dysfunction in patients with severe sepsis. Endothelial cell edema can serve as a surrogate for endothelial injury and potential dysfunction. Edema of the endothelial cells occurs in the initial phases of hypovolemia. Small infusions of hypertonic saline can reduce endothelial volume by approximately 20%, increase tissue

perfusion, and improve cellular function.[107] Microcirculatory blood flow is also improved because the hypertonic fluid produces hemodilution and decreased blood viscosity.

Patients with severe sepsis very often have dramatic decreases in hemoglobin (Hb) levels. This is secondary to a number of factors including hemodilution and impaired erythropoiesis. Further, fluid resuscitation may decrease Hb levels by up to 1 to 3 g/dL.[97] This degree of anemia is tolerated by most patients because the resultant decrease in blood viscosity reduces afterload and improves venous return. Potential benefits of transfusion in this population include an increase in arterial oxygen content and an improvement in systemic oxygen availability. However, transfusions of packed red blood cells have several potentially detrimental effects. These include rheologic changes that decrease red blood cell deformability and increase blood viscosity, immunosuppression, disease transmission, risk of nonhemolytic transfusion reactions, and the fact that oxygen delivery is not immediately restored after transfusion because the infused red blood cells must restore their depleted 2,3-diphosphoglycerate levels to improve oxygen release.

Hebert et al conducted a multicenter, controlled trial of restrictive versus liberal transfusion strategies in a population of critically ill patients.[108] They enrolled 838 euvolemic, critically ill patients who had Hb concentrations below 9.0 g/dL within 72 hours of admission to the ICU. Patients were then randomized to a restrictive transfusion strategy in which Hb concentrations were maintained within the range of 7.0 to 9.0 g/dL and transfusions were administered only if the Hb dropped below 7.0 g/dL or to a strategy in which Hb levels were maintained in the range of 10.0 to 12.0 g/dL and transfusions were given if the Hb dropped below 10.0 g/dL. Even though the overall 30-day mortality rate was similar in the two groups, patients who were less severely ill as stratified by a score no higher than 20 on the Second Acute Physiology and Chronic Health Evaluation (APACHE II) and patients who were younger than 55 years had a significantly lower in-hospital mortality rate (22.2% versus 28.1%; $p = 0.05$). This benefit did not extend to patients with acute coronary syndromes. However, Rivers et al recently released the results of a clinical trial of early goal-directed therapy (EGDT) that suggest that there may be some benefit of Hb concentrations of 10 g/dL or greater, at least as part of a strategy of early resuscitation of patients with severe sepsis and septic shock.[109] Although these results are discussed below, they emphasize the importance of proper tissue oxygenation.

At this time, the optimal Hb level for patients with severe sepsis is unclear. The default transfusion threshold currently used by many ICUs is a conservative one of 7.0 g/dL, unless patients are elderly and have a history of myocardial infarction, in which case a more liberal threshold of 10 g/dL is supported by an 80,000-patient observational study by Wu et al.[110]

CARDIORESPIRATORY SUPPORT

VASOPRESSORS

Patients who remain hypotensive despite aggressive fluid resuscitation are candidates for pressor support; however, vasopressors should not be considered in lieu of adequate fluid resuscitation. BPs determined by a cuff are often inaccurate, and an arterial cannula is usually inserted to monitor intra-arterial BP in patients receiving vasopressor therapy. Many agents with different pharmacodynamic properties are available to treat the hypotensive patient with severe sepsis (Table 46-6). Patients receiving pressor support should be monitored to ensure that treatment restores perfusion to vital organs without compromising stroke volume. Surrogates of improved peripheral perfusion and splanchnic blood flow include an increase in MAP (≥65 mm Hg is often used), warming of the extremities, and resolution of cutaneous mottling and impaired capillary refill. Increased urinary output and improved mentation are other good surrogates of adequate systemic perfusion. Goals should be a urine output greater than 0.5 mL/kg per hour and an alert and oriented cognitive status.

One of the obstacles to determine the "best" pressor in patients with severe sepsis is the lack of large-scale, randomized controlled trials. Most studies of various pressor agents have been observational in nature. Norepinephrine appears to be the preferred agent for initial BP support in patients

TABLE 46-6 Vasoactive Drugs: Usual Hemodynamic Effects[a]

Drug	Dose	Paop	Qt	BP	SVR	Comments
Norepinephrine	2–30 μg/min	↑	↑	↑↑	↑↑	Usual first-line drug; more potent than dopamine
Vasopressin	0.01–0.04 U/min	↔	↔	↑	↑	Caution advised pending large clinical trials; occasionally effective when catecholamines fail
Dobutamine	2–20 μg/kg/min	↓	↑	↓ or ↑	↓	Most useful when Qt is low, typically due to cardiac dysfunction. Can cause hypotension, especially when hypovolemia is present
Phenylephrine	2–10 μg/kg/min	↑	↓	↑↑	↑↑	Increase in BP purely by peripheral vasoconstriction will reduce Qt; best used when Qt is elevated
Dopamine	2–20 μg/kg/min	↑	↑	↑	↔↑	Not effective in renal protection
Epinephrine	5–30 μg/min	↑↔	↑↑	↑↑	↑	Effects and indications similar to norepinephrine, but more often worsens lactic acidosis

[a] Dose of all agents is generally titrated upward from the lower range until a clinically desired hemodynamic effect is achieved.
ABBREVIATIONS: BP, blood pressure; Paop, pulmonary artery occlusion pressure; Qt, cardiac output; SVR, systemic vascular resistance.

with severe sepsis who remain hypotensive despite an adequate fluid challenge. Because of its pure α-adrenergic activity, phenylephrine may be useful in patients with coronary heart disease who may be at risk for tachycardia or arrhythmias from agents with β-agonist properties. Meadows et al evaluated the effects of norepinephrine on reversal of shock in 10 patients with severe sepsis.[111] Patients with severe sepsis who remained hypotensive and oliguric despite expansion of their plasma volume to a target Paop and infusions of increasing doses of dopamine and dobutamine were then treated with norepinephrine monotherapy. After discontinuation of dopamine and dobutamine, an infusion of norepinephrine significantly elevated the MAP, reversed the hypotension, and increased the SVR, left ventricular stroke work index, and urinary output without significantly affecting heart rate. In a separate study, Martin et al evaluated the effect of norepinephrine on the outcome of patients with septic shock.[112] These investigators evaluated the effects of various independent variables that might affect outcome in an observational cohort of 97 adult patients with severe sepsis. Patients who received norepinephrine as a component of their hemodynamic support had a significantly lower hospital mortality rate than did those treated with large-dose dopamine and/or epinephrine (62% versus 82%; 95% confidence interval = 0.68, range = 0.54 to 0.87; $p < 0.001$). Further support for the use of norepinephrine as the pressor of choice was provided by Di Giantomasso et al.[113] They evaluated the effects of norepinephrine on vital organ blood flow in a sheep model. They concluded that norepinephrine infusion does not induce ischemia in vital organs in normal mammalian circulation. In addition, infusion of norepinephrine significantly increases coronary and renal blood flow, with associated improvements in urine output and serum creatinine.

Over a short period, tachyphylaxis may appear as vascular smooth muscle becomes resistant to the effects of norepinephrine and other catecholamines. Vasopressin is involved in cardiovascular homeostasis. Normally, it plays only a minor role in BP control. However, in hypotensive patients, vasopressin released under baroreflex receptor control stimulates vascular smooth muscle and helps restore BP. During the initial phases of severe sepsis-induced hypotension, high levels of vasopressin contribute to the effects of endogenous catecholamines in attempting to restore BP. However, as shock worsens, plasma concentrations of vasopressin decline significantly and become inappropriately low for the patient's MAP, presumably because neurohypophyseal stores of the hormone are depleted in the face of constant baroreceptor stimulation. In support of this hypothesis, Landry et al demonstrated by immunohistochemistry in a canine model that, after 1 hour of hemorrhagic shock, the stainable hormone was essentially absent in tissue from the animal's neurohypophysis.[44] In patients with severe sepsis and other forms of vasodilatory shock, administration of vasopressin to produce concentrations similar to those identified during acute episodes of hypotension increases arterial BP by 25 to 50 mm Hg. It has been postulated that the marked sensitivity of BP to vasopressin in this situation is multifactorial in origin: (1) in patients with severe sepsis and established hypotension, plasma levels of vasopressin are low and its receptors on vascular smooth muscle are unoccupied; (2) patients with severe sepsis may have dysfunction of the sympathetic nervous system and be more responsive to noncatecholamine pressor agents; (3) plasma concentrations of norepinephrine are markedly elevated in patients with vasodilatory shock, and vasopressin potentiates the effects of the catecholamine; (4) vasopressin directly activates K_{ATP} channels in vascular smooth muscle, and; (5) vasopressin directly and indirectly inhibits the vasodilatory activity of NO.[44] Studies have supported the role of vasopressin in this situation. Landry et al reported that an infusion of 0.04 U/min of vasopressin in 10 hypotensive patients with severe sepsis increased arterial BP from a mean of 92/52 mm Hg to 146/66 mm Hg.[114] Importantly, however, withdrawal of vasopressin resulted in hypotension in six patients in whom it was the only pressor. In a blinded study of 24 patients with septic shock, Patel et al compared the effects of norepinephrine and vasopressin.[115] Doses of vasopressin and norepinephrine, starting at 0.01 U/min and 2 μg/min, respectively, were titrated to maintain a clinically acceptable MAP. Treatment with vasopressin produced an important catecholamine-sparing activity ($p < 0.001$), and its use was accompanied by a larger volume of urine output and an improved creatinine clearance ($p < 0.05$). Although these preliminary observations require a large-scale randomized trial to confirm the beneficial effects of vasopressin in patients with vasodilatory shock, critical care specialists are commonly treating patients with severe sepsis who are refractory to catecholamines with vasopressin.

INOTROPIC AGENTS

Patients with severe sepsis have a normal to low BP, elevated cardiac index, and decreased SVR. However, myocardial depression is common.[97] It is characterized by a decreased EF, ventricular dilation, impaired contractile response to volume loading, and a low ratio of peak systolic pressure to end-systolic volume. In patients who are unable to maintain an adequate cardiac index, MAP, mixed venous oxygen content, and/or urine output, an inotropic agent such as dobutamine may be useful.[109] However, because inotropic agents can produce clinically significant tachycardia in patients who have not been adequately resuscitated with fluid, it is important to ensure that the dobutamine candidate has adequate or increased intravascular volume. In addition, the increased myocardial oxygen consumption in patients treated with an inotrope can produce angina or an acute coronary syndrome.

OXYGEN AND MECHANICAL VENTILATION

Sepsis places significant stress on the respiratory system. At presentation, most patients are tachypneic and hypoxemic. These clinical manifestations result from a combination of factors including increased oxygen requirements, decreased pulmonary compliance, increased airway resistance, and impaired efficiency of the respiratory and other muscles.[89] Approximately 88% of patients with severe sepsis will require ventilatory support, generally for 5 to 10 days. Therefore, the patient's arterial oxygen saturation (Sa_{O_2}) and/or the Pa_{O_2} should be evaluated and steps taken to maintain the Sa_{O_2} at 88% or greater by increasing the amount of FI_{O_2} or improving respiratory physiology with institution and adjustments of mechanical ventilation. Prone positioning has the potential to improve oxygenation in critically ill patients with severe sepsis. Position-related changes in respiratory physiology are a function of changes in end-expiratory lung volume, ventilation-perfusion matching, and chest wall mechanics. However, although the maneuver improves oxygenation,

Gattinoni et al were unable to demonstrate an advantage with respect to mortality rate of ARDS patients when using a protocol of prone positioning for 6 hours/day over 10 days.[116] The disconnect between improved oxygenation and mortality rate in this study may be a function of several trial design considerations, including statistical power, low severity of illness of many of the enrolled patients, and the duration of prone positioning employed.[117]

Most patients with severe sepsis will require an $F_{I_{O_2}}$ greater than 50%. Although high-flow oxygen through a face mask can provide an $F_{I_{O_2}}$ in the 70% range, in general, patients with severe sepsis requiring high levels of oxygen supplementation should be treated with positive pressure ventilation. Importantly, the clinician should be proactive and recognize the signs of impending respiratory failure, so that patients can be intubated early and receive respiratory support before they aspirate, develop hypoxemic encephalopathy, or develop a potentially fatal arrhythmia. During intubation and immediately thereafter, the patient should receive an $F_{I_{O_2}}$ in the 95% to 100% range to maximize Sa_{O_2}. However, to avoid potential oxygen toxicity through the formation of free radicals and other mechanisms, the $F_{I_{O_2}}$ should be tapered to no greater than 50% as soon as possible, and Sa_{O_2} should be maintained above 88%.

Oxygen delivery (Q_{O_2}) is a function of $\dot{Q}_T$, Hb level, and Sa_{O_2} ($Q_{O_2} = 10 \times \dot{Q}_T \times [1.34\ Hb \times Sa_{O_2} + 0.003 \times Pa_{O_2}]$). If filling pressures are low, the $\dot{Q}_T$ can be raised by fluids; alternatively, patients who do not respond to fluids and have normal or elevated filling pressures may benefit from an inotrope. Although it is important that Q_{O_2} be adequate, the therapy required to achieve supranormal Q_{O_2} may be injurious in some patients.[118] In a prospective randomized study of 109 critically ill patients, Hayes et al attempted to maximize D_{O_2} by volume expansion.[119] Patients failing volume expansion alone were randomized to a control group or a treatment group. The intervention group was treated with intravenous dobutamine (5 to 200 μg/kg per minute). All nine patients who responded to volume replacement alone survived to leave the hospital. The predicted risk of death for the remaining 100 patients was 34%. However, the in-hospital mortality rate was lower in the control group (34%) than in the supranormal Q_{O_2} (54%) group, suggesting that the aggressive efforts to increase tissue Q_{O_2} were detrimental.

One reasonable ventilatory strategy in patients requiring mechanical ventilation is to employ assist-control ventilation to provide 75% to 100% of the minute ventilation. Positive end-expiratory pressure can be employed to reduce the risk of ventilator-induced injury and reduce the $F_{I_{O_2}}$ required to maintain the Sa_{O_2} at 88% or greater. The results of the ARDSNet Tidal Volume Study indicated that a lung protective strategy using tidal volumes of 6 mL/kg (versus 12 mL/kg) can significantly improve outcomes in patients with ALI or ARDS.[61] Patients who were randomized to the lower tidal volume had a significantly lower mortality rate (31.0% versus 39.8%; $p = 0.007$), more days without a ventilator (12 versus 10; $p = 0.007$), more days without organ failure (15 versus 12; $p = 0.006$), and lower levels of the proinflammatory cytokine, IL-6. It is important that every effort be made to reduce mechanical ventilation settings to detect readiness for extubation from the ventilator. The spontaneous breathing trial is the best indicator of the patient's ability to breathe without mechanical support.[120] Ely et al reported that a spontaneous breathing trial protocol using respiratory therapists and nurses significantly reduced the number of days that patients spent on a ventilator (1 versus 3; $p < 0.001$), decreased the complication rate by half, and cut the costs of ICU care by more than $5000 per patient.[121,122]

IMPORTANCE OF EARLY GOAL-DIRECTED THERAPY

Rivers et al conducted a randomized, nonblinded trial of standard therapy versus early goal-directed therapy (EGDT) in patients with SIRS criteria and systolic BP no higher than 90 mm Hg and who were unresponsive to 20–30 mL/kg of crystalloid or had a lactate concentration of 4 mmol/L or greater.[109] Patients were randomized into two groups and treated by protocol. Hemodynamic goals were identical in the two groups: central venous pressure between 8 and 12 mm Hg, vasopressors for a systolic BP of 90 mm Hg or lower, urinary output maintained at 0.5 mL/kg per hour or greater, and a MAP established at 65 mm Hg or higher. Patients in the group randomized to EGDT also received an oximetric central venous catheter capable of measuring the saturation of blood in the superior vena cava or right atrium (Scv_{O_2}) and were treated early in the emergency department according to protocol for at least 6 hours before they were transferred to the first available inpatient bed. If the Scv_{O_2} of patients in the EGDT group was less than 70%, they received transfusions of packed red blood cells until their HCT was at least 30%. If the Scv_{O_2} was still less than 70%, patients were treated with dobutamine up to a dose of 20 μg/kg per minute. If necessary, mechanical ventilation and sedation were employed to raise Scv_{O_2} to the goal concentration, and interventions were directed at lowering oxygen consumption and, hence, raising the saturation of blood returning to the right heart.

Patients treated with EGDT received approximately 1.5 L of additional fluid during the first 6 hours (5000 versus 3500 mL); they also received significantly more transfusions of packed red blood cells (PRBCs; 64.1% versus 18.5%; $p < 0.001$). Vasopressor support was not significantly different in the two groups during the first 6 hours; however, the EGDT group received significantly fewer vasopressors after 7 hours than did the standard group ($p = 0.03$). Whereas fewer than 1% of the standard therapy group received an inotrope, dobutamine was administered to approximately 14% of the EGDT group. Early EGDT significantly affected outcomes. Patients treated in the EGDT arm of the protocol had a significant benefit in mortality rate at 28 days (30.5% versus 46.5%; $p = 0.009$) and at 60 days (44.3% versus 56.9%; $p = 0.03$). The number needed to treat (NNT) to prevent one death with EGDT was six to eight patients. The results of this study indicated the importance of early identification of patients with severe sepsis at high risk for cardiovascular collapse and implementation of measures designed to restore equilibrium between oxygen demand and supply. The specific features of the protocol that contributed to the benefit with respect to mortality rate (e.g., the relatively large quantity of PRBCs and dobutamine used in the intervention group and the titration of Scv_{O_2} using oximetric central venous catheters) require further study.

INFECTION MANAGEMENT

Infection management consists of source control and the administration of anti-infectives that cover the spectrum of microbial organisms suggested by the patient's initial presentation. Importantly, appropriate cultures should be obtained; in some cases, this is accomplished during the process

of source control (e.g., removal of an infected intravascular device).

SOURCE CONTROL

The term *source control* has replaced *surgical intervention* to describe measures to control the source of infection. This change in terminology is intended to highlight the fact that interventions falling into this category are not limited to surgery. Source control can be divided into three broad categories: (1) drainage of an abscess, (2) débridement of devitalized and infected tissue, and (3) removal of foreign bodies colonized by pathogens and diversion, repair, or excision of an infected focus in a hollow viscus.[123] Attention directed to source control should be included in the initial management of all patients with severe sepsis. Whereas septic foci resulting from a ruptured appendix or a perforated duodenal ulcer may be obvious, other presentations may be subtle. For example, a patient with CAP who remains septic may have an associated empyema. The timing of source control measures must take the patient's clinical condition into account. For example, removal of an infected central line should be performed immediately. Alternatively, transferring an unstable patient to the medical imaging suite, where monitoring may not be as intense, for percutaneous drainage might be best deferred until resuscitative measures have restored cardiopulmonary homeostasis. In other instances, surgical intervention should be early in aggressive disease processes in which early intervention clearly leads to improved outcomes such as necrotizing fasciitis.

ANTI-INFECTIVE THERAPY

Several general principles govern antibiotic therapy of the patient with severe sepsis (Table 46-7). Antibiotic therapy is delayed in approximately 10% of cases, a situation responsible for a mortality rate that can be 10% to 15% higher than that in patients treated early.[124,125] Iregui et al evaluated the basis and consequences of delayed appropriate antibiotic therapy in a study of 107 consecutive patients with VAP.[126] In 75.8% of patients, delays of 24 hours or longer were due to the simple failure to write the order for antibiotics after the diagnosis was made. Microbial resistance could explain only 18.2% of the cases in which therapy was classified as inappropriate. The initial delay of appropriate antibiotic therapy was associated with a significant 41.1% increase in hospital mortality rate from VAP ($p < 0.01$). Kreger et al evaluated the epidemiology and response to therapy in 612 patients with gram-negative bacteremia.[127] They reported that appropriate antibiotic therapy reduced the frequency at which shock developed by approximately 50%. In addition, even after shock had developed, appropriate antibiotic therapy significantly decreased mortality rates. As essential as antimicrobial therapy is, the mortality rate of patients with severe sepsis treated with appropriate antibiotics remains unacceptably high. Pittet et al analyzed bedside predictors of mortality rate in 176 ICU patients with bacteremic sepsis and found that appropriate antibiotic therapy reduced mortality rate by 11%.[124] Nevertheless, in-hospital mortality rate remained at an unacceptable 43%. Kollef et al reported even stronger evidence for the importance of appropriate antibiotic therapy.[128] The infection-related mortality rate for patients receiving inadequate antimicrobial therapy was significantly greater than that seen in patients treated appropriately (42.0% versus 17.7%; $p < 0.001$). Analysis of their data in a logistic regression model indicated that inadequate antimicrobial therapy of infection is the most important independent determinant of hospital mortality rate in critically ill patients admitted to a medical or surgical ICU. Table 46-8 lists some general guidelines for the selection of initial antibiotics for patients with severe sepsis.

TABLE 46-7 Principles of Anti-infective Therapy of the Patient with Severe Sepsis

Obtain cultures of suspected sources of infection
Promptly administer parenteral antibiotics
Antibiotic selection(s) should be based on the following:
Most probable diagnosis and suspected pathogens
Site of acquisition (ie, community or nosocomial)
Results of Gram stain
History of prior antimicrobial treatment
Known resistance patterns in the community or institution
Tissue penetration of drug
Comorbidities
Patient's hepatic and renal function
History of allergy to antibiotics
Potential toxicity
Risk of influencing resistance
Initial therapy should be broad spectrum and progressively narrowed as microbiological data become available
Patients should be monitored closely for
Evidence of a response
Development of drug toxicity
Selection of antibiotic-resistance strains
Appearance of a superinfection

PNEUMONIA

Major potential pathogens in patients with serious CAP include *S. pneumoniae*, *Haemophilus influenzae*, and *Legionella* species (see Chap. 51). Initial therapy can be an extended-spectrum cephalosporin or a β-lactam/β-lactamase inhibitor combination plus a macrolide (azithromycin, clarithromycin, or erythromycin) or an antipseudomonal fluoroquinolone (ciprofloxacin, levofloxacin, or gatifloxacin) alone. If there are concerns about infection by a strain of drug-resistant *S. pneumoniae*, the β-lactam should be cefotaxime or ceftriaxone. Notably, some researchers have advised against fluoroquinolone monotherapy in this situation because most therapeutic trials studying these drugs excluded seriously ill patients.[129] For patients with structural disease of the lung (e.g., bronchiectasis), an antipseudomonal regimen would be an excellent one. If aspiration is suspected, treatment should be clindamycin, metronidazole, or a β-lactam/β-lactamase inhibitor combination, with or without fluoroquinolone. Patients allergic to β-lactams can be treated with a fluoroquinolone with or without the addition of clindamycin. The most probable organisms in a patient with nosocomial pneumonia are *S. aureus* and aerobic gram-negative rods. A possible initial therapy for these patients might be an antipseudomonal β-lactam (cefepime, imipenem/cilastatin, meropenem, or piperacillin/tazobactam) plus an intravenous antipseudomonal fluoroquinolone such as ciprofloxacin.

INTRA-ABDOMINAL INFECTIONS

In serious community-acquired intra-abdominal infections, the major pathogens are most likely to be *E. coli*, *Klebsiella pneumoniae*, and *Bacteroides fragilis* (see Chap. 89). Initial treatment in the ICU to cover these organisms may

TABLE 46-8 Empirical Antibiotics for Initial Treatment of Adults with Severe Sepsis

Suspected Source of Sepsis	Reasonable Initial Antimicrobial Regimen	Alternative Agents
Primary bacteremia (no source evident): normal host	Third-generation cephalosporin Cefotaxime 2 g IV q 6 h *or* Ceftriaxone 2 g IV q 12 h *or* Ceftizoxime 2 g IV q 8 h	Nafcillin and gentamicin, piperacillin/tazobactam, imipenem
Primary bacteremia (no source evident): IV drug user	Ceftazidime 2 g IV q 8 h and nafcillin 2 g IV q 4 h	Piperacillin/tazobactam or imipenem and gentamicin
Febrile neutropenia	Monotherapy: cefepime 2 g IV/IM q 8–12 h Duotherapy: piperacillin 3 g IV q 4 h plus gentamicin 1.5 mg/kg IV q 8 h Vancomycin indicated: add cefepime ± aminoglycoside	Ceftazidime or cefepime plus nafcillin, imipenem or cefepime plus gentamicin
Bacterial meningitis	Ceftriaxone 2 g IV/IM q 12–24 h; if patient >50 y, add ampicillin 3 g IV q 4–6 h	Gram-positive cocci: vancomycin plus broad-spectrum cephalosporin Gram-negative cocci; penicillin G Gram-positive bacilli: ampicillin (or penicillin) plus an aminoglycoside Gram-negative bacilli: broad-spectrum cephalosporin plus aminoglycoside
Cellulitis/erysipelas/fasciitis	Limb-threatening: ciprofloxacin 400 mg IV q 12 h plus clindamycin 900 mg IV q 8 h Life-threatening: imipenem/cilastin 1 g IV q 6–8 h	Vancomycin, metronidazole, aminoglycoside
Community-acquired acute bacterial pneumonia	Third-generation cephalosporin in combination with a fluoroquinolone or a macrolide	Piperacilin/tazobactam plus a fluoroquinolone or a macrolide
Hospital-acquired acute bacterial pneumonia/ventilator-associated pneumonia	Ceftazidime 2 g IV q 8 h and gentamicin 1.5 mg/kg IV q 8 h ± macrolide	Ciprofloxacin ± vancomycin
Mixed aerobic/anaerobic infections Intra-abdominal infections Mediastinitis Fulminant aspiration pneumonia Necrotizing cellulitis and fasciitis Septic abortion, endometritis	Third-generation cephalosporin and clindamycin 900 mg IV q 8 h; *or* Metronidazole 500 mg IV q 8 h plus ampicillin 2 g IV q 4 h plus gentamicin 1.5 mg/kg IV q 8 h	Imipenem or piperacillin/tazobactam plus gentamicin, cefoxitin plus gentamicin, clindamycin plus co-trimoxazole
Urinary tract infection	Gentamicin 1.5 mg/kg IV q 8 h ± ampicillin 2 g IV q 4 h	Third-generation cephalosporin ± gentamicin

ABBREVIATIONS: IM, intramuscularly; IV, intravenously, q, every.

consist of imipenem/cilastatin, ampicillin/sulbactam, or piperacillin/tazobactam with or without an aminoglycoside. The spectrum of potential pathogens increases in patients with nosocomial intra-abdominal infections to include aerobic gram-negative rods, including those that might produce an extended-spectrum β-lactamase, other anaerobes, and *Candida* species.

SKIN AND SOFT TISSUE

In patients with severe sepsis from community-acquired skin and soft tissue infections, the most common pathogens are group A streptococci, *S. aureus*, *Clostridium* species, polymicrobial organisms, various enteric gram-negative rods, and *Pseudomonas aeruginosa* (see Chap. 55). The risk that the infecting organism will be a gram-negative rod increases in patients who are neutropenic. In these patients, initial treatment in the ICU might consist of vancomycin with imipenem/cilastatin or piperacillin/tazobactam. The most probable pathogens in patients with serious nosocomial skin and soft tissue infections are *S. aureus* (including methicillin-resistant *S. aureus*) and aerobic gram-negative rods. A reasonable initial antibiotic regimen in these patients might consist of vancomycin plus cefepime. Patients with vancomycin-resistant organisms can be treated with the streptogramin combination, quinupristin/dalfopristin or the first oxazolidinone, linezolid. If microbiological studies demonstrate that a *Staphylococcal* strain is not resistant to methicillin, nafcillin should be administered instead of vancomycin because of its comparatively superior efficacy and to prevent the emergence of vancomycin-resistant strains. This allows vancomycin to be reserved for infections resistant to other agents.

In patients presenting with severe sepsis from a cutaneous or soft tissue infection with diabetes mellitus, peripheral vascular disease or neutropenia, or a history of recent GI or gynecologic surgery, the index of suspicion should be high for potentially fatal necrotizing fasciitis. These infections are usually polymicrobial and are produced by a combination of anaerobic organisms and aerobic gram-negative rods. This disorder has a high mortality rate unless treated aggressively. Percutaneous aspirates or biopsies should be obtained, gram

stained, and cultured aerobically and anaerobically. If crepitation is detected or radiographs show gas in the deep tissues, the wound and surrounding tissues should be immediately débrided surgically.

UROSEPSIS

The most probable organisms in patients with severe community-acquired urosepsis are *E. coli, Klebsiella* species, *Enterobacter* species, and *Proteus* species (see Chap. 56). Reasonable antibiotic selections for urosepsis include a parenteral fluoroquinolone, an aminoglycoside with or without ampicillin, or an extended-spectrum cephalosporin with or without an aminoglycoside. If a gram stain of the urine demonstrates the presence of gram-positive cocci, a rational choice for initial therapy would be ampicillin/sulbactam with or without an aminoglycoside to cover enterococci. A reasonable initial antibiotic combination in patients presenting with this diagnosis would be ciprofloxacin with or without an aminoglycoside. Although bacteriuria or candiduria is common in catheterized patients in the ICU, an indwelling catheter is uncommonly the cause of urosepsis. Nosocomial urosepsis is most common in patients with a urinary tract obstruction or those who have recently undergone instrumentation of the lower urinary tract. Likely pathogens in patients with serious nosocomial urosepsis are aerobic gram-negative rods and enterococci. Unless the prevalence of vancomycin-resistant enterococci is high in the institution, a reasonable initial choice of antibiotics would be vancomycin plus cefepime.

MENINGITIS

The most probable organisms in patients with serious community-acquired meningitis are *S. pneumoniae*, *Neisseria meningitidis*, *Listeria monocytogenes*, *E. coli,* and *H. influenzae*. Initial treatment of meningitis should be guided by results of the cerebrospinal fluid examination, including examination of a gram stain of an ultracentrifuged specimen of cerebrospinal fluid, plus tests for antigens of *S. pneumoniae*, type B *H. influenzae*, and *N. meningitidis* in patients with purulent meningitis (see Chap. 52). Without a probable pathogen from initial microbiological studies of the cerebrospinal fluid, a reasonable initial treatment regimen for adults 18 to 50 years old would be a broad-spectrum cephalosporin. For patients older than 50 years or those with impaired cell-mediated immunity, ampicillin plus ceftazidime would be appropriate. Organisms that should be suspected in cases of nosocomial meningitis are *Pseudomonas aeruginosa, E. coli*, *Klebsiella* species, and *Staphylococcal* species. A reasonable initial treatment in these cases would consist of cefepime or meropenem plus vancomycin.

LINE SEPSIS

Readily accessible, stable vascular access is a routine requirement in critically ill patients and chemotherapy recipients. The most common pathogens in patients with an infected line are coagulase-negative staphylococci, *S. aureus*, aerobic gram-negative bacilli, and *Candida albicans*[130] (see Chap. 50). Infections of these devices are a major cause of morbidity and mortality in the United States. In a meta-analysis of 2573 cases of line sepsis, Byers et al reported an overall case fatality rate of 14%.[131] Of the various pathogens, *S. aureus* and *S. epidermidis* had the highest and lowest attributable mortality rates, respectively.

Management varies by the type of catheter. In most cases, infected, non-tunneled catheters should be removed and replaced. The decision to replace a tunneled catheter or implanted device is based on documentation that the device is infected, the type of pathogen, and the presence of complications such as septic thrombosis, metastatic infection, or tunnel infection. Until the susceptibility is known, staphylococcal strains should be treated with vancomycin. If the isolate is susceptible to β-lactams, a semi-synthetic penicillin such as nafcillin should be used. Patients who are allergic to penicillin and lack a history of anaphylaxis or angioedema can be treated with a first-generation cephalosporin such as cefazolin; 90% of patients treated in this fashion will not have an allergic response.[130] Empirical antibiotic therapy for patients with gram-negative line sepsis should include drugs active against *P. aeruginosa*. Patients with severe sepsis due to systemic candidiasis have several options, including amphotericin B, fluconazole, voriconazole, and caspofungin. Often patients at high risk of *Candida* species infection and no positive cultures will be treated with presumptive therapy if they are doing poorly on a well-chosen antibiotic regimen.

Specific Antisepsis Interventions

Despite early institution of appropriate antibiotics and organ support measures, 28% to 50% or more of patients with severe sepsis die. This has stimulated basic scientists and clinical investigators to seek and develop unique compounds that can serve as specific antisepsis interventions (Table 46-9). As with any new intervention, however, an evidence-based approach should be taken to ascertain whether the data, in aggregate, are sufficient to change clinical practice.[132] The analysis should include the quality of the evidence, magnitude of treatment effect, precision of treatment effect, magnitude of hazards, cost-benefit analysis, and various intangibles.

The magnitude of treatment effect can be expressed as absolute risk reduction (ARR), relative risk reduction, or NNT. The NNT represents the number of patients who must be treated with a specific intervention to prevent one adverse outcome or to attain one additional benefit. Clinicians can use the NNT, calculated as the reciprocal of the ARR, or 1/ARR, as a tool to guide them in reaching rational therapeutic decisions. Although there are few large-scale, randomized, placebo-controlled trials of specific antisepsis interventions to use as comparators, information from a large database of interventional trials in clinical cardiology has provided measures of the NNT in various medically accepted interventions. Thrombolytic therapy, for example, provides a survival benefit for patients with acute myocardial infarction. An analysis of nine randomized, placebo-controlled trials, each with 1000 patients or more with suspected acute myocardial infarction, demonstrated that thrombolytic therapy saved one life for every 55 patients treated (NNT = 55).[133] In the Thrombolysis in Myocardial Infarction 11B trial of patients with unstable angina pectoris or non–Q-wave myocardial infarction, enoxaparin prevented one composite end point (death, nonfatal myocardial infarction, or severe recurrent ischemia requiring urgent revascularization), compared with unfractionated heparin, for every 40 patients treated (NNT = 40).[134] Clinicians can use the NNT as a yardstick to make a relative comparison among the various interventions described below.

ACTIVATED PROTEIN C

PC is a vitamin K–dependent protein that circulates in the blood as an inactive precursor. Conversion of PC to APC requires thrombin and TM. Once thrombin is bound to endothelial cell TM, the serine protease undergoes a conformational alteration that shifts the substrate specificity of thrombin from fibrinogen to PC. Activation of PC is accelerated by the presence of the EPCR in concert with its plasma cofactor, protein S. APC modulates endothelial cell function, an effect whose phenotypic manifestations include antithrombotic, profibrinolytic, and anti-inflammatory properties.[135] Physiologically, APC limits coagulation and restores endogenous fibrinolytic activity by (1) inactivating coagulation factors Va and VIIIa, (2) inhibiting release of plasminogen activator inhibitor 1, and (3) downregulating activation of TAFI by thrombin. The anti-inflammatory activity of APC results from downregulation of thrombin-induced inflammation, modulation of nuclear factor κB activity, and inhibition of TNFα and macrophage migration inhibitory factor production in monocytes.[136,137] Experimentally, APC also blocked the accumulation of leukocytes at inflammatory foci by inhibiting the ability of leukocytes to bind to endothelial cell selectins.[138] In another experimental model, the activated molecule also blocked p53-mediated endothelial cell apoptosis, an effect that contributes to its neuroprotective activity in ischemic human brain tissue and may help explain its antisepsis activity.[139] In a baboon model, an infusion of *E. coli* at a concentration of 4.0×10^{10} organisms/kg produced septic shock, decreased concentrations of PC, fibrinogen, and platelets, and induced death within 24 to 36 hours.[140] These outcomes can be prevented when plasma-derived APC is added to the *E. coli* infusion. If activation of PC is prevented by preinfusion administration of antibody to PC, shock develops more rapidly, the coagulopathy is worse, and the animals die more quickly. Importantly, the levels of endogenous PC in the experimental animals remained within normal limits during the experiment. These preclinical data suggested that APC had the potential to protect against the morbidity and mortality of severe sepsis.

Low levels of PC are present in more than 85% of patients with severe sepsis.[141] Levels of endogenous PC decrease before the appearance of the clinical signs and symptoms of sepsis with acute organ dysfunction. In a population of cancer patients with chemotherapy-induced neutropenia, Mesters et al determined that the concentrations of PC decreased 16 hours before a diagnosis of severe sepsis could be made.[142] In a review of published experimental and clinical studies, Yan et al reported that the lower levels of PC in patients with sepsis occurred in the absence of appreciable conversion to APC. The safety and efficacy of a range of doses of drotrecogin alfa (activated), a recombinant form of human APC, were tested by Bernard et al in a double-blind, randomized, placebo-controlled, multicenter, dose-ranging (sequential), phase II clinical trial of 139 adult patients with severe sepsis.[141] The investigators demonstrated that the drug was safe and well tolerated and that it produced a significant dose-dependent reduction in D-dimer and IL-6, markers of coagulopathy and inflammation, respectively. Because the endothelium is the largest organ in the body and a component of all other organ systems, the ability of infused recombinant human APC to protect endothelial cells may explain the drug's ability to improve outcomes in patients with MODS.

In the phase III randomized, double-blind, placebo-controlled, multicenter, international Protein C Worldwide Evaluation in Severe Sepsis (PROWESS) trial of 1690 patients, treatment with drotrecogin alfa (activated) produced significant relative and absolute reductions of 19.4% and 6.1%, respectively, in the risk of death ($p = 0.005$).[143] The NNT with drotrecogin alfa (activated) to save a life in the PROWESS trial was 16. Patients treated with the drug showed a trend

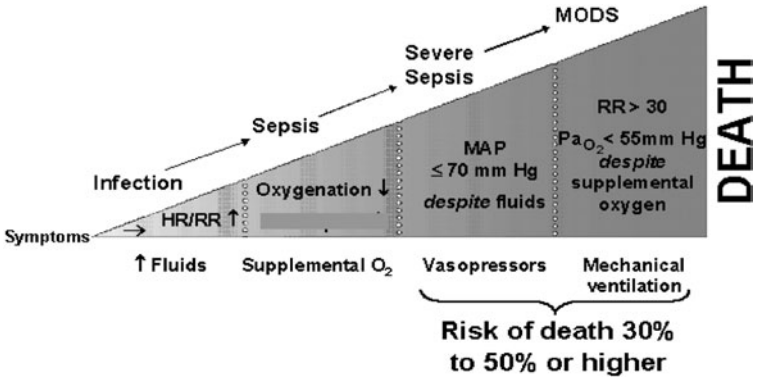

FIGURE 46-4 Sepsis continuum: identifying patients at high risk of death. toward a higher incidence of serious bleeding (3.5% versus 2.0%; $p = 0.06$). In patients at higher risk of death, as stratified by APACHE II scores, the ARR of death was 13% and the NNT was eight. In addition, the benefits of drotrecogin alfa (activated) persisted after discharge. In a cross-sectional observational study of the PROWESS cohort followed for up to 3.6 years, Angus et al reported that patients who were treated with the drug had an increased median survival of 9 months compared with placebo; these persistent benefits were greatest in patients with the most severe disease.[144] In those who have a reasonable life expectancy if they survive the episode, targeting drotrecogin alfa (activated) to the most severely ill patients with severe sepsis has been found to be cost effective according to societal standards.[144,145] Drotrecogin alfa (activated) therapy has recently been approved for inclusion in the hospital prospective payment system and for reimbursement under Section 533 of the Medicare Benefits Improvement and Protection Act of 2000.

IDENTIFYING CANDIDATES FOR DROTRECOGIN ALFA (ACTIVATED) THERAPY

As the first approved therapy specifically for patients with severe sepsis, drotrecogin alfa (activated) has been subjected to intensive evaluations to help determine the ideal candidates and to assess the drug's risk:benefit profile. Drotrecogin alfa (activated) is currently indicated for patients with severe sepsis at high risk of death who are felt to be candidates for aggressive care and lack contraindications for anticoagulation (Fig. 46-4).

In the PROWESS trial, mortality rates in nearly all of the prospectively defined subgroups were lower in the group that received drotrecogin alfa (activated) than in the group that received placebo infusion. However, analysis of the data from the PROWESS trial showed that the greater the baseline predicted risk of death (e.g., APACHE II score $\geq$25 or sepsis-induced organ dysfunction in two or more vital systems), the greater the ARR in mortality rate.[146] At this time, patients with the greatest likelihood of benefit are those who fulfill the following three criteria: (1) severe sepsis with vasopressor dependence and/or requiring mechanical ventilation; (2) no active bleeding, platelet count above 30,000/μL, and international normalized ratio (INR) below 3.0, and no identifiable risks of central nervous system bleeding; and (3) the patient/family and medical team approve of an aggressive approach to management of sepsis in the patient, with a reasonable baseline quality of life to return to after the patient's stay in the ICU. A useful treatment algorithm is provided in Figure 46-5.

Vasopressor dependence can be defined as a systolic BP of 90 mm Hg or lower or a MAP 70 mm Hg or lower despite aggressive fluid resuscitation to maintain adequate intravascular volume status. In the PROWESS trial, the mortality rate of patients treated with conventional therapy with an APACHE II score of 25 or higher was 25%. In this same group, the mortality rate of vasopressor-dependent patients was 32%. As a consequence, vasodepressor dependence is used by some as a surrogate for APACHE II scores of at least 25 (i.e., high risk of death). In the PROWESS trial, patients treated with drotrecogin alfa (activated) had significantly higher MAP by day 5 ($p = 0.01$) and were able to achieve a MAP above 70 mm Hg without vasopressor support over days 1 through 7 more rapidly compared with controls ($p = 0.01$).[147] Likewise, patients with severe sepsis and significantly impaired oxygenation (e.g., respiratory rate > 30 breaths/min, Pa_{O_2} < 55 mm Hg) are at high risk of death. In the PROWESS trial, treatment with drotrecogin alfa (activated) resulted in significantly improved oxygenation by day 7 ($p = 0.01$) and enabled recipients to achieve Pa_{O_2}/FI_{O_2} ratios greater than 400 without ventilator support significantly faster over days 1 through 7 ($p = 0.009$).

In the PROWESS trial, the rate of serious bleeding events attributable to drotrecogin alfa (activated) during drug infusion

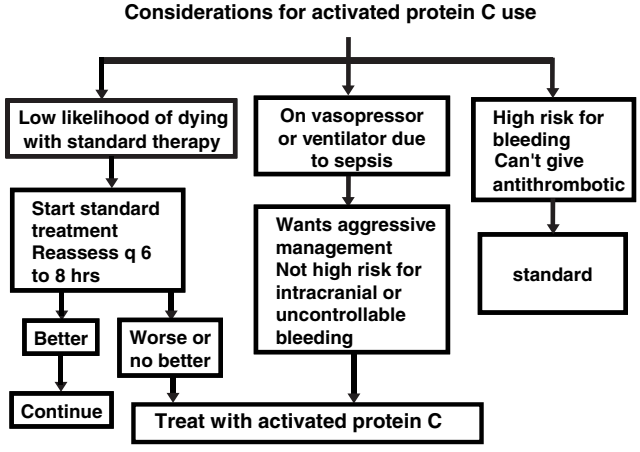

FIGURE 46-5 Algorithm for activated protein C use. ***(Adapted with permission from Lawson WE, Ely EW: Managing severe sepsis with activated protein C: Reaping the benefits requires careful patient selection. J Respir Dis 24:384, 2003.)***

was 1.5%. Most serious bleeding events in the population treated with drotrecogin alfa (activated) occurred in patients with predisposing factors such as GI ulceration, traumatic injury of a blood vessel or a highly vascular organ, or markedly abnormal tests of coagulation. Notably, the presence of material in a nasogastric aspirate that tests positive for heme (e.g., guaiac test) in the absence of overt bleeding should not be considered a contraindication to treatment with drotrecogin alfa (activated). Drotrecogin alfa (activated) therapy should be used with caution in patients with markedly abnormal hemostasis (e.g., platelet count $<30{,}000/\mu L$). An INR above 3.0 is also used as a relative guide; in patients with INRs above this level, the benefits must be carefully weighed against the risks. The potential for intracranial hemorrhage (ICH) represents the most important complication warranting screening. In a review of approximately 3000 patients, the ICH rate was 0.5%; in an ongoing open-label study, the incidence was 0.2%. This incidence should be viewed from the perspective of the placebo rate of ICH in other large-scale, randomized clinical trials of patients with severe sepsis. For example, in the trial of large-dose AT III in severe sepsis, the incidence of ICH in the control arm was 0.4%.[148]

In elderly patients, the cost:benefit ratio for drotrecogin alfa (activated) depends on the patient's potential to have a reasonable quality of life after recovery from the episode of severe sepsis. In general, age should not be used to stratify patients for potential life-saving interventions such as drotrecogin alfa (activated) therapy. In the Study to Understand Prognoses and Preferences for Outcomes and Risks of Treatments (SUPPORT), life support measures such as mechanical ventilation were withheld more often in patients older than 70 years, even after adjusting for severity of illness.[149] However, analysis of the ARDSNet data indicates that, despite a decreasing survival rate with advancing age, 50% of patients 80 years and older survived an episode of ARDS.[150] In the PROWESS trial, the ARR of drotrecogin alfa (activated) in patients 75 years and older was 15%, and the NNT to save a life was six to seven patients.[151] Importantly, this benefit was not accompanied by an increase in the risk of bleeding compared with that of the younger cohort. Although the pivotal study was conducted in a broad range of patients with severe sepsis, the data clearly showed that drotrecogin alfa (activated) produces the greater absolute benefit in those patients with high risk of death. Because a mortality benefit was not demonstrated in PROWESS for patients with a lower severity of illness (using APACHE II scores) and potential for harm could exist in those not likely to benefit, these low-risk patients are currently being evaluated in an 11,000-patient randomized controlled trial.

Several trial design issues have been raised and answered about PROWESS that may have limited its early adoption.[152] These include concerns regarding mid-trial changes to the study protocol and drug preparation, high acquisition costs, and bleeding.[153] The U.S. Food and Drug Administration (FDA) and the principal investigators of the trial have addressed these issues with firm conclusions: (1) large-scale clinical trials are routinely amended, and analysis of PROWESS by the FDA does not support the belief that changes in the protocol or drug were responsible for the outcomes; and (2) the greatest benefits of drotrecogin alfa (activated) are in the most severely ill patients.[154,155] In acknowledging the benefits seen in the most severely ill, the FDA indication specifies that the drug should be prescribed to patients with severe sepsis at high risk of death. In addition, the FDA requested that the manufacturer provide additional clinical trial data on the use of drotrecogin alfa (activated) in patients with severe sepsis at lower risk of death; trials in such low-risk patients are ongoing.

ADMINISTRATION AND MONITORING OF DROTRECOGIN ALFA (ACTIVATED)

Once a decision has been made to treat a patient with drotrecogin alfa (activated), the infusion should be started immediately. Although there was no indication from the clinical trials to indicate that watchful waiting is harmful within the 48-hour window after the development of sepsis-induced organ failure, it would seem prudent to treat a patient with severe sepsis at high risk of death earlier rather than later. This is supported by analysis of data from the ENHANCE trial. Patients treated with Drotrecogin alfa (activated) within the first twenty-four hours had a lower 28-day mortality by degree of organ dysfunction before treatment ($P = 0.014$) and by time to treatment stratified by APACHE II quartile. Patients treated within the first twenty-four hours also had significantly fewer days on the ventilator and lower ICU and hospital lengths of stay ($P < 0.004$). Treatment consists of an infusion of 24 μg/kg per hour of drotrecogin alfa (activated) for a total infusion duration of 96 hours. The dosage is based on the patient's actual body weight rather than ideal body weight. There is no need to monitor the infusion with tests of hemostasis or levels of PC or APC. In the event of clinically significant bleeding, the infusion should be stopped immediately. Drotrecogin alfa (activated) is rapidly cleared by plasma proteases, including PC inhibitor and α_1 antitrypsin: 80% is eliminated within 13 minutes and 98% is cleared within 2 hours. If the nature and severity of bleeding has been clarified and appropriate actions have been successfully taken, the drug infusion may be resumed for the remainder of the total 96-hour duration as long as the management team feels that treatment with an antithrombotic is now safe.

The increased rate of bleeding in patients treated with drotrecogin alfa (activated) is usually related to procedure and predominantly develops during the time of drug infusion. Because of its short half-life, there is no significant residual drug effect if the infusion is temporarily interrupted 2 hours before any surgical procedure. The decision as to when to restart the infusion should be based on the nature of the procedure and assessment of the patient.[156] For minor procedures such as tracheostomy or change or placement of an arterial line or a femoral venous catheter, the drotrecogin alfa (activated) infusion can be restarted immediately thereafter if there is no sign of bleeding. In the absence of bleeding or complications, the drug infusion can be restarted 2 hours after procedures such as placement of a Swan-Ganz catheter or placement of a chest tube. The 2-hour postprocedure interval before the infusion is resumed is also reasonable for patients undergoing lumbar puncture, percutaneous drainage, nephrostomy, or sinus puncture. In the absence of bleeding, the infusion can be restarted after 12 hours in patients undergoing major surgical procedures or removal of an epidural catheter. Once the infusion is restarted, the drug should be administered so that the patient continues to receive the calculated amount for the full 96-hour duration. No attempt should be made to accelerate or "catch-up" and bolus infusions are contraindicated.

Investigational Natural Anticoagulants

Hemostatic abnormalities are common in patients with severe sepsis.[157] In addition to APC, the body has a number of other natural antithrombotics that have the potential to improve outcomes in patients with severe sepsis. These include AT, TF pathway inhibitor (TFPI), and endothelial cell glycosaminoglycans.

ANTITHROMBIN

AT III is a serine protease that is a slow, progressive inhibitor of thrombin and factor Xa; binding of heparin to a lysine site on the AT protein produces a conformational change in the molecule that converts it to a rapid inactivator of thrombin and factors Xa, IXa, XIa, and XIIa.[158] Experimentally, AT III supplementation has been shown to decrease inflammatory changes associated with severe sepsis.[159] Based on experimental and early clinical studies, Warren et al evaluated the safety and efficacy of AT III in a double-blind, placebo-controlled, multicenter study of 2314 adult patients with severe sepsis.[148] At 28 days, overall mortality rates were 38.9% in the treated group and 38.7% in the placebo group ($p = 0.94$). Study subjects who received AT III had a relative risk of bleeding greater than 1.7. Studies of this natural antithrombotic for the treatment of severe sepsis have been discontinued.

TISSUE FACTOR PATHWAY INHIBITOR

TFPI is a Kunitz-type inhibitor; after binding and inactivating factor Xa, TFPI then inhibits factor VIIa within the factor VIIa/TF complex.[160] Circulating TFPI has been shown to modulate the activity of the extrinsic pathway. Experimentally, TFPI inhibits LPS-induced pulmonary edema and tissue damage.[161] These features suggest that recombinant human (rh) TFPI (tifacogin) therapy might decrease the coagulopathy and inflammatory changes of severe sepsis in a fashion similar to that of rhAPC. Because the proposed benefits of tifacogin would be anticipated to be through stabilization of coagulation, trials of the drug have focused on patients with a mild coagulopathy (INR $\geq$ 1.2). Although a phase II trial showed a trend toward reduction in the 28-day all-cause mortality rate in the rhTFPI group compared with placebo, the phase III OPTIMIST (Optimized Phase III Tifacogin in Multicenter International Sepsis Trial) study failed to show a mortality benefit.[162,163] Overall mortality rate at 28 days in the group

treated with tifacogin ($n = 880$) was 34.2% versus 33.9% in the placebo group ($n = 874$), a difference that did not reach statistical significance ($p = 0.88$). In addition, there was an increase in serious adverse events for bleeding in the treatment group; this difference was irrespective of the patients' INR. A second phase III study of TFPI is now being conducted to determine if a higher dose of the drug will produce a survival advantage.

GLYCOSAMINOGLYCANS

Endothelial cells have important anticoagulant systems, including the heparan sulfate-AT system. Heparan sulfate is an endothelial cell glycosaminoglycan similar in structure and pharmacodynamic properties to heparin. By interacting with endothelial cell surface heparan sulfate, endogenous AT III stimulates prostacyclin generation and inhibits cytokine and TF production in endothelial cells and monocytes.[164] It may also be involved in the AT III–associated desensitization of leukocyte chemoattractant receptors. Ahmed et al demonstrated that heparin also possesses clinically significant anti-inflammatory properties that are independent of AT III.[165] They showed that inhaled enoxaparin can produce a dose-dependent, statistically significant inhibition of exercise-induced bronchoconstriction independent of the drug's anti–factor Xa activity. In a hypothesis-generating exercise, Davidson et al reported that their analysis of the PROWESS and AT III trials suggests that administration of small-dose heparin to enrollees in the two trials is associated with a 45% (95% confidence interval = 1.18 to 1.78; $p < 0.001$) improvement in the odds for survival among the placebo recipients compared with those who did not receive heparin.[166] Similar observations have been made about a heparin effect in the trials of other natural anticoagulants. In the AT trial, mortality rate was lower in the placebo group who received heparin.[148] In the OPTIMIST trial, mortality rate was lower in patients receiving placebo and heparin than in those who did not.[163] Heparin's potential anti-inflammatory and antileukoadhesive properties were investigated in a human endotoxemia model by Derhaschnig et al.[167] They showed that, although the drug displayed little effect on cytokine production and endothelial cell activation in endotoxemia, it downregulated expression of L-selectin and produced lymphocytopenia. As intriguing as these observations are, experimental studies in a sepsis model reported that heparin does not prevent ALI produced by smoke inhalation.[168] Thus, the clinical relevance of heparin's anti-inflammatory properties is unclear and requires further studies.

OTHER AGENTS

Several experimental approaches are underway to investigate other hemostasis-related agents for the treatment of patients with severe sepsis. They include soluble TM (sTM), an inhibitor of activated coagulation factor VII (rhFVIIa), and PAF inhibitor. TM is an endothelial cell protein that alters thrombin's substrate specificity from fibrinogen to PC, thereby converting PC to APC. Studies have indicated that endotoxin and proinflammatory cytokines such as TNFα decrease endothelial cell TM expression. This may be a consequence of downregulation of TM expression, increased degradation of the protein, or some combination thereof. When coupled with a glycosaminoglycan moiety, a soluble form of TM can block the fibrin formation and cell activation, convert PC to APC, and promote thrombin inhibition by AT III and heparin cofactor II.[169] These properties suggest that sTM might be useful in sepsis. In an experimental model, rh-sTM blocked endotoxin-induced disseminated intravascular coagulation (DIC) and pulmonary vascular injury.[170,171] Although rh-sTM has been shown to be safe in normal human volunteers, no clinical trials have been published describing its efficacy in patients with severe sepsis.[172]

Upregulation of TF on monocytes and perhaps endothelial cells is a significant element in the evolution of severe sepsis. Although clinical trials of TFPI failed to demonstrate a survival benefit, the extrinsic pathway of coagulation remains an attractive target. Active site-inhibited rhFVIIa can act as a competitive inhibitor of factor VIIa generated during activation of coagulation. Welty-Wolf et al and Carraway et al demonstrated in a primate model that rhFVIIa can prevent sepsis-induced pulmonary and renal dysfunction and attenuate organ damage in established sepsis.[173,174] However, Jilma et al reported that, although rhFVIIa was an effective inhibitor of TF-induced thrombin generation, it did not alter endotoxin-induced changes in fibrinolysis, cytokine release, or markers of endothelial cell or platelet activation.[175] Studies of this drug are ongoing.

During the systemic inflammatory response to infection, phospholipase A_2 is released. This enzyme catalyzes conversion of cell membrane phospholipids to PAF and arachidonic acid. It has been hypothesized that a phospholipase A_2 inhibitor administered within the first 18 hours of sepsis-induced organ failure may improve survival rate. However, a recent multicenter, double-blind, placebo-controlled trial of 14-kd group IIA secretory phospholipase A_2 inhibitor failed to provide evidence that this approach offers a survival benefit.[176]

PAF acts as a signaling molecule that can trigger and amplify inflammatory and coagulation signals.[177] Levels of PAF are increased in patients with severe sepsis and there is evidence that PAF signaling is defective. Human recombinant PAF-acetyl-hydrolase inhibits monocyte/macrophage and neutrophil activation in response to inflammation. In patients at risk for multiple organ dysfunction syndrome, rhPAF-acetyl-hydrolase was safe and improved organ scores.[178] However, a phase II clinical trial failed to demonstrate benefits of this drug compared with placebo on survival rate, hemodynamic status, respiratory function, or organ failure scores.[179]

The results of these studies raise an interesting issue: with the demonstrated efficacy of drotrecogin alfa (activated) and preclinical data that support the use of other natural antithrombotics in patients with severe sepsis, why have the results of the clinical studies of these compounds been so disappointing? The answers to these questions are unknown but several possibilities exist. Recombinant human APC has multiple mechanisms of action that may be additive to its antithrombotic properties. These include several anti-inflammatory, profibrinolytic, and endothelial cell survival properties. Other issues may be related to trial design. In the trials of AT III and TFPI, the lack of overall benefit may have been related to the dose, the ability of thromboprophylactic doses of heparin to block the drug's anti-inflammatory effect, or the concept. For example, the continuous infusion of AT III may have been insufficient to maintain supraphysiologic

levels of AT III in severely septic patients. Because AT III must bind to endothelial cell and neutrophil glycosaminoglycans to promote local anticoagulant and anti-inflammatory activities, prophylactic heparin administered to some patients may have prevented the infused drug from significantly binding to its target on endothelial cells.

Replacement-Dose Steroids (see Chap. 79)

Cortisol is the predominant glucocorticoid secreted by the adrenal cortex. During acute illness, cortisol production increases as much as sixfold, an increase that is roughly proportional to the severity of the illness.[180] Increased cortisol levels in acutely ill patients are a result of a combination of increased production of CRH and ACTH plus a reduction in the degree of cortisol-mediated feedback inhibition. Other factors that may contribute to the adrenal cortical stress response include loss of the normal diurnal secretory pattern, increased levels of free cortisol resulting from a combination of a decrease in the levels of cortisol-binding globulin and cleavage of cortisol-binding globulin by neutrophil elastase, plus inflammatory cytokine-mediated alterations in peripheral cortisol metabolism and changes in the affinity of cellular glucocorticoid receptors for their ligand.

There are several potential mechanisms of action that suggest that glucocorticoid therapy might be beneficial in patients with severe sepsis: (1) correction of a state of relative adrenal insufficiency, (2) inhibition of the synthesis of iNOS, (3) improved hemodynamics secondary to restoration of the sensitivity of vascular catecholamine receptors, and (4) liberation of bound IκB-a with decreased transcription of inflammatory cytokines and increased synthesis and release of the receptor antagonist for IL-1.[181,182]

Megadose steroid therapy for patients with severe sepsis was abandoned in the late 1980s when it failed to improve mortality rate.[183] However, in 1998, Bollaert et al reported the results of a prospective, randomized, double-blind, placebo-controlled study of small doses of hydrocortisone (100 mg intravenously, three times daily for 5 days) on hemodynamics and survival.[184] After 28 days, patients treated with glucocorticoids demonstrated a significant ability to reverse the hemodynamic alterations of shock ($p = 0.005$) and had a 31% reduction in mortality rate (32% versus 63%; 95% confidence interval = 1% to 61%; $p = 0.091$). Because there was no correlation between the outcomes and the results of a short corticotropin test, the investigators commented that the results do not appear to be related to the presence of adrenal cortical insufficiency. However, in 2000, Annane et al described a three-level prognostic classification for septic shock based on cortisol levels and response to a short corticotropin stimulation test.[185]

In a follow-up placebo-controlled, randomized, double-blind, parallel-group trial, Annane et al reported the effect of hydrocortisone and fludrocortisone on mortality rate in 300 medical and surgical patients with severe sepsis.[186] Other eligibility criteria included mechanical ventilation, hypotension unresponsive to fluids, and dysfunction of other organ systems characteristic of severe sepsis. Patients who fulfilled the usual criteria for septic shock were enrolled after undergoing a short ACTH stimulation test. Steroid therapy consisted of 200 mg of hydrocortisone (50 mg at 6-hour intervals) and a single 50-μg dose of fludrocortisone daily for 7 days. In patients characterized on the basis of the short ACTH stimulation test as having relative adrenal insufficiency (i.e., nonresponders), steroid therapy significantly decreased mortality rate and the duration of vasopressor therapy. Steroid treatment of the nonresponder population produced 16% and 10% relative and absolute reductions, respectively, in the risk of 28-day mortality ($p = 0.04$). Further, steroid treatment of this subpopulation improved hemodynamics and enabled the investigators to wean patients from vasopressors 3 days earlier than placebo-treated controls. The contribution of the administered mineralocorticoid to the outcomes is unclear. Adverse events potentially associated with steroids such as superinfection, GI bleeding, and psychiatric disorders did not increase in the treatment group.

IDENTIFYING CANDIDATES FOR LOW-DOSE STEROID THERAPY

As opposed to absolute adrenal insufficiency, which is relatively uncommon in patients with severe sepsis, evidence of inadequate adrenal reserves is common. Annane et al reported that evidence of an inability of the adrenal cortex to respond to ACTH-releasing hormone (nonresponders) was present in approximately 66% of patients with severe sepsis in their study.[186] This observation coupled with the results of the study and the ready availability of glucocorticoids and mineralocorticoids provide preliminary support for low-dose steroids in appropriate patients with severe sepsis. Notably, however, steroids did not provide uniform benefits in all subgroups: in patients with normal adrenal function (i.e., responders to ACTH stimulation), administration of low doses of hydrocortisone plus fludrocortisone was associated with increased mortality rate (61% versus 53%; p = not significant). Although the results were not statistically significant, when combined with previous studies indicating that steroids can have adverse effects in patients with severe sepsis, the possibility was raised that steroid therapy may be detrimental to patients in this population with adequate adrenal reserve.[187] Because the number of patients in this study was small and demonstrated interesting results, an ongoing large European trial is evaluating this intervention.

ADMINISTRATION AND MONITORING OF LOW-DOSE STEROID THERAPY

In patients with severe sepsis at high risk of death, it is reasonable to administer combination glucocorticoid/mineralocorticoid therapy with the 7-day protocol described by Annane et al.[186] Therapy should begin immediately after a short ACTH stimulation test (ACTH 250 μg [one vial of Cosyntropin] intravenously or intramuscularly with a serum cortisol level 45 to 60 minutes later). Once the results become available, steroids can be discontinued in patients whose baseline serum cortisol is increased by 10 μg/dL or greater (i.e., responders). Nonresponders, patients with a change in their serum cortisol levels of 9 μg/dL or less, can continue to receive low-dose steroids for the full 7-day period. The significance of the level of serum total cholesterol in patients with sepsis is unclear since values fall with the development of critical illness-associated hypoproteinemia. Serum

free cholesterol may more accurately reflect adrenal function. Consequently, some patients may be selected for low-dose steroid therapy unnecessarily. There is no evidence that steroids and drotrecogin alfa (activated) are competitive therapies. Patients in the PROWESS trial received the best therapy as determined by their treating physicians; in many cases, this included steroids plus drotrecogin alfa (activated) or placebo. In an editorial accompanying the low-dose steroid trial, Abraham et al pointed out that more than 50% of the patients with inadequate adrenal reserve died despite treatment.[187] They emphasized that this observation underscores the need for additional therapies that can reverse organ dysfunction and improve outcomes in this population.

Other Investigational Approaches

TUMOR NECROSIS FACTOR ANTAGONISTS

TNFα is thought to play a major role in the pathogenesis of the clinical manifestations of patients with severe sepsis. Evidence supporting the cytokine's central role in the process includes: (1) experimentally, TNFα levels increase after an endotoxin or a bacterial challenge; (2) increased levels of TNFα can be demonstrated in preclinical models and patients with sepsis; (3) presence of increased levels in patients with the disease and persistent high concentrations are associated with nonsurvival; (4) TNFα challenge simulates manifestations of sepsis and can lead to organ dysfunction; and (5) neutralization of TNFα frequently leads to a decrease in sepsis-associated symptoms and increases survival rate in experimental models.[188] Compounds designed to test the efficacy of TNF antagonists can be divided into two broad groups: (1) monoclonal antibodies against human TNFα (e.g., afelimomab, CDP571) and (2) soluble TNFα receptors (e.g., p55-IgG). Studies of these compounds have indicated that they may produce small survival benefits in some subgroups of patients with severe sepsis.[188,189] Future studies of these agents require methods to better indicate patients who might benefit from the drugs and multimodal therapy that also includes TNFα neutralization.

OTHER POTENTIAL STRATEGIES

The autonomic nervous system plays a major role in the pathophysiology of severe sepsis. Studies have shown that electrical stimulation of the vagus nerve attenuates the release of TNF and other cytokines in response to endotoxin and can prevent the development of shock.[80] At a molecular level, strategies to neutralize macrophage migration, block apoptosis, or inhibit the activity of poly(adenosine 5′-diphosphate-ribose) synthase can also provide protection against the effects of severe sepsis.[190–192] Activation of the classic or alternate pathway of complement generates C5 convertase. This enzyme converts C5 to C5a and C5b. In the presence of C6, C7, and C8, C5b forms the membrane attack complex responsible for complement's lytic activity. In contrast, C5a is a proinflammatory peptide also known as anaphylatoxin. Antibodies to the C5a peptide decrease bacteremia, inhibit apoptosis, and improve survival in experimental models of sepsis.[193–195]

General Supportive Measures

NUTRITIONAL SUPPORT AND GLYCEMIC CONTROL

IMPORTANCE OF ADEQUATE NUTRITION

Severe sepsis is a catabolic state. Metabolic changes associated with the disease include rapid breakdown of proteins, carbohydrates, and lipids, protein diversion, negative nitrogen balance, hyperglycemia with insulin resistance, and altered blood flow to key metabolic sites. As with any other critically ill population, patients with severe sepsis require adequate nutritional support to correct any previous nutritional deficiencies, maintain organ system structure and function, compensate for anticipated or existent inadequate self-feeding, improve wound healing, promote immune function, decrease susceptibility to superinfection, and increase survival rate (see Chap. 11).

Energy needs can be calculated by determining the patient's basal energy expenditure from the patient's weight, height, and age inserted into the Harris-Benedict equation.[196] The weight inserted into the equation should be based on clinical evaluation. Although it is reasonable to use the ideal body weight for obese patients, the pre-illness weight can be used for those patients whose weight has been stable before hospital admission. In most instances, the basal energy expenditure will be approximately 25 to 30 kcal/kg per day; however, due to the catabolic nature of severe sepsis, which seems to reach its maximum during the second week, the basal energy expenditure may be multiplied by a stress factor of 0.5 to 2.5.[197,198] The normal protein requirements for a well-nourished individual are 0.6 to 1.0 g/kg per day.[199] In contrast, patients with severe sepsis may require up to 2.0 g/kg per day. Glutamine and arginine supplementation may improve outcomes.[200,201] Glucose should consist of 30% to 70% of the total nonprotein calories to maintain blood glucose within an acceptable range (see below). Lipids should comprise 15% to 30% of nonprotein calories. The ω-6 polyunsaturated fatty acid content of nutritional support for a septic patient should be decreased while maintaining a level that will prevent a deficiency of essential fatty acids. The ω-3 fatty acids are important for cell membrane integrity, receptor expression and function, and activation and signal transduction. Enteral preparations supplemented with these important lipids are available.

ENTERAL VERSUS PARENTERAL NUTRITION

Enteral nutrition offers several advantages including lower cost, preservation of the GI mucosal barrier, buffering of gastric acid, preservation of enteral hormone secretion, provision of unique nutrients, decreased incidence of infections, improved wound healing, and avoidance of parenteral nutritional catheters and their complications.[202] Immunomodulatory enteral preparations that are supplemented with arginine, nucleotides, and fish oil have been shown to improve outcomes in critically ill patients, although much work is needed in this area.[203,204] For septic patients who cannot tolerate enteral nutrition because of an ileus or other complications, parenteral nutrition is a consideration. Heyland et al conducted a meta-analysis of 26 randomized clinical trials of 2211 patients that compared morbidity and mortality rates in patients receiving enteral or total parenteral nutrition.[205] The mortality rate of critically ill patients was higher among those receiving TPN (RR, 1.78; 95% CI, 1.11–2.85). Notably, the

hypothesis that parenteral nutrition is superior to no nutrition during the acute episode has not been rigorously tested.

MANAGEMENT OF BLOOD GLUCOSE LEVELS

Stress-induced hyperglycemia (>200 mg/dL) is common in patients with severe sepsis. If doubt exists, it can be differentiated from chronic diabetic hyperglycemia by an assay of HbA_{1c} concentrations, values that will be within the normal range in a previously healthy patient. The etiology of this metabolic derangement in patients with severe sepsis is insulin resistance coupled with increased gluconeogenesis, abnormalities that can be compounded by excessive parenteral nutritional support. Insulin resistance is multifactorial in origin and can result from a combination of endotoxin, elevated levels of cytokines such as TNFα, IL-1, and increased circulating concentrations of epinephrine, glucocorticoids, and growth hormone. The effects of cytokines and hormones on blood glucose levels result primarily from the development of insulin resistance in skeletal muscles.[206,207] Despite hyperglycemia, the liver is also resistant to the effects of insulin and is driven to gluconeogenesis by counterregulatory hormones such as glucagon, epinephrine, and growth hormone. An associated cause that may be overlooked in a critically ill patient is provision of excess parenteral glucose. Rosmarin et al reported that nondiabetic patients who received total parenteral nutrition in which dextrose was infused at rates greater than 4 mg/kg per minute had a 50% chance of developing hyperglycemia.[208]

The deleterious effects of hyperglycemia in patients with severe sepsis have been considered to be predominantly related to concerns about an increased risk of infection.[209] Although it is not completely clear whether secondary infections in critically ill patients with hyperglycemia is directly due to the elevated glucose or is another manifestation of latent or overt diabetes mellitus, evidence suggests that hyperglycemia directly impairs immune function.[210,211] Prolonged elevation of blood glucose may potentiate the coagulopathy of severe sepsis. Rao et al demonstrated that prolonged hyperglycemia activates the TF pathway of blood coagulation.[212] Activation of the extrinsic pathway of coagulation was independent of insulin levels, hypertriglyceridemia, and hyperosmolality. This was presumably due to activation of monocytes and/or endothelial cells, upregulation of TF expression, and enhanced conversion of factor VII to VIIa.[213]

Good glycemic control requires regular monitoring of the blood glucose and attention to parenteral nutrition and insulin therapy. However, the target blood glucose level has been unclear. For example, long-term outcomes are improved in patients with diabetes who have had a myocardial infarction if their blood glucose level is maintained at a level below 215 mg/dL or 11.9 mmol/L.[214,215] Recently, van den Berghe et al reported the results of a prospective, randomized controlled trial of more than 1500 mechanically ventilated surgical ICU patients treated with intensive versus conventional insulin therapy.[216] They reported that patients who were randomly assigned to intensive insulin therapy (target blood glucose = 80 to 110 mg/dL, or 4.4 to 6.1 mmol/L) or standard care (target blood glucose = 180 to 200 mg/dL, or 10 to 11.1 mmol/L) had significantly different outcomes. Tight glucose control produced the following advantages: (1) decreased overall ICU mortality rate (4.6% versus 8.0%); (2) decreased ICU mortality rate in patients admitted longer than 5 days (10.6% versus 20.2%; $p = 0.005$); and (3) lower in-hospital mortality rate (7.2% versus 10.9%). Other benefits included a 46% relative reduction in bloodstream infections, a 41% decrease in the need for renal replacement therapy (RRT), a 50% decrease in the median number of red blood cell transfusions, and a 44% reduction in the incidence of critical-illness polyneuropathy. More than 97% of the patients in the tight-control group received intravenous insulin, compared with 33% in the control group. Episodes of hypoglycemia (glucose < 40 mg/dL, or 2.2 mmol/L) were more common in the intensive-control group (5.0% versus 0.7%); however, these episodes were not accompanied by hemodynamic instability or seizures. Although these findings need to be confirmed, they suggest that patients with severe sepsis should receive intensive insulin therapy to maintain their blood glucose levels between 80 and 110 mg/dL (4.4–6.1 mmol/L). Realistically, accomplishing tight glycemic control is often difficult. Many internists have adopted protocols that have adjusted glucose in the range of 100 to 140 mg/dL (5.6–7.8 mmol/L). A point of interest deserving future research is whether or not the benefits of this approach are due primarily to the lower glucose area under the curve or result from glucose-independent effects of insulin.[217] Recently, Finney et al evaluated the relation between glucose control and mortality rate in 523 critically ill patients.[218] They reported a positive association between increased insulin administration and death, independent of prevailing glucose level. They suggested that it is the control of glucose rather than absolute levels of exogenous insulin administered for glucose management that accounts for the mortality benefits of glycemic control. Further, regression analysis of their data suggests that the mortality benefit occurs at blood glucose levels below 145 mg/dL. If these data are supported by others, less stringent glycemic management may provide many of the benefits without intense resource utilization.

RENAL REPLACEMENT THERAPY

Transient oliguria is common in patients with severe sepsis and vasodilatory hypotension or shock. Notably, anuria is rare, and fewer than 5% of patients with severe sepsis develop acute renal failure requiring RRT.[89] Importantly, when it occurs, acute renal failure and its associated metabolic derangements increase the risk for potentially fatal extrarenal complications.[219,220] Therefore, steps should be taken to preserve renal function in the setting of severe sepsis. Important measures include adequate volume replacement, monitoring drug dosage and avoiding nephrotoxins, and excluding lower urinary tract obstruction as the cause for oliguria or anuria. There is no evidence that low-dose dopamine administered by continuous intravenous infusion can protect against renal dysfunction in the critically ill population.[221] If potential nephrotoxins such as aminoglycosides must be used, the dosage should be adjusted for the patient's degree of renal impairment, and drug levels should be monitored. In a patient with severe sepsis and acute renal failure, renal replacement therapy should be considered early in the disease course. In addition to providing renal replacement, continuous renal replacement therapy (CRRT) has become a part of the overall management of the critically ill.

In the ICU, peritoneal dialysis and conventional forms of hemodialysis have been superseded by various forms of

CRRT (see Chap. 75).[222] CRRT is better tolerated than other renal replacement therapies because solutes and fluids are removed in a slower fashion. The choice of a CRRT modality is based on a number of factors, including access to the equipment, experience of the staff, the degree of hemodynamic stability, vascular access, and whether the primary need is for fluid and/or solute removal. Detailed explanations of these interventions are beyond the scope of this chapter and are discussed elsewhere in the textbook.

In addition to removal of metabolic wastes, other indications for CRRT in patients with severe sepsis include establishing hemodynamic stability and providing more precise fluid and electrolyte control. Although cytokines can be found in the dialysate or ultrafiltrate of patients undergoing renal replacement, there is no evidence that cytokine removal by CRRT improves outcomes. CRRT can help to improve outcomes in patients with severe sepsis and ARDS. This potential benefit may be primarily the effect of extravascular lung water. However, the procedure can also be used to stabilize the pH of the blood in patients treated with permissive hypercapnia. Whereas benefits of CRRT are known, until recently the "dose" of CRRT has been unclear. Schiffl et al conducted a prospective study in 160 patients with acute renal failure to compare the effect of intensive (daily) HD with conventional (alternate-day) HD on mortality rate.[223] They found that daily HD reduces mortality rate without increasing hemodynamically induced morbidity compared with the alternate-day approach. Patients treated with intensive HD had better control of uremia, fewer hypotensive episodes during the procedure, and more rapid resolution of acute renal failure (mean $\pm$ SD $= 9 \pm 2$ days versus 16 ± 6 days; $p = 0.001$) than did those undergoing conventional HD. In an intention-to-treat analysis, the mortality rates were 28% for intensive HD and 46% for alternate-day dialysis ($p = 0.01$). In a multiple regression analysis, conventional (versus daily) HD was an independent risk factor for death. Currently, large-scale, multicenter trials are evaluating the effects of CRRT on survival rate in critically ill patients.

THROMBOPROPHYLAXIS

Patients with severe sepsis have at least one risk factor that places them at increased risk for venous thromboembolism (VTE). In addition to immobilization, they may have risk factors such as advanced age, recent trauma or surgery, respiratory failure, or the presence of a central venous access device. Serial scans with radiolabeled fibrinogen or ultrasonograms have indicated that approximately 30% of critically ill patients have evidence of VTE.[224,225] Importantly, VTE can occur even in patients receiving pharmacologic thromboprophylaxis. Thrombi are most common in the lower extremities, and most pulmonary emboli arise from veins in that region. The incidence of embolic events increases as the thrombus extends proximally to the popliteal fossae. Thrombi can also occur in the veins of the upper extremities; the presence of cancer or a central venous catheter increases the risk of VTE originating in this region.

All patients with severe sepsis should be assessed for VTE risk factors, and, in the absence of contraindications, they should receive pharmacologic thromboprophylaxis. Treatment can be with low-dose unfractionated heparin (UFH), adjusted-dose UFH, or low-molecular-weight heparin (LMWH). The most widely employed regimen is 5000 U of UFH administered subcutaneously, twice daily. Although LMWHs are more expensive, they offer several advantages over UFH. These include improved pharmacokinetics and negligible effects on standard tests of coagulation. The thromboprophylactic dose of a specific LMWH should be the one recommended by the manufacturer. In a meta-analysis, LMWH was demonstrated to provide at least equivalent prophylactic activity as UFH for the prevention of postoperative VTEs and was shown to be associated with less bleeding.[226] Fondaparinux is a chemically synthesized anticoagulant that possesses the critical pentasaccharide sequence responsible for the anti–factor Xa of UFH and LMWH. Its acquisition cost should be balanced with a safety and efficacy profile that is superior to LMWH for the reduction of VTE events demonstrated in patients undergoing major orthopedic surgery.[227,228] Treatment with thromboprophylactic doses of UFH or LMWH is not contraindicated during or after a 96-hour infusion of drotrecogin alfa (activated). The incidence of serious bleeding events in those who received drotrecogin alfa (activated) alone and in those who were also treated with heparin was similar (3.7% versus 3.5%).[143] In patients with severe sepsis who are judged to be at high risk of serious bleeding or who are actively bleeding, mechanical prophylaxis with graduated compression stockings or intermittent pneumatic compression devices can be employed. However, the efficacy of these devices is significantly less than that of available antithrombotic drugs. Therefore, once the bleeding risk has decreased, pharmacologic thromboprophylaxis can be started or resumed.

STRESS ULCER PROPHYLAXIS

Patients with severe sepsis have an increased risk for GI bleeding. The incidence of GI bleeding is proportional to the number of risk factors, including prolonged mechanical ventilation, coagulopathy, head injury, solid organ transplant, burns, severe sepsis, and a history of peptic ulcer disease.[229] In a prospective study of 174 patients admitted to a medical ICU, Schuster et al reported that overt or occult GI bleeding developed in 14%.[230] Risk factors for bleeding were mechanical ventilation for longer than 48 hours and/or the presence of a coagulopathy. Patients who developed GI bleeding had a higher mortality rate (64% versus 9%), longer duration of ICU stay (median = 14.2 days versus 4.2 days), increased risk for mechanical ventilation (84% versus 26%), and a requirement for extended duration of mechanical ventilation (9.5 versus 4.2 days) compared with those who did not bleed. The risk of bleeding can be reduced by strategies that decrease acid secretion (H_2 blockers), buffer the acid (antacids), or protect the gastric mucosal barrier (sucralfate). In a study of 1200 mechanically ventilated patients, Cook et al compared the efficacy of sucralfate and ranitidine for the prevention of GI bleeding in this population.[231] They reported that administration of ranitidine was significantly more effective than sucralfate in reducing the rate of clinically significant GI bleeding. The incidences of clinically important GI bleeding were 1.7% in patients treated with the H_2 blocker and 3.8% in those receiving mucosal protection ($p = 0.02$). The NNT to prevent one clinically significant bleed with ranitidine over sucralfate was 48.

Nevertheless, it has been hypothesized that mucosal protective strategies such as sucralfate might be superior to H_2 blockers for raising gastric pH above 4.0 because gastric acidity would prevent proliferation of bacteria in the stomach. That is, the raised pH with H_2 blockers might result in an increased risk of nosocomial pneumonia from reflux of bacteria colonizing the stomach into the respiratory tract. However, there is little evidence to support this hypothesis. Prod'hom et al randomized 244 intubated patients to GI bleeding prophylaxis with ranitidine (150 mg as a continuous infusion), sucralfate (1 g every 4 hours), or antacids (20 mL of aluminum and magnesium hydroxide every 2 hours).[232] Although the incidence of early onset pneumonia was not significantly different among the three groups, among 213 patients observed longer than 4 days, late onset pneumonia was less common in the mucosal protective group than in those treated with antacid or ranitidine (5%, 16%, and 21%, respectively; $p = 0.022$). However, there are several problems with this hypothesis, and the studies by Cook et al found no significant differences in the rates of VAP among those treated with sucralfate or ranitidine.[231] Therefore, in patients with severe sepsis, stress ulcer prophylaxis with ranitidine or the newer available intravenous proton pump inhibitors may decrease the incidence of serious GI bleeding without a convincing increase in cases of VAP.

SEPSIS COAGULOPATHY

In patients with severe sepsis, coagulation is activated and fibrinolysis is suppressed. A sepsis-associated coagulopathy is a sign of dysfunction of the hematologic organ system. In the Ibuprofen in Sepsis Trial, a coagulopathy with elevated levels of D-dimer and decreased levels of PC was almost universal in patients with severe sepsis.[233] The coagulopathy in patients with this disease is linked to endothelial cell dysfunction and fibrin deposition, pathologic processes that contribute to multiple organ system dysfunction and death. Thrombocytopenia, prolongation of the prothrombin time and/or the activated partial thromboplastin time, or any combination thereof are uncommon in patients with severe sepsis. Although there is no single clinical manifestation or laboratory value that is diagnostic of DIC, the following changes are reasonably consistent with the diagnosis: (1) presence of a disorder such as severe sepsis that is known to be linked with DIC, (2) musculocutaneous bleeding and dysfunction of one or more organ systems, and (3) ongoing consumption of coagulation factors. The first two criteria are detected by clinical examination; the last criterion can be recognized by thrombocytopenia and prolongation of one or more global tests of coagulation. Taylor et al proposed a scoring system for the diagnosis of DIC.[234] It uses the characteristics described above to provide a DIC score; values of at least 5 are characteristic of DIC.

In the absence of bleeding, patients with severe sepsis-associated coagulopathy can simply be monitored. In most instances, once the infection is controlled, the abnormal laboratory parameters return toward normal. In patients who are bleeding despite active treatment of the infection, a careful examination should be conducted to rule out a discrete and correctable anatomic lesion (e.g., peptic ulcer) as the cause of the bleed. If bleeding is from multiple sites, treatment is generally broken down into three general areas: (1) platelets and coagulation factor replacement, (2) antithrombotics, and (3) fibrinolysis inhibitors. Replacement of platelets and coagulation factors is generally the first step. Platelet transfusions are often used to maintain the platelet count above 20,000/μL, although the risk of spontaneous bleeding in the absence of anticoagulants occurs at platelet counts lower than 10,000/μL. Importantly, to avoid the risk of intracranial hemorrhage in patients who are to receive drotrecogin alfa (activated), platelet counts should be above 30,000/μL. In patients with severe sepsis, platelet turnover is accelerated; therefore, patients receiving platelets should be monitored with regular platelet counts. Although some patients are transfused with platelets to maintain the threshold, drotrecogin alfa (activated) is not usually given to patients who require multiple platelet transfusions or who have bleeding diathesis due to DIC. Coagulation factors can be replaced with cryoprecipitate or fresh frozen plasma. Each unit of these products has the equivalent of 1 U of fresh whole blood. Cryoprecipitate contains fibrinogen, factor VIII, factor XIII, VWF, and fibronectin. Each bag of cryoprecipitate has approximately 250 mg of fibrinogen and 100 U of factors VIII and XIII in a volume of approximately 10 mL. One unit of fresh frozen plasma contains all hemostatic proteins and albumin, globulins, and electrolytes in 1 U of fresh whole blood. It consists of approximately 225 mL of plasma. Cryoprecipitate may be administered to maintain the fibrinogen level above 100 mg/dL and the level of coagulation factors above 0.5 U/mL. Notably, platelets, cryoprecipitate, and fresh frozen plasma can transmit blood-borne infectious agents.

Low-dose heparin has been used in the past to interrupt the vicious cycle of coagulation, thrombosis, and factor depletion in patients with DIC. However, despite 20 years of calls for such studies, its efficacy has not been demonstrated in large-scale randomized clinical trials.[235] Aoki et al reported that low-dose rhAPC corrected the clinical and laboratory abnormalities in patients with DIC more effectively than UFH.[236] The 28-day all-cause mortality rates in patients treated with APC and heparin were 20.4% and 40%, respectively ($p < 0.05$). In addition, patients treated with APC had significantly less bleeding ($p = 0.009$). Joyce et al performed a retrospective subgroup analysis to determine the effect of drotrecogin alfa (activated) on patients with severe sepsis and DIC.[237] Treatment with drotrecogin alfa (activated) produced a 42% reduction in the relative risk of death compared with placebo (95% confidence interval = 58 to 19). Fibrinolytic inhibitors are not recommended in patients with severe sepsis and DIC because they may convert a hemorrhagic DIC to a thrombotic DIC. These agents are recommended only for patients with primary or excessive secondary fibrinolysis.

TEMPERATURE MANAGEMENT

An abnormality in temperature (i.e., $\leq 36^\circ$C or $\geq 38^\circ$C) is one of the four SIRS criteria and a manifestation of sepsis that will resolve once the infection is controlled. In most instances, mild hypothermia does not need to be actively corrected; however, hypothermia that leads to shivering can increase tissue oxygen requirements and usually can be managed by covering the patient with a blanket. If the patient is to receive large amounts of refrigerated blood, significant hypothermia can be prevented by the use of an in-line blood warmer. For every 1°C above 37°C, fever increases basal oxygen

consumption 13%. In most instances, mild fever requires no treatment. However, fever in patients can aggravate preexisting cardiac or pulmonary disease and worsen behavioral changes in patients with organic brain disease. Measures to lower core temperatures are prudent in patients with temperatures above 40°C to 41°C (104°F to 105.8°F). Steps taken in this situation can include antipyretics such as acetaminophen and measures such as a cooling blanket or tepid water sponging. Notably, however, cooling measures may induce shivering with its undesirable metabolic effects. Therefore, to prevent shivering, the patient can be treated with parenteral meperidine (25 to 50 mg). Muscle relaxants such as pancuronium or vecuronium may be required on rare occasions to control shivering and rigors in adequately sedated and mechanically ventilated patients who are hyperpyrexic.

Prognostic Assessment

In the past two decades, several scoring systems have been developed to identify and describe patient populations in the ICU. These scoring systems also have been useful for ensuring comparability in clinical trial populations. These outcome prediction models and organ dysfunction scores are discussed in detail in Chapter 6. Therefore, we confine our discussion specifically to points relevant to prognostic assessment in patients with severe sepsis. These models can be subdivided into two broad categories: outcome prediction models and organ dysfunction scoring systems.

OUTCOME PREDICTION MODELS (SEE CHAP. 6)

General outcome prediction models include the APACHE, Mortality Probability Model (MPM), and the Second Simplified Acute Physiology Score (SAPS). The APACHE score has become the most commonly used survival prediction model in the critical care unit. APACHE II is a simplified version with a point score derived from initial values of 12 physiologic measurements, age, and previous health status. The APACHE III model was developed in 1991. It is complex, requires software to determine values, and is proprietary; therefore, most investigators have continued to use APACHE II. The MPM consists of two scores: MPM_0, the admission model with 15 variables, and, MPM_{24}, the 24-hour model that uses five of the admission variables and eight additional variables. The SAPS II uses 12 physiologic variables, age, type of admission, and three variables related to the nature of the underlying disease. When attempting to apply outcome prediction models at the bedside, three caveats should be kept in mind. (1) Outcome prediction models are incorporated into clinical trials of severe sepsis interventions to predict and evaluate mortality rate for cohorts of patients; at this time, it is inappropriate to use them to predict outcome or determine therapy for individual septic patients. (2) For the sake of comparability, the models must be used as originally validated. For example, the APACHE II model is validated for the use at the time of admission or within the first 24 hours. However, to obtain consistency in clinical trials, the APACHE II score is often computed from the worst values in the first 24 hours before *randomization*, not during the first 24 hours after admission. Because many of the physiologic variables used to compute the APACHE II score can be corrected within the first 24 hours in a patient with severe sepsis (e.g., pH, electrolytes), this trial design practice limits comparison to the original APACHE database. (3) There are other inherent limitations of outcome prediction models. For example, they are cumbersome to use outside a clinical trial setting, imprecise diagnoses can invalidate the results, they are poor discriminators, and they have lead-time bias.[238,239] Lead-time bias is reflected by the fact that the admission source predicts hospital mortality rate independent of APACHE II. For example, a septic patient who is admitted to the ICU from an inpatient floor has a higher probability of death than one who is admitted from the emergency department.[240]

ORGAN DYSFUNCTION SCORING SYSTEMS

The risk of death in patients with severe sepsis is a function of the number of dysfunctional organs. Organ dysfunction scoring systems supply a tool to characterize the severity of illness in patients with sepsis. Commonly used organ dysfunction scoring systems in patients with severe sepsis include the Sequential Organ Failure Assessment (SOFA), the Multiple Organ Dysfunction Score, the Logistic Organ Dysfunction System, and the Brussels Score. Vincent et al used the SOFA Score to assess the incidence of organ dysfunction in critically ill patients.[241] They reported that mortality rates were lowest in patients without organ dysfunction (9%) and that rates increased progressively in patients with dysfunction in one (22%), two (38%), three (69%), and four or more organs (83%; $p < 0.00001$). Using logistic regression analysis of the results of a simple Multiple System Organ Failure Score, Hebert et al reported that the type of dysfunctional organ system was also linked to mortality rate.[242] The odds ratios for covariates most predictive of mortality rate by organ system were hematologic (odds ratio = 6.2), neurologic (odds ratio = 4.4), hepatic (odds ratio = 3.4), and cardiovascular (odds ratio = 2.6). However, like the outcome prediction models, there are caveats when attempting to employ organ dysfunction scores for the management of individual patients with severe sepsis. (1) The nature of the score is a morbidity, not a mortality, score. (2) Organ dysfunction is an analog parameter that varies from mild laboratory abnormalities to overt organ failure. (3) The degree of organ dysfunction is not static; instead, it changes over time. For example, the platelet count can change considerably over time. Therefore, trends are sometimes more important than absolute values. (4) Because the degree of organ dysfunction must be evaluated over time, by different individuals, and in a variety of community and academic settings, any variables employed in organ dysfunction scores should be objective, routinely measured, and easy to assess.

Acknowledgments

The authors thank George H. Karam, MD, Paul Garvey Manship Professor of Medicine, Louisiana State University School of Medicine, New Orleans for his thoughtful review of the infectious disease and antibiotic issues in this chapter.

Chapter 47

APPROACH TO INFECTION IN PATIENTS RECEIVING CYTOTOXIC CHEMOTHERAPY FOR MALIGNANCY

E.J. BOW

KEY POINTS

- *Risk of infection increases as the circulating absolute neutrophil count (ANC) declines below 1.0×10^9/L. The greatest risk of bacteremic infection occurs when the ANC is $<0.1 \times 10^9$/L.*
- *Cytotoxic therapy for remission-induction therapy for acute myeloid leukemia or conditioning therapy for bone marrow transplantation (high-risk patients) is associated with periods when the ANC is $<0.1 \times 10^9$/L for 14 to 21 days. The time to marrow recovery (ANC $> 0.5 \times 10^9$/L) can vary from 21 to 42 days.*
- *Intermittent administration of cytotoxic therapy for solid tissue malignancies or lymphoreticular malignancies (low-risk patients) is often associated with a neutrophil nadir at 10 to 14 days from beginning treatment and with periods of neutropenia (ANC $< 0.5 \times 10^9$/L) of less than 5 to 7 days. This pattern of neutrophil recovery influences the natural history of febrile neutropenic episodes.*
- *Febrile episodes during neutropenia are defined by an oral temperature of 38.3°C (101°F) or more in the absence of other noninfectious causes of fever such as administration of blood products or pyrogenic drugs (e.g., cytotoxic therapy or amphotericin B), the underlying disease, thromboembolic or thrombophlebitic events, or hemorrhagic events.*
- *A single neutropenic episode may be characterized by one or more febrile episodes, of which one or more may represent infections.*
- *Body sites most often associated with infection in the neutropenic patient are those associated with integumental surfaces (skin, upper and lower respiratory tract, and upper and lower gastrointestinal tract).*
- *Antibacterial prophylaxis with oral agents such as cotrimoxazole, norfloxacin, or ciprofloxacin can reduce the frequency of febrile episodes and bacteremic events in patients with protracted neutropenia.*
- *Patients undergoing remission-induction for acute myeloid leukemia or bone marrow transplantation with a history of herpetic stomatitis or who are IgG seropositive for herpes simplex virus (HSV) are at risk for severe herpetic mucositis. Such patients should be given acyclovir prophylaxis.*
- *Empiric antimicrobial therapy for suspected infection in the febrile neutropenic patient usually is composed of a broad-spectrum antibacterial regimen of an anti-pseudomonal penicillin or carbapenem administered as a single agent (monotherapy). Aminoglycoside-based combinations do not add to the efficacy of the single agent, but do add toxicity.*
- *Neutropenic patients responding to empiric antibacterial therapy generally require at least 5 days for the response to be observed in half the cases. Patients remaining febrile at 5 days should be systematically re-evaluated, while consideration of modification of the antimicrobial regimen can be made at day 7 or 8 unless clinical deterioration is evident. Glycopeptides administered as second-line empiric therapy for persistent fever after 3 to 5 days do not influence time to defervescence or febrile episode-related mortality.*

Critical care physicians are often called on to provide metabolic, hemodynamic, and respiratory support for patients with various inherited or acquired defects in host defense that render them susceptible to potentially lethal infections. Patients with single host defense system defects, such as those with inherited immune deficiency syndromes such as congenital agammaglobulinemia, are susceptible to particular encapsulated respiratory pathogens such as *Streptococcus pneumoniae* that require the presence of opsonizing antibody for clearance. In contrast, cancer patients undergoing potentially curative high-intensity myeloablative cytotoxic therapy acquire defects in multiple host defense systems that lead to increased susceptibility to different groups of pathogens normally contained and controlled by the absent or damaged systems. Four broad categories of defects in host defense are clinically relevant: disruption of the integrity of the integumental surfaces, quantitative neutrophilic phagocyte defects, diminished B lymphocyte (humoral) function, and diminished T lymphocyte system function. A working knowledge of the sources of failure in these host defense systems is particularly important for predicting the types of offending pathogens likely to be involved in the kind of life-threatening infections requiring the services of the critical care team. This, in turn, provides a basis for a rational approach to the choice of antimicrobial therapy. This chapter reviews the approach to managing suspected or proven infection in patients with multiple defects in host defense systems, with a particular emphasis on patients undergoing active myelosuppressive cytotoxic therapy, since this represents the largest group of immunocompromised patients who will require critical care services. Infections in patients with the acquired immunodeficiency syndrome (AIDS) are discussed in Chap. 48, and infections in those with organ or bone marrow transplantation are discussed in Chaps. 73 and 90; the problem of lung infiltrates in immunocompromised patients is covered in Chap. 51.

Hematologists and oncologists have long recognized the existence of the direct relationship between dose and response in cancer therapy. Over the last 10 to 15 years, the supportive care strategies for cancer patients undergoing remission-induction or salvage therapy have improved sufficiently to permit the extension of dosing to the very limits of toxicity and beyond. For many malignant diseases this has translated into significantly higher response rates and disease-free survival. Cure is now a goal that can be adopted realistically for many more patients with these diseases.

Despite these encouraging results, newer dose-intensive therapeutic approaches render patients highly susceptible to life-threatening infection, which in itself or in association with tumor-related end-organ damage may be accompanied

by multisystem failure. Whereas some investigators have suggested that admission of cancer patients to the ICU is costly and ultimately futile,[1–4] others have challenged this assumption.[3,5–7] The outcome for cancer patients admitted to an ICU is directly related to the degree of end-organ damage rather than to the status of the underlying malignancy.[6,8,9] The rates of mortality are highest (80% to 100%) when cancer patients admitted to intensive care units (ICUs) have serious damage to three or more organ systems,[8,9] or those who develop respiratory failure and require mechanical ventilation.[6,7,10–13] Further need for critical care services beyond 14 days has been associated with a 100% hospital mortality rate in a number of studies.[8,9] Some factors are additive for ICU-related mortality. For example, a German study reported a mortality rate of 55% in patients with persistent severe neutropenia, 72% for neutropenic cancer patients requiring mechanical ventilation, and 90% for neutropenic cancer patients with invasive fungal infection who require mechanical ventilation.[7] The critical care consultant must give careful consideration to these factors to estimate the probability that a critically ill febrile neutropenic patient will survive the episode long enough for the antineoplastic treatments to have their desired effect.

Deficits in Host Defenses Related to Cancer Chemotherapy

MYELOSUPPRESSION AND NEUTROPENIA

The absolute number of circulating segmented neutrophils (ANC) represents the most important single parameter predictive of the risk for life-threatening infection.[14] An ANC of 1.5 to 8.0 $\times$ 10^9/L can be considered normal for adults. As the ANC declines below 1.0 $\times$ 10^9/L the risk of infection increases, with greatest risk for bacteremic infection at neutrophil counts below 0.1 $\times$ 10^9/L. Figure 47-1 illustrates the relationship between the neutrophil count and infection for a series of patients undergoing remission-induction therapy for acute leukemia.

The ANC is calculated by multiplying the proportion of white blood cells (WBCs) that are segmented neutrophils on a Romanovsky-stained blood smear by the total number of WBCs in a specified volume of blood measured in an automated blood cell counter. Since neutropenic patients with acute leukemia undergoing cytotoxic therapy frequently have total WBC counts of $<0.5 \times 10^9$/L, neutrophils may be difficult to detect on a manually reviewed stained smear; accordingly, the range of error for the procedure increases dramatically. Further, automated blood cell counters may give misleading results when abnormal cells such as leukemic blasts of similar size as segmented neutrophils are present in the circulation. This should dissuade the clinician from relying too heavily on a single ANC to judge the risk of infection. Rather, the clinical relevance of the ANC lies in the recognition of the range associated with a specific infection risk.

The pattern of change of the ANC also has a significant independent influence on infection risk. In one study, 29% of the bacteremic episodes occurred as the neutrophil count was falling but before the ANC fell below 0.5 $\times$ 10^9/L.[15] Therefore, with a falling neutrophil count, multiple observations over time are necessary to establish a pattern for the neutrophil profile and to estimate the relative infection risk. Survival of an infection during severe neutropenia is also intimately linked to marrow recovery and recovery of the circulating neutrophil count.[16,17] The poorest outcomes for the infectious episodes occur among patients in whom the ANC continues to decline or fails to increase.[18,19]

The duration of severe neutropenia (ANC $< 0.5 \times 10^9$/L) is also related directly to infection risk. For example, bacteremic infections occur 3.5 times and 5.4 times more often when neutropenia lasts 6 to 15 days and >15 days, respectively.[20] The duration of neutropenia is related to the degree of hemopoietic stem cell damage caused by the underlying disease

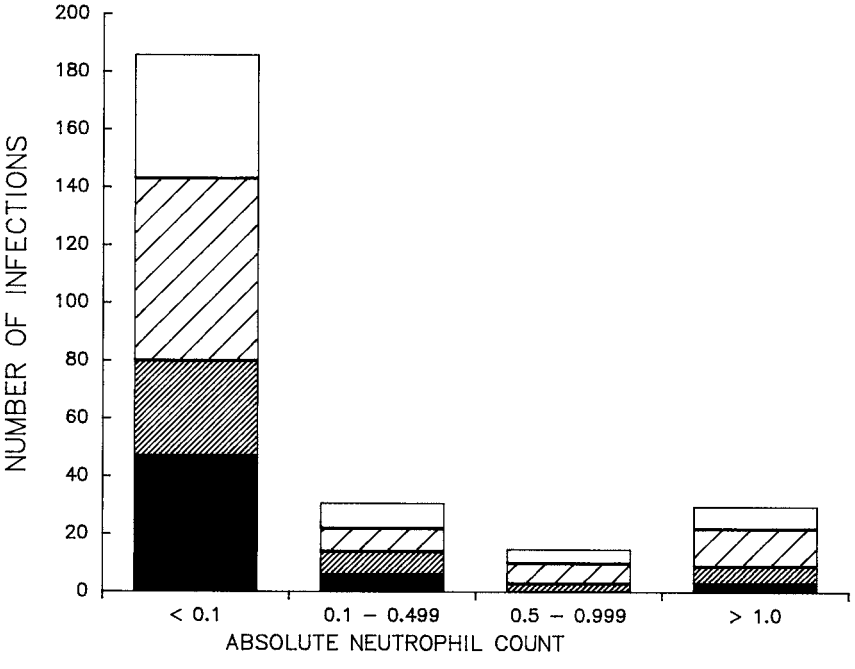

FIGURE 47-1 The relationship between the ANC and occurrence of infection in 98 patients undergoing remission-induction therapy for acute myeloid leukemia (AML). The proportions of the infections classified as possible infection, clinical infections, nonbacteremic microbiologically documented infection, and bacteremic infection are shown. The greatest risk for infection occurs when the ANC is $<0.1 \times 10^9$/L. Possible infections, open bars; clinical infections, open crosshatch bars; nonbacteremic microbiologically documented infections, close crosshatch bars; bacteremia, black bars.

process and by myelosuppressive regimens. Following stem cell suppression, the peripheral neutrophil count falls at a rate inversely proportional to the size of the circulating and marginated peripheral neutrophil pools and the size of the marrow storage pool of mature segmented neutrophils. Marrow recovery follows the recruitment of committed stem cells that are the precursors of granulocytic, monocytic, erythroid, and megakaryocytic cell lines from the resting pluripotential stem cell pool. These hemopoietic stem cells must be able to proliferate to increase their numbers and then differentiate to provide the functional effector cell populations.

Patients receiving pulse doses of chemotherapy for solid tissue malignancies or lymphoreticular malignancies sustain only temporary damage to the hemopoietic stem cell pool. The expected circulating neutrophil nadir generally occurs between days 10 and 14. Although the neutrophil nadirs may be $<0.5 \times 10^9$/L, the duration of neutropenia is rarely longer than 5 to 7 days (median = 3 to 5 days). For example, a patient receiving cyclophosphamide, doxorubicin (hydroxydaunomycin), vincristine (Oncovin), and prednisone (CHOP) beginning on day 1 of a 21-day cycle of treatment for an intermediate- to high-grade non-Hodgkin's lymphoma might develop a febrile episode on day 12 in association with an ANC of 0.1×10^9/L. The patient's neutrophil count would be expected to have reached its nadir, and a rise in circulating neutrophils would be predicted to occur between days 15 and 21. The likelihood that this prediction is correct is increased if a relative monocytosis is observed on the differential WBC count. The recovery of peripheral blood monocytes precedes that of circulating neutrophils in chemotherapy-induced aplasia and often heralds the recovery of the ANC.

In general, the more dose-intensive myelosuppressive regimens are associated with more hemopoietic stem cell damage and longer durations of neutropenia. Standard remission-induction regimens for acute myeloid leukemia (AML) are composed of anthracycline drugs such as daunorubicin administered in intravenous doses of 30 to 60 mg/m^2 daily over 3 days, and an antimetabolite, cytarabine, administered as an intravenous bolus or as a continuous infusion at doses of 100 to 200 mg/m^2 daily over 5 to 7 days. These regimens predictably produce periods of profound myelosuppression, in which a median of 24 days passes until the circulating neutrophil count rises above 0.5×10^9/L.[21] If more than one cycle of therapy is required to achieve a complete remission, then the median time until marrow recovery may be prolonged by as long as 6 weeks. This additional period of myelosuppression is associated with a significant increase in infectious morbidity.[21,22]

More intensive regimens using high-dose cytarabine (HDARAC) in doses 15 to 30 times that for standard induction regimens have been successful for salvage therapy of relapsed or resistant leukemia, for initial remission-induction therapy, and for postremission consolidation therapy for acute leukemia.[21] The median time until neutrophil recovery ($>0.5 \times 10^9$/L) following administration of HDARAC (3.0 g/m^2 infused over 1 hour every 12 hours for 12 consecutive doses) is 25 to 30 days. Surprisingly, this period of myelosuppression is not substantially longer than for standard induction regimens. However, the period of risk for infection can be significantly longer (e.g., extending the time to neutrophil recovery to 40 to 60 days) for heavily pretreated patients, in whom there may be more prolonged direct effects of cytotoxic therapy on the marrow stem cell pool or the marrow microenvironment.

OTHER IMMUNOSUPPRESSIVE EFFECTS OF CYTOTOXIC THERAPY

The remission-induction regimens commonly used for acute leukemia have important immunosuppressive effects in addition to the myelosuppressive effects discussed above. Anthracyclines and similar agents (e.g., doxorubicin, daunorubicin, idarubicin, epirubicin, amacrine, mitoxantrone, and rubidazone), antimetabolites (e.g., cytarabine, methotrexate, thioguanine, and mercaptopurine), and alkylating agents (e.g., cyclophosphamide, ifosfamide, melphalan, busulfan, and platinum analogues) have profound suppressive effects on the numbers of circulating T and B lymphoid cells that parallel the acquired functional defects in cell-mediated and humoral immune mechanisms. At the clinical level, the consequences of these effects are reflected by an increased susceptibility to pathogens normally controlled by these mechanisms. The ultimate impact on immune responsiveness appears to depend on the schedule of administration.

T-LYMPHOCYTE FUNCTION

Indications from in vitro testing of lymphoid cell responsiveness to mitogen-induced blastogenesis suggest that T-cell function may be moderately depressed in patients with acute leukemia. Among patients undergoing remission-induction therapy for acute leukemia, decreased cell-mediated immune responsiveness can be detected for up to 6 months following chemotherapy-induced remission.[23,24] Immune function has been observed in some patients to decline once again as a herald to relapse.[23]

The clinical consequences of T-cell dysfunction vary with the underlying disease and the cytotoxic regimen. For example, *Pneumocystis carinii* infection is an uncommon phenomenon among adult patients undergoing remission-induction for AML, but relatively common among children undergoing consolidation and maintenance-phase chemotherapy for acute lymphoblastic leukemia (ALL).[25] An intermediate degree of risk for pneumocystosis appears to be present in those undergoing bone marrow allografting or autografting. The immunosuppressive potential of the conditioning regimens for bone marrow transplantation (BMT) appears to be greater than that associated with AML induction regimens. Accordingly, most centers managing these patients recommend administering primary prophylaxis for *P. carinii* in BMT recipients or patients with ALL. These infections rarely occur during the primary period of myelosuppressive therapy–induced neutropenia.

B-LYMPHOCYTE FUNCTION

Modern cytotoxic therapy for acute leukemia appears to have a more profound effect on humoral immune competence than on T-lymphocyte function. Serum immunoglobulin concentrations and the efficiency of new antigen-induced immunoglobulin synthesis have been observed to decline following institution of remission-induction therapy, reaching a nadir at approximately 5 weeks. It has been difficult to separate the effects of the underlying malignant disease from the effects of the cytotoxic therapy. There does not appear to be a prognostically useful parameter of T- or B-cell function

that predicts infection risk in neutropenic patients that is analogous to the predictive value of the ANC for pyogenic bacterial or fungal infection. However, presence of hypogammaglobulinemia may help identify increased risk of infection by encapsulated bacteria.

INTEGUMENTAL BARRIERS

Integumental barriers are among the most important and most often damaged defense systems for cancer patients. These barriers include the epithelial surfaces of the skin, the upper and lower respiratory tract, the upper and lower gastrointestinal (GI) tract, and the mucosal surfaces lining the genitourinary tract. In critically ill patients, the barrier function of these surfaces also may be compromised by procedures such as percutaneous intravenous catheterization, endotracheal intubation, endoscopic procedures, nasogastric intubation, and indwelling urinary catheterization (Table 47-1).

Integumental damage secondary to cytotoxic therapy has become more prevalent as the dose intensity of the remission-induction regimens has increased.[26] The epithelial surfaces of the GI tract appear to be at greatest risk. The antiproliferative effect of therapy prevents cell recruitment into mucosal areas denuded by erosion or by cellular attrition, resulting in the appearance of superficial erosion and ulceration. The absorptive capacity of the GI mucosa also may be impaired significantly among recipients of regimens such as HDARAC, and both anatomic mucosal disruption and absorptive dysfunction appear to temporally parallel that of the neutrophil profile.

A high proportion of patients receiving cytoreductive therapy also experience painful, often debilitating inflammatory lesions within the oral cavity.[27] The tissues of the periodontium, gingival surfaces, oral mucosa, and mucosal surfaces of the upper and lower bowel are affected.[26] Cytotoxic regimens affect the developing basal epithelial cells of the oral mucosa in a manner that parallels the effect on the marrow system cell pool and the intestinal mucosal surface.[28] Mucosal atrophy, cytolysis, and denudation of the mucosal surface result in the painful foci of local ulceration typically observed 4 to 7 days after the administration of the cytotoxic agents and which usually resolve spontaneously between days 14 and 21.[27,29]

Cytotoxic therapy–induced intestinal mucosal damage has been described in three stages.[28] The first stage of initial injury begins during the first week of cytotoxic therapy and is characterized by replacement of the normal crypts and mucus-secreting goblet cells by atypical undifferentiated cells. The second stage represents progressive mucosal injury that occurs during the second and third weeks. This stage is characterized histologically by cellular necrosis, lack of mitotic activity, and focal loss of villous surfaces, and clinically by abdominal pain, diarrhea, electrolyte loss, and invasive infection. The third stage of cellular regeneration occurs after the third week and is characterized by resumption of mitotic activity and cellular proliferation in the crypts with subsequent repopulation of the denuded surfaces by differentiated cells.

The maximum cytotoxic therapy–induced intestinal epithelial damage occurs in the second week between days 10 and 14.[30–32] This corresponds to the median time of onset of bacteremic infection on day 14 due to the microorganisms that normally colonize these surfaces.[33] To a limited extent, the type of pathogens recovered in bacteremic infections can be predicted from the pool of microorganisms colonizing damaged mucosal surfaces. Oral mucosal ulceration, particularly that involving periodontal tissues, is often associated with viridans group streptococcal bacteremia.[34,35] Colonic mucosal damage is more likely to be associated with aerobic gram-negative bacillary infection with *Escherichia coli, Klebsiella* species, *Pseudomonas aeruginosa,* or opportunistic yeasts when these pathogens are colonizing the lower GI tract.[33]

Mucositis not only predisposes patients to invasive infection, but also imposes a significant cost with respect to the resources needed to manage the consequences of mucositis.[36,37] Recent cost estimates suggest that an episode of severe mucositis may cost an average of $7985 (U.S. dollars; USD) (year 2002) per patient (95% CI $6164 to $9806).[37] Neutropenia with or without infection is estimated to cost an average of $9316 USD (year 2002) per inpatient (95% CI $8522 to $10,110). In times of fiscal restraint, these complications have great significance for institutions charged with the responsibility for managing cancer patients.

INFECTIONS AND PATHOGENS

In a review of bloodstream infections occurring in patients with hematologic malignancies over a 14-year period in a tertiary cancer center in Sweden, gram-negative bacilli accounted for 45% and gram-positive organisms accounted for 55%.[38] Coagulase-negative staphylococci accounted for 17.5%; *Escherichia coli* for 16.3%; viridans group streptococci for 12.7% (with *S. mitis* being the most common in 50 of 178 isolates); *Klebsiella* and *Enterobacter* spp. for 12.7%; *Staphylococcus aureus* for 8.9%; *Enterococcus* spp. for 7.3%; and *Pseudomonas aeruginosa* for 5.5%.[38] Of note in this experience was the rising incidence of enterococcal bloodstream infections due to penicillin-resistant *E. faecium* and the high 30-day mortality (24%) compared to other gram-positive 30-day mortality rates (~15%).[38]

The infections documented among febrile neutropenic patients have been classified as microbiologically documented with the identification of a pathogen and a focus of infection; as clinically documented with the identification of a clinical focus of infection without isolation of a putative pathogen; and as an unexplained fever wherein neither a

clinical focus nor a pathogen are identified.[39] Among febrile neutropenic cancer patients not receiving fluoroquinolone chemoprophylaxis managed during the early 1990s, Cornelissen and colleagues reported that microbiologically-documented infections were observed in 33% of patients, with gram-negative infections comprising 18%, gram-positive infections in 9%, and mixed gram-negative and gram-positive infections in 6%.[40] Forty-two percent of patients had clinically documented infections and the remaining 24% had unexplained fevers. Among a similar group of patients who had received ciprofloxacin chemoprophylaxis, there were no gram-negative infections. Gram-positive infections were observed in 38% of patients, clinically-documented infections in 47% of patients, and unexplained fevers in only 15%.

A more recent study wherein the investigators identified all potential clinical foci of infections reported the GI tract as the focus of infection in 41% of patients with the oropharynx accounting for 70%, the esophagus 3%, clinical neutropenic enterocolitis 17%, and perirectal soft tissue infection 10%.[41] Other foci included the respiratory tract in 10%, urinary tract in 6%, and skin and soft tissue in 10%. Of the skin foci, indwelling central venous catheter sites accounted for 59%, folliculitis for 6%, and cellulitis for 35%.[41] Unexplained fevers accounted for only 10% of cases and microbiologically-documented bloodstream infections were seen in 23% of patients, of which gram-negative bacillemia accounted for 37%, coagulase-negative staphylococcemia 19%, streptococcemia 27%, and other gram-positive microorganisms in 16%.[41] These observations illustrate that with clinical diligence, clinical foci of infection may be identified in the majority of febrile neutropenic patients receiving cytotoxic therapy.

Approach to Fever Associated with Neutropenia

Fever is the hallmark of infection for most patients during periods of prolonged severe neutropenia. The definition of what constitutes a febrile episode due to suspected infection in a neutropenic patient has varied greatly in different studies.[18–20,34,41–52] The International Antimicrobial Therapy Cooperative Group (IATCG) of the European Organization for Research and Treatment of Cancer (EORTC),[20,47,48] the Intercontinental Antimicrobial Study Group,[50] and others[49] have used an oral temperature of >38°C (100.8°F) sustained over a 12-hour period or a single oral temperature of >38.5°C as the criterion for infection-related fever. The recently published German guidelines define an unexplained fever by a single oral temperature of >38.3°C or >38.0°C lasting over an hour or measured twice within 12 hours.[53] The National Cancer Institute of Canada Clinical Trials Group also has used a single oral temperature of >39°C together with chills or rigors instead of a single temperature of >38.5°C.[18,54] In order to avoid the administration of antimicrobial therapy to patients with noninfectious causes of fever, a qualifier often has been added to these definitions stipulating that other causes of noninfectious fever should be excluded. Such causes include blood products, pyrogenic drugs such as amphotericin B, thrombophlebitis, or hematoma. The Infectious Diseases Society of America (IDSA) has suggested that a single oral temperature of >38.3°C (101°F) in the absence of other obvious environmental causes would be a reasonably safe working definition for an infection-related fever in neutropenic patients.[55]

The extent to which characteristics of the febrile episode predict a bacteremic event has been somewhat variable in different studies; however, most agree that initial oral temperatures of >39°C (102.2°F), shaking chills, clinical shock, initial ANC of $<0.1 \times 10^9$/L, and initial platelet count of $<10 \times 10^9$/L are to some degree predictive of gram-negative bacteremia.[15,20,42,56] Viscoli and associates[20] demonstrated an 8.4-fold increase in risk for bacteremic infection in neutropenic patients with initial temperatures of >39°C (102.2°F). The duration of fever prior to evaluation, however, does not appear to influence the risk of gram-negative bacteremia.[15]

The risk of developing a febrile neutropenic episode during each cycle of outpatient cancer chemotherapy for solid tissue malignancies or lymphoreticular malignancies is generally low.[57] However, this risk increases with the number of cycles administered and with the dose intensity of the regimen selected.[58] In a study of patients with lymphoma from the M.D. Anderson Cancer Center, the cumulative incidence of febrile neutropenic episodes increased from 12% among recipients of cyclophosphamide, vincristine (Oncovin), and prednisone (COP) to 27% among patients receiving a related regimen where doxorubicin (hydroxydaunomycin) was substituted for the cyclophosphamide (HOP) and 46% among recipients of cyclophosphamide, doxorubicin, vincristine (Oncovin), and prednisone (CHOP).[59] In recent studies, the incidence of infection among CHOP recipients has been lower, approximately 15% of all cycles.[60] Similarly to the findings of the study by Feld and Bodey,[59] the addition of cytotoxic agents to a chemotherapy regimen has the effect of increasing the likelihood of myelosuppression. For example, the addition of paclitaxel or docetaxel to carboplatin for the treatment of gynecologic malignancies increased the incidence of severe neutropenia (ANC $< 0.5 \times 10^9$/L) from <1% to 7% and 73%, respectively.[61] However, the addition of irinotecan to carboplatin and paclitaxel increased the incidence of severe neutropenia from 7% to 61%, but did not enhance the odds of developing a febrile neutropenic episode (odds ratio 3.56, 95% CI 0.71 to 17.94).[61] The median incidence of febrile neutropenic episodes in patients with small-cell lung cancer is reported as 35% for recipients of cyclophosphamide, doxorubicin, and etoposide (CAE) compared with 18% for recipients of a less myelosuppressive regimen containing cyclophosphamide, doxorubicin (Adriamycin), and vincristine (CAV).[62] In addition to the factor of neutropenia, the propensity of a given regimen to induce mucosal damage resulting in mucositis correlates directly with the incidence of febrile neutropenic episodes. The severity of mucositis is directly related to the incidence of febrile events, the duration of hospitalization, the costs of medical care, and treatment-related mortality.[36]

In contrast, febrile neutropenic episodes occur in 70% to 90% of patients receiving intensive cytotoxic therapy for acute leukemia and bone marrow transplantation.[54,63] This difference is due to the more prolonged cytotoxic therapy-induced myelosuppression and greater intestinal epithelial damage in these patients.[32]

Prolonged neutropenic periods may be punctuated by one or more febrile episodes, and a single febrile neutropenic episode may represent more than one infectious process. For example, a febrile neutropenic episode associated with a

viridans group streptococcal bacteremia may not be seen to defervesce promptly despite the administration of appropriate antibacterial therapy and despite the documentation of a microbiologic cure on the basis of subsequent sterile blood cultures. This phenomenon of a persistent febrile state may occur in association with the concomitant administration of pyrogenic blood products, the presence of a coexisting infection such as a herpes simplex virus (HSV) mucositis, or a possible fungal superinfection. It is frequently impossible to distinguish clinically the boundaries defining separate sequential infectious processes by the pattern of fever unless a clear pattern of defervescence is seen between one infection and the next. This is particularly frustrating for clinicians managing febrile neutropenic patients without a defined clinical focus of infection or a defined pathogen.

DIAGNOSIS

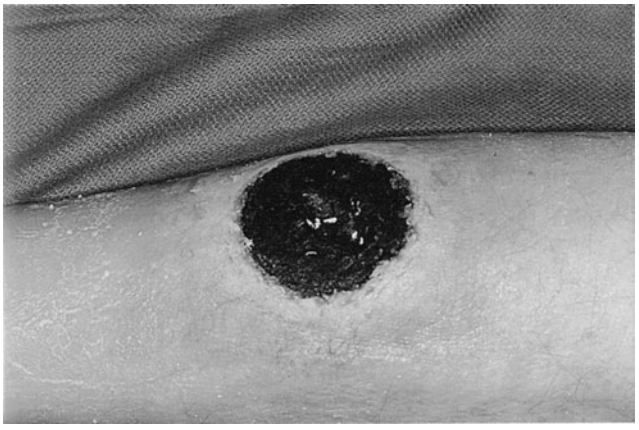
Most febrile neutropenic episodes are assumed to represent infection. The diagnosis of a febrile state in a neutropenic patient requires a complete but directed clinical history and physical examination designed to identify potentially infected foci for which those patients are at special risk.

Important historical facts may be obtained from the patient, from significant others, and from the patient's medical record. The physician must verify that the patient is neutropenic, the degree of neutropenia, and when the patient is a recipient of cytotoxic therapy, the day of the chemotherapy cycle. The latter is determined relative to the first day of the last cycle of chemotherapy, or in the case of BMT recipients, the day of the BMT.

To avoid omitting the consideration of other noninfectious causes of fever in neutropenic patients, the clinical evaluation should include questions pertaining to the temporal association of the febrile episode to the administration of blood products, to a history of fever associated with the underlying disease, to the administration of chemotherapeutic agents or amphotericin B, to the presence of thrombophlebitis, and to the possible association of the febrile episode with thromboembolic or hemorrhagic events. For example, in a series of neutropenic patients undergoing remission-induction therapy for acute leukemia,[17] 26 of 72 (36%) febrile episodes were due to noninfectious causes (blood products in 33%, underlying disease or cytotoxic drugs in 15%, and unexplained causes in 47%). However, the majority of these patients had further febrile episodes for which a diagnosis of infection could not be excluded confidently.

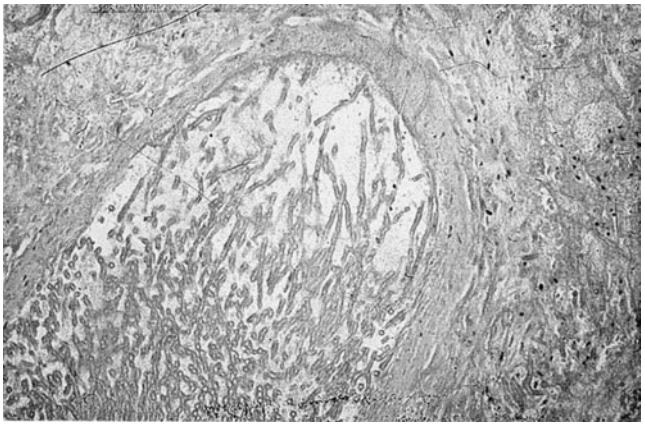
The physical signs of inflammation and infection are influenced by the ANC. The incidence and magnitude of localizing findings such as exudate, fluctuance, ulceration, or fissure formation are reduced in a direct relationship to the ANC.[64] Other localizing findings, such as erythema and focal tenderness, appear to remain as useful and reliable signs of infection regardless of the ANC.

The body systems most often involved with infection in neutropenic patients are those associated with integumental surfaces (i.e., the upper and lower respiratory tracts, the upper and lower GI tracts, and the skin).[42,64,65] Table 47-2 lists the pertinent historical and physical clues to be sought in the clinical evaluation of a febrile neutropenic patient.



Examination of the head and neck area should include eyegrounds, the external auditory canals and tympanic membranes, the anterior nasal mucosa, the vermilion border of the lips, and the mucosal surfaces of the oropharynx. The eyeground examination should look for retinal hemorrhages as evidence of a bleeding diathesis and retinal exudates (often described as "cotton wool" exudates) that would suggest endophthalmitis associated with disseminated candidiasis. Examination of the external auditory canals and tympanic membranes for erythema or vesicular lesions can implicate this as a focus for infection by respiratory pathogens or herpes viruses. The anterior nasal mucosal surfaces should be examined for ulcerated lesions that might suggest the presence of a local filamentous fungal infection such as that due to *Aspergillus* species. The skin of the external nares should be examined for vesicular or crusted lesions that would suggest HSV infection. Nasal stuffiness and tenderness over the maxillary sinuses suggests that sinusitis is the infectious problem.

The oropharyngeal examination consists of inspection of the dentition, gingival surfaces, mucosal surfaces of the cheeks, hard and soft palate, tongue surfaces, and posterior pharyngeal wall. The presence of decaying teeth and gingival hyperemia implicates those sites as possible sources of bacteremic infection. The presence of shallow, painful mucosal ulcers on an erythematous base suggests herpes mucositis. Progression of this kind of lesion with local tissue necrosis can suggest a polymicrobic infection due to oropharyngeal anaerobic bacteria (e.g., *Fusobacterium nucleatum, Bacteroides melaninogenicus,* and peptostreptococci), particularly if cultures for HSV are negative or if such lesions develop during prophylactic or therapeutic administration of acyclovir. Oral thrush or pseudomembranous pharyngitis evolves from an overgrowth of opportunistic yeasts such as *Candida* species. These lesions are characterized by a thick creamy pseudomembrane consisting of masses of fungi existing in both the yeast and the mycelial phases. The distribution may be patchy, confluent, or discrete. The pseudomembrane is frequently closely adherent to the underlying mucosal surface such that attempts at removal reveal an erythematous or hemorrhagic base. The diagnosis is suspected by the clinical appearance and confirmed by the demonstration of the pathogen in culture and by the microscopic appearance of budding yeasts and pseudohyphae on a Gram's stain or potassium hydroxide preparation.



Chest examination should emphasize evaluation of the lower respiratory tract and central venous catheter sites. The typical signs of pulmonary consolidation may be muted or absent in neutropenic patients; however, localized crepitation on auscultation often precedes the appearance of pulmonary infiltrates radiologically, and thus often represents the earliest clue (and often the only clue) to a developing pneumonia in a neutropenic patient. Purulent sputum is similarly reduced in incidence and amount. Therefore the symptoms of the neutropenic patient with a developing pneumonia may manifest only as febrile illness associated with an increased respiratory rate and a few localized crepitations, with or without an associated cough or radiologic changes.[66] The clinician must search for additional differential diagnostic clues such as the origin of the suspected pneumonia (community- or hospital-acquired), the tempo of the illness, the association of the illness with other potentially noninfectious factors such as pulmonary edema, exposure to certain chemotherapeutic agents associated with lung injury (bleomycin, busulfan, or cytarabine), radiation therapy, pulmonary thromboemboli,

TABLE 47-2 Clinical Evaluation of the Febrile Neutropenic Patient

	FINDINGS TO BE SOUGHT	
Body System	Historical	Physical
Eye	Blurring of vision Double vision Loss of vision Pain	Scleral abnormalities Icterus Hemorrhage Local swelling Conjunctival abnormalities Focal erythema Petechiae Retina Hemorrhage "Cotton wool"exudates (e.g., candidal endophthalmitis)
Skin	Skin rash Pruritus (focal or diffuse) History of drug reactions Focal pain/swelling IV catheter site(s)	Central venous catheters Insertion site erythema/pain Tunnel site erythema/pain Exit site erythema/pain/exudate Peripheral IV catheters Focal tenderness Focal erythema Exudate at the insertion site Skin rash Papular/macular/vesicular Ulceration Focal areas of necrosis (e.g., ecthyma gangrenosum) Distribution
Upper respiratory	Painful ear Nasal stuffiness Sinus tenderness Epistaxis	External auditory canals Thympanic membrane erythema
Lower respiratory	Cough Increased respiratory secretions Dyspnea Hemoptysis Chest pain	Tachypnea Tachycardia Hyperpnea Localized crepitations Consolidation
Upper gastrointestinal	Odynophagia Dysphagia History of denture use History of herpes stomatitis	Gingival bleeding Pseudomembranous exudate over buccal and gingival surfaces and tongue Mucosal erythema Mucosal ulceration Focal pain Preexisting periodontitis
Lower gastrointestinal	Abdominal pain Constipation Diarrhea ± bleeding Perianal pain with defecation Jaundice	Focal abdominal pain Right upper quadrant (e.g., biliary tree) Right lower quadrant (e.g., cecum/ascending colon) Left lower quadrant (e.g., diverticular disease) Perianal abnormalities Focal tenderness Focal/diffuse erythema Fissures Ulcerations Hemorrhoidal tissues

pulmonary hemorrhage, or hyperleukocytosis. The physical assessment of the chest can do little to differentiate infectious or noninfectious causes of pulmonary findings, but it can help identify the lower respiratory tract as the potential infected focus.

The symptoms and signs of an intra-abdominal infection may be obvious or muted, focal or diffuse. The most important finding is focal tenderness.[64] For example, tenderness in the right lower quadrant might suggest neutropenic enterocolitis (typhlitis); right upper quadrant tenderness might suggest a biliary tract focus or hepatomegaly; epigastric pain suggests an upper GI focus; and left lower quadrant tenderness suggests colitis or diverticular disease. It is important to examine the perianal tissues for signs of excoriation, local erythema, swelling, tenderness, fissure formation, or hemorrhoidal tissues, since this area is frequently the site of major life-threatening infection in neutropenic patients. Digital examination of the rectum is not recommended in neutropenic patients because of the additional risk of tissue damage, bleeding, and infection. However, a light perianal digital examination can be informative about focal areas of cellulitis without increasing the risk of bacteremic infection.

The examination of the skin should consist of a thorough search for focal areas of pain, swelling, or erythema, especially in association with indwelling vascular access devices. Particular attention should be paid to the venous insertion, tunnel, and exit sites associated with central venous catheters. In contrast, nonspecific local pocket tenderness may be the only clue to infection associated with the totally implantable venous access port-reservoir systems.

Skin rashes are a common phenomenon among neutropenic patients. The differential diagnosis must include both infectious and noninfectious causes. Among the former group are focal ulcerative and necrotic lesions caused by metastatic pyogenic bacterial infection such as that associated with bacteremic *P. aeruginosa* or *Staphylococcus aureus* (infections causing ecthyma gangrenosum), or by disseminated angioinvasive filamentous fungi such as that due to *Aspergillus* species, *Pseudallescheria boydii* (formerly called *Allescheria boydii*; the conidial [asexual] state is *Scedosporium apiospermum*), or *Fusarium* species (Fig. 47-2). Pustular erythematous lesions diffusely distributed over the skin surface suggest the possibility of disseminated fungal infection such as that caused by *Candida tropicalis*. Vesicular skin lesions suggest the possibility of infection due to HSV or herpes zoster virus.

The list of possible noninfectious causes of skin rash is long. The three most important considerations are hemorrhagic petechial or ecchymotic rashes associated with profound thrombocytopenia; hypersensitivity rashes associated with specific drugs such as β-lactam antibacterial drugs, allopurinol, or trimethoprim-sulfamethoxazole (TMP-SMX); and specific chemotherapy regimen–related rash syndromes (e.g., the exfoliative palmar/plantar syndrome associated with high-dose cytarabine; Fig. 47-3). These skin rash syndromes may coexist simultaneously. For example, experience has shown that patients undergoing remission-induction therapy with high-dose cytarabine for AML may develop hemorrhagic petechial rashes due to thrombocytopenia, palmar/plantar erythema, and edema due to cytarabine; macular penicillin-related hypersensitivity rash; and hemorrhagic cutaneous infarcts secondary to angioinvasive bacteremic or fungemic infection, all simultaneously. Only careful attention to the pertinent details of history and thorough laboratory

FIGURE 47-3 Palmar/plantar desquamation occurring on day 9 of treatment in a patient receiving high-dose cytarabine.

investigations can increase the likelihood that the correct diagnosis and therapeutic decisions will be made.

Once the relevant historical details and physical findings are established, the complete evaluation of the febrile neutropenic patient should include a series of laboratory and radiologic investigations designed to complement the clinical examination. Specimens of body fluids such as blood, urine, cerebrospinal fluid, and lower respiratory secretions should be submitted to the clinical microbiology laboratory for culture and antimicrobial susceptibility testing where appropriate. At least two sets of blood cultures should be obtained, at least one of which should be taken from a peripheral venous site. Furthermore, it has been recommended that for patients with multilumen indwelling central venous catheters, each lumen of the catheter should be sampled in addition to blood from the peripheral venous site.[55]

The basic radiologic investigation is the chest radiograph (posteroanterior and lateral views). When suggested by clinical clues, sinus radiographs are useful for detecting sinus opacification or fluid levels. Panoramic x-ray radiographs can be helpful for evaluating periodontal infection. High-resolution computed tomographic (HRCT) examinations of the lungs has a high yield of abnormalities in febrile neutropenic patients despite normal or nondiagnostic chest radiographs.[67,68] In one study, 60% of febrile neutropenic patients with normal chest radiographs had a pulmonary infiltrate demonstrable on the chest HRCT.[67] Computed tomography (CT) of the abdomen or hepatic ultrasonography is valuable for assessing the significance of abnormalities in cholestatic enzymes (γ-glutamyltransferase [GGT] and alkaline phosphatase). This is particularly important if the possibility of hepatosplenic candidiasis exists. Abdominal pain and tenderness with diarrhea in a persistently febrile neutropenic patient suggests the possibility of neutropenic enterocolitis. Abdominal CT examination looking for evidence of bowel wall thickening, pneumatosis, wall nodularity, mucosal enhancement, bowel dilation, ascites, and mesenteric stranding is very useful in making the diagnosis.[69]

Tissue obtained by biopsy of infected sites can be important in the diagnostic evaluation. Biopsied material should be submitted to the clinical microbiology laboratory for culture and to the pathology laboratory for histopathologic or etiologic evaluation. It is relatively common for pathogens to be observed histopathologically in infected tissue specimens without recovery of the organism by culture. Such is the case in the syndrome of hepatosplenic candidiasis, where budding yeasts and pseudohyphae observed in liver biopsy specimens frequently fail to grow in microbiologic cultures. Skin biopsies are often helpful to distinguish drug-related lesions from those caused by specific pathogenic microorganisms. Although ideally desirable for a complete evaluation, tissue biopsies of suspect sites in neutropenic thrombocytopenic patients carry the additional risks of further infection and bleeding. In addition to skin, the body sites most often considered for biopsy are esophagus (to differentiate mucositis secondary to fungi, pyogenic microorganisms, herpes viruses, or chemotherapeutic agents), liver (to evaluate hepatic lesions due to fungi, herpes viruses, pyogenic bacteria, and drug-related or disease-related hepatic damage), and lung (to evaluate the etiology of progressive infiltrates). Institutions caring for these patients should have a protocol for specimen collection and handling developed in consultation with the appropriate laboratories, the operating theaters, and surgical services.

RISK ASSESSMENT

Neutropenia-related febrile episodes are heterogeneous with respect to the cause of neutropenia, the duration of neutropenia, the risks of developing fever, the cause of fever, and the cause of infection. Furthermore, patients differ in their response to treatment and in the risks of complications, including those which are serious and life threatening. Accordingly, the practice standard has been to hospitalize all febrile neutropenic patients for assessment, administration of empiric broad-spectrum intravenous antimicrobial therapy,[55] and monitoring for and management of complications. Such complications include management of hemodynamic instability and hypotension; respiratory insufficiency requiring oxygen administration; control of pain, nausea, vomiting, and dehydration; investigation and management of confusion, delirium, and altered mental status; hemorrhage requiring blood product transfusion; cardiac dysrhythmia requiring monitoring; changes in metabolic function requiring intervention; and death.

Investigators from the Dana-Farber Cancer Institute[70] examined the natural history of febrile neutropenic patients to identify patients at risk for complications due to the neutropenia, the infection, the underlying cancer, and other comorbid conditions. Concurrent comorbidity included hypotension (defined by a systolic blood pressure of $<$90 mm Hg), altered mental status, respiratory failure (defined by a partial pressure of arterial oxygen of $<$60 mm Hg), uncontrolled bleeding, severe thrombocytopenia (defined by a platelet count of $<40 \times 10^9$/L), inadequate outpatient fluid intake or pain control, suspected spinal cord compression, symptomatic hypercalcemia, the need for hospitalization for induction therapy, serious localized infections, acute abdomen, new deep venous thrombosis, syncope, bowel obstruction, and poor performance status (Karnofsky performance status of $<$50%). Medical complications included hypotension, respiratory failure, new cardiac dysrhythmia or electrocardiographic changes, altered mental status, new focal neurologic abnormalities, hemorrhage requiring $>$3 units of packed red blood cell transfusion within 24 hours, congestive heart failure, emergency surgery, acute abdomen, pulmonary thromboembolism, acute renal failure, and diabetic ketoacidosis. Based on these comorbidities and complications, febrile neutropenic patients could be classified into three groups at high risk for complications and one low-risk group. Group 1 (39% of the total) was comprised of hospitalized patients usually with hematologic malignancies or hemopoietic stem cell transplant. Complication and morbidity rates were 34% and 23%, respectively. Group 2 (8% of the total) was comprised of outpatients with concurrent comorbidity and had complication and mortality rates of 55% and 14%, respectively. Group 3 (10% of the total) was comprised of outpatients with as yet uncontrolled or progressive cancer and had complication and mortality rates of 31% and 15%, respectively. Group 4 (the low-risk group, 43% of the total) was comprised of outpatients with controlled or responding cancer and no comorbid processes. This group had a complication rate of 2% and no deaths. These observations were prospectively validated in follow-up studies.[70,71] These results suggest that high-risk

patients with characteristics corresponding to groups 1 to 3 should be admitted and managed as inpatients with careful monitoring for serious complications, whereas low-risk patients corresponding to group 4 can be managed safely and effectively on an outpatient basis.[71–79]

The Multinational Association for Supportive Care in Cancer developed a scoring system to identify low-risk patients for serious medical complications that would require admission to the hospital.[26,80] Identifying factors included absence of symptoms, hypotension, airflow obstruction, hematologic malignancy, invasive fungal infection, or dehydration. Furthermore, status as an outpatient at the onset of the febrile neutropenic episode and age <60 years were also identifying factors. A score of >21 of a possible 26 identified low-risk patients with a positive predictive value of 91%, specificity of 68%, and sensitivity of 71%. This system has been offered as a strategy for identifying patients eligible for studies of more cost-effective, safe, outpatient-based management strategies.

EMPIRIC ANTIMICROBIAL THERAPY

The empiric initial therapy for suspected infection in febrile neutropenic patients is based on three assumptions:

1. The majority of infections are due to bacteria.[81]
2. The principal pathogens are aerobic gram-negative bacilli (*E. coli, Klebsiella pneumoniae,* and *P. aeruginosa*).[42,81]
3. Inappropriate therapy for aerobic gram-negative bacillemia is associated with high mortality with a median survival of less than 72 hours.[82]

Accordingly, the antibiotic regimens that have been recommended for empiric first-line therapy of first fever in neutropenic cancer patients are designed to have excellent activity against these pathogens. With the recognition of various factors favoring infection by gram-positive organisms,[83] the addition of agents with an improved spectrum of activity against these pathogens when appropriate also has been recommended.[84]

Empiric antibacterial therapies may be administered either as combination regimens or as single-agent regimens (monotherapy) (Tables 47-3 and 47-4). Combination regimens include β-lactam agents combined together[18,85,86] (double β-lactam regimens), combined with aminoglycosides,[42–44,47,49,50,87] or combined with fluoroquinolones.[41,88] Single-agent regimens consist of β-lactam agents[48–50,52,89–92] with or without β-lactamase inhibitors (tazobactam, clavulanic acid, or sulbactam) or fluoroquinolones.[93–95] Monotherapy with aminoglycosides is not recommended.[55]

β-Lactam antibacterial agents may be categorized as extended-spectrum antipseudomonal penicillins (e.g., carbenicillin, ticarcillin with or without clavulanic acid, piperacillin with or without tazobactam, azlocillin, or mezlocillin), third- or fourth-generation antipseudomonal cephalosporins

TABLE 47-3 Antimicrobial Therapy Used for Therapy in Febrile Neutropenic Patients

β-Lactam antibiotics	
Ticarcillin ± clavulanic acid	
Piperacillin ± tazobactam	200–300 mg/kg per day IV
Azlocillin	4–6 divided doses daily
Mezlocillin	3 g q4–6h IV
Cefoperazone	2 g q12h IV
Ceftriaxone	2 g q24h IV
Ceftazidime	2 g q8h IV
Imipenem/cilastatin	500 mg q6h IV
Meropenem	1 g q8h IV
Aminoglycosides	
Gentamicin	1.5–2 mg/kg q8h IV
Netilmicin	1.5–2.0 mg/kg q8h IV
Tobramyicn	1.5–2 mg/kg q8h IV
Amikacin	7.5 mg/kg q12h IV
Fluoroquinolones	
Ciprofloxacin	400 mg q12h IV 500–750 mg q12h PO
Ofloxacin	400 mg q12h PO
Perfloxacin	400 mg q12h PO
Enoxacin	400 mg q12h PO
Other agents	
Vancomycin	1.0 g q12h IV or 30 mg/kg per 24 h
Metronidazole	500 mg q8h IV/PO
Erythromycin	0.5–1.0 g q6h IV
TMP-SMX	10–20 mg/50–100 mg/kg per day in 4 divided doses
Acyclovir	250–500 mg/m^2 q8h IV
Ganciclovir	5 mg/kg q8-12 h IV
Amphotericin B	0.5–1.5 mg/kg per day IV
Amphotericin B lipid complex	5 mg/kg per day IV
5-Fluorocytosine	150 mg/kg per day PO in 4 divided doses
Fluconazole	200–400 mg IV/PO qd
Itraconazole	200–400 mg PO qd

TMP-SMX, trimethoprim-sulfamethoxazole.

TABLE 47-4 Considerations Governing the Choice of Empiric Antibacterial Regimen

β-Lactam	High-risk neutropenia
+	Risk of *P. aeruginosa* infection
Fluoroquinolone or	Nosocomial infection
aminoglycoside	Prolonged severe neutropenia
Monotherapy	Patients with renal impairment
	Recipients of other nephrotoxic agents
	High-risk neutropenia
Oral therapy	Short-term neutropenia
	Low-risk neutropenia
Other agents	
Vancomycin	Suspect coagulase-negative staphylococcal infection
	Suspect vascular catheter infection
	Skin or soft tissue infection
Metronidazole	Suspect intra-abdominal infection
	Necrotizing gingivitis
	Severe oral mucositis
	Suspect perianal infection

(e.g., moxalactam, ceftriaxone, ceftazidime, cefoperazone with or without sulbactam, cefpirome, or cefepime), or as carbapenems (e.g., imipenem-cilastatin, meropenem, or ertapenem). The addition of β-lactamase inhibitors to the broad-spectrum antipseudomonal penicillins, ticarcillin and piperacillin, enhances their spectrum of activity against β-lactamase–producing bacteria and their roles in the management of the febrile neutropenic patient.[47,51,96–115]

In a recent review of physician prescribing behavior for 214 febrile neutropenic patients in Canadian centers, initial empiric therapy with a single agent was administered in 42% of cases in which a third-generation cephalosporin such as ceftazidime was used in 32%, a carbapenem in 2.3%, and a fluoroquinolone in 0.9%.[116] Combination therapy was administered in 58% of cases in which an antipseudomonal penicillin plus an aminoglycoside was given in 29% of cases, an antipseudomonal cephalosporin plus an aminoglycoside in 15%, and an antipseudomonal β-lactam plus a glycopeptide in 11%.[116] Vancomycin was part of the initial empiric antibacterial therapy in 15% of cases. First modification with second-line therapy for persistent fever was administered in 87% of the 214 cases after a median of 5 days. Systemic empiric amphotericin B was administered for persistent fever in 48% of the 214 febrile neutropenic episodes after a median of 9 days. Previous studies have demonstrated that glycopeptides are employed as empiric second-line therapy in 40% to 50% of cases in which extended-spectrum cephalosporins are administered as first-line empiric therapy.[48,51,97–100,117–128]

THE ROLE OF AMINOGLYCOSIDES IN TREATMENT OF FEBRILE NEUTROPENIC PATIENTS

Aminoglycosides were part of the standard combination empiric antibacterial therapy for the management of febrile neutropenic patients from the early 1970s to the 1990s. The combination of an aminoglycoside with an antipseudomonal β-lactam antibacterial agent was designed to have a broad spectrum of antibacterial activity, achieve bactericidal serum concentrations, exert a synergistic antibacterial effect, and prevent emergence of resistance. Such combinations have been recommended in published guidelines by the Infectious Diseases Society of America (IDSA),[55] the National Comprehensive Cancer Network,[129] and the Infectious Diseases Working Party of the German Society of Hematology and Oncology,[53] but not the Spanish guidelines, however.[130] The aminoglycoside antibiotics having proven roles for use with β-lactam antibiotics in neutropenic patients include gentamicin, netilmicin, tobramycin, and amikacin. The choice of aminoglycoside must be based on local institutional bacterial susceptibility patterns, the availability of a mechanism for serum aminoglycoside concentration monitoring, and drug cost.

A recent large randomized controlled trial from the University of Perugia, Italy, compared piperacillin-tazobactam to piperacillin-tazobactam plus amikacin.[51] The primary outcome was defervescence of all signs and symptoms of infection without modification of the initial antibacterial regimen. Response was observed in 179 of 364 (49%) monotherapy recipients and in 196 of 369 (53%) combination recipients ($p = 0.2$). The response rates in single-pathogen gram-positive bacteremias were low (27% and 32 %, respectively) because of the high proportion of coagulase-negative staphylococcal bacteremias (response rates 17% and 18%, respectively; $p = 0.8$). In contrast, the response rates for streptococcal and enterococcal bacteremias between the two groups were significantly higher (60% and 71%, respectively, $p = 0.7$). The response rates for single gram-negative bacteremias were also similar (36% and 34%, respectively; $p = 0.9$). The aminoglycoside failed to enhance the response rates in any circumstance. Studies such as this question the therapeutic value of combination antibacterial therapy with an aminoglycoside.

Two systematic reviews of the literature have examined the safety and efficacy of β-lactam plus aminoglycoside combinations in febrile neutropenic patients.[131,132] Furno and associates reviewed 4795 heterogeneously treated febrile neutropenic episodes entered into 29 randomized controlled clinical trials comparing monotherapy (ceftazidime, 9 trials; cefepime, 2 trials; cefoperazone, 1 trial; imipenem-cilastatin, 9 trials; meropenem, 4 trials; ciprofloxacin, 2 trials; and ofloxacin, 2 trials) and aminoglycoside-based combination therapy. The pooled odds ratios for overall treatment failure and for treatment failure in bloodstream infections were 0.88 (95% CI, 0.78 to 0.99) and 0.70 (95% CI 0.54 to 0.92), respectively, demonstrating fewer failures in the monotherapy groups.[131] Paul and colleagues examined 7807 febrile neutropenic patients entered into 47 randomized controlled trials comparing β-lactam monotherapy to β-lactam plus aminoglycoside combination therapy. The main outcome was overall mortality. While there was no significant difference in overall mortality (relative risk 0.85; 95% CI 0.72 to 1.02), there were fewer failures among β-lactam monotherapy recipients (relative risk 0.92; 95% CI 0.85 to 0.99).[132] Monotherapy recipients also experienced fewer adverse events overall (relative risk 0.85; 95% CI 0.73 to 1.00) and less nephrotoxicity (relative risk 0.42; 95% CI 0.32 to 0.56).[132] On the basis of these analyses, β-lactam plus aminoglycoside combinations offer no advantages over broad-spectrum β-lactam monotherapy. Rather they present significant disadvantages with respect to toxicity and costs related to drug monitoring and administration. Based on these observations and considerations, investigators are now recommending that the standard of care for initial therapy of febrile neutropenic cancer patients should be with a broad-spectrum β-lactam agent as monotherapy.[132]

FLUOROQUINOLONES IN THE TREATMENT OF FEBRILE NEUTROPENIC PATIENTS

The fluoroquinolones evaluated in studies of the empiric treatment of febrile neutropenic patients include ciprofloxacin,[41,133] perfloxacin,[134] ofloxacin,[73,74] levofloxacin,[135] and clinifloxacin.[94,95] These agents have the advantage of availability in both oral and intravenous formulations, which can facilitate intravenous-to-oral conv- ersion.[133,136,137]

The studies of empiric fluoroquinolones as first-line therapy for febrile neutropenic patients have largely targeted those patients at lower risk for medical complications.[129] Ciprofloxacin as well as other agents such as clindamycin, aztreonam, or amoxicillin have been the most completely studied.[72,73,75–78,108,135,138–142] The administration of ciprofloxacin 750 mg orally and amoxicillin-clavulanate 625 mg orally both every 8 hours was well tolerated and as effective as intravenous ceftriaxone plus amikacin[138] or ceftazidime[139] administered on an inpatient basis. Similar results have been reported for trials comparing oral ciprofloxacin-based regimens and intravenous regimens on an outpatient basis.[72,73,75–78,108,135,138–142] These strategies appear to be safe and effective for low-risk patients. The National Comprehensive Cancer Network Clinical Practice Guidelines in Oncology have included as an alternative regimen for initial empiric antibacterial therapy of higher-risk febrile neutropenic cancer patients the use of ciprofloxacin plus an antipseudomonal penicillin.[129] One large trial compared piperacillin plus ciprofloxacin and piperacillin plus tobramycin in a group of intermediate- to high-risk febrile neutropenic cancer patients.[41] Success rates (i.e., defervescence with initial regimen modification) were similar, 27% and 22% for the piperacillin-ciprofloxacin and piperacillin-tobramycin groups, respectively; however, times-to-defervescence were faster among the piperacillin-ciprofloxacin recipients, 5 days versus 6 days ($p = 0.005$).

Reports of fluoroquinolone resistance among aerobic gram-negative bacilli associated with bloodstream infections in neutropenic cancer patients began to emerge in the early 1990s.[143–145] The incidence of fluoroquinolone-resistant *Escherichia coli* (FREC) bacteremia among patients treated on the EORTC-IATCG clinical trials from 1983 to 1993 increased from zero during the period from 1983 to 1990 to 28% during the period from 1991 to 1993.[143] Of note, the incidence of resistance among strains of *Pseudomonas aeruginosa* and *Klebsiella pneumoniae* remained largely unchanged at less than 10%.[143] This has been more of a problem among cancer patients treated in institutions with high prevalence rates for gram-negative bacillary fluoroquinolone resistance (>10%) despite community-related resistance prevalences of less than 1%.[146] Carratala and colleagues reported in 1995 a 37% incidence of fluoroquinolone resistance in 35 of 230 neutropenic cancer patients previously treated with norfloxacin.[145]

Fluoroquinolone resistance among community-derived gram-negative bacilli, and FREC in particular, has emerged in parallel with the increased prescribing of these products in the community.[147–149] There is a significant correlation between the incidence of ciprofloxacin-resistant *Escherichia coli* bloodstream infection and the increased community and hospital use of fluoroquinolones ($r = 0.974$, $p = 0.005$ and $r = 0.975$, $p = 0.005$, respectively).[147] Among those who had not heretofore received fluoroquinolone therapy, Garau and colleagues reported the prevalence of FREC in the stools of adults and children in the Province of Barcelona, Spain, to be 24% and 26%, respectively.[149] These investigators also observed a very high prevalence of FREC in the stools of pigs (45%) and poultry (90%) and argued that the increased prevalence of human carriage of FREC may be linked to the high prevalence in animal-based food products. The increased use of fluoroquinolones in animal feeds and in humans is believed to play a role in the selection for FREC. In an environment with a high (15%) prevalence of fluoroquinolone resistance among gram-negative bacilli, cancer patients receiving ciprofloxacin antibacterial chemoprophylaxis while undergoing high-dose chemotherapy with stem cell rescue became colonized with FREC in one third of cases,[150] a phenomenon that increases the likelihood of FREC bloodstream infections in such patients.[151]

In addition, inappropriate use of fluoroquinolones is common. A recent case-control study of fluoroquinolone use in emergency departments in Philadelphia demonstrated inappropriate prescription of these agents in 81% of cases.[152] Lastly, gram-negative bacilli that are co-resistant to fluoroquinolones and other antibacterials such as aminoglycosides, cefotaxime, ampicillin, amoxicillin-clavulanate and trimethoprim-sulfamethoxazole are more frequently being reported.[149,153] Thus overuse and inappropriate use of fluoroquinolones in the community is common and is strongly linked to resistance, and ultimately will reduce the likelihood that this class of agents will be useful in a variety of patient populations, including neutropenic cancer patients, who require critical care services.[143,145] It is incumbent upon prescription writers of empiric antibacterial therapy to have some understanding of the prevalence of gram-negative bacillary resistance in the institution and the community.

DOUBLE BETA-LACTAM COMBINATIONS

Regimens consisting of an antipseudomonal broad-spectrum β-lactam plus an extended-spectrum third-generation cephalosporin are relatively safe and effective alternatives to regimens of a β-lactam plus an aminoglycoside,[18,85,86] but they are costly and do not offer any advantages over those of broad-spectrum β-lactam monotherapies. Cost, hypokalemia, selection of bacterial resistance, and antagonism have been cited as potential disadvantages, although these regimens may have an occasional role in the setting of preexisting renal insufficiency, in which the patient is receiving concomitant nephrotoxic agents such as cyclosporine or cisplatin-containing chemotherapeutic regimens, or where gram-positive organisms such as viridans streptococci are suspected.[18,54] The availability of effective β-lactam and fluoroquinolone or β-lactam monotherapy-based regimens has largely rendered double β-lactam regimens obsolete. Of note, these combinations appear in the National Comprehensive Cancer Network guidelines.[129]

EXTENDED-SPECTRUM CEPHALOSPORINS

The intrinsic activity of many of the third- and fourth-generation cephalosporins such as ceftriaxone, cefoperazone, ceftazidime, or cefepime against aerobic gram-negative bacilli is high. These agents have been used effectively as single agents for empiric treatment of suspected infection.[42–45,47–50,87,92,154] Empiric monotherapy has been shown to be effective in both low- and high-risk febrile neutropenic patient populations and in those in whom the expected duration of severe neutropenia (ANC $< 0.5 \times 10^9$/L) is either longer or shorter than 7 days. The experience to date suggests that single-agent empiric regimens will require

modification, usually by the addition of other antimicrobials, in one third to one half of patients with neutropenic periods in excess of 1 week.[48–50,87] There is a lower likelihood that modifications will be necessary for patients with short-term (<1 week) neutropenia.

A meta-analysis examining the efficacy of ceftazidime monotherapy compared to standard combination therapy for the empiric treatment of febrile neutropenic patients failed to demonstrate a difference with respect to the odds of overall treatment failure and failure in bloodstream infections (odds ratio 1.27; 95% CI 0.79 to 2.03 in 1077 patient episodes; and OR 0.72, 95% CI 0.33 to 1.58 in 248 patient episodes, respectively).[92] Another meta-analysis[154] compared the efficacy of ceftriaxone with (7 trials) or without (1 trial) an aminoglycoside and ceftazidime with (6 trials) or without (1 trial) an aminoglycoside or azlocillin plus an aminoglycoside (1 trial). The pooled odds ratio for overall treatment failure in the eight trials was 1.04 (95% CI 0.84 to 1.29), demonstrating no differences in the comparison for this outcome. There was also no difference in overall mortality (OR 0.84; 95% CI 0.57 to 1.24). These analyses demonstrate that empiric antibacterial therapy of febrile neutropenic patients with once-daily ceftriaxone is as effective as thrice daily ceftazidime. This has important implications for potential outpatient once-daily intravenous therapy.

CARBAPENEMS FOR TREATMENT OF FEBRILE NEUTROPENIC PATIENTS

Both imipenem-cilastatin and meropenem have been studied widely as empiric therapy in febrile neutropenic patients. A meta-analysis examined the efficacy of imipenem-cilastatin compared to a β-lactam plus aminoglycoside combinations (11 trials) and to β-lactam monotherapy (ceftazidime, 4 trials; cefoperazone-sulbactam, 1 trial), or β-lactam plus glycopeptide (ceftazidime, 3 trials) or double β-lactam therapy (cefoperazone-mezlocillin, 1 trial; cefoperazone-piperacillin, 1 trial). There were fewer treatment failures among imipenem-cilastatin recipients compared to β-lactam plus aminoglycoside combinations (OR 0.77; 95% CI 0.61 to 0.98) or to non–aminoglycoside-containing regimens (OR 0.67; 95% CI 0.54 to 0.84).[91] These analyses support the superiority of imipenem-cilastatin over control arms largely based on third-generation cephalosporins.

Another meta-analysis comparing carbapenem monotherapy to β-lactam plus aminoglycoside combination therapy demonstrated fewer treatment failures among the carbapenem recipients (OR 0.80; 95% CI 0.66 to 0.96, Peto fixed effects model),[131] in contrast to antipseudomonal cephalosporin monotherapy (OR 0.92; 95% CI 0.77 to 1.10, Peto fixed effects model). A similar analysis of the published clinical trials of meropenem monotherapy compared to ceftazidime-based regimens with or without an aminoglycoside demonstrated greater response rates among meropenem recipients (OR 1.28; 95%CI 1.08 to 1.51).[155] These systematic observations suggest the inferiority of third-generation cephalosporin monotherapy regimens compared to the carbapenem monotherapy.

PIPERACILLIN-TAZOBACTAM FOR THE TREATMENT OF FEBRILE NEUTROPENIC PATIENTS

Piperacillin-tazobactam plus amikacin therapy was successful in 210 of 342 (61%) febrile neutropenic patients studied by the European Organisation for the Research and Treatment of Cancer, compared to 196 of 364 (54%) patients receiving ceftazidime plus amikacin ($p = 0.05$).[47] Furthermore, the time-to-defervescence was shorter among piperacillin-tazobactam recipients ($p = 0.01$), and the frequency with which the initial regimen was modified by the addition of a glycopeptide was lower (24% versus 35%; $p = 0.002$) in that study. Another large Italian trial examined the role of the aminoglycoside amikacin, when combined with piperacillin-tazobactam.[51] The response rates overall between the two groups were similar regardless of the classification of the febrile neutropenic episode as bacteremic, clinically documented, or unexplained fever. Clearly, the aminoglycoside offered no advantage over the piperacillin-tazobactam monotherapy. Piperacillin-tazobactam monotherapy has been studied compared to extended-spectrum cephalosporins with or without aminoglycosides.[96–100] Overall unmodified success rates were significantly higher among piperacillin-tazobactam recipients (OR 1.39; 95% CI 1.08 to 1.79).[100] Furthermore, the frequency of second-line therapy with glycopeptides was significantly lower among piperacillin-tazobactam recipients (OR 0.77; 95% CI 0.60 to 0.99).[100] These observations demonstrate the superiority of initial piperacillin-tazobactam monotherapy over extended-spectrum cephalosporins with or without aminoglycosides. Furthermore, the need to modify the initial antibacterial regimen by the addition of a glycopeptide such as vancomycin or teicoplanin for persistent fever is also significantly less than for the cephalosporin-based comparator groups. This has important implications with respect to cost, drug-related toxicities, and for selection for resistant microorganisms such as vancomycin-resistant *Enterococcus* spp.

THE ROLE OF GLYCOPEPTIDES AS FIRST-LINE AND SECOND-LINE THERAPY IN FEBRILE NEUTROPENIC PATIENTS

There has been a significant increase in the proportion of the microbiologically documented infections observed in neutropenic patients that are due to gram-positive bacteria. Two decades ago approximately 70% of bacteremic isolates were gram-negative bacilli, whereas more recently approximately 60% to 70% are gram-positive cocci.[41,83] Previously published clinical trials of ceftazidime-based empiric antibacterial therapy observed more fatal gram-positive superinfections than expected.[156] A subsequent small study demonstrated that the addition of vancomycin to ceftazidime therapy reduced the superinfection rate from 24% to zero and the infection-related mortality rate by 91% (OR 0.07; 95% CI 0.01 to 0.63).[157] Such observations have led investigators to advocate the inclusion of glycopeptides vancomycin or teicoplanin as part of the first-line empiric antibacterial therapy in febrile neutropenic patients. In contrast, two further studies from the National Cancer Institute suggested that the vancomycin therapy may be safely delayed without increased morbidity or mortality.[49,158] In order to examine this question further, the European Organization for Treatment and Research in Cancer and the National Cancer Institute of Canada Clinical Trials Group conducted a large randomized trial comparing empiric therapy with ceftazidime plus amikacin (CA) and ceftazidime plus amikacin plus vancomycin (CAV).[45] The overall response rate among the 377 CAV recipients was 288 (76%), whereas the response rate for 370 CA recipients was 232 (63%; $p < 0.001$), the difference largely due to differential response rates for gram-positive bloodstream infections among CAV recipients. Despite the apparent superiority of the CAV arm, persistently febrile CA patients at day +3

received vancomycin, resulting in no differences in overall success rates or mortality.

Treatment failures were due to lack of prompt response and to persistent fever observed at a time very early after the initiation of the allocated regimen rather than objective indicators of failure such as persistence of resistant pathogens or progression at foci of infection. Patients receiving CA were more likely to receive vancomycin with persistence of fever at day +3 than recipients of the CAV regimen.[159] Since the median time to defervescence among high-risk febrile neutropenic patients is day 5 (range = day +3 to day +7),[41,47,48,50,128] many patients were considered failures unnecessarily because of regimen modification before they would have had a chance to defervesce. The physician compulsion to modify the initial antibacterial regimen for reasons of persistent fever at day +3 is driven in part by previously published protocols[49] reinforced by previously published guidelines.[160]

Three other trials[161–163] examining the role of initial glycopeptide therapy in febrile neutropenic cancer patients came to similar conclusions as for the EORTC/NCIC trial;[45] that is, the inclusion of glycopeptides as initial therapy in febrile neutropenic patients results in modest improvements in response rates, particularly in the circumstances of gram-positive bacteremia, but has no impact on overall survival of the neutropenic episode. Accordingly, it is recommended in the recent American, German and Spanish guidelines that glycopeptides not be used as part of the initial empiric antibacterial regimen for the treatment of fever in neutropenic cancer patients unless there is evidence of gram-positive infection.[53,55,130,164]

The above trials demonstrated that among patients with persistent fever due to gram-positive infection at day +3 vancomycin could be added to the regimen at that time with no excess morbidity or mortality.[45,49,158,163] Accordingly, second-line glycopeptide-based empiric antibacterial therapy for persistent fever has become quite common. As noted above, almost half of cases enrolled in clinical trials have a glycopeptide administered for these reasons.[48,51,97–100,117–128] The efficacy of empiric second-line glycopeptide therapy has been studied in two randomized controlled trials.[101,165] Both studies failed to demonstrate a significant treatment effect with regard to defervescence or overall mortality (OR 1.05; 95% CI 0.66 to 1.67 and OR 0.80; 95% CI 0.33 to 1.90, respectively) compared to placebo.[166] The results of these two trials together with the small published meta-analysis confirm that in stable, persistently febrile, neutropenic patients, empiric second-line glycopeptide therapy after 48 to 96 hours is unnecessary.[166] Furthermore, the initial antibacterial therapy can be safely extended in such patients unmodified for an additional 72 to 96 hours for a total of 4 to 8 days.

The use of glycopeptide antibiotics as part of the initial first-line regimen should be reserved for patients at highest risk for serious gram-positive infection.[55,129] Such circumstances include clinical catheter-related infection, infection in patients receiving fluoroquinolone-based antibacterial chemoprophylaxis associated with severe mucositis predisposing patients to viridans group streptococcal bloodstream infections,[34,35,167] infection in the setting of colonization by methicillin-resistant *Staphylococcus aureus* (MRSA), a bloodstream isolate characterized as gram-positive cocci in groups and clusters (suggesting *Staphylococcus* spp. and the likelihood of a methicillin-resistant coagulase-negative *Staphylococcus*), and the setting of hypotension or septic shock syndrome without an identified pathogen. The caveat is that the glycopeptide antibiotic should be discontinued in 2 to 3 days if a resistant gram-positive infection has not been identified.

THE ROLE OF HEMATOPOIETIC GROWTH FACTORS IN THE MANAGEMENT OF FEBRILE NEUTROPENIC PATIENTS

The inclusion of hematopoietic growth factors (HGF), granulocyte and granulocyte-macrophage colony-stimulating factors (G-CSF; GM-CSF) in strategies for the prevention and management of febrile neutropenic patients remains unsettled.[168] Berghmans and colleagues published a systematic review of the literature with a meta-analysis to critically examine the evidence for or against use of these products in the treatment of febrile neutropenic episodes.[169] Eleven studies encompassing 1218 febrile neutropenic episodes published between 1990 and 1998 were considered in the analysis. Although six trials reported treatment effects for the primary outcome analyzed (mortality), overall there was no effect on mortality (relative risk 0.71; 95% CI 0.44 to 1.15). Furthermore, there were no differences when analysis was conducted by HGF and G-CSF versus GM-CSF. The impact of HGF on length of hospitalization was decreased in four trials, unaffected in four trials, and not reported in three trials. Only three of six trials reporting on the impact of HGF on duration of antibacterial therapy demonstrated a reduction in this outcome. In nine trials in which the impact of HGF on the duration of fever was reported, no treatment effects were observed in seven trials, fever reduction was observed in one trial, and no analysis was provided in one other. The studies included in this analysis were flawed by the failure to control for important variables, including the duration and intensity of neutropenia, type of cytotoxic therapy, and type of malignancy. On the basis of this review, Berghmans and colleagues could not recommend routine use of HGF in the treatment of febrile neutropenic episodes.[169]

The guidelines of the American Society of Clinical Oncology do not recommend their use as adjunctive therapy for neutropenic patients who are febrile and have suspected infection.[170] However, less than half of specialists follow these guidelines, given that usage appears to be influenced more by reimbursement than evidence.[171–173]

HGF have been evaluated in other non-neutropenic patient populations including patients with community-acquired pneumonia, human immunodeficiency virus–infected patients, neonatal sepsis, diabetic foot ulcer infections, acute hepatic failure or cirrhosis, in orthotopic liver transplantation, and in the critical care unit. While there appears to be some promising results in some subgroups of patients, HGF have no proven clinical benefit in non-neutropenic critically ill patients with regard to morbidity or mortality.[174]

THE ROLE OF SECOND-LINE THERAPY FOR PERSISTENT FEVER IN NEUTROPENIC PATIENTS

Patients with fever persisting beyond 72 hours on broad-spectrum antibiotic therapy should be re-evaluated carefully.[55,129] Table 47-5 lists several of the possible explanations for this. A nonbacterial etiology for the febrile episode should be considered. The various noninfectious causes have been discussed already. Factors such as localized tenderness,

TABLE 47-5 Differential Diagnosis of Fever >72 Hours Despite Broad-Spectrum Antibacterial Therapy

Fever is due to a nonbacterial process
Viral infection (HSV, CMV)
Fungal infection (candidiasis, invasive aspergillosis)
Noninfectious fever (blood products, drugs, etc.)
Bacterial infection is resistant to the antibiotic regimen
Second or subsequent infection has developed
Bacterial infection is not responding because of inadequate antibiotic serum/tissue levels
Infection is associated with an undrained focus (e.g., abscess or prosthetic material [IV catheters])

CMV, cytomegalovirus; HSV, herpes simplex virus.

change in sensorium, hyperventilation, hypotension, progressive renal insufficiency, and acidosis suggest an infectious cause. The re-evaluation should occur between day 3 and day 5 and include a thorough examination to identify a focus. Cultures of blood (one set from each lumen of the central venous catheter and one set from a peripheral vein), urine, and other potentially infected sites should be submitted to the clinical microbiology laboratory. Repeat chest radiography or diagnostic imaging studies such as ultrasonography or high-resolution computed tomographic studies may be performed when abnormalities suggest a specific organ as a potential site for infection. When re-evaluation fails to identify the etiology of the persistent fever, the clinician may elect either to continue the initial empiric antibacterial regimen if the patient's condition shows no clinical change or deterioration, or to modify the empiric regimen appropriate to the findings of the re-evaluation (Table 47-6).

Persistently febrile severely neutropenic patients despite administration of at least 3 to 5 days of broad-spectrum antibacterial therapy are at risk of having an invasive fungal infection as the cause for the ongoing fever.[55] Such patients are candidates for empiric antifungal therapy with amphotericin B deoxycholate,[175,176] a lipid formulation of amphotericin B,[177] an echinocandin, or with an extended-spectrum azole.[178,179] The two randomized clinical trials upon which the practice of empiric antifungal therapy was based failed to demonstrate a treatment effect with respect to defervescence compared to an untreated control group (OR 0.13; 95% CI 0.01 to 1.26 for the study by Pizzo and colleagues[175] and OR 0.14; 95% CI 0.02 to 1.23 for the EORTC study[176]).

While it is widely felt that the majority of persistent fevers in the setting of severe neutropenia do not represent invasive fungal infections, approximately 20% may be related to invasive fungal infection with an attendant high mortality rate sufficient to compel physicians to administer empiric antifungal therapy. Such strategies may be considered in patients persistently febrile after 7 days of broad-spectrum antibacterial therapy. Patients should undergo a second work-up for persistent fever to investigate the possibility of invasive fungal infection which includes blood cultures from peripheral and indwelling central venous access sites and sensitive HRCT images of the chest.[67,68] In 60% of persistently febrile neutropenic patients with normal or non-diagnostic chest roentgenograms the HRCT scan of the chest demonstrated a pulmonary infiltrate.[67] Such procedures can permit the earlier diagnosis and management of invasive mold infections involving the lungs by approximately 1 week.[180]

Surveillance cultures for detecting potential fungal pathogens have had some limited usefulness for predicting fungal infection. The recovery of filamentous fungi (e.g., *Aspergillus* species) in a nasopharyngeal surveillance culture in the clinical setting of a persistently febrile, profoundly neutropenic patient receiving broad-spectrum antibiotics and who develops new focal pulmonary infiltrates are to some extent predictive of *Aspergillus* pneumonia.[181] The recovery of *Candida albicans* from oropharyngeal, rectal, or urine surveillance cultures has had a positive predictive value of 10% to 15% for systematic candidiasis. The recovery of other non-albicans *Candida* species such as *Candida tropicalis*, particularly from multiple sites, has had a positive predictive value of >70% for systemic infection. In contrast, the failure to recover *Candida* species in surveillance cultures has been associated with a negative predictive value of >90% for invasive disease from *C. albicans* or *C. tropicalis*.[182] This experience suggests that clinicians cannot use surveillance cultures to predict the presence of a candidal infection (except perhaps for *C. tropicalis*). However, the clinician may be reassured by negative surveillance cultures that are properly obtained and processed, that antifungal therapy may not be indicated.[55]

TABLE 47-6 Considerations for Regimen Modification: Day 5

Progressive necrotizing mucositis/gingivitis	Anaerobic coverage (metronidazole)
Progressive ulcerating mucositis/gingivitis	Antiviral therapy (acyclovir)
Dysphagia	Antifungal (± antiviral) therapy if pseudomembranous pharyngitis
Cellulitis or inflammatory changes at venous access sites	Antistaphylococcal therapy (vancomycin)
Interstitial pulmonary infiltrates	TMP-SMX ± erythromycin Consider bronchoalveolar lavage
Focal pulmonary infiltrates	Observe if ANC is recovering Consider lung biopsy Empiric amphotericin B
Abdominal foci	*Typhlitis* Diverticulitis Anaerobic disease coverage Perirectal focus

ANC, absolute neutrophil count; TMP-SMX, trimethoprim-sulfamethoxazole.

Surrogate molecular markers of yeasts and molds are showing promise in the diagnosis of invasive fungal infection. Galactomannan is a component of the cell wall of *Aspergillus* spp., certain dematiaceous fungi such as *Alternaria* spp., and some *Penicillium* spp.,[183–185] and has been used to aid in the diagnosis of invasive aspergillosis.[180,186] A enzyme-linked immunosorbent serum assay which uses a rat monoclonal antibody EB-A2 that targets the D-galactofuranoside side chains of the *Aspergillus* spp. galactomannan[187] has been developed for the diagnosis of invasive aspergillosis.[188] The antibody may cross react with galactomannan-like materials from other molds such as *Penicillium* spp., *Paecilomyces* spp., and *Alternaria* spp.,[189] or from foods that are exposed to molds originating from the soil during growth or harvesting, such as rice, pasta, cereals, and vegetables,[190] and even milk[191] consumed by premature infants.[192] Translocation of dietary antigens into the blood of healthy adults is well documented.[193] The antibody also cross-reacts with *Bifidobacterium* spp. lipoteichoic acid, an organism that heavily colonizes the gut of neonates and infants.[194] Translocation of *Bifidobacterium* spp. has occurred in the setting of reduced integrity of the intestinal mucosal barrier.[195] The clinical setting of severe mucositis or intestinal graft-versus-host disease with intestinal mucosal damage may be circumstances in which false-positive serum galactomannan tests may be expected. In addition, false-positive serum tests have been reported in association with administration of certain antibiotics such as piperacillin-tazobactam or amoxicillin derived from cross-reacting species of mold such as *Penicillium* spp.[190,196–198] This has implications for clinicians using this test to investigate the possibility of invasive aspergillosis while administering drugs like piperacillin-tazobactam for the treatment of infection.

DURATION OF ANTIBACTERIAL THERAPY

In general, the IDSA recommendations for duration of the antibacterial regimen encompass the period until neutrophil recovery (ANC $> 0.5 \times 10^9$/L for at least two consecutive days), all signs and symptoms of infections have resolved, and the temperature has remained normal for 48 hours or more.[55] For patients with prolonged severe neutropenia who have defervesced and for whom no focus of infection appears to be ongoing, the antibiotic regimen may be discontinued after 2 weeks provided the patient remains under careful observation. Some investigators have advocated substituting a fluoroquinolone-based antibacterial chemoprophylaxis regimen for the systemic antibacterial regimen under these circumstances.[199] The response assessment definitions used in clinical trials of antibacterial therapy have often included a stipulation that the patient must remain afebrile for 4 to 5 days in addition to resolution of other signs and symptoms of infection in order for a response to be valid. This seems prudent and consistent with the natural history of these episodes. While the time until response to empiric antibacterial therapy varies with the underlying causes of neutropenia,[17,50,200] the median time to response (defervescence) for high-risk patients is 5 to 7 days[41,45,47,50,87,88,100] and 2 to 4 days for low-risk patients.[138,139] If the antibacterial regimen is to be administered for an additional 4 to 5 days by the above criteria, then high-risk patients and low-risk patients would be expected to have received a 9- to 12-day and 6- to 9-day course of antibacterial therapy, respectively.

Specific Infection Syndromes in Patients Undergoing Cytotoxic Chemotherapy

Infections occur at a limited number of body sites in febrile neutropenic patients and usually involve the microorganisms colonizing those sites.[129] The three systems most commonly involved are the gastrointestinal (GI) tract (oropharynx, gingiva and teeth, esophagus, gut, and perirectal tissues), the respiratory system (sinuses, middle ear, nasopharynx, tracheobronchial tree, and pulmonary parenchyma), and the skin (including biopsy sites and sites of vascular access such as indwelling central venous catheter exit sites, tunnel sites, or insertion sites).

OROPHARYNGEAL MUCOSAL AND ESOPHAGEAL INFECTIONS

The natural history of oral mucositis is influenced by the cytotoxic therapy–induced neutropenia,[34] which plays a permissive role in the clinical expression of acute-on-chronic periodontal infections.[201] This process usually reaches its maximum intensity at the time of neutropenic nadir, approximately days 10 to 14.[27,29–31] At this time, polymicrobial infection becomes superimposed on the chemotherapy-induced mucositis. This in turn extends the morbidity into the third and fourth weeks following the commencement of chemotherapy. Although oropharyngeal bacterial flora (viridans group streptococci, anaerobic gram-negative bacilli, and anaerobic gram-positive cocci) probably contribute to disease in most cases of simple mucositis, in several studies fungi (e.g., *C. albicans*) have played important pathogenic roles in up to 60% of the oral infections among patients with acute leukemia.[202] In addition, reactivated latent HSV infections of the oral cavity have been reported in 50% to 90% of seropositive patients undergoing remission-induction therapy or BMT with a median onset between 7 and 11 days.[203,204] Acute exacerbations of preexisting, asymptomatic, chronic periodontitis occurred in 59% of one series of adult patients undergoing remission-induction therapy for acute leukemia.[201] These infections typically occurred when the ANC was $<0.13 \times 10^9$/L. The severity and duration of chemotherapy-associated mucositis correlate to some degree with the extent of preexisting dental plaque and periodontal disease.[205]

CLINICAL APPROACH

Herpetic infections of the oropharynx and esophagus may be anticipated in patients with a history of herpetic stomatitis or in those known to possess IgG antibodies to HSV, indicating infection in the past. Although the typical discrete vesicular lesions on an erythematous base may be observed in neutropenic patients, herpetic infections also may manifest as areas of painful ulceration over a diffusely erythematous base. Such lesions must be distinguished from a typical presentation of oropharyngeal candidiasis or cytotoxic therapy–induced mucositis. Pseudomembranous pharyngitis suggests yeast infection. A thorough examination of the gingival and periodontal tissues for focal areas of pain, erythema, swelling, and bleeding can suggest the periodontium as a potential focus of infection (particularly as a source of bacteremic infection) by viridans streptococci and oropharyngeal gram-negative anaerobic bacilli.[206]

Laboratory aids include virus culture techniques, direct fungal stains, direct electron microscopic examination for virus particles, cytologic examination of cellular material from the base of the ulcer (e.g., Tzanck preparation for the detection of multinucleated giant cells and intranuclear inclusions), or direct herpes simplex antigen detection techniques. The material from a specific lesion should be submitted to the clinical microbiology laboratory for culture and for direct examination. Routine Gram's stain can be helpful in demonstrating the presence of budding yeasts and pseudohyphae suggestive of *Candida* species. A potassium hydroxide mount (to digest extraneous unwanted cellular material) also can provide a clue to this diagnosis by demonstrating the presence of these structures.

MANAGEMENT

The morbidity associated with oropharyngeal or esophageal mucositis can be life threatening, particularly when local pain interferes with an adequate nutritional intake. Pain control becomes a high priority. A topical anesthetic such as lidocaine in a 2% water-soluble gel or 5% water-insoluble ointment has been used widely with inconsistent success. Continuous intravenous morphine infusions have been successful for symptom control among BMT recipients with cytotoxic therapy–induced mucositis or acute oral graft-versus-host disease. Herpetic mucositis involving the oropharynx or esophagus should be treated with acyclovir. Intravenous acyclovir (250 mg/m^2 q8h) may be administered for severe cases until oral administration (200 mg q4h) can be tolerated for a total course of 7 days. Pseudomembranous candidiasis involving the oropharynx or esophagus may be treated with various approaches. Topical therapy with oral nystatin suspension (2 to 30 million units daily in four divided doses) remains a popular first-line approach. Many physicians prefer to prescribe orally absorbed azole antifungal agents such as ketoconazole (200 to 600 mg daily) or fluconazole (50 to 400 mg daily). It is important to remember that the efficacy of ketoconazole may be compromised by concomitant use of antacid therapy or in the setting of gastric achlorhydria. Invasive candidal esophagitis should be treated with intravenous amphotericin B to a cumulative dose of 500 to 1500 mg (approximately 5 to 15 mg/kg), while oropharyngeal candidiasis has been treated successfully with cumulative doses of about 500 mg (5 mg/kg). Necrotizing polymicrobial anaerobic mucositis responds well to metronidazole (500 mg PO or IV q8h).[129]

Evidence is accumulating that much of the extra morbidity caused by these infections superimposed on chemotherapy-induced mucositis can be reduced significantly by the prophylactic use of antiviral agents such as acyclovir among HSV-seropositive individuals,[207] antiseptics such as chlorhexidine,[208] and antifungal agents such as oral azoles.[209] Further work is required to determine the optimal dose schedules and routes of administration for these agents.

ENTERIC INFECTIONS

Invasive enteric bacterial infections of the gut due to *Salmonella* or *Shigella* species are relatively uncommon in neutropenic patients. Two clinical entities, however, must be considered in febrile neutropenic patients with abdominal pain and diarrhea: toxigenic enterocolitis due to the toxin elaborated from an overgrowth of Clostridium difficile and neutropenic enterocolitis (typhlitis).

CLOSTRIDIUM DIFFICILE–ASSOCIATED DIARRHEA

Clostridium difficile–associated diarrhea (CDAD) is not a rare problem among neutropenic patients receiving broad-spectrum antibiotic therapy, particularly those who are recipients of antibacterial agents that have high biliary excretion rates and are active against intestinal anaerobic bacteria. Approximately 5% to 10% of high-dose chemotherapy recipients have been reported with this complication.[210–212] This problem must be considered when such patients develop abdominal pain in association with watery diarrhea with or without blood. The differential diagnosis includes other infectious (cytomegalovirus [CMV] enterocolitis or typhlitis) and noninfectious (cytotoxic therapy–induced mucosal damage or peptic ulcer disease) causes. Protozoa and helminths are unlikely causes of this syndrome unless there is an associated history of travel to or immigration from areas where pathogens such as *Giardia lamblia* or *Strongyloides stercoralis* are endemic.

Diarrheal stools from outpatient clinics should be submitted to the clinical microbiology laboratory for bacterial culture (to rule out the remote possibilities of salmonellosis, shigellosis, and *Campylobacter* or *Yersinia* infection), examination for ova and parasites (unless this has been done earlier in the patient's course), and culture for *C. difficile* and the detection of *C. difficile* toxin. CDAD is much more common among hospitalized patients. If *C. difficile* is cultured or the toxin detected, this is sufficient to warrant therapy with either metronidazole (500 mg PO q8h for 10 days) or vancomycin (125 to 250 mg PO q6h for 10 days) without a sigmoidoscopic examination for detection of the pseudomembranous changes associated with this infection. In patients with a sufficiently typical clinical presentation, it is also reasonable to begin therapy empirically before laboratory confirmation is available.

TYPHLITIS AND NEUTROPENIC ENTEROCOLITIS

Typhlitis, also called *neutropenic enterocolitis*, *necrotizing enterocolitis*, or *ileocecal syndrome*, is a serious, potentially life-threatening infection of the bowel wall seen in up to 32% of patients undergoing remission-induction therapy for acute leukemia.[213–216] The pathologic process includes diffuse dilatation and edema of the bowel walls, with varying degrees of mucosal and submucosal hemorrhage and ulceration.[217] The cecum appears to be favored for the development of this syndrome, possibly related to its relatively tenuous blood supply. Bacterial invasion through an ischemic gut wall in the setting of neutropenia and cytotoxic therapy–induced mucosal surface damage is the probable pathogenesis.[213,214] The syndrome presents a spectrum of severity from mild self-limiting cecal inflammation to fulminant bowel wall necrosis with perforation. The clinical syndrome is typically characterized by a triad of diarrhea, abdominal pain, and fever in the setting of cytotoxic therapy–induced neutropenia.[217,218] Abdominal distention, nausea, vomiting, and diffuse watery or bloody diarrhea are also commonly observed. Bacteremia with enteric microorganisms (*E. coli* or *Klebsiella* species) and *Pseudomonas aeruginosa* is associated with typhlitis in up to 28% of cases.[213] Clinical examination usually reveals a diffusely tender abdomen; however, localization to the right lower or upper quadrant is not uncommon.

FIGURE 47-4 CT scan of the abdomen of a woman receiving high-dose cytarabine for acute leukemia who complained of severe right lower quadrant pain. The wall of the cecum is thickened and edematous consistent with typhlitis.

Ultrasonographic[219] or CT imaging of the abdomen frequently demonstrates thickening and edema of the colonic walls with or without inflammatory changes in the surrounding pericolic tissues (Fig. 47-4). Gas in the intestinal wall (pneumatosis) or an inflammatory phlegmon also may be seen in approximately 20% of cases.[69] CDAD is associated with the greatest degree of bowel wall thickening.[69] There appears to be a correlation between the thickness of the bowel wall, presumably reflecting the degree of inflammation, and mortality. Cartoni and colleagues, using ultrasonographic examinations, noted mortality rates of 60% among those with mural thickness of more than 10 millimeters.[219] Mural thickness also correlated with prolonged duration of symptoms of more than a week compared to patients without thickening (mean duration of symptoms was 7.9 vs. 3.8 days).[219]

Neutropenic enterocolitis is associated with significant impairment in the functional integrity of the gut mucosal surface. Malabsorption of D-xylose has been shown to precede clinical neutropenic enterocolitis by at least a week.[32] This intestinal mucosal damage increases the risk for translocation of bacteria and opportunistic fungi that colonize the intestinal lumen. For example, *Candida* mannoprotein antigen associated with intestinal colonizing *Candida* spp. may be detected in patients with neutropenic enterocolitis.[220] Translocation of colonizing yeast in the setting of cytotoxic therapy–induced neutropenic enterocolitis is part of the pathogenesis of invasive candidiasis with portal fungemia and subsequent hepatosplenic fungal infection.[32,221]

Management consists of early recognition, bowel rest with nasogastric decompression, intravenous fluid replacement, blood product transfusion, and broad-spectrum antibacterial agents directed against the aerobic, microaerophilic, and anaerobic enteric microflora (e.g., piperacillin-tazobactam, imipenem-cilastatin, and meropenem plus an agent effective against obligate anaerobic bacteria such as metronidazole). Although surgical consultation early in the evolution of the syndrome is recommended so that all potential management strategies can be planned before an intra-abdominal catastrophe occurs, medical management is recommended for the majority of patients who do not have evidence of a major intra-abdominal catastrophe. Surgical intervention with right hemicolectomy or local resection of necrotic segments of bowel with anastomosis or diverting ileostomy or colostomy should only be considered in the setting of cecal perforation, massive uncontrollable GI bleeding, uncontrollable sepsis, complete bowel obstruction, or pneumatosis cystoides intestinalis.[215] With optimal management, the mortality rate has declined from over 50% to less than 20%.[217,218] The optimal outcome for these patients appears to require a high index of suspicion for the syndrome, aggressive supportive care, and marrow recovery. It is important to recognize the high risk of recurrence (up to two-thirds of cases) with subsequent cycles of cytotoxic therapy.[214]

PERIRECTAL INFECTIONS

Infections of the perirectal tissues may be life threatening in neutropenic patients. The majority of cancer patients with this complication have received cytotoxic therapy for leukemia or lymphoreticular malignancy within the preceding month and are severely neutropenic (ANC $< 0.5 \times 10^9$/L) at the time of presentation.[222] Although the presence of neutropenia may preclude the development of frank suppuration, perirectal infection must be suspected if there is focal tenderness, perirectal induration, or erythema with or without fluctuance or tissue necrosis.[64] Although some cases may be associated with a preexisting pathologic process such as an anal fissure or thrombosed hemorrhoidal tissues, most patients present no obvious predisposing factor. Conceivably, small abrasions or tears in the rectal mucosa may be the primary event allowing tissue invasion by the microflora colonizing the rectum, anus, and perineum. The etiology of these infections is polymicrobial.[223,224] The most common microorganisms associated with perirectal infections are enteric gram-negative bacilli (e.g., *E. coli*, *Klebsiella* spp., or *Enterobacter* spp.), *P. aeruginosa*, obligately anaerobic gram-negative bacilli (e.g., *Bacteroides* spp.), enterococci, and peptostreptococci. Recurrent episodes of infection are frequent (up to 26% of episodes in one series) among patients recovering from one perirectal infection and receiving subsequent cycles of cytotoxic therapy.[222]

The optimal approach to management is controversial. In general, neutropenic patients should be managed medically unless local care, systemic antimicrobials, and blood product support fail to contain the infection, or if an obvious inflammatory collection must be surgically drained. The likelihood of success of medical management is increased if the antimicrobial regimen contains agents effective in severe intra-abdominal sepsis,[225] and should include a single agent such as piperacillin-tazobactam or a carbapenem, imipenem-cilastatin or meropenem, or a combination regimen including an agent effective against anaerobic bacteria (e.g., clindamycin or metronidazole) and either a cephalosporin or a fluoroquinolone. Furthermore, vancomycin may be added if despite these antimicrobials the cellulitis appears to progress. The therapeutic role of antimicrobial agents active against *Enterococcus* spp. remains difficult to evaluate since the role of these bacterial species in the pathogenesis of these infections is controversial. Cephalosporins are inactive against *Enterococcus* spp. and the carbapenem-related susceptibility profiles tend to mirror that of ampicillin and therefore are less reliable.[226] Enterococcal colonization must be differentiated from infection. Furthermore, the rising incidence of vancomycin-resistant *Enterococcus* species argues to minimize

the use of vancomycin for suspected but unproven enterococcal infection.[129] Recent observations with regard to the emergence of vancomycin-resistant *Enterococcus* species following piperacillin-based antibacterial therapy[227] are of concern given the frequency of use of this agent in the treatment of bacterial infections in cancer patients.

INVASIVE FUNGAL INFECTIONS

OPPORTUNISTIC YEAST INFECTIONS

This group of opportunistic unicellular fungal organisms of the form-class Blastomycetes and form-family Cryptococcaceae includes six genera: *Cryptococcus* (e.g., *C. neoformans*, the agent of cryptococcal meningitis), *Malassezia* (e.g., *M. furfur*, the agent of pityriasis versicolor), *Rodotorula* (e.g., *R. rubra*, an agent causing pulmonary and systemic infections), *Candida* (e.g., *C. albicans*, the most common cause of candidiasis), *Trichosporon* (e.g., *T. beigelii*, the agent of white piedra and systemic infections in compromised hosts), and *Torulopsis* (e.g., *T. glabrata*, now reclassified under the genus *Candida*). *C. albicans, C. tropicalis, C. glabrata*, and *Trichosporon* species are part of the normal microflora of the mouth, colon, and vagina. Consequently, it is not surprising to find these agents involved in the pathogenesis of infections among immunocompromised patients with damaged mucosal and integumental surfaces. This has been recently reviewed.[228]

Invasive candidiasis encompasses deep infections of various organ sites with *Candida* species.[229,230] *C. albicans* is the most commonly observed; however, *C. tropicalis*, *C. glabrata*, *C. parapsilosis*, *C. krusei*, and *C. guilliermondii* are causal agents of infection in neutropenic patients as well. When multiple organ sites are involved, the term *disseminated candidiasis* may be more appropriate. The most common forms of invasive candidiasis encountered in neutropenic patients are candidemia with or without associated central venous catheter infection, chronic systemic candidiasis (hepatosplenic candidiasis), endophthalmitis, hematogenously spread skin infection, and renal candidiasis. The pathogenesis is the invasion of damaged integumentary surfaces by colonizing yeasts during severe immunosuppression and myelosuppression.

Candidemia without evidence of metastatic infection is frequently associated with indwelling central venous catheters. Such patients should have the catheter removed and should receive antifungal therapy[229,231] with intravenous amphotericin B deoxycholate 0.6 to 1.0 mg/kg per day to a total dose of 500 to 1000 mg, or with intravenous or oral fluconazole 400 to 800 mg daily, or intravenous caspofungin 70 mg on day 1 followed by 50 mg daily.[232] Patients with evidence of dissemination to other organs should be treated with amphotericin B deoxycholate or a lipid-based formulation of amphotericin B to total doses of 30 to 60 mg/kg (2 to 4 g for a 70-kg patient). The overall response rates for amphotericin B in candidemia have been as high as 70% in teaching hospitals.[233] Patients with CNS involvement probably also should receive 5-flucytosine (5-FC). Imidazoles such as ketoconazole or miconazole are not recommended under these circumstances. The role of the newer triazoles fluconazole and itraconazole in the treatment of invasive candidiasis in neutropenic patients appears promising.[230]

Two randomized trials in non-neutropenic surgical and ICU patients with invasive candidiasis have demonstrated equivalency of fluconazole and amphotericin B.[234,235] One retrospective, matched-cohort study[236] and one randomized controlled study comparing fluconazole and amphotericin B in a mixture of neutropenic and non-neutropenic cancer patients with invasive candidiasis also have demonstrated similar response rates of 64% to 73%.[236,237]

The combination of a triazole and a polyene antifungal may be potentially antagonistic given that both classes act on the fungal cell membrane.[238,239] Azoles interfere with the 14-demethylation of lanosterol in the synthetic pathway of ergosterol, the predominant sterol in the fungal cell membrane to which polyene antifungal agents such as amphotericin B bind to produce their fungicidal effects. Clinical reports have suggested that sequential treatment with lipophilic azoles such as itraconazole followed by amphotericin B may be deleterious.[240] This effect may not be as prominent with the more lipophobic azoles such as fluconazole, with less accumulation of the agent in the lipid-rich environment of the cell membrane. A recent randomized blinded placebo-controlled trial from the National Institutes of Allergy and Infectious Disease Mycoses Study Group compared the safety and efficacy of fluconazole with or without amphotericin B for the treatment of candidemia in severely ill non-neutropenic patients with high Acute Physiology and Chronic Health Evaluation (APACHE) II scores.[241] The response rates were somewhat higher in the combination group (60 of 107, 56% vs. 77 of 112, 69%; $p = 0.043$) and no evidence of antagonism was observed. The odds of treatment failure were increased by high APACHE II scores (OR 1.09; 95% CI 1.03 to 1.14), and decreased if *C. parapsilosis* was the etiology of the bloodstream infection.[241]

Most episodes of candidemia are caused by *C. albicans*;[230] however, there is an increasing incidence of non-albicans candidemia.[242–245] In a multicenter prospective, observational study of candidemia in 427 consecutive patients from four tertiary care hospitals,[242] *C. albicans* accounted for 52% of the bloodstream isolates overall. However, over the course of the 3.5-year study, the proportion of all bloodstream isolates that were non-albicans candidal species increased from 40% to 53%. Risk factors for candidemia due to *C. albicans* included no prior use of antifungal therapy, solid organ transplant recipient, and having a wound as portal of entry. The single most important risk factor for *C. tropicalis* fungemia was neutropenia. Prognostic factors for *C. glabrata* fungemia included prior use of amphotericin B, hemodialysis, and an abdominal portal of entry; for *C. krusei* fungemia, prior use of fluconazole, and neutropenia; and for *C. parapsilosis*, prior use of fluconazole. Breakthrough candidemia occurred in 13% of patients receiving an antifungal agent for prophylaxis or empiric therapy. Under these circumstances, the candidemias were due to non-albicans species that were resistant to fluconazole. These observations have important implications for neutropenic patients in whom agents such as fluconazole are being used more widely for prophylaxis[246,247] and therapy.[236,237,241,248]

Chronic systemic candidiasis, also referred to as granulomatous hepatitis, focal hepatic candidiasis, or hepatosplenic candidiasis, has emerged as a significant problem among recipients of high-dose cytotoxic therapy.[230,249–253] The typical clinical presentation is a patient who has received high-dose cytarabine, followed by a febrile illness that persists despite broad-spectrum antimicrobial therapy and recovery of the circulating neutrophil count. There may be associated right upper quadrant tenderness, hepatomegaly,

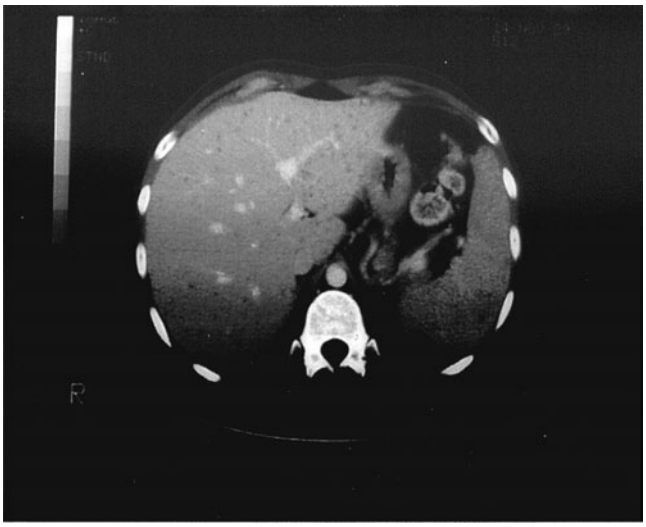

FIGURE 47-5 CT scan of the abdomen in a 22-year-old male recipient of high-dose cytarabine for relapsed high-grade non-Hodgkin's lymphoma. Multiple areas of decreased attenuation are noted in the hepatic and splenic parenchyma consistent with hepatosplenic candidiasis.

splenomegaly, and elevated serum alkaline phosphatase and γ-glutamyltransferase levels. The diagnosis may be established by imaging studies of the abdomen using ultrasonography or CT showing multiple abscesses in the liver and splenic parenchyma (Fig. 47-5). Where possible, a tissue biopsy should be considered for histopathologic and microbiologic confirmation. Biopsy of these lesions demonstrates the presence of necrotizing granulomata, frequently (but not uniformly) containing budding yeasts and pseudohyphal elements consistent with *Candida* species. Liver biopsy specimens should be submitted in a dry, sterile container to the clinical microbiology laboratory and processed for pyogenic bacteria, mycobacteria, viruses, and fungi. Specimens for histopathologic evaluation may be submitted to the pathology laboratory in fixative and processed for staining with hematoxylin and eosin, with periodic acid-Schiff (PAS), with an acid-fast stain, and with methenamine silver. Multiple sections through the paraffin-embedded tissue fragments may be necessary to detect the pathogens. Open liver biopsy is the most reliable means of definitively establishing the diagnosis. The pathogen is often not grown despite appropriate culture of the tissue specimen. The determination of a correct diagnosis becomes an important factor contributing to the planning of potentially curative postremission therapeutic strategies.

About half the patients respond to systemic amphotericin B (1.0 to 1.5 mg/kg per day) with or without 5-FC (100 mg/kg per day) in cumulative amphotericin B doses as high as 9 g. However, even in those who respond, the difficulty with diagnosis and the requirement for prolonged antifungal therapy frequently result in failure to complete planned postremission therapeutic regimens for the underlying malignancies, leading to shortened disease-free survival.[221] The toxicities of prolonged systemic amphotericin B (anemia, renal insufficiency, hypokalemia, fever, chills, and nausea) and 5-FC (myelosuppression) are also limiting. More recently, experience with the newer triazole antifungal agent fluconazole has suggested that this may be a useful approach for patients unable to tolerate or failing amphotericin B–containing regimens.[230]

Amphotericin B toxicity is often a limiting factor in therapy. Acute infusional toxicities occur in approximately 70% of patients during the first 7 days of therapy,[254] and include fever (51%), chills (28%), nausea (18%), and headache (9%). Prophylactic use of diphenhydramine, acetaminophen, and corticosteroids (alone or in combination) has been no more effective than no prophylaxis in preventing these infusional toxicities.[254] Meperidine (0.2 to 0.5 mg/kg) may ameliorate the rigors. Hydrocortisone has not been shown to be effective, and as a sterol itself, may compete with fungal cell membrane ergosterol for the binding of amphotericin B.[255] Metabolic toxicities including potassium and magnesium wastage or elevated serum creatinine occur in more than 80% of patients.[256] Approximately one third of amphotericin B deoxycholate recipients can be expected to experience a doubling of the serum creatinine from pretreatment levels.[177]

The newer lipid-based formulations of amphotericin B have been developed to reduce the amphotericin B–related toxicities and to permit the administration of larger doses.[230] These agents include liposomal amphotericin B, amphotericin B colloidal dispersion, and amphotericin B lipid complex (ABLC). At least one randomized controlled trial comparing ABLC (5 mg/kg per day) with conventional amphotericin B (0.6 mg/kg per day) in patients with invasive candidiasis has shown similar results with respect to efficacy and infusional toxicities, but with reduced nephrotoxicity in ABLC recipients.[257] Lipid-based formulations of amphotericin B have been studied in clinical trials of empiric antifungal therapy.[177,179]

The optimal dosing protocol for amphotericin B for empiric therapy in the setting of persistent fever unresponsive to broad-spectrum antibacterial therapy in neutropenic patients has never been established. A daily dose of at least 0.5 mg/kg amphotericin B until marrow recovery has been recommended.[258] Medoff suggested a total cumulative amphotericin B dose of 5 to 20 mg/kg given over 3 to 6 weeks for candidemia.[259] The recommended doses for invasive candidiasis have ranged from 0.5 to 1.0 mg/kg per day to cumulative doses of 2 to 4 g.[260] For a 70-kg patient receiving 0.5 mg/kg per day, this amount would require between 2 and 4 months to administer. It is unknown whether the efficacy of amphotericin B therapy is correlated with total cumulative dose or with duration of therapy.

The IDSA has suggested that patients with prolonged neutropenia who are persistently febrile despite 4 to 7 days of broad-spectrum antibacterial therapy are candidates for empiric antifungal therapy with amphotericin B.[55] This recommendation is based on two previously published trials.[175,176] The incidence of empiric amphotericin B use is significantly higher compared with the incidence of documented invasive fungal disease in neutropenic patients with acute leukemia (36% to 69% vs. 3% to 11%, respectively).[261–264] In BMT recipients, empiric amphotericin B use is also significantly higher than the incidence of invasive fungal infection (38% to 82% vs. 3% to 28%, respectively).[265–268] These differences are likely related to the difficulties in diagnosing invasive fungal infection in these patients. At least one randomized controlled clinical trial[248] compared fluconazole (6 mg/kg per day up to 400 mg/d) and amphotericin B (0.8 mg/kg per day), and demonstrated similar efficacy but with less drug-related toxicity in the fluconazole recipients compared with amphotericin B recipients (32% vs. 82%, respectively). These results

are consistent with those in neutropenic and non-neutropenic patients with invasive candidiasis.[234–237,241]

The echinocandins, a class of antifungal agents that inhibit the activity of 1, 3-β glucan synthase at a critical step in fungal cell wall synthesis, are fungicidal against species of *Candida*. Among patients with candidemia, caspofungin recipients have responded only marginally better than conventional amphotericin B deoxycholate recipients, 73% vs. 62%, respectively.[269] However, caspofungin was associated with fewer adverse events such as nephrotoxicity. Among the small number of neutropenic patients enrolled into that study, the response rates were 3 of 8 (38%) for amphotericin B deoxycholate recipients and 6 of 8 (75%) among caspofungin recipients (OR 5.0; 95% CI 0.42 to 42.3). Based on these observations and those from the fluconazole trials, the National Comprehensive Cancer Network Clinical Practice guidelines in Oncology recommend the use of either caspofungin 70 mg intravenously as a loading dose followed by 50 mg intravenously daily, or fluconazole 400 to 800 mg daily in adults with invasive candidiasis instead of conventional amphotericin B deoxycholate on the basis of equivalence of efficacy and superior safety profiles.[129] Furthermore, caspofungin or a lipid formulation of amphotericin B may be recommended for clinically unstable patients with candidemia due to *C. krusei* or *C. glabrata*.

The duration of antifungal therapy for fungemic patients should be at least 14 days following the last positive blood culture and resolution of signs and symptoms of fungal infection in neutropenic and non-neutropenic adult patients.[232] The duration for patients with hepatosplenic fungal infections is a period of 3 to 6 months along with resolution of signs and symptoms of infection or calcification of radiologically detectable lesions. The duration for oropharyngeal candidiasis should be 7 to 14 days after clinical improvement and 7 to 21 days for esophageal candidiasis.[232]

The IDSA guidelines recommend the removal of all indwelling vascular access catheters in candidemic patients.[232] The purpose of this recommendation is to reduce the risk for metastatic visceral infections and excess mortality.[270] Earlier studies suggested that catheter removal at diagnosis of candidemic episodes reduced the duration of candidemia[271] and mortality.[270] More recent studies among candidemic patients receiving either caspofungin or amphotericin B deoxycholate with or without central venous catheters left in situ failed to confirm those earlier observations with regard to response rates and to duration of candidemia.[269]

OPPORTUNISTIC FILAMENTOUS FUNGAL INFECTIONS

Opportunistic filamentous fungal infections are frequently life threatening complications among neutropenic patients undergoing remission-induction treatment for acute leukemia or hemopoietic stem cell transplantation. These infections are most often caused by *Aspergillus* species, and more often by fumigatus *Aspergillus* spp. as compared to nonfumigatus *Aspergillus* spp., including *A. flavus*, *A. niger*, and *A. terreus*, *Fusarium* spp., the dematiaceous fungi (black molds), or the Zygomycetes (e.g., *Absidia* spp., *Rhizopus* spp., *Rhizo- mucor* spp., *Mucor* spp. or *Cunninghamella* spp.).[228] They produce similar clinical syndromes in compromised hosts, including necrotizing nasal mucosal infection, sinusitis, endophthalmitis, cerebral parenchymal infection, pulmonary parenchymal infection, cutaneous infection, typhlitis, hepatosplenic abscesses, osteomyelitis, and intravascular infections.[272]

FIGURE 47-6 CT scan of the brain shows an intracerebral infarct in a 27-year-old man being treated for acute myeloid leukemia (AML) complicated by disseminated aspergillosis.

Infections by these molds are characterized by blood vessel invasion resulting in thrombosis and blood vessel obstruction, which in turn cause ischemia and infarction of the distal tissues.[273–276] This is the mechanism for the clinical manifestations such as pulmonary cavitary disease, hemoptysis, cutaneous infarcts (see Fig. 47-2), stroke-like syndromes due to intracranial infection (Fig. 47-6), and parenchymal hepatic infarction (Fig. 47-7). Infection occurs following the germination of inhaled conidia on the respiratory epithelium with the production of invasive hyphae.[275]

Characterization of these infections is important in determining prognosis and outcome of antifungal therapy. The National Institute of Allergy and Infectious Diseases Mycoses Study Group (NIAID/MSG) of the National Institutes of Health and the European Organization for the Treatment and Research of Cancer/Invasive Fungal Infections Cooperative Group (EORTC/IFICG) have developed an international consensus of diagnostic criteria for invasive fungal infections (IFI).[277] These infections are classified into three levels of probability as proven, probable, or possible, based on the robustness of the evidence supporting the diagnosis. A recent study from Spain conducted among patients undergoing peripheral blood stem cell transplants who developed IFI reported that mortality rates were related to the classification of the IFI as possible (mortality 20%), probable (mortality 57%), or proven (mortality 80%).[278] Ascioglu and colleagues caution, however, that these criteria were developed in the context of clinical

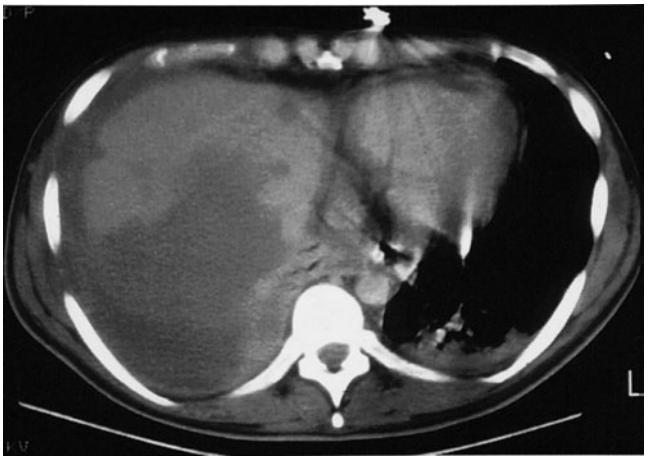

FIGURE 47-7 CT scan of the abdomen in a patient with acute myeloid leukemia (AML) shows massive hepatic infarction secondary to disseminated aspergillosis.

trials rather than for clinical application.[277] The clinical applicability is limited by false-negative observations wherein patients classified as only probable IFI may ultimately have widespread IFI at postmortem examination.[279] These observations underscore the need for more sensitive and predictive tests. However, despite the limitations of diagnostic technology, it seems prudent to use these criteria as guidelines for determining the robustness of the clinical diagnosis and the need to proceed to more invasive diagnostic procedures or for epidemiologic research.[280]

Molds are ubiquitous in the environment[183,273] and present in a wide variety of natural and synthetic materials such as soil,[274] decaying vegetation,[274] fireproofing materials,[281] water,[282] and air.[283] *Aspergillus* species frequently have been detected in the air of hospital rooms, and in particular, in circumstances associated with construction and renovation.[284,285] The management of leukemia and BMT patients in specialized self-contained hospital nursing units outfitted with high-efficiency particulate air filtration (HEPA) has reduced the incidence of invasive aspergillosis,[286] and overall mortality rates, particularly among hemopoietic stem cell transplant recipients.[287] Guidelines are available for planning infection control strategies to contain the excess risk of invasive mold infections among high-risk patients managed in environments where hospital maintenance and renovation projects are underway.[288–290] HEPA-filtered nursing units have lower concentrations of airborne fungal conidia than their non–HEPA-filtered counterparts.[291]

Invasive aspergillosis in leukemia and hemopoietic stem cell transplant patients has been reported to have extremely high mortality rates almost regardless of treatment.[292] The risk of this infection increases with the duration of neutropenia to a plateau of 70% to 80% at 5 weeks.[293] Marrow recovery represents the single most important factor relating to survival of invasive fungal infection in neutropenic patients.[294]

The clinical findings relate to the infected organ site. Fever is almost invariably present. Evidence of tissue ischemia and infarction may provide clues to the diagnosis. The most common presentation is that of focal pulmonary infiltrates in a persistently febrile, severely neutropenic patient unresponsive to broad-spectrum antibacterial therapy. Some investigators have suggested that nasal cultures positive for *Aspergillus* species in this setting can be highly predictive (~90%) of invasive aspergillosis.[181] Positive cultures from other respiratory specimens such as sputum, bronchial brushings, or bronchoalveolar lavage fluid also can be predictive of invasive aspergillosis in high-risk patients;[230,295] however, these relationships have not been universally accepted. Based on multivariate analysis of patients with acute leukemia, a number of factors predictive of invasive opportunistic fungal disease have been identified by different investigators.[293,296–298] In each of these studies the duration of severe neutropenia was the most important independent variable. Other related variables were the duration of cytotoxic therapy (which gives rise to prolonged neutropenia), the duration of neutropenia associated with antibacterial therapy, and colonization by fungi at surveillance culture sites.

The definitive diagnosis of invasive aspergillosis usually requires microscopic and microbiologic examination of tissue biopsied from sites of infection.[273] The demonstration of septate hyphae branching at acute angles in methenamine silver stained or periodic acid-Schiff–stained tissue sections suggests the diagnosis; however, these morphologic characteristics in stained tissue sections are also shared by species of *Fusarium* and *Scedosporium*.[273] Microbiologic identification in culture is required to confirm the diagnosis. This is important because organisms such as *Fusarium* spp., *S. apiospermum,* and *S. prolificans* are not susceptible to amphotericin B. Where available, immunodiagnostic techniques may increase the positive predictive value of the classic microscopic appearance of these organisms in tissue sections.[299]

In leukemia patients the reported mortality rates from invasive pulmonary aspergillosis have had a wide range (between 13% and 100%), whereas in BMT patients the mortality rate approaches 100%.[292] Marrow recovery represents the single most important determinant of survival.[294] Aspergillosis can develop and progress despite the concomitant administration of amphotericin B at daily doses of 0.5 mg/kg.[300] Improved responses and survival rates for leukemia patients have been reported with the use of high-dose amphotericin B (1.0 to 1.5 mg/kg per day in contrast to a more standard dose of 0.5 to 0.7 mg/kg per day) without serious or permanent renal damage.[300] Anecdotal reports and studies in animal models support the use of 5-FC with amphotericin B.[239,292] Doses of 5-FC of 100 to 150 mg/kg per day in four divided doses orally usually result in serum levels of 50 to 100 mg/L. There is an increased risk of excess myelosuppression with serum levels above these values. Since 5-FC is excreted predominantly in the urine and concomitant amphotericin B therapy is almost always associated with a significant decline in renal function, regular monitoring of 5-FC levels and appropriate adjustment of dose to maintain levels in this range are mandatory.

Caspofungin has recently been approved in the United States for the treatment of invasive aspergillosis in patients refractory or intolerant of polyene-based therapy.[301] The initial experience in such patients demonstrated response rates of 50% in invasive pulmonary aspergillosis, 23% in disseminated aspergillosis, and 26% in neutropenic patients. Among patients receiving caspofungin for empiric therapy of suspected fungal infection in neutropenic patients and in whom invasive aspergillosis ultimately was determined to be the cause of the persistent fever, the response rate was 42% compared to only 8% among liposomal amphotericin B recipients.[302]

Amphotericin B lipid complex (ABLC) has been widely used in patients with invasive fungal infections refractory to or intolerant of conventional amphotericin B deoxycholate. In a review of 556 such patients receiving ABLC on an emergency drug release program, the response rate among 130 patients with invasive aspergillosis was 42%.[303] A 47% response rate was reported in an historic control study of ABLC in 39 solid organ transplant recipients with invasive aspergillosis.[304] In a series of pediatric patients with invasive aspergillosis, a 56% response rate was reported.[305]

Amphotericin B–related nephrotoxicity impacts upon patient morbidity, mortality, and the cost of management.[306–308] The safety profiles of the lipid formulations of amphotericin B in the published literature have been consistent in demonstrating advantages of reduced amphotericin B–related nephrotoxicity.[177,307] Even among patients with elevated serum creatinine levels at the outset of ABLC therapy, the advantage persists. The elevated serum creatinine levels have been observed to fall after the first week with continued administration of the drug.[309] This reduction in elevated serum creatinine after the first week of therapy may occur even when initially normal serum creatinine levels rise within the first week of ABLC therapy.[308] This experience is useful to physicians managing severely ill patients with impaired renal function and for whom polyene-based antifungal therapy is deemed necessary.

The extended-spectrum azoles such as itraconazole, voriconazole, and posiconazole have proven useful in the management of invasive mold infections.[310–313] Voriconazole proved to be superior to conventional amphotericin B deoxycholate or other licensed antifungal therapy for the management of invasive aspergillosis in a large multinational trial.[312] The treatment effect was observed in different analyses including hemopoietic stem cell transplant recipients, neutropenic patients, patients with proven or probable invasive aspergillosis, and those with pulmonary and extrapulmonary aspergillosis.

There is a high risk of relapse (>50%) in cancer patients surviving an initial episode of invasive aspergillosis during subsequent cytotoxic treatments.[314] For this reason many investigators recommend secondary prophylaxis with antifungal agents such as itraconazole or lipid formulations of amphotericin B for patients with treated invasive aspergillosis undergoing subsequent high-dose cytotoxic therapy.[315] A combination of high-dose amphotericin B (1.0 mg/kg per day) and 5-FC (100 mg/kg per day) has been used successfully to protect leukemia patients who developed invasive pulmonary aspergillosis during initial remission-induction against reactivation of the infection during subsequent cycles of cytotoxic therapy, without delay of marrow recovery.[316–318] This seems to be a rational approach for leukemic patients, but its validity for BMT patients remains to be proven.[318] The role of combinations of amphotericin with other agents such as rifampin or the azoles remains unclear and cannot be recommended at the present time.[239]

INDWELLING VASCULAR ACCESS DEVICE INFECTIONS

Indwelling peripheral and central vascular access catheters have long been recognized as a source of sepsis for critically ill cancer patients. This subject has been reviewed recently.[231,319,320] Venous and arterial cannulas physically disrupt the integrity of the skin and blood vessels, thus providing an avenue for ingress of bacteria or fungi colonizing the skin surfaces at the site of cannula placement. Determinants of intravenous cannula infection include the type of cannula, the duration of use, the technique of skin preparation for insertion, and the use of venotoxic infusates. The most common microorganisms causing intravenous site infection are gram-positive organisms such as *Staphylococcus aureus*, the coagulase-negative staphylococci, and *Corynebacterium jeikeium*; gram-negative bacilli such as the Enterobacteriaceae, *P. aeruginosa*, *Stenotrophomonas maltophilia*, and *Acinetobacter* spp; and fungi such as *Candida* species. Erythema, swelling, exudate, and focal tenderness at a peripheral intravenous catheter site should always alert the clinician to these etiologic possibilities. Suspect catheters should be removed promptly and carefully using aseptic technique and submitted to the clinical microbiology laboratory in a sterile dry container for microbiologic evaluation.

Venous access is a major problem for patients with complex multisystem problems. The need for repeated blood sampling for monitoring and for the administration of different therapies has led to the widespread use of indwelling tunneled central venous catheters. These devices provide reliable access for venous blood sampling and administration of chemotherapy, blood products, antimicrobial agents, total parenteral nutrition, crystalloids, and vasoactive agents. Infection of these devices may occur at the exit site (the point at which the catheter exits the skin), the tunnel site (that portion of the catheter buried subcutaneously and extending from the exit site to the insertion site), and the insertion site (the site, often associated with an infraclavicular or small lateral neck incision, where the catheter is inserted into a large central vein, such as the subclavian or internal jugular vein).

Erythema, exudate, and focal tenderness at the exit site suggest, but do not prove, the presence of infection. A quantitative increase in bacterial colony counts in culture swabs from the exit site has been associated with an increased probability that central venous catheter infection is present.[321,322] *Staphylococcus epidermidis* and *C. jeikeium* are the most commonly isolated colonizing microorganisms at the exit site and represent the most common etiologic agents of catheter sepsis in cancer patients.[323,324] Catheter-related sepsis is suspected if bacteremia or fungemia is present unassociated with any other site of suspected infection. The predominant mechanism of infection appears to be bacterial migration from the exit site along the outside surface of the catheter.[320] Suspected catheter exit-site infection, with or without bacteremia, may be treated with antimicrobials without removing the line.[325] Unless exit-site surveillance cultures dictate otherwise, the empiric antibacterial therapy should include an agent such as vancomycin that is active against *S. epidermidis* and *C. jeikeium*, in addition to *S. aureus* and streptococci. Infection of the subcutaneous tunnel site is more difficult to control with antimicrobial agents alone and often requires catheter removal.[326] Catheter removal is also often recommended in the setting of bacteremia due to more highly pathogenic organisms such as *S. aureus*, *P. aeruginosa*, or *Serratia marcescens*, catheter-related fungemia, or persistent catheter-related bacteremia that has not responded to appropriate antibacterial therapy. The differential time-to-positivity (i.e., the time difference between the time that the blood culture from the

peripheral site and central venous catheter site was obtained to the time the cultures became positive) of >2 hours has been used as a method for predicting catheter-related infections.[327]

Infection Prevention in the Neutropenic Host

ANTIBACTERIAL PROPHYLAXIS

Antibacterial chemoprophylaxis is used widely for preventing or modifying the etiology of bacterial infection in patients for whom the expected duration of neutropenia is longer than 7 days. Oral nonabsorbable antimicrobial regimens consisting of agents such as aminoglycosides including neomycin, gentamicin, or tobramycin, vancomycin, polymyxin B, colistin, and oral nystatin or amphotericin B have not been consistently effective for reducing the incidence of febrile neutropenic episodes, documented superficial or invasive infection, or overall mortality. In addition, they are unpalatable and costly. On the other hand, oral absorbable antibacterial regimens consisting of trimethoprim-sulfamethoxazole (TMP-SMX) or fluoroquinolones including norfloxacin, ciprofloxacin, enoxacin, ofloxacin, levofloxacin, or perfloxacin have proved useful, although investigators have cautioned that efficacy appears to be intimately linked with compliance,[328] personal hygiene, the spectrum of antimicrobial activity of the regimen,[329] the cytotoxic potential of the antineoplastic regimen, and the timing of the administration of the regimen relative to the onset of the neutropenia-related risk for bacterial infection.[17,330]

The experience with oral fluoroquinolones has shown a significant reduction in the morbidity and mortality due to infection by aerobic gram-negative bacilli compared with TMP-SMX.[17,331] The tradeoff for this appears to be an increase in the risk of infection due to gram-positive organisms such as coagulase-negative staphylococci, *Enterococcus* spp., and viridans group streptococci. The presence of a tunneled indwelling central venous catheter adds to the risk for infections due to coagulase-negative staphylococci,[332] whereas severe mucositis and periodontal disease appear to predispose to viridans streptococcal infection.[34,35,206,333] A syndrome of viridans streptococcal bacteremia has been recognized among high-dose cytarabine or BMT recipients that is often associated with pulmonary infiltrates and hypotension.[34,334,335] The pathogenesis is believed to involve severe cytotoxic therapy–induced intestinal mucosal damage in the setting of severe prolonged neutropenia and gastrointestinal luminal colonization by these organisms. Oral fluoroquinolone use tends to select for these microorganisms.[336] Of clinical importance is the inconsistent susceptibility of these organisms to penicillin G and the apparent need to modify the empiric antibacterial regimen by the addition of intravenous vancomycin to improve the likelihood of a successful outcome for the febrile neutropenic episode. Bacterial infections among TMP-SMX recipients have been due to coagulase-negative staphylococci, viridans streptococci, and TMP-SMX–resistant aerobic gram-negative bacilli such as *P. aeruginosa*.[330]

Four meta-analyses have been published examining the role of fluoroquinolone-based antibacterial chemoprophylaxis in neutropenic cancer patients.[63,167,337,338] Within each of these publications are contained multiple meta-analyses. Cruciani and colleagues examined 13 trials comprising 1155 randomized subjects comparing fluoroquinolones to TMP-SMX, nonabsorbable antimicrobials, or placebo.[63] These investigators also reported on a meta-analysis examining the efficacy of fluoroquinolones plus additional agents that augmented coverage for gram-positive microorganisms.[63,167] Rotstein and associates reported on four meta-analyses; namely, five trials with 394 randomized subjects comparing fluoroquinolones to placebo, 16 trials with 1362 randomized subjects comparing fluoroquinolones to other antibacterial agents, 3 trials with 902 randomized subjects comparing ciprofloxacin to other fluoroquinolones, and 6 trials with 922 subjects comparing fluoroquinolones plus additional gram-positive coverage to control regimens.[337] Lastly, Engels and colleagues reported two meta-analyses; first, 9 trials with 731 randomized subjects comparing fluoroquinolones and untreated controls, and second, 9 trials with 677 randomized subjects comparing fluoroquinolones to TMP-SMX.[338]

These systematic reviews were able to detect prophylactic treatment effects for the fluoroquinolones in a variety of outcomes, including microbiologically documented infection overall, gram-negative infections overall, and gram-negative bacteremia regardless of whether the controls were placebo, no treatment, or TMP-SMX. Infection-related mortality and overall mortality were not affected by fluoroquinolone prophylaxis. Reduction in the incidence of febrile episodes was demonstrable only in the 8 placebo-controlled trials (OR 0.85; 95% CI 0.75 to 0.99); however, this effect was observed only among unblinded trials and not blinded trials.[338] Treatment effects were not observed for clinically documented infections or for gram-positive infections.

The combination of fluoroquinolones with agents with additional gram-positive activity such as penicillin, macrolides, or rifampin effectively prevents gram-positive bacteremias as well.[54,339–341] A recent updated meta-analysis from the University of Padua encompassing 1202 randomized subjects in 9 trials comparing fluoroquinolones plus augmented gram-positive coverage to fluoroquinolones alone demonstrated a reduction in total bacteremic episodes (relative risk 1.54; 95% CI 1.26 to 1.88), streptococcal infections (RR 2.2; 95% CI 1.44 to 3.37), coagulase-negative staphylococcal infections (RR 1.46; 95% CI 1.04 to 2.04), and incidence of fever (RR 1.08; 95% CI 1.00 to 1.16).[167] The incidence of clinically documented infections, unexplained fever, and infection-related mortality were not affected. Gram-positive prophylaxis, however, increased the incidence of prophylaxis-related drug toxicities (RR 0.46; 95% CI 0.28 to 0.76), particularly with the use of rifampin.[167]

Based upon these observations, antibacterial chemoprophylaxis using oral fluoroquinolones under circumstances in which the prevalence of fluoroquinolone-resistant *Escherichia coli* (FREC) is low (<3% to 5%) can reliably reduce the risk for invasive gram-negative bacillary infection, and if supplemented by gram-positive agents such as rifampin, penicillin, or macrolides, can reduce the risk for invasive infections due to gram-positive microorganisms including viridans streptococci and coagulase-negative staphylococci. Fluoroquinolone-based chemoprophylaxis does not reliably reduce the incidence of febrile neutropenic episodes, neutropenic episode-related mortality, or physician-initiated systemic antimicrobial prescribing behavior.

Under the appropriate conditions, it is possible that fluoroquinolone-based antibacterial chemoprophylaxis can influence physician prescribing behavior for febrile neutropenic episodes.[342–344] A study from Duke University among autologous hemopoietic transplant recipients with ciprofloxacin prophylaxis demonstrated that febrile neutropenic episodes could be safely treated with an empiric glycopeptide-based regimen.[343] A study from the University of Manitoba, Canada, demonstrated that patients developing febrile neutropenic episodes while receiving ciprofloxacin prophylaxis during remission-induction therapy for acute myeloid leukemia could be treated safely and effectively with a vancomycin plus ceftazidime–based strategy wherein the ceftazidime was discontinued before the patient defervesced, provided the serial rectal surveillance cultures and 24- to 36-hour blood cultures revealed no evidence of aerobic gram-negative bacilli.[344] In both these studies, the oral ciprofloxacin prophylaxis regimen was continued throughout the treatment for the febrile neutropenic episode. A third study from Europe demonstrated that empiric systemic antibacterial therapy for febrile neutropenic episodes could be safely discontinued after 72 to 96 hours if the initial work-up failed to provide evidence for clinically or microbiologically documented infection and if prophylaxis was continued.[342] These observations, while provocative, have not been followed up in large randomized controlled studies.

Not all fevers in neutropenic patients represent infection; thus fever is a poor outcome for clinical trials of antibacterial prophylaxis in this patient population. Better discriminators for infection are needed before the kinds of strategies suggested by these trials can enter the domain of standard practice.[345] Although the results of antibacterial prophylaxis studies have not yet had a major influence on how physicians use empiric antibacterial therapies, there is reason to believe that they will do so in the future.[345] The prophylaxis-related decrease in documented infections has been offset by an increase in unexplained fevers.[54] It is possible that these unexplained fevers may be due to increased absorption of pyrogenic endotoxins through cytotoxic therapy–induced damage to the intestinal epithelium.[346] This consideration, if true, suggests that at least some unexplained fevers do not require continued antibacterial therapy.

ANTIFUNGAL PROPHYLAXIS

The major goals of antifungal prophylaxis strategies are to reduce the morbidity and mortality due to superficial and invasive opportunistic fungal infections, and to reduce the use of toxic expensive antifungal therapy. Prophylactic strategies should be applied with a clear understanding of the pathogenesis of the microorganisms involved.

FILAMENTOUS FUNGI

Filamentous fungi such as *Aspergillus* species, the dematiaceous fungi, *Fusarium* spp., Zygomycetes, and *Scedosporium* spp. are acquired by inhalation of spores called *conidia*. The conidia germinate on the respiratory epithelium to produce invasive hyphae. There are three possible ways to prevent this. First, patients may be managed in nursing units outfitted with HEPA filtration systems. This reduces the concentration of airborne conidia and the risk of patient exposure. Although this approach is effective for reducing the risk of filamentous fungal infection,[286,287,347] it is expensive and has no impact for patients exposed to high concentrations of airborne conidia outside the nursing unit or for those who are already infected before entering the unit. Second, topical agents such as amphotericin B sprayed by aerosol into the nares theoretically might reduce the risk of conidial germination. One randomized study from the Institute Jules Bordet in Brussels[348] evaluated the use of intranasal amphotericin B (5 mg/mL in sterile water with a total daily dose of 10 mg in three divided doses) in 90 neutropenic episodes. There was no significant difference in the empiric use of intravenous amphotericin B (35% versus 27%); however, only 1 of 46 recipients of aerosolized amphotericin B developed suspected or proven invasive aspergillosis compared with 7 of 44 controls. Although this is encouraging, intranasal amphotericin cannot be accepted as a satisfactory alternative to air filtration until further studies are done. Inhalation of aerosolized amphotericin B has been studied as a strategy to reduce invasive aspergillosis.[349] The incidence of possible, probable, or proven invasive aspergillosis in the aerosolized amphotericin B recipients was 4% compared to 7% in untreated control subjects. Furthermore, there were no differences in overall mortality or in infection-related mortality. Third, systemic antifungal therapy might prevent the progression of hyphal growth once germination occurs. Systemic amphotericin B plus 5-FC has been used successfully to prevent reactivation of previously documented invasive pulmonary aspergillosis among leukemia patients undergoing further postremission cytotoxic therapy.[316] Since this combination may be myelotoxic as well as nephrotoxic, it may be prudent to reserve this approach for those in whom opportunistic filamentous fungal infection has been proved by microbiologic or histopathologic methods. The prophylactic role of newer approaches such as lipid formulations of amphotericin B, echinocandins including caspofungin and micafungin, or the extended-spectrum triazole antifungal agents such as itraconazole, voriconazole, or posaconazole, with greater in vitro activity against *Aspergillus* species is being studied.

Itraconazole, a lipophilic extended-spectrum azole, has been evaluated for antifungal prophylaxis in a number of trials of very heterogeneous patient populations.[350–352] A recent meta-analysis of these trials failed to identify a prophylactic benefit of itraconzole against fungal disease due to *Aspergillus* spp.[247] However, studies performed in patients at higher risk for invasive aspergillosis have been more positive.[353,354] In hemopoietic stem cell allograft recipients Winston and colleagues evaluated itraconazole administered intravenously 200 mg twice daily for 2 days, then 200 mg intravenously daily for 12 days, then 200 mg orally daily until day 100, compared to fluconazole 400 mg given intravenously daily for 14 days, then 400 mg orally until day 100.[353] There was a significant reduction in the overall incidence of proven invasive fungal infection (OR 0.37; 95% CI 0.15 to 0.88), but the protective effect on mold infection was not statistically significant (OR 0.38; 95% CI 0.11 to 1.32). A similar study from the Fred Hutchison Cancer Center was able to demonstrate a significant reduction in the overall incidence of invasive fungal infection (15% to 7%; OR 0.46; 95% CI 0.56 to 0.99) and in invasive mold infections (12% to 5%; OR 0.44; 95% CI 0.17 to 0.98).[354] Despite this promising result, treatment-related adverse events necessitating treatment withdrawal resulted in a higher overall mortality among itraconazole recipients. The study drug was discontinued for reasons of intolerance

in 36% of itraconazole recipients compared to only 16% of fluconazole recipients.[354] A recent meta-analysis from the University of Bonn, Germany, critically examined the efficacy of itraconazole for antifungal prophylaxis against invasive fungal infection in 13 randomized controlled trials encompassing 3597 randomized subjects, and demonstrated reductions in the mean relative risks for invasive fungal infection overall (relative risk reduction [RRR] 40% ± 13%), invasive yeast infection (RRR 53% ± 19%), and fungal infection–related mortality (RRR 35% ± 17%) in neutropenic cancer patients.[355] The risk for invasive aspergillosis was reduced only in trials in which the cyclodextrin-based oral or intravenous formulations of itraconazole were used (OR 0.52; 95% CI 0.30 to 0.90; RRR 48% ± 21%).[355]

Echinocandin antifungal agents may also be useful for prophylaxis in high-risk patient populations. A study comparing a newer echinocandin, micafungin, to fluconazole in a heterogeneous group of autologous and allogeneic transplant recipients demonstrated a significant reduction in the use of empiric systemic antifungal therapy among the micafungin recipients (15% compared to 21%; $p = 0.018$).[356] The incidence of invasive aspergillosis was 0.2% and 1.5% in micafungin and fluconazole recipients, respectively ($p = 0.07$).

OPPORTUNISTIC YEASTS

Yeast infections, primarily *Candida* spp., colonize the patient and cause infection by invading damaged integumental surfaces. HEPA filtering plays no role in the prevention of these infections. The use of topical agents such as nystatin or amphotericin B has had a small impact on colonization profiles, but no significant impact on the incidence of invasive fungal infection or the need to use empiric systemic amphotericin B for suspected invasive fungal infection. Topical chlorhexidine mouth rinses (0.12% chlorhexidine digluconate three times daily) have been effective in reducing the morbidity of oropharyngeal candidiasis in a series of marrow allograft recipients.[208] Furthermore, a reduction in candidemia also was noted, suggesting the oropharynx as a possible source for these events. The overall value of this strategy must be evaluated in further trials in different populations at risk.

Systemic antifungal therapy for the prevention of opportunistic yeast infections is better established.[246,247,355,357] Published studies using the imidazoles ketoconazole, clotrimazole, and miconazole have demonstrated a reduction in yeast colonization, but have failed to demonstrate a consistent reduction in clinical disease or the need to use empiric systemic amphotericin B. There also has been a selection for more resistant yeasts such as *Candida krusei* and *Candida glabrata* in the surveillance cultures of azole recipients.[242] The triazole antifungal agents fluconazole and itraconazole have been shown to be effective in reducing the need for empiric antifungal therapy with amphotericin B, superficial fungal infection, proven invasive yeast infection, and fungal infection–related mortality.[247] Furthermore, these agents are effective when applied to patient populations with a high risk for invasive fungal infection (10% to 15%),[246,247] when doses of 400 mg or more daily are administered,[247,355] and when the agents are absorbed.[355]

It is recommended that antifungal prophylaxis be administered only to defined populations at highest risk for invasive fungal infection and for whom clinical trials have been able to demonstrate a treatment effect. Accordingly, the populations of patients for whom this applies include patients undergoing remission-induction or reinduction therapy for acute leukemia, patients undergoing allogeneic hemopoietic stem cell transplantation, and those undergoing autologous hemopoietic stem cell transplantation without hemopoietic growth factor support.[358,359] Furthermore, the duration of prophylaxis should be from day 1 of the cytotoxic regimen until neutrophil recovery for acute leukemia patients. For allogeneic hemopoietic stem cell transplant recipients, treatment from the first day of conditioning until day 75 to 100 is recommended.[347,360]

ANTIVIRAL PROPHYLAXIS

Reactivation of herpes simplex virus (HSV) infection is one of the most common causes of oropharyngeal and esophageal mucositis in patients undergoing remission-induction for leukemia or BMT.[361] This complication is painful and can substantially impair adequate nutritional intake and drug administration. Herpes mucositis, stomatitis, or esophagitis can be prevented largely by prophylactic use of acyclovir. Patients at risk for these infections are those with a history of previous herpetic infection. They may be reliably identified by a clear history of the typical vesicular lesions of herpetic stomatitis or by the identification of IgG antibodies against HSV in their sera. Between 60% and 80% of HSV-seropositive patients will reactivate during cytotoxic therapy. It has been recommended that patients undergoing remission-induction therapy, consolidation therapy, or salvage therapy for acute leukemia and those undergoing bone marrow allografting or autografting who are IgG-seropositive for HSV-1 are candidates for acyclovir prophylaxis.[207,362,363] Oral and intravenous routes of administration have been studied and found effective. It remains unclear whether oral administration is as effective as intravenous administration in patients receiving regimens highly toxic to intestinal mucosal surfaces, such as high-dose cytarabine or etoposide-containing regimens or BMT conditioning regimens. Acyclovir in doses of 250 mg/m^2 administered intravenously every 12 to 8 hours or oral acyclovir administered in doses of 200 to 400 mg four to five times daily has prevented HSV mucositis successfully.[207] Prophylaxis for 1 month or less from initiation of treatment has been associated with recurrences in 58% to 70% of patients after the acyclovir was discontinued. Accordingly, it has been recommended that prophylaxis be continued for 6 weeks from the beginning of induction or conditioning,[207] or up to 6 weeks following marrow recovery in BMT recipients. Acyclovir doses of 800 mg orally every 12 hours appear to be effective for this. Valacyclovir has been shown to be as effective as acyclovir.

Chapter 48

AIDS IN THE INTENSIVE CARE UNIT

PETER PHILLIPS
JULIO S. G. MONTANER
JAMES A. RUSSELL

KEY POINTS

- *The acquired immunodeficiency syndrome (AIDS) is caused by chronic infection with the human immunodeficiency virus (HIV), which through its relentless replication causes progressive depletion of T-helper lymphocytes leading to severe cellular immunodeficiency.*
- *In the absence of treatment, after a variable period, usually years from infection, multiple opportunistic infections or neoplasms characteristic of AIDS develop. Despite substantial progress in antiretroviral therapy, cure of the disease remains elusive.*
- *HIV transmission is limited to sexual exposure (homosexual or heterosexual), exposure to blood or blood products (including transplanted organs), and perinatal exposure (transplacentally, at the time of delivery, or through lactation).*
- *HIV cannot be transmitted through casual contact. Universal precautions, however, should be implemented and enforced to minimize the risk of occupational exposure to HIV as well as other infectious agents. The rate of seroconversion following a single accidental needle stick or mucous membrane exposure appears to be well below 1%.*
- *Combination antiretroviral therapy has been shown to prolong survival as well as disease-free interval. The widespread availability of plasma viral load monitoring and increasing access to genotype resistance testing in developed countries have led to further optimization of therapy and hence further improvement in outcomes.*
- *Acute respiratory failure (ARF) secondary to* Pneumocystis carinii *pneumonia (PCP) is a frequent cause of ICU admission among HIV-infected individuals.*
- *PCP usually is diagnosed in the ICU using bronchoalveolar lavage (BAL). BAL fluid always should be processed to allow identification of* P. carinii, *fungi, common bacteria, mycobacteria, and viruses.*
- *PCP-related ARF should be treated aggressively with specific antimicrobials, adjunctive systemic corticosteroids, and oxygenation support.*
- *The mortality of PCP-related ARF has decreased substantially with the use of adjunctive systemic corticosteroids. Patients developing ARF despite corticosteroid treatment, however, continue to have a dismal prognosis.*
- *Initiation of highly active antiretroviral therapy or revision of a failing regimen should be delayed until completion of PCP therapy because of the risk of pulmonary deterioration related to PCP immune reconstitution syndrome.*
- *The issue of life support should be discussed early and reassessed frequently with HIV-infected individuals. ICU admission and life support, however, should be discouraged for patients with multiple life-threatening complications for which there is no effective therapy. Because the outlook of AIDS and its related diseases is changing rapidly, rigid policies regarding ICU eligibility should be strongly discouraged.*

HUMAN IMMUNODEFICIENCY VIRUS INFECTION

The acquired immunodeficiency syndrome (AIDS) is caused by chronic infection with the human immunodeficiency viruses (HIV-1, HIV-2). Continuous HIV replication leads to progressive dysfunction and gradual depletion of the helper T-lymphocytes or CD4+ lymphocytes.[1,2] It is clear, however, that HIV can infect other cells, including macrophages and B-lymphocytes. Eventually, this results in the development of the otherwise unusual opportunistic infections and neoplasms characteristic of AIDS.

The total number of people infected with HIV/AIDS globally as of December 2000 has been estimated to be 58 million, of whom 21.8 million have died since the beginning of the epidemic. The number of people in the United States living with HIV or AIDS was estimated to be 920,000 and 320,000, respectively.[3]

The proportion of AIDS cases requiring either hospitalization or admission to the ICU has declined since the introduction of highly active anti-retroviral therapy (HAART) in 1996. In recent years, HIV-related hospitalizations are less often due to opportunistic diseases compared with the pre-HAART era. Since the increase in HIV infection among injection drug users, a significant proportion of hospital admissions for HIV patients now are accounted for by other complications of injection drug use (e.g., liver disease from chronic hepatitis B and C, cellulitis, endocarditis etc.).

TRANSMISSION

The most common route of transmission of HIV remains sexual intercourse. It must be emphasized that homosexual and heterosexual transmission occurs, and in both cases, bidirectional transmission is possible.[4] The second most prevalent form of transmission is through exposure to infected blood or blood products, including transplanted organs. Since the widespread adoption of HIV screening of donated blood, however, parenteral transmission of HIV is limited almost exclusively to intravenous drug use. Finally, the infection also can be transmitted perinatally. This refers to infection of offspring transplacentally, at the time of delivery, or through lactation.[5]

It is important to emphasize that HIV is not transmitted through casual contact. After a single accidental needle stick exposure to contaminated material, the rate of seroconversion is approximately 1 per 300 exposures, or 0.3 percent. This is particularly reassuring for the families and health care providers of AIDS patients. In the ICU setting, the "universal precautions" recommended for patients infected with the hepatitis B virus are sufficient to deal appropriately with HIV.[6] Nevertheless, the risk of acquiring HIV infection in the workplace is real; this issue, therefore, should not be hidden but rather discussed openly, and health care institutions should adopt exemplary policies to deal fairly and compassionately with such occurrences. A case-control study conducted by the Centers for Disease Control and Prevention (CDC) showed that zidovudine use following accidental

Copyright © 2005, 1998, 1992 by The McGraw-Hill Companies, Inc. Click here for terms of use.

exposure to HIV in health care workers reduced the risk of transmission by approximately 80%.[7] Consequently, the need for antiretroviral therapy immediately following accidental exposure to HIV should be evaluated on a case-by-case basis by qualified specialists. According to published guidelines, counseling and possibly combination antiretroviral therapy, depending on the details of the potential exposure, should be offered immediately to health care workers.[8]

PATHOPHYSIOLOGY

HIV preferentially infects T-lymphocytes bearing the surface marker CD4, the so-called helper T cells or T4 cells. This tropism is mediated through a specific interaction between GP160, a viral envelope glycoprotein, and the CD4 molecule itself. HIV is also capable of infecting a number of other bone-marrow-derived cells, including monocytes, macrophages, Langerhans dendritic cells, microglial cells, B-lymphocytes, and bone marrow stem cells.[9]

Once within the cell, the viral ribonucleic acid (RNA) and reverse transcriptase are released. The reverse transcriptase generates a deoxyribonucleic acid (DNA) sequence complementary to the viral RNA, which then integrates into the host cell's genome to produce new viral particles, which in turn will infect other susceptible cells. Relentless HIV replication causes T4 cell dysfunction and death, leading to severe cellular immunodeficiency.[9]

NATURAL HISTORY

Acute HIV infection is associated with retrospectively identified transient symptomatic illness in 40% to 90% of patients.[10] This is most often a nonspecific flulike illness often confused with acute infectious mononucleosis and characterized by fever (>80% to 90%), fatigue (>70% to 90%), rash (>40% to 80%), headache (32% to 70%), lymphadenopathy (40% to 70%), pharyngitis (50% to 70%), and aseptic meningitis (24%), as well as other symptoms. This usually benign and self-limited syndrome, also known as *seroconversion illness,* is believed to be an immune-complex-mediated phenomenon resulting from early antibody response to the infection by HIV. Typically, after a variable period (rarely less than 2 years) with few or no symptoms, progressive immunodeficiency develops, rendering the individual susceptible to the development of opportunistic infections, wasting, and/or neoplasms characteristic of AIDS. AIDS remains incurable despite considerable progress in antiretroviral therapy. The often-prolonged period of clinical latency is characterized by continued viral replication and decline of the immune system, as illustrated by the progressive destruction of the lymph node architecture.[11]

SURROGATE MARKERS

A number of laboratory tests have been shown to correlate with prognosis among HIV-infected individuals. These tests generally are referred to as surrogate markers of disease progression.[12] The CD4+ lymphocyte count traditionally has been the most commonly used surrogate marker. A range of 400 to 1400 cells/μL (0.40 to 1.40 $\times$ 10^9/L) is considered normal in most laboratories. The CD4 count usually is reported as a fraction and an absolute count. Although the absolute CD4 count is usually a good reflection of the degree of immunodeficiency in a given patient, it must be noted that under specific circumstances this may be misleading. It is therefore advisable to monitor the CD4 fraction to ensure that this is in general agreement with the absolute CD4 count. CD4 counts are used widely to guide therapeutic decisions regarding the use of antiretrovirals and preventive strategies, yet they are subject to considerable variability. CD4 counts show circadian variation, which is lowest in the morning and highest in the evening. In normal individuals, the evening CD4 cell count can be nearly double the morning nadir. Although this variation may be reduced in HIV-infected patients, specimens for CD4 counting should be collected in a standardized fashion. Other factors that may affect the count include acute infections such as common viral illnesses, certain pharmaceutical agents, stress, smoking, and exercise. The results also may be influenced by differing laboratory methodologies. Despite controlling the time of collection, HIV-infected individuals who are stable clinically will still show considerable variation in CD4 counts. Short-term CD4 count fluctuations of nearly 30% may occur that are not attributable to a change in disease status. In addition, correlation between CD4 count and clinical status can be quite different from one patient to the next. Overall, it is important to monitor the trends in CD4 counts over time to avoid placing too much emphasis on the specific number derived from a single determination. Despite these limitations, the CD4 count remains a valuable tool when attempting to establish the differential diagnoses in a given patient. For example, it would be very unusual (although still possible, particularly in the context of immune reconstitution syndromes) to have a case of PCP, *Mycobacterium avium* complex (MAC), or cytomegalovirus (CMV) disease with a CD4 count within the normal range.

Strong evidence has been generated regarding the prognostic value of viral load determinations in seroincidence and seroprevalent cohorts. In one such study, seroprevalent individuals who had high viral loads were shown to have a substantially worse prognosis with regard to survival. Whereas median survival was in excess of 10 years for individuals with a plasma viral load under 5000/mL, those with plasma viral loads over 34,000/mL had a median survival on the order of 3 years.[13] These data were confirmed by the results of virologic studies within the AIDS Clinical Trials Group Protocol 175 (ACTG 175). This study demonstrated a 10-fold increase in the rate of death and progression to AIDS or death when individuals with lower viral loads (<5000 copies/mL) were compared with those with high loads (>54,000 copies/mL). In this study, CD4 counts and viral load were shown to be independent prognostic markers at enrollment. More important, decreases in viral load with treatment between weeks 0 and 8 were shown to be statistically significantly associated with improved survival and decreased progression to AIDS within this protocol. Of note, increases in CD4 counts with treatment, during the same period, failed to demonstrate a statistical association with clinical outcomes. These data strongly support the independent contribution that viral load determinations can have in terms of monitoring prognosis and response to antiretroviral therapy. Plasma viral load determinations should be obtained in tandem with CD4 counts. However, although viral load determinations play a major role in the management of HIV-infected individuals, this marker has no demonstrated role in the ICU care of HIV-infected individuals.

ANTIRETROVIRAL TREATMENT

Combination therapy regimens have been shown to prolong survival and the disease-free interval substantially among HIV-infected individuals. More recently, a number of new drugs have been added to our therapeutic armamentarium. The currently available classes of antiretrovirals are the nucleoside or nucleotide reverse-transcriptase inhibitors (NRTIs, NtRTIs), nonnucleoside reverse-transcriptase inhibitors (NNRTIs), protease inhibitors (PIs), and fusion inhibitors. The NRTIs include zidovudine (AZT), didanosine (ddI), stavudine (D4T), lamivudine (3TC), abacavir, and tenofovir. The NNRTIs include nevirapine, delavirdine, and efavirenz. The protease inhibitors include indinavir, ritonavir, saquinavir (hard-gel [Invirase], soft-gel [Fortovase]), nelfinavir, amprenavir (and fos-amprenavir), atazanavir, tipranavir, and the coformulation of lopinavir plus ritonavir (known commercially as Kaletra). PIs are increasingly coadministered with low-dose ritonavir for the purpose of taking advantage of the drug interaction, which results in higher drug levels (pharmacologic boosting) of the coadministered PI. This applies to indinavir/ritonavir, saquinavir/ritonavir, amprenavir/ritonavir, tipranavir/ritonavir, and lopinavir/ritonavir; such combinations are considered to count only as a single drug from the antiviral perspective. Currently, triple (or quadruple) drug combinations, including two nucleosides (zidovudine or stavudine plus lamivudine or didanosine) and a PI (or boosted dual PI combination) or NNRTI are recommended to achieve a greater level of suppression of viral replication.[14] Recently, regimens containing both d4T and ddI have been associated with high rates of toxicity. Alternative NRTIs (or NtRTI) include abacavir and tenofovir, which cannot be given together due to a yet to be understood interaction that compromises their antiviral effect.

In the ICU, it is particularly important to be aware of the more prevalent adverse effects of these agents (Table 48-1). As patients are increasingly treated with multiple antiretroviral agents, often including experimental agents, it is important to remain open to the possibility of new and previously unrecognized adverse effects. Also, whenever antiretroviral therapy is discontinued, viral replication will rebound within days to weeks. Patients receiving combination therapy who develop an adverse effect or drug intolerance to one of the antiretrovirals precluding its continuation should be reviewed by an HIV specialist. Temporary interruption of one drug or part of the antiretroviral regimen in particular may seriously compromise the long-term efficacy of the regimen by promoting the development of resistance to the remaining agents in the regimen.[14] Under these circumstances, interruption of the full antiretroviral regimen is a more appropriate strategy.

It is likely that as experience with some of the newer antiretroviral agents increases, new adverse effects and toxicities will be uncovered. Also, physicians should pay particular attention to possible drug interactions in these often heavily medicated patients.[15] In particular, the profound effect of ritonavir on drug metabolism always should be kept in mind in this setting.

THE SPECTRUM OF DISEASE IN THE ICU

Although HIV-infected individuals develop many medical complications, those leading to ICU admission are few. The complications may be divided according to their relationship to the HIV infection. Causes of ICU admission unrelated to the HIV infection generally are similar to those found in non-HIV-infected individuals of comparable age and risk groups (i.e., young intravenous drug users or homosexual males in North America), and since HIV infection generally is asymptomatic early in its course, many patients with clinically unsuspected HIV infection are treated in ICUs and emergency rooms. Patients with these conditions usually respond to standard management, and their prognosis appears to be similar to that of non-HIV-infected patients who have the same condition unless there is concomitant severe immunodeficiency, in which case the prognosis tends to be determined by the severity of the immunodeficiency.

Of the causes of ICU admission related to the HIV infection, acute respiratory failure (ARF) secondary to *Pneumocystis carinii* pneumonia (PCP) is much less common than in previous years. However, it remains a problem among patients who have barriers to accessing medical care and others who are nonadherent or fail to respond to antiretrovirals and PCP prophylaxis. Various conditions, such as cerebral toxoplasmosis, bacterial pneumonia, disseminated infections (such as bacterial sepsis or mycobacterial infection), gastrointestinal bleeding, Kaposi's sarcoma, lymphoma, endocarditis, and cardiomyopathy account for other HIV-related ICU admissions. The broad differential diagnosis of opportunistic diseases should be kept in mind to avoid delays in diagnosis.[16] Less frequently, a person with AIDS may be admitted to the ICU without prior knowledge of her or his HIV status. Certainly, the presence or history of minor or major opportunistic infections, wasting, otherwise unexplained extensive herpes zoster, or persistent generalized lymphadenopathy combined with a history (or clinical evidence) of high-risk activities will necessitate consideration of HIV infection and related diseases in the differential diagnosis. Also, a number of laboratory features found commonly among HIV-infected individuals can provide the initial basis for considering HIV infection within the differential diagnosis. Among them, lymphopenia, anemia, thrombocytopenia, and hypergammaglobulinemia are the most common. It must be emphasized, however, that HIV infection should not be diagnosed unless this has been confirmed using specific serologic tests, most commonly, enzyme-linked immunosorbent assay (ELISA) and Western blot.

Respiratory Disease Complicating HIV Infection

Acute respiratory failure secondary to PCP remains a frequent cause of ICU admission among HIV-infected individuals. Despite this, the initial diagnostic workup of patients with acute pulmonary disease always should consider less frequent causes, among them fungal, bacterial, mycobacterial, and viral infections. Other infections that may mimic PCP both clinically and radiologically include various causes of "atypical" pneumonia (influenza, *Mycoplasma pneumoniae*), miliary tuberculosis, disseminated histoplasmosis, cryptococcosis, coccidioidomycosis, and acute respiratory distress syndrome (ARDS). Although severe acute respiratory syndrome (SARS) has not been reported in HIV-infected patients, its progression to diffuse pulmonary infiltrates in association with lymphopenia[17] would resemble PCP in an HIV-positive

TABLE 48-1 Main Toxicities of Licensed Antiretroviral Agents

Agent	Toxicities
Nucleoside RT Inhibitors (NRTIs)	
Zidovudine (ZDV, AZT or RETROVIR)	Bone marrow suppression: macrocytic anemia, leukopenia (these effects can be accentuated when zidovudine is combined with lamivudine). GI intolerance, headache, insomnia, rash, lactic acidosis and hepatic steatosis and myositis (with elevated CPK).
Didanosine (ddI or VIDEX)	Pancreatitis, GI intolerance, sensory peripheral neuropathy, hypertriglyceridemia, hyperuricemia, gout, lactic acidosis and hepatic steatosis.
Zalcitabine (ddC or HIVID)	Sensory peripheral neuropathy, painful mouth ulcers, pancreatitis, lactic acidosis and hepatic steatosis.
Stavudine (d4T or ZERIT)	Pancreatitis, sensory peripheral neuropathy, neuromuscular weakness (resembling Guillian-Barre), lactic acidosis and hepatic staetosis.
Lamivudine (3TC or EPIVIR)	Neutropenia, anemia, lactic acidosis and hepatic steatosis
Abacavir (ZIAGEN)	Hypersensitivity reaction may be fatal (symptoms may include fever, rash, fatigue, vomiting, abdominal pain, diarrhea, cough, shortness of breath). If hypersensitivity diagnosed, then abacavir should be stopped and never restarted.
Nucleotide RT Inhibitors (NtRTIs)	
Tenofovir disoproxil fumarate (VIREAD)	GI intolerance, renal dysfunction, lactic acidosis and hepatic steatosis.
Nonnucleoside RT Inhibitors (NNRTIs)	
Nevirapine (NVP or VIRAMUNE)	Rash, hepatitis. Drug interactions caused by induction of cytochrome P450.
Delavirdine (RESCRIPTOR)	Rash, elevated transaminase levels, headaches. Drug interactions caused by inhibition of cytochrome P450.
Efavirenz (SUSTIVA)	Rash, central nervous system symptoms (e.g. abnormal dreams, confusion, agitation, hallucinations), hepatitis, teratogenic in monkeys. Drug interactions caused by induction of cytochrome P450.
Protease inhibitors (PIs)	
Saquinavir (SQV or INVIRASE OR FORTOVASE)	GI intolerance, headache, transaminase elevation, hyperglycemia, fat redistribution, lipid abnormalities, possible increased bleeding episodes in hemophilia.
Ritonavir (RTV or NORVIR)	GI intolerance, peripheral and circumoral paresthesias, headache, muscle weakness, fever and lightheadedness, liver enzyme abnormalities, elevated CK, uric acid, blood glucose, fat redistribution, lipid abnormalities. Drug interactions caused by inhibition of cytochrome P450. Possible increased bleeding episodes in hemophilia.
Indinavir (IDV or CRIXIVAN)	Nephrolithiasis, GI intolerance, benign indirect hyperbilirubinemia, headache, blurred vision, rash, alopecia, transaminase elevation, thrombocytopenia, hemolytic anemia, hyperglycemia, fat redistribution, lipid abnormalities, possible increased bleeding episodes in hemophilia.
Nelfinavir (VIRACEPT)	Diarrhea, hyperglycemia, transaminase elevation, fat redistribution, lipid abnormalities, possible increased bleeding episodes in hemophilia.
Atazanavir (REYATAZ)	hyperglycemia, transaminase elevation, fat redistribution, asymptomatic hyperbilirubinemia, QT interval prolongation, possible increased bleeding episodes in hemophilia
Tipranavir	Rash, diarrhea.
Fusion Inhibitors (FI)	
T20 (ENFURVIRTIDE)	Injection site reactions, pneumonia, eosinophilia.

patient. Among 19 AIDS patients hospitalized together with 95 SARS patients on the same floor of a hospital in the Province of Guangdong, none developed SARS, in contrast to 6 of 28 medical staff who did.[18] This has raised the questions of whether HIV-1 interferes with SARS virus replication in the same host or combination antiretroviral regimens may prevent SARS.[18] Although Kaposi's sarcoma (KS) can result in ARF, this seldom occurs in the absence of overt mucocutaneous disease. Progression to ARF in KS patients is usually a reflection of overwhelming disease.

Patients who have ARF present with varying degrees of hypoxemia, hypocapnia, and other nonspecific abnormalities related to the underlying HIV disease, as discussed earlier.[19] If available, the CD4 count can aid in the differential diagnosis because the occurrence of PCP when the CD4 count is greater than 250 cells/μL would be unusual. An elevated lactic dehydrogenase (LDH) concentration in a patient with known HIV infection and respiratory distress is typical of PCP, and the LDH level tends to correlate with the severity of the episode. Furthermore, changes in the LDH level tend to parallel the course of PCP.[23] However, an elevated LDH concentration is nonspecific because this enzyme also can be elevated in various other settings, including other pneumonias, pulmonary embolism, lymphoma, megaloblastic anemia, liver disease, shock liver, and hemolysis (commonly seen among HIV-infected patients receiving dapsone treatment or prophylaxis for PCP) or during long-term AZT therapy.

By the time ARF secondary to PCP requiring ICU admission develops, the chest radiograph usually has evolved to a diffuse alveolar pattern characteristic of ARDS. However, a careful review of previous radiographs can, at times, aid in the differential diagnosis, as shown in Table 48-2.[20,21] The clinical, laboratory, and radiologic pattern is seldom specific enough to establish the diagnosis, which should be confirmed using appropriate laboratory examinations. This is particularly important when the patient does not yet carry a diagnosis of AIDS because of the serious prognostic and therapeutic implications of this diagnosis. If sputum is available, this should be cultured for bacteria, fungi, and mycobacteria. Blood cultures also should be obtained, and in selected patients, mycobacterial and fungal blood cultures should be obtained. The key to the etiologic diagnosis relies on obtaining tracheobronchial secretions.[19] In the ICU setting, particularly in ventilated patients, bronchoscopic bronchoalveolar lavage (BAL) is the preferred approach. This should be performed by an experienced specialist. Bronchoscopy should be performed using appropriate cardiorespiratory monitoring, including pulse oximetry and an electrocardiogram (ECG).

TABLE 48-2 Major Radiologic Differential Diagnosis of Lung Involvement in AIDS

Normal chest x-ray:	PCP, CMV, MAC, MTB
Diffuse or localized interstitial pattern:	PCP, MTB, CMV, ALI/ARDS, cryptococcosis
Diffuse alveolar pattern:	PCP, viral pneumonia, cryptococcosis, cardiogenic pulmonary edema, ALI/ARDS, VALI, ventilator-associated pneumonia
Miliary pattern or reticulonodular:	MTB, histoplasmosis, coccidiodomycosis
Consolidation:	common bacteria, MTB, PCP, KS, ventilator-associated pneumonia
Nodular opacity:	PCP, common bacteria, KS, cryptococcosis
Upper lung field involvement:	PCP, MTB
Pneumothorax:	PCP, ventilator-associated barotrauma
Cavity:	Aspergillosis, PCP, bacteria, MTB
Pleural effusion:	KS, common bacteria, mycobacteria

ABBREVIATIONS: PCP, Pneumocystis carinii pneumonia; CMV, Cytomegalovirus; MAC, Mycobacterium avium complex; MTB, M. tuberculosis; KS, Kaposi's sarcoma; ALI, acute lung injury; VALI, ventilator-associated lung injury; ARDS, adult respiratory distress syndrome.

The sensitivity of BAL for *P. carinii* and other treatable pathogens commonly found in AIDS patients exceeds 95%. BAL specimens should be concentrated to increase sensitivity. Aliquots should be referred for viral, bacterial, fungal, and mycobacterial studies. *P. carinii* screening should be requested specifically because this is not performed routinely in most laboratories. Sputum induction and transbronchial biopsies, although valuable techniques in the routine evaluation of less critically ill patients, are not recommended in critically ill and ventilated patients. In the few patients for whom the initial BAL does not provide a diagnosis, a transbronchial or open lung biopsy should be considered.[20] However, the appropriateness of such intervention is best decided on a case-by-case basis after careful assessment of the general status of the patient, as well as the likelihood of diagnosing a treatable condition.

P. CARINII PNEUMONIA

P. carinii, recently reclassified as a fungus but having some properties of protozoa, is a ubiquitous organism that produces human disease throughout the world, usually in the setting of severe immunosuppression. Asymptomatic primary infection generally occurs early in life. Rarely, *P. carinii* can be found incidentally at autopsy in the absence of symptoms. It is not clear whether this represents late infection or early disease not yet manifested clinically.

PCP was the index disease that facilitated the clinical recognition of AIDS. Since then, it also has become the first major AIDS-related opportunistic infection for which development of effective therapy has led to important improvement in survival. Despite these advances, PCP remains a serious opportunistic infection among those infected with HIV, typically occurring among those who do not get tested for HIV or who have problems with access or adherence to antiretroviral and prophylactic therapies. PCP is generally a late event in the evolution of HIV infection, usually occurring when the CD4 count is below 200 cells/μL.[22] Therefore, it is recommended that all HIV-infected individuals with CD4 counts below 200 cells/μL or those who have had an episode of PCP should receive lifelong PCP prophylaxis unless immune reconstitution occurs owing to antiretroviral therapy (sustained increase in absolute CD4 count to more than 200 cells/μL for at least 3 months)[22] (Table 48-3).

CLINICAL AND RADIOLOGIC FEATURES

Dyspnea, nonproductive cough, and fever are the classic features of PCP. In critically ill patients, the physical examination usually demonstrates evidence of acute respiratory distress, with surprisingly few adventitious sounds on auscultation of the chest. Acute hypoxemic respiratory failure requiring mechanical ventilation has been reported to occur in as many as 20% of hospitalized patients.[23] Most often this occurs within the first 3 days of starting antimicrobial therapy; less frequently acute hypoxemic respiratory failure develops as a complication of diagnostic bronchoscopy and rarely as the initial presentation to the emergency room.[23]

Clinically overt PCP usually develops over a period of several days to weeks, and in this time, the radiologic picture tends to progress from a normal chest radiograph to a diffuse bilateral interstitial pattern. Varying degrees of alveolar involvement can be seen; even frank consolidation may occur, as seen in Figs. 48-1 through 48-3. A number of atypical

TABLE 48-3 Guidelines for Discontinuation of Primary and Secondary Prophylaxis for Selected Opportunistic Infections Following Antiretroviral-induced Immune Reconstitution

Opportunistic Infection	Initiate Primary Prophylaxis	Discontinue Primary Prophylaxis	Discontinue Secondary Prophylaxis
***Pneumocyctis carinii* Pneumonia**	• CD4 < 200 cells/μL or history ororpharyngeal candidiasis	• CD4 > 200 cells/μL for $\geq$ 3 months	• CD4 > 200 cells/μL for $\geq$ 3 months
***Toxoplasma* encephalitis**	• Toxoplasma seropositive and CD4 < 100 cells/μL	• CD4 > 200 cells/μL for $\geq$ 3 months	• CD4 > 200 cells/μL for $\geq$ 6 months‡
***Mycobacterium avium* Complex**	• CD4 < 50 cells/μL	• CD4 > 100 cells/μL for $\geq$ 3 months	• CD4 > 100 cells/μL for $\geq$ 6 months*
Crypotcoccus neoformans	not indicated	not applicable	• CD4 > 100–200 cells/μL for $\geq$ 6 months¶

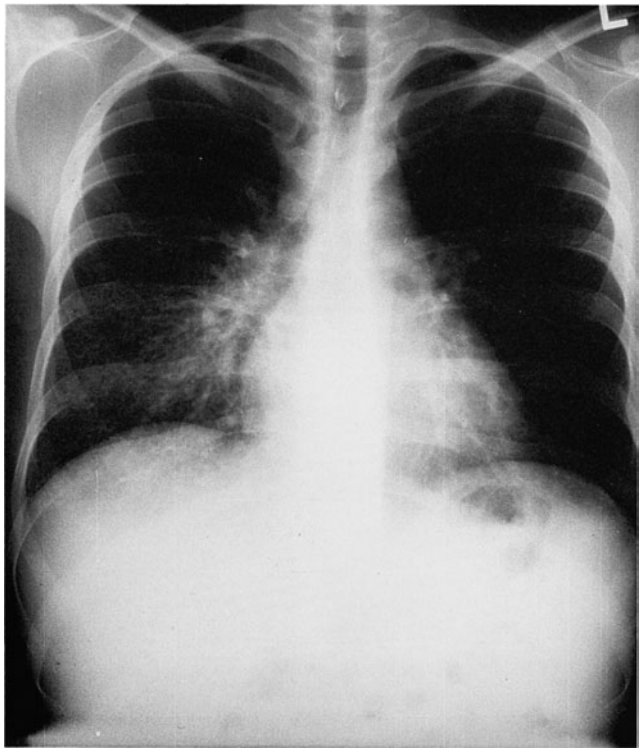
‡ if asymptomatic from toxoplasma encephalitis and initial therapy completed
* if asymptomatic from MAC and 12 months of MAC therapy completed
¶ if asymptomatic from cryptococcosis and initial therapy completed
SOURCE: Derived from Montaner et al.[22]

radiologic presentations have been described, including cystic changes, pneumothoraces (Fig. 48-4), nodular or masslike opacities, and even cavities.[20] Upper lung field involvement, as seen in Fig. 48-5, also has been recognized increasingly, particularly (but not exclusively) in the context of aerosol pentamidine prophylaxis. To what extent aerosol pentamidine prophylaxis is responsible for the apparent increased frequency of PCP-related pneumothoraces remains controversial.

DIAGNOSIS

As discussed earlier, given the nonspecific nature of the clinical, laboratory, and radiologic picture of PCP, diagnostic confirmation is desirable. BAL is a rapid, safe, and effective means of obtaining tracheobronchial secretions to provide an adequate diagnostic specimen. Lung biopsy is seldom required to confirm the diagnosis of PCP. As seen in Fig. 48-6 (Color Figure 48-6), the usual pathologic picture of PCP consists of a mild to moderate interstitial inflammatory reaction with predominance of lymphocytes and alveolar macrophages and the presence of a foamy alveolar exudate (as seen with hematoxylin and eosin [H&E] staining). The foamy appearance of

FIGURE 48-1 Posteroanterior chest x-ray of PCP patient demonstrating interstitial disease preferentially localized to the right hilum and lower lung zone.



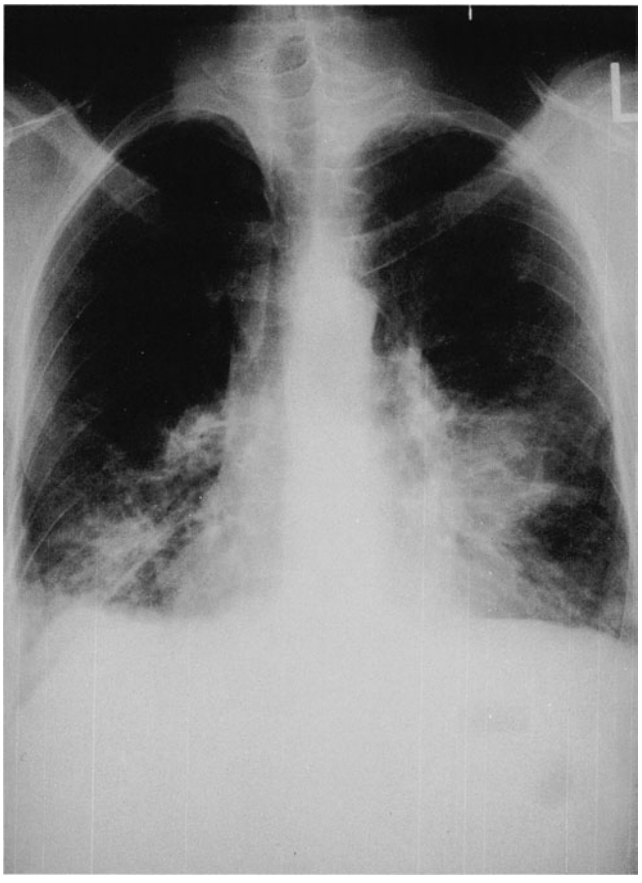


FIGURE 48-2 Posteroanterior chest x-ray of PCP demonstrating extensive bilateral basilar lung involvement.

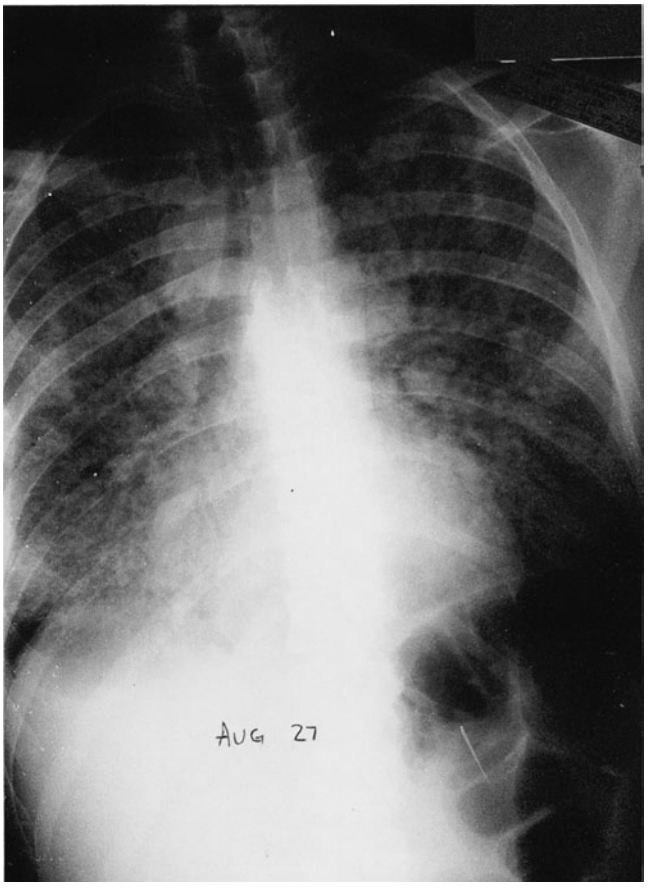

FIGURE 48-3 Anteroposterior chest x-ray demonstrating diffuse bilateral lung disease secondary to PCP in a patient with respiratory failure immediately prior to intubation. Air bronchograms can be seen throughout the lung, particularly in the upper lung fields bilaterally.

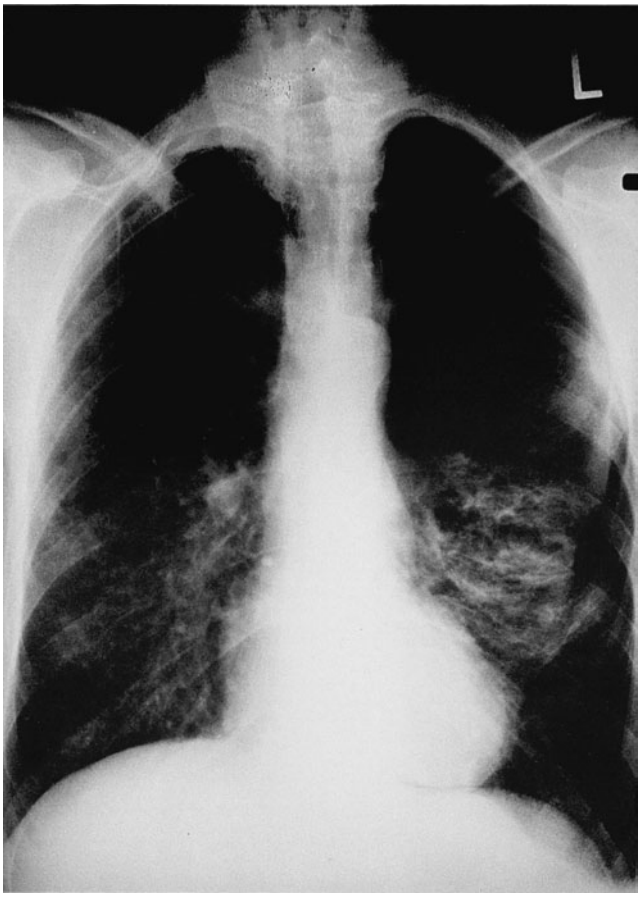

FIGURE 48-4 Posteroanterior chest x-ray of a patient with PCP who presented with a left-sided pneumothorax.

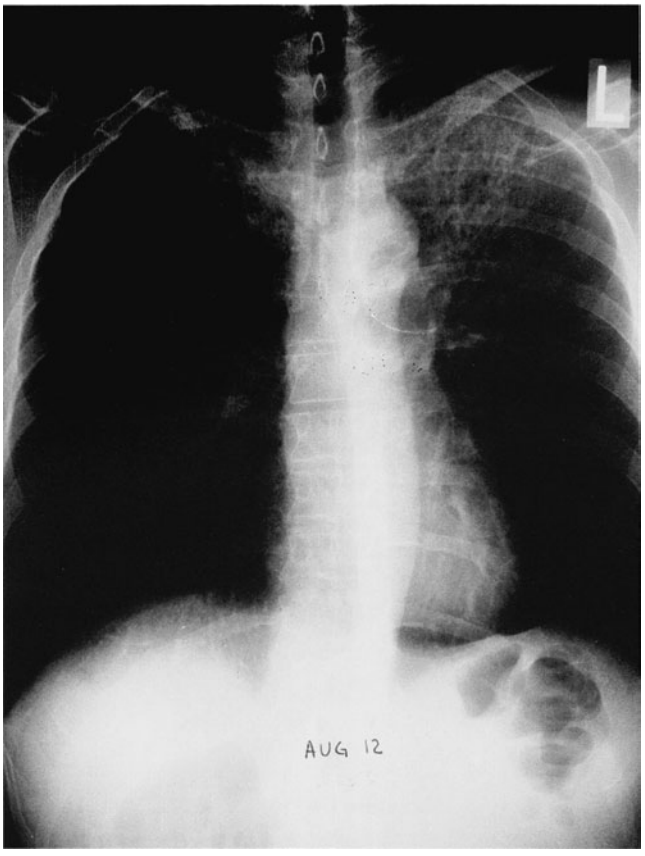
the alveolar exudate is caused by the presence of the cystic form of the organism, which is not stained with H&E but can be easily recognized using readily available special stains (Fig. 48-7 and Color Figure 48-7). As seen in Fig. 48-8 (Color Figure 48-8), BAL allows clear identification of the organism if the specimen is concentrated and stained appropriately.[19,20] The composition of the alveolar exudate has not been established conclusively. However, BAL studies suggest that this is an inflammatory exudate rich in immunoglobulins, macrophages, and suppressor cytotoxic lymphocytes.[24] Although *P. carinii* infection usually is confined to the lungs, systemic pneumocystosis (involving liver, spleen, lymph nodes, adrenals, and eyes), has been reported occasionally.[25] Polymerase chain reaction (PCR) methodology has been applied to the diagnosis of PCP using blood, sputum, and BAL but is not widely available and remains investigational.

PCP IMMUNE RECONSTITUTION SYNDROME

Immune reconstitution syndrome (IRS; also known as *immune reconstitution inflammatory syndrome*) is the clinical deterioration or "paradoxical reaction" that may develop in almost any organ system as a result of augmented immune response to preexisting clinical or subclinical infection.[26,27] Among HIV-negative patients, this phenomenon occurs occasionally during the course of chronic hepatitis B and during treatment for borderline lepromatous leprosy (reversal reaction, Lepra type I) or tuberculosis (e.g., central nervous system tuberculomas) and is due to improvement in cell-mediated immunity.[28] A similar pathogenesis is believed to account for IRS among HIV-infected patients. IRS has been reported increasingly since the introduction of highly active antiretroviral therapy (HAART) in 1996. IRS has been described as both an unmasking of subclinical latent infection or a worsening of already documented preexisting disease. Most of the reports have been related to CMV retinitis, tuberculosis (TB), MAC, PCP, cryptococcosis, progressive multifocal leukoencephalopathy, and herpes zoster infection.

A diagnosis of IRS begins with a suspicion of clinical events occurring usually within weeks or months after initiating or revising an antiretroviral regimen. The differential diagnosis may include adverse drug effects and coexisting unrecognized infections (nosocomial or community-acquired). Some opportunistic infections show atypical features in the context of IRS, particularly MAC, CMV retinitis, and cryptococcal meningitis.[29] The diagnosis cannot be made without convincing evidence of a response to the antiretroviral regimen (e.g., ≥ 1 $\log_{10}$ reduction in HIV RNA and usually a CD4 increase). For preexisting opportunistic infections (e.g., TB), the diagnosis of IRS is one of exclusion. In contrast, MAC IRS is usually an unmasking of subclinical infection, and when the organism is recovered from a normally sterile body site, the diagnosis is established. It is important to make the



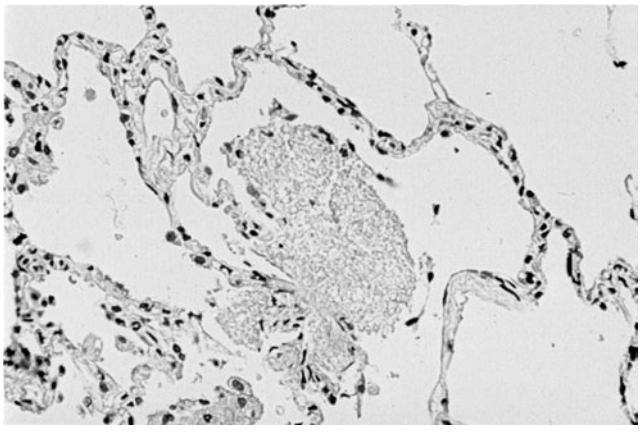


FIGURE 48-5 Posteroanterior chest x-ray of a patient with PCP who presented with bilateral upper lung disease.

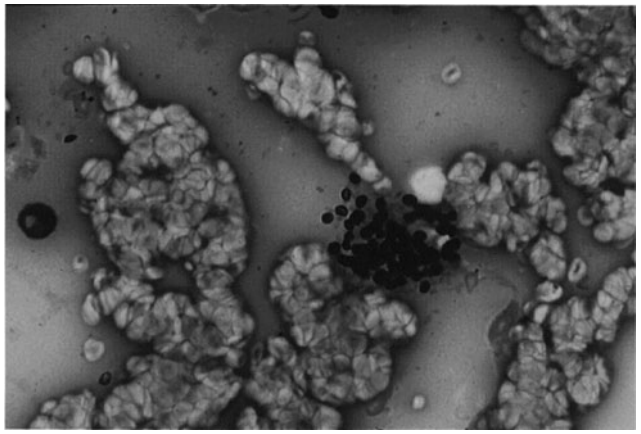
diagnosis of IRS in order to avoid inappropriate therapy (e.g., chemotherapy for suspected multidrug resistant TB).

Initiation of combination antiretrovirals during therapy for PCP has been associated with a paradoxical worsening of the pulmonary infiltrates and lung function in up to 5% to 18% of patients.[30] Among the 17 patients with PCP immune reconstitution syndrome reported to date, the clinical worsening was observed 3 to 17 days after starting the antiretroviral regimen. Flow cytometry of BAL specimens in such patients may show a higher CD4/CD8 ratio than usually observed in PCP owing to an influx of CD4 cells during immune reconstitution.[31]

FIGURE 48-6 Characteristic foamy honeycomb material seen in alveolar spaces in *Pneumocystis* pneumonia (H&E stain, × 3100). (See color version of figure.)



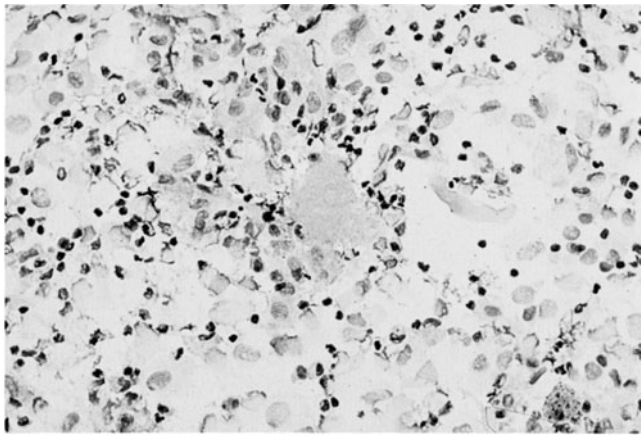


FIGURE 48-7 Cup-and-saucer–shaped *Pneumocystis* organisms seen on BAL (GMS 3 100). (See color version of figure.)

Transbronchial lung biopsy may reveal a prominent alveolar infiltrate consisting of lymphocytes, macrophages, and neutrophils with few or no demonstrable PCP organisms.[32] The diagnosis is established by endoscopy and transbronchial biopsy in order to demonstrate the above-mentioned findings and exclude other possible opportunistic diseases. Any diagnosis of IRS should be supported by evidence of a virologic (HIV viral load reduction of usually $\geq$1 $\log_{10}$) and/or immunologic (CD4 count increase) response to the antiretroviral regimen. Some patients with PCP IRS have developed respiratory failure and appeared to respond to systemic corticosteroids. The incidence of this complication may be reduced by delaying the initiation of antiretrovirals until after PCP therapy has been completed because reported cases usually have developed within the first few weeks following the dagnosis of PCP.

MANAGEMENT

Trimethoprim-sulfamethoxazole (TMP-SMX) is effective against *P. carinii,* as well as various gram-negative and gram-positive bacterial organisms. TMP-SMX is administered intravenously or orally at a dose of 15 and 75 mg/kg daily, respectively, in three divided doses for 14 to 21 days. Poor tolerance of TMP-SMX among HIV-infected patients is a significant problem, with adverse drug reactions occurring in

FIGURE 48-8 BAL specimen showing characteristic granular material found in *Pneumocystis* pneumonia infection (H&E stain, × 3100). (See color version of figure.)

60% to 100% of patients. These include rash, fever, liver dysfunction, renal dysfunction, leukopenia, thrombocytopenia, hyponatremia, anemia, and gastrointestinal upset. Less common but at times severe are mucocutaneous reactions, occurring generally at the end of the first week of treatment. A number of reports have documented successful desensitization of TMP-SMX-allergic patients using progressively larger doses of the drug. Hypersensitivity-type reactions such as fever or rash also can be treated with diphenhydramine or corticosteroids.[33,34]

Pentamidine isethionate was used initially for the treatment of African trypanosomiasis. Since 1958, it has been known to be effective against *P. carinii*. Pentamidine usually is administered intravenously once daily at a dose of 4 mg/kg diluted in 250 mL of 5% dextrose and water for 14 to 21 days. Adverse reactions are common, occurring in up to 100% of patients in some series. Common adverse drug reactions include renal and liver dysfunction, neutropenia, thrombocytopenia, hyponatremia, rash, fever, and gastrointestinal upset. Hypotension is commonly associated with pentamidine infusion. This can be minimized by administering the drug slowly over several hours; if severe or long-lasting hypotension occurs, this should be treated supportively because it is readily reversible. Occasionally, carbohydrate metabolism abnormalities (hypo- or hyperglycemia) may develop, including insulin-dependent diabetes mellitus. Ventricular arrhythmias and pancreatitis also have been reported. Finally, observations suggest an increased risk of pancreatitis among patients receiving didanosine and systemic pentamidine concomitantly. Coadministration of these two drugs therefore is contraindicated. Owing to delayed elimination of intravenous pentamidine, ddI should not be coadministered for several weeks after stopping IV pentamidine. Because adverse reactions to pentamidine are related to its systemic concentration, and because of its poor absorption through the alveolar surface, aerosol therapy has been investigated. In a pilot study, a high cure rate with no significant systemic toxicity was achieved using 5 mg/kg daily via a nebulizer in a highly selected group of patients with mild PCP. The only reported adverse effects were cough and bronchospasm in the majority of patients; however, these adverse effects were easily prevented by premedication with a β_2-agonist bronchodilator. However, because of variable efficacy and increasing concern regarding the possibility of uneven drug distribution, early relapse, and extrapulmonary pneumocystosis, aerosol pentamidine therapy is not recommended; it should be reserved for use as a prophylactic agent only.[35–37]

Dapsone (DPS), a sulfone used for the treatment of leprosy and dermatitis herpetiformis, has been shown to be effective against *P. carinii,* particularly when DPS, 100 mg by mouth daily, is combined with trimethoprim (TMP), 320 mg by mouth q8h (or 15 mg/kg daily, divided q8h). DPS-TMP has been shown to have similar efficacy and better tolerability than TMP-SMX.[38] Adverse reactions are common, including hemolytic anemia with methemoglobinemia, thrombocytopenia, neutropenia, liver dysfunction, rash, and gastrointestinal upset, which often interferes with oral administration. The DPS-induced methemoglobinemia and hemolytic anemia are particularly severe among individuals with glucose-6-phosphate dehydrogenase deficiency. It is also important to note that the hemolytic anemia will produce an increase in LDH that should not be misinterpreted as a sign of worsening PCP.[19]

Atovaquone, a newly developed hydroxynaphthoquinone, has been shown to be a useful second-line agent for the treatment of PCP. Although slightly less effective than TMP-SMX, atovaquone has shown similar efficacy to IV pentamidine, with a very favorable safety profile. This agent is available only in an oral formulation. Furthermore, the drug is not to be used in the presence of moderate to severe diarrhea. For these reasons, atovaquone does not lend itself well to use in the critical care setting.[39]

Clindamycin-primaquine also has been shown to be effective in the treatment of PCP. This regimen usually is reserved for those who fail or are intolerant to TMP-SMX and IV pentamidine. Clindamycin is given orally or intravenously at doses of 450 to 600 mg four times daily, and primaquine is given orally at a dose of 15 to 30 mg daily.[40] Finally, trimetrexate has failed to find a place in the therapeutic armamentarium against PCP despite early favorable reports.[41]

Prospective, randomized placebo-controlled studies have demonstrated a beneficial short-term effect of adjunctive corticosteroid therapy,[42] which prevents the characteristic early deterioration in gas exchange seen in untreated patients and results in a faster resolution of the episode (as measured by respiratory rate, temperature, heart rate, Pa_{O_2}, and LDH). Adjuvant corticosteroids also have been shown to decrease mortality significantly among patients with PCP-related ARF in a prospective, placebo-controlled trial.[43] Systemic corticosteroids are recommended routinely as adjuvant therapy for moderate and severe PCP if no contraindications are present.[44] A regimen consisting of oral prednisone 40 mg twice daily for the initial 7 days followed first by 40 mg orally daily for 7 days and then by 20 mg orally daily for the final 7 days is recommended.[44] Corticosteroids should be started early in the course of the disease, and to this end, a Pa_{O_2} threshold of 70 mm Hg has been proposed.[44] It must be emphasized that adjuvant corticosteroid therapy should be continued while patients are on anti-PCP antimicrobials to avoid the rapid deterioration often seen following premature discontinuation of adjuvant corticosteroids. Adjuvant corticosteroids also may exert a similarly beneficial effect even among patients with milder forms of PCP.[45]

The initial selection of the antimicrobial agent usually occurs outside the ICU. Patients with mild to moderate PCP generally are started on dapsone-trimethoprim or TMP-SMX orally. If there is a concern regarding superimposed bacterial infection, additional antibacterial coverage should be added for community-acquired pneumonia.[46] Pentamidine generally should be reserved for in-patients with PCP and documented intolerance to TMP-SMX. If the patient is first diagnosed in the ICU, TMP-SMX intravenously generally will be the preferred antimicrobial. Corticosteroids should be started at once in any patient whose Pa_{O_2} is below 70 mm Hg while breathing room air. Response to antimicrobials generally is slow, and significant improvement usually does not occur until after 5 to 7 days.[33] With the use of adjunctive corticosteroids, however, significant improvement can be observed within the first 3 days of treatment.[42] Patients who fail to improve within the first 5 days of therapy should be reviewed thoroughly to rule out potential intercurrent infections (such as ventilator-associated pneumonia) or other complications, including pneumothorax and fluid volume overload. Evidence of *P. carinii* resistance to sulfamethoxazole has been demonstrated in patients with prior sulfonamide exposure by the presence of mutations in the gene of sulfamethaxazoles'

target enzyme, dihydropteroate synthase (DHPS).[47] The results of studies that have evaluated the clinical significance of such mutations are conflicting. A retrospective Danish study suggested that DHPS mutations are predictive of mortality,[48] whereas another did not confirm this prediction.[49] Lack of improvement within 7 days of therapy generally is interpreted as a failure of treatment and therefore an indication for a trial of the alternative agent. A change in antimicrobial also would be warranted if severe adverse reactions develop despite the use of adjunctive corticosteroids. There is no evidence of increased efficacy, but there is increased toxicity when combining TMP-SMX with pentamidine. However, when switching from TMP-SMX to pentamidine, it may be advisable to administer both drugs for a few days until therapeutic levels of pentamidine can be expected in lung tissue.

PROGNOSIS

Untreated, PCP is universally fatal. With the use of appropriate antimicrobials, overall mortality of AIDS-related PCP is below 10%. However, the mortality clearly increases with the severity of the episode.[21,23,44] The expected mortality of a mild first episode of PCP, therefore, usually is negligible. In addition, young age and early diagnosis have been correlated with better outcome.[21,23,50] The mortality of ARF secondary to AIDS-related PCP appears to be changing. In the early days of the epidemic, mortality was greater than 80% in most series.[51,52] Mortality has been reduced to less than 50% with the addition of systemic corticosteroids.[23,43,44] However, if PCP-related ARF develops despite early intervention with maximal therapy, including corticosteroids and appropriate antimicrobial agents, the prognosis appears to be dismal, with a mortality greater than 90% in some series.[53]

MYCOBACTERIUM TUBERCULOSIS (MTb)

Tuberculosis occurs with varying degrees of frequency among HIV-infected individuals, reaching 20% in some series. Because the risk of developing tuberculosis is proportional to the risk of developing it prior to the acquisition of HIV, its incidence in North America is greatest among intravenous drug users, blacks, and Latin Americans. Tuberculosis usually develops within the year prior to the diagnosis of other AIDS-defining conditions. Either pulmonary or disseminated tuberculosis in an HIV-infected individual is diagnostic of AIDS according to the CDC classification of HIV disease.

The symptoms of tuberculosis in the context of HIV generally are nonspecific. This is particularly the case because "classic" tuberculosis symptoms such as fatigue, malaise, weight loss, fever, and night sweats are extremely common, even in moderately advanced stages of HIV disease. In contrast to the immunocompetent host, in the context of HIV disease, reactivating tuberculosis usually has radiologic features similar to those of primary tuberculosis, including hilar and/or mediastinal adenopathy, middle and lower lung infiltrates, pleural effusions, or a miliary pattern. Apical infiltrates or cavities are seen only in a minority of patients. As many as 9% of patients with CD4 counts of less than 200 cells/μL have a normal chest x-ray with a positive sputum culture for MTb.[54] Furthermore, PCP is diagnosed simultaneously in as many as 25% of the cases of tuberculosis. Prospective tuberculin skin testing (PPD) is useful among HIV-infected individuals because tuberculosis develops more frequently in patients known to have a previously positive test; however, at the time of diagnosis of AIDS, at least 30% of patients are anergic. MTb usually can be diagnosed with smear and culture of sputum or BAL. Of particular note is the diagnostic yield of blood culture (2% to 12%) in some patients. Rapid diagnostic tests have been approved for the detection of *M. tuberculosis* RNA or DNA in respiratory tract specimens within 24 hours. Such tests are particularly useful in the management of selected patients who are positive or negative for an acid-fast bacilli smear, particularly for those with an intermediate pretest probability of having tuberculosis.[55] Treatment guidelines for tuberculosis have been revised recently by the American Thoracic Society (ATS) and the CDC. Tuberculosis (i.e., first-line antituberculous drug–susceptible) in HIV-infected adults should be treated with isoniazid (plus pyridoxine), rifampin, pyrazinamide, and ethambutol for the initial 2 months (initial phase) of therapy. Ethambutol and pyrazinamide are then discontinued. The continuation phase of treatment consists of isoniazid (plus pyridoxine) and rifampin for 4 more months (total 6 months). Patients who respond slowly to treatment should have the continuation phase of treatment increased to 7 months (total 9 months, or 6 months after documented culture conversion). During the continuation phase, treatment may be administered either on a daily basis or three times weekly. However, twice-weekly therapy is not recommended, particularly for those with CD4 counts of less than 100 cells/μL.[56] Numerous significant drug interactions have been identified between rifamycins and many antiretrovirals, except for NRTIs and NtRTIs. Patients with CD4 counts of less than 300 cells/μL likely will require concurrent antituberculous and antiretroviral therapy. Those with CD4 counts between 200 and 300 cells/μL should be considered for antiretroviral therapy. Rifabutin may be substituted for rifampin and has the advantage of being associated with fewer and less profound antiretroviral drug interactions.[56,57]

A high proportion of patients with multi-drug-resistant tuberculosis (MDR-TB) have been HIV-infected. MDR-TB should be suspected in patients with persistent fevers after 14 days of therapy, particularly in areas of high prevalence.[58] Persistent fevers also have been associated with extensive pulmonary or miliary disease in cases of non-MDR-TB. In contrast to previous reports, HIV-infected patients with MDR-TB had survival rates similar to those with non-MDR-TB when an early diagnosis was established and treatment was initiated with a regimen containing at least two drugs to which the isolate was susceptible in vitro.[58] Expert consultation is recommended for the management of patients with suspected or proven drug-resistant TB. Principles of therapy include the use of at least three previously unused drugs, not limiting regimens to three drugs if other active unused drugs are available (since four- to six-drug regimens appear to be more effective), using directly observed therapy (DOT), and avoiding intermittent therapy except possibly for injectable drugs after the first 2 to 3 months.[56] MTb IRS is important to consider in the differential diagnosis of any HIV+ patient who appears to worsen during the course of therapy for MTB.

M. TUBERCULOSIS IMMUNE RECONSTITUTION SYNDROME

M. tuberculosis immune reconstitution syndrome (MTb-IRS) is a paradoxical worsening of the signs and symptoms of tuberculosis during the course of antituberculous therapy.

This phenomenon was reported occasionally in the pre-AIDS era and considered to be a consequence of resolution of mycobacterial-induced suppression of cell-mediated immunity. MTb-IRS has been reported to occur in up to 36% of HIV-infected patients who initiate HAART.[59] MTb-IRS is important to consider in the differential diagnosis of any HIV+ patient who appears to worsen during the course of therapy for MTb infection. The manifestations may include fever, worsening pulmonary infiltrates, lymphadenopathy, and CNS granulomas. Case reports suggest a possible benefit of systemic corticosteroids for the management of moderate to severe IRS related to MTb and IRS related to other organisms. The diagnosis of MTb-IRS is one of exclusion, including consideration of coexisting opportunistic infections and also multi-drug-resistant MTb.

Among tuberculosis patients with advanced HIV disease (CD4 count <200 cells/μL), HAART recipients have improved 12-month survival compared with historic controls in the pre-HAART era (95% versus 85%).[60] However, problems related to polypharmacy and overlapping drug toxicities argue against the simultaneous initiation of antituberculous and antiretroviral therapy. Consequently, a more appropriate time to begin HAART may be after 4 to 8 weeks of antituberculous therapy[56]; furthermore MTb-IRS may be less likely to occur then.[61]

Mycobacterium Avium Complex (MAC) Disease

MAC disease is usually disseminated (90%) and occurs later than MTb in the course of HIV infection, typically when the CD4 lymphocyte count has fallen below 50 cells/μL. A number of nonspecific symptoms, signs, and routine laboratory abnormalities are encountered frequently in patients with MAC, including fever (87%), night sweats (78%), diarrhea (47%), weight loss (38%), anemia (hemoglobin = 8.5 g/dL; 85%), and elevated serum alkaline phosphatase levels (53%).[62] Clinical and radiologic evidence of lower respiratory tract involvement (4% to 10%) is usually absent. Occasional patients have few or no symptoms in the face of MAC bacteremia.

The diagnosis is established by isolating the organism from blood (mycobacterial blood culture, using radiometric broth or lysis-centrifugation method) or less often from tissue biopsy (e.g., bone marrow, liver) or other normally sterile body fluids. Recovery of the organism from sputum, BAL, bowel, or stool specimens may represent colonization or localized or disseminated disease. In a prospective study, multivariate analysis identified three independent predictors of mycobacteremia in patients with CD4 counts of less than 50 cells/μL: (1) fever for 30 days during the previous 3 months, (2) serum albumin concentration of less than 3.0 g/dL, and (3) hematocrit of less than 30%.[63] When applied prospectively to a validation set, the presence of at least one of the three predictors provided a sensitivity of 94%, a specificity of 42%, and a positive predictive value of 30%.

Significantly improved survival (median = 8.6 versus 5.2 months) and eradication of mycobacteremia was demonstrated with a three-drug combination of clarithromycin, ethambutol, and rifabutin (versus a four-drug regimen of ciprofloxacin, rifampin, ethambutol, and clofazimine) in a prospective, randomized trial.[64] Adverse effects of rifabutin included uveitis, which occurred much less often at a daily dose of 300 mg (6%) compared with 600 mg (38%).[64] Results from a randomized trial of combination therapy for MAC bacteremia indicated a survival benefit for a regimen containing clarithromycin 500 mg bid compared with 1000 mg bid.[65] In a randomized trial, Chaisson and coworkers[66] reported higher mortality among patients receiving clofazimine (61%) compared with placebo (38%, $p = 0.032$) in combination with clarithromycin and ethambutol.

Rifabutin does not need to be added to clarithromycin-ethambutol for treatment of AIDS-related MAC bacteremia, as outlined below. No clinical or microbiologic benefit was associated with the addition of rifabutin (versus placebo) to a clarithromycin-ethambutol regimen in AIDS-related MAC bacteremia. Among those who responded to therapy, subsequent development of clarithromycin resistance occurred in 2% (1 of 44) and 14% (6 of 42) who received rifabutin and placebo, respectively ($p = 0.055$).[67] However, the significance of the protective effect of rifabutin on subsequent clarithromycin resistance is doubtful in the HAART era because long-term survival and subsequent MAC bacteremia relapses are related primarily to immune reconstitution rather than continued clarithromycin susceptibility of the MAC isolate.

Primary prophylaxis of MAC is indicated for patients with CD4 counts below 50 cells/μL. A randomized comparative study indicated that azithromycin 1200 mg once weekly is a more effective prophylactic than rifabutin 300 mg daily,[68] in addition to being less expensive and less problematic with respect to drug interactions. Clarithromycin is also effective for MAC prophylaxis; however, when breakthrough mycobacteremia occurs, 29% to 58% of MAC isolates are clarithromycin-resistant. MAC drug resistance has not been a problem among failures of rifabutin prophylaxis and was observed in only 11% of azithromycin failures.[68] The interest in preserving clarithromycin as an active drug for treatment of MAC bacteremia provides the rationale for restricting its use as an alternative prophylaxis drug. Primary prophylaxis for MAC bacteremia may be discontinued if there is a sustained rise in the CD4 count to more than 100 cells/μL for at least 3 months[22] (see Table 48-3).

CYTOMEGALOVIRUS (CMV) DISEASE

CMV isolation from pulmonary secretions in AIDS patients appears to have little prognostic value, even when corticosteroids are added to the treatment of PCP. Patients with confirmed PCP respond to anti-*Pneumocystis* treatment whether or not CMV is also recovered in BAL specimens.[69] However, the prominent role of CMV as a gastrointestinal or ocular pathogen among these patients is clearly recognized.

CMV pneumonitis in the context of AIDS should be diagnosed only if hypoxemia and diffuse pulmonary infiltrates coexist with evidence of CMV cytopathic effect (i.e., intranuclear and intracytoplasmic inclusions) in lung tissue and with histologic absence of other likely causes to explain the pulmonary disorder.[70] Unfortunately, CMV blood and urine cultures have poor diagnostic and predictive value in the setting of HIV disease, and the likelihood of a positive result correlates inversely with CD4 count.[71] CMV disease usually is treated with ganciclovir or foscarnet, as outlined in Table 48-4. Long-term maintenance therapy is required for CMV retinitis but may not always be needed in gastrointestinal

TABLE 48-4 Antimicrobial Therapy of Common Infections in AIDS Patients

Infection	Drug of Choice	Total Daily Dose	Dose Interval	Route	Usual Duration	Alternative Therapy
Protozoa						
Toxoplasmosis *(Toxoplasma gondii)*	Pyrimethamine[1]	200 mg loading dose, then 50–75 mg	Daily	PO	4–6 weeks[2]	Pyrimethamine *plus* clindamycin 600–900 mg IV[3] q6h until marked clinical improvement, then 450 mg PO q6h
	plus					
	Sulfadiazine	4–8 g (100 mg/kg)	6 h	PO	4–6 weeks	
	Maintenance therapy:					
	Pyrimethamine[1]	25–50 mg	Daily	PO	Indefinitely	Pyrimethamine[1] 25–50 mg/d PO *plus* clindamycin 300–450 mg PO q6h (at least 1200 mg daily)
	plus					
	Sulfadiazine	2 g	6 h	PO	Indefinitely	
Cryptosporidiosis *(Cryptosporidium)*	No proven effective therapy					Azithromycin 600 mg PO daily plus Paromomycin 1 gm PO BID (optimize antiretroviral therapy)
	Restore immune function					
Giardiasis *(Giardia lamblia)*	Metronidazole	750 mg	8 h	PO	5 d	Tinidazole 2g once (not marketed in North America), or furazolidone 100 mg qid for 7–10 days, or albendazole 400 mg PO daily for 5 days
Amebiasis (symptomatic) *(Entamoeba histolytica)*	Metronidazole[4]	2.25 g	8 h	PO, IV	10 d	Tinidazole 1 gm BID for 3 days (800 mg tid for 5 days for liver abscess) (not marketed in North America), followed by a luminal agent (e.g., iodoquinol, diloxanide furoate, or paromomycin)
	followed by					
	paromomycin	1.5 g	8 h	PO	7 d	
Isosporiasis *(Isospora belli)*	Trimethoprim-sulfamethoxazole	640 mg 3200 mg	6 h	PO, IV	10 d[5]	Pyrimethamine 50–75 mg PO daily plus folinic acid 5–10 mg PO daily for 4 weeks; or ciprofloxacin 500 mg PO BID × 7d
	Maintenance therapy:					
	Trimethoprim, 160 mg, sulfamethoxazole, 800 mg		3 times per week	PO	Indefinitely	Pyrimethamine 25 mg PO daily *plus* folinic acid 5 mg PO daily
Pneumocystosis *(P. carinii)*	*Intravenous therapy*					
	Trimethoprim,	15 mg/kg	6–8 h	IV	21 d	Pentamidine 4 mg/kg per day IV, (IM[6]) *or* clindamycin 600 mg q6h IV *plus* primaquine 15–30 mg daily PO
	sulfamethoxazole	75 mg/kg				
	Oral therapy					
	Trimethoprim	15 mg/kg	8 h	PO	21 d	Trimethoprim-sulfamethoxazole 2 DS tablets q8h PO; *or* clindamycin 450 mg q6h PO *plus* primaquine
	plus					
	dapsone	100 mg	Daily	PO	21 d	15 mg (base) daily PO; or atovaquone 750 mg q12h PO with food
Candidiasis						
Oropharyngeal	Fluconazole	100 mg	Daily	PO/IV	7–14 d	Itraconazole 100 mg PO daily for 14 d[7] (or 100 mg BID for 7 d); or topical antifungal (nystatin or clotrimazole 3–5 times daily)

(cont.)

TABLE 48-4 (Continued)

Infection	Drug of Choice	Total Daily Dose	Dose Interval	Route	Usual Duration	Alternative Therapy
Esophageal	Fluconazole	200 mg loading dose then 100–200 mg	Daily	PO/IV	3 weeks	Itraconazole 200 mg PO daily (3 wks),[7] *or* amphotericin B 0.3–0.6 mg/kg, or caspofungin 50 mg IV daily for 7–14 d
Fluconazole-refractory mucosal candidiasis (oral, esophageal)	Itraconazole oral solution[7]	200 mg–400 mg	12 h	PO (swish and swallow)	2 weeks	Higher-dose fluconazole (400–800 mg/day), or caspofungin 50 mg IV daily *or* amphotericin B 0.3–0.6 mg/kg per day IV for 1–2 weeks
Candidemia						
a) Unstable	Amphotericin B	0.8–1.0 mg/kg	Daily	IV (± step down after 7d to fluconazole)	14 d after last positive blood culture	Caspofungin 70 mg 1st dose, then 50 mg IV daily; or fluconazole 400–800 mg IV daily (PO after 7 days); *or* Amphotericin B lipid complex (ABLC, ABELCET) 5 mg/kg per day
b) Stable	Fluconazole	400 mg	Daily	IV	14 d after last positive blood culture	Amphotericin B 0.5–1.0 mg/kg/d (total dose 0.5–1.0 gm); or caspofungin 70 mg 1st dose, then 50 mg IV daily
c) Focal invasive or disseminated candidiasis	Amphotericin B	0.7–1.0 mg/kg	Daily	IV	Until total dose 1–2 g and clinical resolution	Fluconazole 400–800 mg/d; or caspofungin 70 mg 1st dose, then 50 mg IV daily; *or* Amphotericin B lipid complex (ABLC, ABELCET) 5 mg/kg per day
	plus/minus					
	5-Flucytosine[8]	100 mg/kg	6 h	PO/IV		
Cryptococcal meningitis *(Cryptococcus neoformans)*	Amphotericin B	0.7–1.0 mg/kg	Daily	IV	2–3[9] weeks	Liposomal amphotericin B 3 mg/kg/d IV (Ambisome); or fluconazole 800 mg/d, plus 5-flucytosine 100 mg/kg per day
	plus					
	5-Flucytosine	100 mg/kg	6 h	PO/IV	2–3 weeks	(divided q6h)
	then					
	Fluconazole	400 mg	Daily	PO/IV	8 weeks	Itraconazole 200 mg bid PO[7]
	Maintenance therapy:					
	Fluconazole	200 mg	Daily	PO	Indefinitely	Itraconazole 200 mg bid[10]
Histoplasmosis *(Histoplasma capsulatum)*	Liposomal Amphotericin B	3 mg/kg	Daily	IV	14 d	Amphotericin B 0.5–1.0 mg/kg/d (total dose 10–15 mg/kg). For mild disease itraconazole 300 mg bid for 3 days, then 200 mg BID for 12 weeks[7]
	Maintenance therapy[11]*:*					
	Itraconazole	400 mg[7]	BID	PO	Indefinitely	Amphotericin B, 50 mg IV once weekly
Coccidioidomycosis *(Coccidioides immitis)*						
a) Diffuse Pneumonia	Amphotericin B	0.7–1.0 mg/kg	Daily	IV	until clinical improvement (2–3 gm total dose), then step down to azole indefinitely	fluconazole 400–800 mg/d IV/PO; or itraconazole 200 mg IV/PO BID
b) Meningitis	Fluconazole	400–800 mg	Daily	IV/PO	Indefinite	Amphotericin B 0.5–1.0 mg/kg per day IV until total dose 1–2 g IV plus intrathecal[12] amphotericin (dose range 0.01–1.5 mg daily to once weekly); *or* itraconazole 200–300 mg bid,[7]

(cont.)

TABLE 48-4 (Continued)

Infection	Drug of Choice	Total Daily Dose	Dose Interval	Route	Usual Duration	Alternative Therapy
	Maintenance therapy: Fluconazole	400 mg	Daily	PO	Indefinitely	Itraconazole 200 mg bid[7]
Viruses						
Herpes simplex						
Mucocutaneous	Acyclovir	2.0 g	5 ×/d	PO	14–21 d[13]	Famciclovir 500 mg bid for 7 days; *or* valacyclovir 500–1000 mg PO BID for 7 days; or acyclovir 5 mg/kg IV q8h for 7 days
Severe or refractory mucocutaneous	Acyclovir	15 mg/kg	8 h	IV (over 1 h)	7–10 d[13]	Acyclovir 800 mg PO 5 times daily, *or* famciclovir 500 mg bid-tid PO, or foscarnet 40–60 mg/kg IV q8h (infusion over 1 h by infusion pump)[14], *or* trifluridine (topically) in a 5% ophthalmic solution; or topical cidofovir
Visceral or disseminated	Acyclovir	30 mg/kg	8 h	IV (infusion over 1 h)	10–21 d	Foscarnet 60 mg/kg IV q8h (infusion over 1 h by infusion pump)[14]
Herpes zoster						
Dermatomal	Famciclovir	1500 mg	8 h	PO	7 d	Valacyclovir 1000 mg tid for 7 days; or acyclovir 800 mg PO 5 times daily or 10–12 mg/kg IV (infusion over 1 h) q8h; or foscarnet 40 mg/kg IV q8h (infusion over 1 h by infusion pump)[14]
Disseminated (cutaneous or visceral) or ophthalmic zoster	Acyclovir	30–36 mg/kg	8 h	IV (infusion over 1 h)	7–14 d	Foscarnet 40–60 mg/kg IV q8h (infusion over 1 h by infusion pump)[14]
CMV cytomegalovirus)	Ganciclovir	10 mg/kg	12 h	IV	21 d	Foscarnet 90–100 mg/kg IV q12h (infusion over 2 h by pump)[14]. For non-ICU patients with CMV retinitis; valganciclovir 900 mg PO BID for 21 d
	Maintenance therapy[15] Ganciclovir	5 mg/kg	Daily	IV	Indefinite	Valganciclovir 900 mg PO daily; or foscarnet 90–120 mg/kg once daily IV (infusion over 2 h by pump) 5–7 d/week, or other options for CMV retinitis (e.g., intraocular sustained release ganciclovir implant)
Bacteria						
Streptococcus pneumoniae						
a) Uncomplicated pneumonia	Penicillin G	12–18 million units	4 h	IV	7–10 d	ceftriaxone, or cefotaxime or respiratory quinolone eg. levofloxacin, moxifloxacin, gatifloxacin
b) Pneumonia (decreased pneumococcus susceptibility)[16] Intermediate Resistance (penicillin MIC >0.1 and ≤1.0 μg/mL)	ceftriaxone	1–2 gm	Daily	IV	7–10 d	Cefotaxime, imipenem, respiratory quinolone (eg. Levofloxacin, moxifloxacin, gatifloxacin). (Penicillin > 10 million units/d likely adequate for pneumonia)

(cont.)

TABLE 48-4 (Continued)

Infection	Drug of Choice	Total Daily Dose	Dose Interval	Route	Usual Duration	Alternative Therapy
c) Pneumonia[16] : High-level Resistance (penicillin MIC ≥2 μg/mL)	Vancomycin	2 g	12 h	IV	7–10	Imipenem or respiratory quinolone (eg. levofloxacin, moxifloxacin, gatifloxacin) or cefotaxime or ceftriaxone (if cefotaxime and ceftriaxone MIC <2 μg/mL)
Staphylococcus aureus						
Pneumonia, bacteremia (uncomplicated)	Nafcillin *or* oxacillin *or* cloxacillin[17]	12 g	4 h	IV	21–28 d, 14 (if bacteremia with removable focus, no endocarditis)	Cefazolin 2 gm IV q8h; or if MRSA: vancomycin 15 mg/kg IV q12h
Hemophilus influenzae						
Pneumonia	Ceftriaxone	1–2 g	Daily	IV	10–14 d	Ampicillin 2 g IV q6h (if susceptible) *or* cefotaxime 2 g IV q8h *or* cefuroxime 1.5 g IV q8h or trimethoprim-sulfamethoxazole, or respiratory quinolone
Salmonella						
Bacteremia	Ciprofloxacin	800 mg	12 h	IV	2–4 weeks	Step down to ciprofloxacin 750 mg PO BID when possible. Ampicillin 2 g IV q6h for 1–4 weeks (if susceptible), then amoxicillin 500 mg tid to complete a 2–4 week course of therapy;[18] or cefotaxime; *or* ceftriaxone[18]
Listeria						
Meningitis	Ampicillin *plus*	200 mg/kg	4 h	IV	6–8 weeks	Trimethoprim-Sulfamethoxazole (TMP-SMX) 20 mg/kg per day (based on the trimethoprim component) divided q6h plus/minus ampicillin; or meropenem
	Gentamicin[19]	5–7 mg/kg	8 h	IV	2 weeks	
Syphilis[20]						
Primary, secondary, and early latent (i.e. aquired during preceding year)[21]	Benzathine penicillin G	2.4 million units	Once	IM	(some specialists recommend weekly doses × 3)	Doxycycline 100 mg PO bid for 2 weeks *or* tetracycline 500 mg PO qid for 2 weeks[22]
Late Latent[23] (acquired > 1yr before, or unknown)	Benzathine penicillin G	2.4 million units	Weekly	IM	3 weeks (3 doses)	Aqueous crystalline penicillin G 18–24 million units/d divided q4h IV for 10–14 days; *or* procaine penicillin G 2.4 million units IM daily *plus* probenecid 500 mg qid PO; or ceftriaxone 2g IV/IM daily for 10–14 days[23,24]
Neurosyphilis (includes meningitis or ocular syphilis)	Aqueous crystalline penicillin G	18–24 million	4 h	IV	10–14 d	Ceftriaxone 2 g IM or IV daily for 10–14 d[24,25]; *or* procaine penicillin G 2.4 million units IM daily plus probenecid 500 mg PO qid for 10–14 d[24]

(cont.)

TABLE 48-4 (Continued)

Infection	Drug of Choice	Total Daily Dose	Dose Interval	Route	Usual Duration	Alternative Therapy
Mycobacteria						
Mycobacterium tuberculosis	Isoniazid[26]	5 mg/kg (max. 300 mg)	Daily	PO	6–9 months[27]	For suspected drug resistant TB obtain expert consultation
	Plus					
	Pyridoxine (vitamin B6)	50 mg	Daily	PO	6–9 months	
	plus					
	Rifampin	10 mg/kg (maximum 600 mg)	Daily	PO, IV	6–9 months[27]	
	plus					
	Pyrazinamide	25 mg/kg	Daily	PO	2 months	
	plus					
	Ethambutol	25 mg/kg	Daily	PO	2 months	
M. avium complex (MAC)	Clarithromycin	1000 mg	12 h	PO	Indefinite	Alternatives include azithromycin 500 mg daily (instead of clarithromycin)[28] and ciprofloxacin 750 mg bid
	plus					
	Ethambutol	15 mg/kg	Daily	PO	Indefinite	
	plus/minus					
	Rifabutin	300 mg	Daily	PO	Indefinite	

ABBREVIATIONS: PO, by mouth; IV, intravenous; IM, intramuscular; d, days; q6h, every 6 h; tid, three times per day; qid, four times per day.

[1]Pyrimethamine should be used in conjunction with folinic acid (10–50 mg/d for primary therapy, 10–20 mg/d for maintenance therapy) in order to minimize hematologic toxicity (anemia, leukopenia, thrombocytopenia). AZT should be used with caution during the acute phase of treatment of toxoplasmosis.

[2]Primary therapy for toxoplasmosis should be continued until complete resolution or marked improvement has occurred clinically and radiologically (usually 4–6 weeks).

[3]Clindamycin (plus pyrimethamine) is as effective as sulfadiazine (plus pyrimethamine) for induction but less effective for maintenance therapy of cerebral toxoplasmosis.

[4]Indicated for intestinal disease and or liver abscess. Asymptomatic cyst passers may be treated with a luminal agent, e.g., paromomycin 500 mg PO tid for 7 d (alternatives: iodoquinol 650 mg tid for 20 d or diloxanide furoate 500 mg tid for 10 d). Chloroquine phosphate 600 mg base (1 g)/d for 2 d, then 300 mg base (500 mg) daily for 2–3 weeks may be used in the management of amebic liver abscess.

[5]Continue treatment for 3 more weeks with trimethoprim (160 mg)-sulfamethoxazole (800 mg) 1 DS tablet PO bid (see Pape et al[123]).

[6]Intramuscular pentamidine may be associated with sterile abscess formation. The preferred route is slow IV infusion over 2 to 4 h.

[7]Take itraconazole capsules with food or cola. However, itraconazole solution is best absorbed fasting.

[8]Consider addition of 5-flucytosine (100 mg/kg per day PO, IV in 4 divided doses) in patients with overwhelming infection or local involvement with meningitis or endophthalmitis.

[9]Patients should receive amphotericin B with 5-flucytosine (100 mg/kg per day in 4 divided doses) until significantly improved and stable (usually by 2–3 weeks), at which time treatment can be changed to fluconazole 400 mg/d PO/IV to complete a 10-week course of treatment. Itraconazole 200 mg bid PO is an alternative to fluconazole in this situation provided that drug interactions and poor absorption are not a concern.

[10]High relapse rate (24%) associated with lower dose of itraconazole 200 mg daily.

[11]Relapse rates for maintenance therapy are as follows: itraconazole, 5%; amphotericin B, 19%; fluconazole, 33%; ketoconazole, 50%.

[12]Intrathecal (IT) amphotericin B (cisternal, cervical, ventricular, or lumbar) should be started at a low dose (0.01–0.025 mg) and increased gradually as tolerated to a dose of 0.1–0.3 mg 3 times weekly. The best intrathecal route of administration is cisternal. IT amphotericin B should be given 3 times per week for 3 months then 1–2 times per week for several months. Further dosage tapering is based upon clinical course and spinal fluid parameters.

[13]Treatment should be continued until all lesions have crusted. Long-term suppressive therapy (acyclovir 200–400 mg 3–4 times daily) may be required to control frequent relapses.

[14]Saline loading may reduce foscarnet-associated nephrotoxicity.

[15]Maintenance therapy is mandatory for CMV retinitis but not always required for gastrointestinal involvement.

[16]Meningitis caused by S. pneumoniae with decreased susceptibility should be treated with vancomycin plus ceftriaxone.

[17]Vancomycin is less effective than β-lactam antibiotics against methicillin-susceptible S. aureus infections.

[18]If recurrence of bacteremia, then consider indefinite ciprofloxacin 500 mg bid or trimethoprim-sulfamethoxazole.

[19]Some specialists also recommend intrathecal gentamicin.

[20]Some specialists advise CSF examination and/or treatment with a regimen appropriate for neurosyphilis for all patients coinfected with syphilis and HIV, regardless of the clinical stage of syphilis. HIV-infected patients should have frequent follow-up and serologic testing at 1, 2, 3, 6, 9, and 12 months. Any patient without a four-fold decline in nontreponemal serology (i.e. RPR or VDRL) by 3 months for primary or secondary syphilis, or 6 months in early latent syphilis, or a four-fold rise in titer at any time should have a CSF examination and be treated with the neurosyphilis regimen unless reinfection can be established as the cause of the increased titre (see reference No. 80 Centers for Disease Control and Prevention. Sexually transmitted diseases guidelines 2002).

[21]Failed therapy and development of neurosyphilis has been reported with benzathine penicillin G (see Gordon et al[81]). CSF abnormalities are common in early syphilis in HIV patients and are of uncertain prognostic significance. Some specialists recommend CSF examination and modification of treatment accordingly.

[22]Treponemacidal antibiotics (e.g., penicillin rather than doxycycline) are preferred for syphilis in HIV-infected patients. Document penicillin allergy (history ± skin testing) and consider desensitization.

[23]HIV-infected patients who have late latent syphilis should undergo cerebrospinal fluid examination. Those patients who have a normal spinal fluid examination (including negative CSF VDRL) do not require high-dose IV penicillin therapy and should receive benzathine penicillin G 2.4 million units IM weekly for 3 doses If lumbar puncture not done to exclude asymptomatic neurosyphili (present in half of such patients), then treat with high-dose IV penicillin, or IV/IM ceftriaxone, or IM procaine penicillin G. Therapy with either benzathine penicillin G IM or ceftriaxone IV/IM is associated with serologic or clinical failures in > 20% of HIV-infected patients with latent syphilis or asymptomatic neurosyphilis.

(cont.)

TABLE 48-4 (Continued)

[24]Since the durations of these regimens are shorter than that recommended for latent syphilis, some specialists recommend benzathine penicillin 2.4 million unit IM (once) after completion of any of the 10–14 day regimens
[25]Significant failure rate in HIV-related neurosyphilis, even with high dose IV penicillin.
[26]Isoniazid: higher dose of 10 mg/kg recommended for tuberculous meningitis until clinical response observed.
[27]Antituberculous therapy should be continued for at least 6 months. Slow responders should receive 9 months of treatment, or at least 6 months after conversion to culture negative state.
[28]A possible regimen for macrolide (clarithromycin and azithromycin) resistant disseminated MAC may include: moxifloxacin, ethambutol, rifabutin, plus/minus amikacin; however optimal management depends upon antiretroviral therapy with immune reconstitution which should be the therapeutic priority.

disease. In the context of AIDS, CMV disease tends to occur at a late stage, usually when the CD4 count is less than 50 cells/μL. Mean survival with intravenous or oral ganciclovir maintenance therapy following an episode of CMV retinitis is approximately 13 months without HAART.[72]

OTHER CAUSES OF PULMONARY INFILTRATES

Bacterial pneumonias tend to occur with increased frequency among HIV-infected individuals. Community-acquired pneumonias usually are caused by *Streptococcus pneumoniae*, *Haemophilus influenzae*, *Staphylococcus aureus*, or gram-negative bacilli. *Legionella* pneumonitis, contrary to early reports, occurs infrequently among HIV-infected individuals. Clinical features of community-acquired bacterial pneumonia are indistinguishable from those described in the immunocompetent host. Chest radiographs usually demonstrate segmental or lobar consolidation. Treatment of bacterial infections is included in Table 48-4.[73,74]

Nosocomial pneumonias among HIV-infected individuals are indistinguishable from those occurring in other hospitalized patients. These are usually caused by gram-negative organisms and tend to have a high mortality despite appropriate therapy.

Ventilator-associated pneumonia (VAP) may complicate the course of HIV-infected patients who require mechanical ventilation. There is an increasing frequency of *S. aureus* (methicillin-resistant *S. aureus* [MRSA] or methicillin-sensitive *S. aureus* [MSSA]) as the cause of VAP. In addition, aerobic gram-negative bacilli remain common causes of VAP. The other diagnosis to consider in patients who have pulmonary infiltrates and who require mechanical ventilation is ventilator-associated lung injury. The details of mechanical ventilation are discussed in Chaps. 36 and 38. HIV-infected patients who have acute lung injury (diffuse bilateral infiltrates, Pa_{O_2}/F_{IO_2} <300 mm Hg, and no cardiac cause of pulmonary edema) should receive lung-protective ventilation.[75]

Fungal pneumonias are a rare cause of respiratory failure among HIV-infected individuals. Disseminated infection is often present. Aspergillosis, cryptococcosis, histoplasmosis, and coccidioidomycosis are encountered most frequently and usually are associated with advanced HIV disease. Although reported rarely in AIDS prior to 1990, invasive aspergillosis had an incidence estimated to be between 0.9% and 8.6% among patients with AIDS in the pre-HAART era.[76] Respiratory tract syndromes caused by *Aspergillus* spp. in AIDS include invasive pulmonary aspergillosis, obstructing bronchial lesions, and tracheobronchitis. The presenting symptoms frequently are cough and fever; less common complaints include dyspnea, chest pain, and hemoptysis.[76] A common radiologic finding in AIDS-related invasive pulmonary aspergillosis is a thick-walled cavity.[77]

Candidiasis of the trachea, bronchi, or lungs, despite being recognized by the CDC as an AIDS-defining condition, is a very infrequent problem among these patients. Treatment of fungal disease is outlined in Table 48-4.[78–81]

Kaposi's sarcoma (KS) involves the lungs in up to 25% of patients with mucocutaneous KS. Clinically significant pulmonary KS without obvious mucocutaneous involvement is rare. Pulmonary KS often is indistinguishable from other HIV-related pulmonary diseases. Cough and dyspnea are common presenting features. Fever, wheezing, hoarseness, and even upper airway obstruction can occur. Sputum production usually is scant or absent. Hemoptysis, however, is relatively frequent. Chest radiograph usually shows nodular opacities of varying sizes coexisting with varying degrees of interstitial disease. Pleural and nodal involvement is also frequent. Bronchoscopic evaluation usually helps to rule out a superimposed treatable HIV-related disease in patients with pulmonary KS. It also may allow visualization of the characteristic red-violaceous lesions in the endobronchial tree. Although biopsy of these lesions at times can provide diagnostic confirmation, this is rarely required. No definitive therapy is currently available for the treatment of systemic KS, although significant improvement has been observed among some patients treated with HAART. Interferon has been used with some limited success for the treatment of early disease. Radiation therapy and chemotherapy have had some success in providing palliation. Given the poor prognosis of KS-related ARF at this time, these patients are unlikely to benefit from ICU support.[82]

Neurologic Complications in HIV-Infected Patients

Neurologic disease secondary to opportunistic infection or neoplasm may be associated with a depressed level of consciousness and occasionally precipitate ICU consultation and care. Often the neurologic disease may be a concomitant problem in patients requiring ICU care for other reasons.

The most frequently encountered neurologic syndromes in HIV-infected patients are meningitis, dementia, encephalopathy, focal neurologic deficits, myelopathy, peripheral neuropathy, and myopathy.[83,84] The various etiologic agents responsible for these syndromes, in addition to key points of clinical presentation and diagnostic evaluation, are summarized in Table 48-5. In general, most of the treatable infections complicating AIDS produce either meningitis or progressive focal neurologic deficits owing to localized inflammatory lesions in the brain, and both these syndromes

TABLE 48-5 Neurologic Complications in HIV-Infected Patients

Neurologic Syndrome	Etiologic Agents	Clinical Presentation	Diagnostic Evaluation
Meningitis	*C. neoformans*	Often headache, fever, and vomiting; sometimes confusion, seizure, meningismus, cranial nerve palsies; occasionally meningitis symptoms are minimal and presentation is fever, fungemia and/or extrameningeal lesion (e.g., skin, pneumonia).	CSF white blood count usually < 20/μL; CSF, glucose and protein often normal; cryptococcal antigen positive in CSF (> 90%) and serum (99%); positive India ink smear 50% – 90%; fungal cultures (blood, CSF, urine).
	Aseptic (?HIV)	Headache, meningismus, and fever (all less common in chronic cases), with/without cranial neuropathies (V, VII, VIII); may occur with seroconversion, but more common later in HIV disease.	CSF examination: mild mononuclear pleocytosis, protein elevated, glucose normal (differential diagnosis also includes syphilis and lymphomatous meningitis).
	M. tuberculosis	Usually subacute-chronic meningitis. Clinical manifestations similar to those in HIV-negative patients. Fever (89%), headache (59%), meningeal signs (65%), altered mentation (43%), focal deficits (19%), and clinical or radiologic evidence of extrameningeal tuberculosis (65%).[a]	CSF exam: lymphocytic pleocytosis, low glucose, and increased protein; smear for acid-fast-bacilli insensitive; cultures for *M. tuberculosis.* Rapid CSF diagnosis by polymerase chain reaction (PCR) appears promising,[b] but remains investigational. Detection of extrameningeal MTB facilitates early diagnosis.[a] Prior to obtaining positive CSF smears or culture, empiric therapy is indicated if clinical and spinal fluid profile are compatible with MTB.
	Coccidioides immitis	Fever, lethargy, headache, with/without meningismus, confusion (consider if travel/residence history for endemic zone, e.g., southwestern United States).	Serum tube precipitin or complement-fixing (CF) antibody titer positive in 83% of patients with AIDS-related coccidioidomycosis.[c] Any positive CSF titer of CF antibodies is usually diagnostic of meningitis. CSF profile: lymphocytic pleocytosis usually > 50 cells/μL, elevated protein, low glucose. Fungal cultures of blood and CSF.
	Bacterial (pneumococcus, meningococcus, *Listeria, H. influenzae)*	Fever, headache with/without meningeal signs, confusion, seizures. Bacterial meningitis rare in HIV-infected patients.	CSF exam: polymorphonuclear pleocytosis, high protein, low glucose, with/without positive Gram stain and/or bacterial antigens (pneumococcus, meningococcus, *H. influenzae)*; bacterial cultures of blood and CSF.
Diffuse brain disease			
AIDS dementia complex	HIV	Usually alert, but impaired cognition (usually concentration and memory), behavior (apathy, personality change), and motor function (slowing and reduced coordination); sometimes organic psychosis or mania.	Abnormalities on neuropsychologic testing Other findings may include hyperreflexia, ataxia, release signs, leg weakness, incontinence and mutism. Nonspecific CSF abnormalities may include elevated protein, IgG, β2-microglobulin, neopterin, and positive HIV-1 p24 core antigen. CT or MRI: atrophy ± patchy or diffuse abnormalities of hemispheric white matter seen on MRI (T2-weighted).[d]
Diffuse encephalopathies	Toxic metabolic disorders (e.g., hypoxia, sepsis, drugs), CNS toxoplasmosis, CNS lymphoma, occasionally viral infection (CMV, HSV).	Impaired alertness and cognition, with/without focal neurologic deficits.	Blood chemistry to exclude metabolic causes, with/without drug levels, serology for toxoplasmosis. MRI or contrast-enhanced CT head scan: focal lesions may be seen in toxoplasmosis, lymphoma, *Herpes simplex* encephalitis.

(cont.)

TABLE 48-5 (Continued)

Neurologic Syndrome	Etiologic Agents	Clinical Presentation	Diagnostic Evaluation
Focal brain disease			
Toxoplasmosis	*Toxoplasma gondii*	Headache (55%), confusion (52%), fever (47%), seizures (29%), reduced level of consciousness (42%), and focal deficits (69%) usually progressing over days.	MRI or contrast-enhanced CT scan: spherical ring-enhancing lesions in cortex, thalamus, or basal ganglia, but may have atypical appearances. Toxoplasma serum serology (IgG) usually positive (84%); possible brain biopsy (see Fig. 48-9).
Lymphoma	Strong association with Epstein-Barr virus (EBV)	Confusion, lethargy, memory loss, progressive focal deficit(s), headache, seizure; more slowly progressive than toxoplasmosis. CD4 count usually < 50 cells/μL.	MRI or contrast-enhanced CT scan: usually 1–2 lesions in white matter (often periventricular), may mimic toxoplasmosis but enhancement usually weaker and homogenous; possible brain biopsy. Spinal fluid PCR for EBV DNA has sensitivity and specificity of 80–90% and almost 100%, respectively. Combined sensitivity of positive PCR for EBV DNA or increased uptake on thallium SPECT scan almost 100%.
Progressive multifocal leukoencephalopathy (PML)	JC virus (papovavirus)	Slowly progressive focal deficits (over weeks), but no systemic toxicity or reduced level of consciousness in the early stage.	MRI or contrast-enhanced CT scan: non-enhancing white matter lesions without mass effect. Definitive diagnosis requires brain biopsy. Spinal fluid PCR for JCV 60–100% sensitive depending on case definitions and methodology. Compatible clinical presentation plus positive PCR supports diagnosis; negative PCR does not exclude PML.
Neurosyphilis	*Treponema pallidum*	Focal neurologic deficits (meningovascular involvement) with prodromal symptoms for weeks–months such as headache and behavioral changes. Syphilitic meningitis may include cranial nerve palsies. Ocular syphilis (e.g., optic neuritis) often associated with CNS involvement.	Positive serum VDRL, and FTA-ABS; CSF exam: mononuclear pleocytosis, elevated protein, with/without positive VDRL; CSF profile (if VDRL negative) may be indistinguishable from CSF abnormalities caused by HIV.
Myelopathy			
a) Subacute, chronic (diffuse)	HIV (vacuolar), HTLV-1	Slowly progressive, painless ataxia and spasticity; bowel-bladder dysfunction occurs late; often coexistent with dementia. Usually no distinct sensory/motor level.	MRI or CT scan, with/without myelography are negative and are not indicated in typical cases (best reserved for patients with atypical findings where segmental lesions are to be excluded). Consider HTLV-1 serology.
b) Acute, subacute (transverse myelitis, segmental)	Varicella zoster, lymphoma, cytomegalovirus	More rapid onset of myelopathy than for HIV.	CT scan or MRI, myelography.
Peripheral neuropathy			
a) Axonal neuropathy	?HIV	Distal, mainly sensory, painful ("burning feet"), symptoms more prominent than signs.	With/without nerve conduction studies.
b) Toxic axonal neuropathy	ddI, ddC, d4T, others	As for axonal neuropathy. Neuropathy may progress for a few weeks after stopping the offending drug.	With/without nerve conduction studies.
Acute-chronic demyelinating neuropathy	?Autoimmune response to HIV	Similar to Guillain-Barré syndrome; usually occurs during the early period (CD4 $>500/\mu$L) of HIV infection, or at the time of seroconversion.	Nerve conduction studies. CSF abnormalities: elevated protein, and mild pleocytosis.
Radiculopathies	Varicella zoster virus	Herpes *zoster* dermatomal vesicular lesions.	Clinical diagnosis, with/without viral antigen detection in smears prepared from skin lesions. Tzanck smear is rapid but insensitive. Viral culture is slow for demonstration of cytopathic effect.

(cont.)

TABLE 48-5 (Continued)

Neurologic Syndrome	Etiologic Agents	Clinical Presentation	Diagnostic Evaluation
	Cytomegalovirus	Subacute and progressive ascending polyradiculopathy with sensory loss, urinary retention, and flaccid paraparesis.	CSF: polymorphonuclear pleocytosis, elevated protein, low glucose, with/without CSF culture positive for CMV; rule out bacterial and tuberculous meningitis.
Mononeuritis multiplex	Autoimmune vascular lesion in early HIV (CD4 200–500/μL). Multifocal CMV infection later in HIV disease (CD4 <200 μL)	Findings compatible with involvement of multiple distinct peripheral nerves. More severe in advanced HIV disease.	Nerve conduction studies.
Myopathy	AZT	Ranges from asymptomatic elevation of CPK to progressive myalgia, atrophy, and weakness (especially proximal leg muscles).	Consider muscle biopsy (mitochondrial abnormalities with/without inflammatory cell infiltrates) if persists after stopping AZT.
	HIV?	As for AZT-induced myopathy.	Consider muscle biopsy: myopathic changes (variable fiber size, vacuolar change and fiber destruction), with/without inflammatory infiltrates; ultrasound if localized inflammation to rule out pyomyositis.

usually are associated with headache. However, most of the causes of diffuse brain involvement are not associated with headache. A suggested sequence of investigations in the HIV-infected patient with headache or CNS dysfunction is outlined in Fig. 48-9. Antimicrobial therapy is outlined in Table 48-4.[85–88]

MENINGITIS

The clinical presentation of both acute and chronic meningitis is little different in the AIDS patient from that seen in the immunocompetent host; presentation includes headache, fever, and nuchal rigidity of variable duration and severity.

The most important cause of meningitis in the HIV-infected patient is *Cryptococcus neoformans*. Uncommon etiologies include *Mycobacterium tuberculosis*,[89,90] *Coccidioides immitis*,[91] *Histoplasma capsulatum, Treponema pallidum* (syphilis*), Listeria monocytogenes*, and the usual causative agents of bacterial meningitis (pneumococcus, meningococcus, *Haemophilus influenzae*). Antimicrobial therapy is outlined in Table 48-4. HIV-related aseptic meningitis may occur at the time of seroconversion but is more common later in the course of HIV disease, when both acute and chronic presentations have been described. The role of antiretroviral therapy for HIV-related aseptic meningitis has not been evaluated.

DIFFUSE BRAIN DISEASE (DEMENTIA AND ENCEPHALOPATHY)

AIDS dementia complex (ADC) appears to be caused by chronic HIV infection of the CNS. Patients with ADC manifest varying degrees of impaired cognition, behavior, and motor function but usually remain alert. In contrast, the diffuse encephalopathies associated with toxic and metabolic disorders, CNS toxoplasmosis, lymphoma, or viral infection (e.g., herpes simplex or CMV) usually result in impairment of cognition associated with a disturbance in the level of consciousness. Patients with ADC should be treated with combination antiretroviral therapy. There is evidence that antiretroviral therapy can both prevent and ameliorate ADC. Zidovudine (AZT) has been associated with sustained improvement in neurologic performance in up to 50% of patients.[92] The role of other antiretroviral agents in the management of ADC has not been determined; however, in a meta-analysis of clinical trials of patients switching from AZT to didanosine (ddI), there was no evidence of any increase in the incidence of ADC during ddI therapy. Despite the absence of definitive clinical trials clarifying the efficacy of HAART for the prevention or treatment of ADC, extrapolation from the monotherapy trials and anecdotal experience supports this approach. Although unproven, improved clinical response may be associated with regimens that include drugs that have good brain penetration (AZT, abacavir, stavudine, and nevirapine).

FOCAL NEUROLOGIC DISEASE

Patients presenting with focal neurologic deficits should have urgent magnetic resonance imaging (MRI) or a computed tomographic (CT) head scan with contrast material, which usually yields evidence of CNS toxoplasmosis (Fig. 48-10), lymphoma (Fig. 48-11), or progressive multifocal leukoencephalopathy (PML). Occasional cases of subacute focal brain disease may be caused by aspergillosis, cryptococcoma, tuberculoma, varicella-zoster virus infection, or herpes simplex

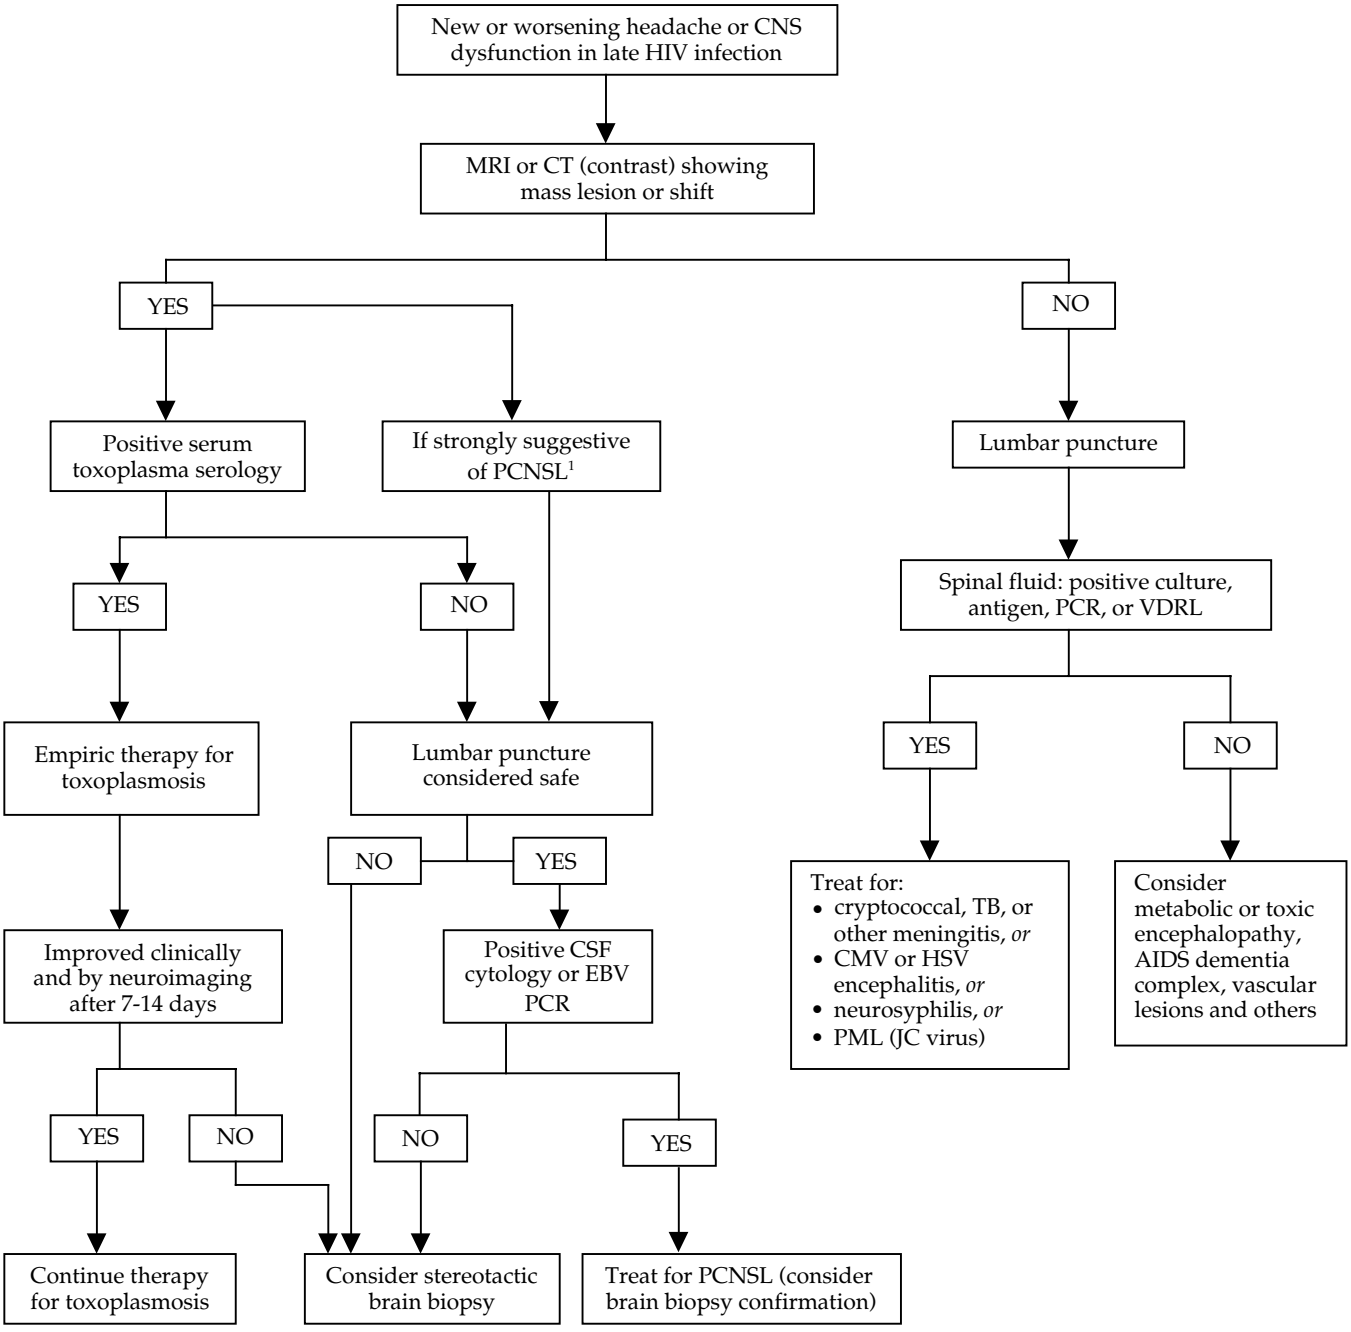

FIGURE 48-9 Approach to the HIV-infected patient with headache or CNS dysfunction.
[1]Factors which favor PCNSL include: i) negative serum serology for toxoplasma, ii) on chronic prophylaxis with TMP-SMX or dapsone, and iii) neuroimaging lesions which are periventricular, or involve deep white matter, or demonstrate diffuse (vs ring enhancement) or weak contrast enhancement.
Abbreviatons: PCNSL, primary central nervous system lymphoma; PCR, polymerase chain reaction; EBV, Epstein-Barr virus; PML, progressive multifocal leukoencephalopathy.

encephalitis. The abrupt onset of focal neurologic deficit suggests either a seizure or vascular disorder. Patients with a CT scan or MRI compatible with toxoplasmosis should be treated empirically (see Table 48-4). The diagnosis of toxoplasmosis usually is presumptive on the basis of a clinical and radiologic response to empirical therapy, without brain biopsy. Early brain biopsy should be considered for patients with mass lesion(s) who are unlikely to have toxoxplasmosis based on the combination of neuroimaging findings, toxoplasma serology, and whether the patient developed the lesions while taking TMP-SMX or dapsone prophylaxis (see Fig. 48-9). Corticosteroids should be avoided unless there is life-threatening cerebral edema and the risk of brain herniation. Since lymphoma may respond transiently to corticosteroids, coadministration with empirical toxoplasmosis therapy may confound the assessment of response to therapy and reduce the diagnostic yield of brain biopsy. Those who are not responding to empirical therapy, particularly when associated with negative serum serology (IgG) for toxoplasmosis, should be considered for brain biopsy.[93]

FIGURE 48-10 Double-dose delayed CT scan of the head demonstrating two lesions of cerebral toxoplasmosis. Note the ring-enhancing appearance of the right cerebral lesion.

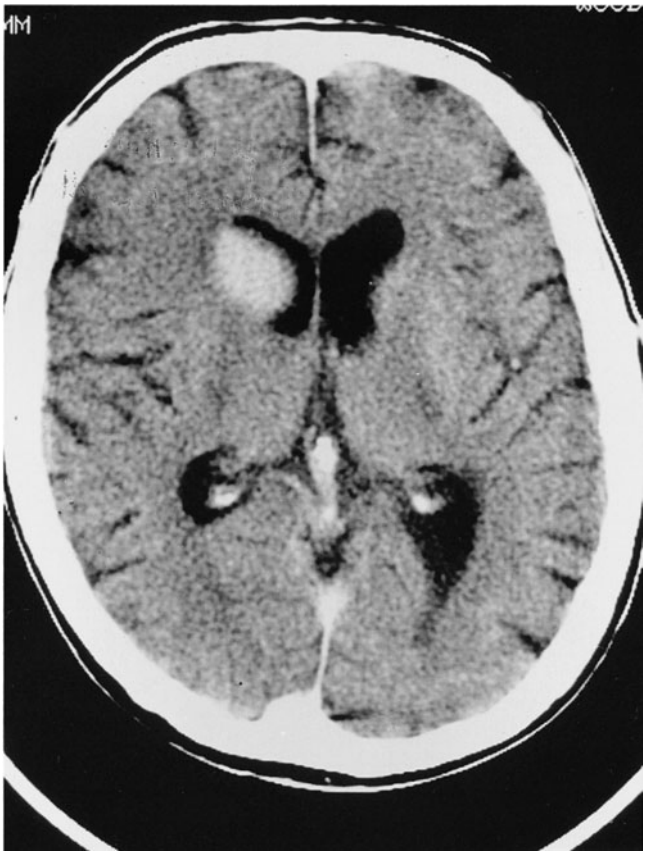

FIGURE 48-11 Double-dose delayed CT scan of the head demonstrating a lesion of cerebral lymphoma in a patient with HIV infection. Note the subependymal localization of the lesion, which is common in cerebral lymphoma.

Although less responsive to therapy, some patients with CNS lymphoma may have a significant response to radiotherapy and chemotherapy. HAART has been associated with improved clinical course and survival time in HIV-related PML for the subset of patients having relatively high CD4 counts and low spinal fluid JC viral load at the time of diagnosis.[94] JC viral load in spinal fluid usually becomes undetectable for PML patients who respond to HAART. A possible role for cidofovir in the management of PML has been suggested by observational studies.[95] Neurosyphilis is responsible only occasionally for focal neurologic deficit, but it is important to consider this treatable condition.[86]

MYELOPATHY, PERIPHERAL NEUROPATHY, AND MYOPATHY

Vacuolar myelopathy is slowly progressive and characterized by diffuse involvement of the spinal cord in HIV-infected individuals. A clinically indistinguishable presentation may be seen in human T-cell lymphotropic virus 1 (HTLV-1) infection. In contrast, a much less common form of myelopathy has a more rapid onset and is associated with segmental pathology of the spinal cord (transverse myelitis). The etiologic agents for this latter condition include lymphoma, varicella-zoster virus (VZV) infection, CMV infection, and toxoplasmosis. CMV occasionally may cause a subacute progressive polyradiculopathy[96]; patients present with sacral sensory loss, urinary retention, and flaccid paraparesis within days to weeks. The cerebrospinal fluid (CSF) is markedly abnormal in CMV polyradiculopathy, with a polymorphonuclear pleocytosis, hypoglycorrhachia, and elevated protein. CMV may be cultured or demonstrated by PCR from the CSF, but treatment should be started empirically with ganciclovir. Herpes zoster may result in a painful radiculopathy that persists long after resolution of the dermatomal vesicular lesions. However, postherpetic neuralgia is less common in HIV-infected patients.

Peripheral neuropathy may occur at any time during the course of HIV infection. During seroconversion or the latent period (usually CD4 count >500 cells/μL), an inflammatory demyelinating neuropathy may occur with a presentation similar to that of the Guillain-Barré syndrome. This neuropathy may respond to corticosteroids, intravenous immune globulin, or plasmapheresis. Later in the course of HIV infection, an axonal neuropathy, possibly caused by HIV, results in a painful distal neuropathy that is predominantly sensory. Treatment is symptomatic with analgesics or pain-modifying agents (e.g., gabapentin, amitriptyline, or carbamazepine). A similar picture may be caused by drugs, particularly didanosine (ddI), or stavudine (d4T).

AZT has been associated with myopathy, which may present with asymptomatic elevation in the creatine kinase (CK) level or progressive myalgia and weakness, particularly

in the proximal leg muscles. AZT should be discontinued in symptomatic patients, and clinical improvement and a decrease in the CK level usually occur within 2 weeks.[97] Muscle biopsy should be considered if the myopathy persists after withdrawal of AZT. If muscle biopsy shows significant inflammatory infiltrates but no opportunistic pathogens or mitochondrial changes, then an immune-mediated myopathy should be suspected. HIV-1-associated myopathy may be mediated by an immune mechanism, and some patients have responded to corticosteroids.[97]

Fungal Infections in the HIV-Infected Patient

CANDIDIASIS

Although candidiasis is the most common opportunistic fungal infection in AIDS, most such infections are limited to mucosal disease involving the oropharynx, esophagus, or vagina. Treatment therefore is aimed at control of symptoms, as outlined in Table 48-4. Deep *Candida* infections (e.g., endophthalmitis or vertebral osteomyelitis) and disseminated candidiasis are encountered rarely in the setting of HIV infection, and in such instances, the usual risk factors for invasive candidiasis often can be identified. These include granulocytopenia, immunosuppressive therapy, prolonged vascular catheterization, recent surgery (e.g., gastrointestinal, cardiac), broad-spectrum antibiotic use, and intravenous drug abuse. Management of candidemia includes removal of any potentially infected vascular catheters and careful assessment for the presence of metastatic sites of infection such as endophthalmitis. Antifungal treatment options for candidemia and other invasive forms of candidiasis include fluconazole,[80,81] amphotericin B, lipid formulations of amphotericin B, and caspofungin, as outlined in Table 48-4.

CRYPTOCOCCOSIS

Although less common now since the introduction of HAART, cryptococcosis occurred in approximately 5% to 10% of individuals at some point during the course of HIV infection in the pre-HAART era (i.e., before 1996). Cryptococcal disease in AIDS usually presents as a subacute to chronic meningitis. However, up to 9% of patients with AIDS-related cryptococcosis develop ARF, which in one series was associated with a 100% mortality rate.[98] The diagnosis of cryptococcal ARF often is not considered before death, but a serum cryptococcal antigen titer is a rapid and sensitive screening test. Predictors of ARF in AIDS-related cryptococcosis are African-American ethnicity, serum LDH concentration of more than 500 IU/L, interstitial infiltrates, and cutaneous lesions.[98] The duration of symptoms before presentation varies from a few days to several weeks. It is important to note that the diagnosis of meningitis may be overlooked because headache and other neurologic symptoms may be mild or absent. Furthermore, meningeal signs are present in only a minority of cases. Other presentations of cryptococcosis include skin lesions and unexplained fever.[99]

An elevated opening pressure at lumbar puncture is common in cryptococcal meningitis. However, the abnormalities in CSF cell count and glucose and protein concentrations may be minimal or absent despite positive results for India ink smear, fungal culture, and cryptococcal antigen. The CSF white blood cell count usually is less than 20/μL and predominantly lymphocytic. The CSF glucose concentration is usually normal but may be low. The serum cryptococcal antigen determination provides a rapid, noninvasive test that is particularly helpful in identifying the HIV-positive patient with extrapulmonary cryptococcal disease.[99] The organism may be cultured from spinal fluid, blood, urine, sputum, and skin lesions. Patients with *C. neoformans* isolated from an extraneural site should be investigated for the presence of disseminated disease, including a lumbar puncture, even in the absence of headache or neurologic symptoms.

A suggested sequence of investigations in the HIV-infected patient with headache or CNS dysfunction is outlined in Fig. 48-9. An HIV-infected patient presenting with an illness compatible with cryptococcosis whose serum cryptococcal antigen titer is positive (except if the titer is 1:8 or less, which may represent a false-positive result) should be started on antifungal therapy before completion of the investigations if there are delays involved in obtaining a CT head scan (or MRI) or contraindications to performing a lumbar puncture (e.g., mass lesion or shift on CT head scan or coagulopathy). Initial treatment of AIDS-related cryptococcal meningitis (see Table 48-4) should be initiated with amphotericin B at 0.7 mg/kg per day (plus flucytosine) rather than with fluconazole.[100,101] The role of flucytosine in the management of AIDS-related cryptococcal meningitis has been controversial, although in a recent randomized trial the addition of flucytosine to amphotericin B was associated with improved CSF sterilization at 2 weeks of treatment (confirmed by multivariate analysis) and fewer subsequent relapses. However, there was no survival benefit.[102] The best-studied alternative treatment is liposomal amphotericin B, which appears to be of equal efficacy but is better tolerated than amphotericin B.[103] Similar results were obtained with liposomal amphotericin at 3 or 6 mg/kg per day compared with conventional amphotericin B at 0.7 mg/kg per day.[103] Limited human and animal studies provide evidence of delayed CSF sterilization with amphotericin B–lipid complex (Ablecet), arguing against its use in the management of cryptococcal meningitis.[104] Investigational approaches to salvage therapy include high-dose fluconazole (800 to 1200 mg/d) plus 5-flucytosine (100 to 150 mg/kg per day divided q6h).[105] Increased intracranial pressure is common, and its documentation and management should not be overlooked.[106] Usually this entails serial lumbar punctures or placement of a CSF shunt in order to reduce intracranial pressure. After a clinical response has been obtained (usually after 2 to 3 weeks), patients should be switched to oral fluconazole at 400 mg daily in order to complete 10 weeks of therapy.[102] Thereafter, the fluconazole dosage is reduced to 200 mg daily and continued lifelong as suppressive therapy, unless the patient undergoes immune reconstitution with antiretroviral therapy (see Table 48-3).[107] An unacceptably high relapse rate has been observed during suppressive therapy with itraconazole at 200 mg daily (24%) compared with fluconazole at 200 mg daily (4%).[108] Despite its importance for initial diagnosis, the serum cryptococcal antigen titer has not been helpful in assessing either the response to initial treatment or a suspected relapse of cryptococcal meningitis.[109]

IRS (immune reconstitution syndrome) has been described in patients with cryptococcosis who subsequently receive

HAART. Presentations may include pulmonary or soft tissue lesions that often are culture-negative but demonstrate organisms consistent with cryptococcus on smear or histology.[110] Others may experience an exacerbation of cryptococcal meningitis associated with a negative CSF culture and a higher than usual CSF pleocytosis.[111] Cryptococcal meningitis also may be unmasked by HAART-induced immune reconstitution. HAART may precipitate symptomatic disease in those with latent CNS cryptococcal infection. Cryptococcal meningitis IRS exacerbation may respond to systemic corticosteroids, according to anecdotal reports. Antiretroviral therapy should be interrupted for life-threatening IRS and possibly reintroduced at a later date along with corticosteroid coadministration.

HISTOPLASMOSIS

In North America, histoplasmosis is usually restricted geographically to the endemic zone extending from Mexico and Texas up through the central United States (especially the Mississippi Valley area) and into eastern Canada. Most patients with histoplasmosis will have a history of exposure to endemic areas. Although less common at present, during the pre-HAART era (before 1996), histoplasmosis occurred in 2% to 5% of HIV-infected patients in endemic areas but in as many as 25% in certain cities. Although over 90% of cases have occurred in patients whose CD4 count was less than 100 cells/μL, histoplasmosis was the first AIDS-defining illness in half the cases.

Histoplasmosis in the context of AIDS is almost always a disseminated infection. The clinical presentation is usually that of a nonspecific febrile illness often accompanied by other features such as pulmonary infiltrates, hepatosplenomegaly, lymphadenopathy, pancytopenia, and liver enzyme elevations.[112] The spectrum of disease ranges from a nonspecific febrile illness (often with constitutional and/or respiratory symptoms) to a syndrome resembling septic shock (10% of patients) with respiratory and multiorgan failure. Chest radiographs reveal diffuse infiltrates (interstitial or reticulonodular) in approximately half the patients, but radiologic findings are normal in one-third of patients.[113] A rapid presumptive diagnosis can be obtained by demonstrating the organism in a buffy coat smear (30% sensitivity), bone marrow biopsy, or occasionally other tissues. The small intracellular yeast forms may be seen within leukocytes. The diagnosis is confirmed by fungal culture (blood, bone marrow, respiratory tract specimens, lymph node, or skin biopsy), although a positive result may take several weeks. Complement-fixation titers are negative in up to 30% of non-AIDS patients with histoplasmosis. Similarly, in AIDS patients, a negative serology for histoplasmosis does not reliably exclude the disease. However, antigen detection in serum and urine is rapid and reliable,[114] but the test is not widely available, and specimens must be sent to the reference laboratory. A helpful clue to the diagnosis of disseminated histoplasmosis is the presence of a markedly elevated serum LDH concentration (>600 IU in 73% of patient in one series),[115] which also may be seen in AIDS-related disseminated toxoplasmosis. Therapy is outlined in Table 48-4. A prospective, double-blind study in moderate to severe AIDS-related disseminated histoplasmosis demonstrated greater efficacy and significantly increased survival with liposomal amphotericin B (3 mg/kg per day) compared with conventional amphotericin B (0.7 mg/kg per day) as induction therapy.[116] Itraconazole is effective therapy for patients with mild to moderate disease.

COCCIDIOIDOMYCOSIS

The endemic zone for coccidioidomycosis in North America is limited to the southwestern United States and extends into northern Mexico. Coccidioidomycosis is an important opportunistic infection in endemic areas, occurring in 6% of HIV-infected patients in Arizona during the pre-HAART era (before 1996).[91] Most patients have a CD4 count of less than 250 cells/μL at the time of diagnosis. This infection should be considered in HIV-infected individuals who have history of exposure to endemic areas and who present with a compatible illness. Clinical features are nonspecific and may include fevers, dyspnea, focal or diffuse pulmonary infiltrates, meningitis, skin lesions, arthritis, and lymphadenopathy. Some patients have fevers and weight loss with no focal lesions.[117] The most common clinical presentations include diffuse or focal pulmonary infiltrates and meningitis. The diagnosis is made by histologic examination and fungal culture of respiratory secretions, tissue biopsies (skin or lymph node), spinal fluid, and blood. The characteristic coccidioidal spherules may be identified using lactophenol cotton blue stain, Gomori's silver methenamine stain, or Papanicolaou's stain. The CSF characteristics in coccidioidal meningitis usually include a pleocytosis of greater than 50 cells/μL that consists of predominantly lymphocytes. The CSF glucose concentration is low, and the protein concentration is elevated. Serology for coccidioidomycosis is positive in approximately 90% of HIV-related cases.[117] Positive CSF serology (complement fixation) for *C. immitis* usually indicates the presence of coccidioidal meningitis. Therapy is outlined in Table 48-4. Fluconazole represents an important advance in the therapy of coccidioidomycosis because of the efficacy and lower side-effect profile of fluconazole compared with amphotericin B. Lifelong suppressive azole therapy is required in coccidioidal meningitis.[118–120] Survival is shortest among patients with diffuse pulmonary disease.

Supportive Care for AIDS Patients in the ICU

Resuscitation and supportive care of AIDS patients in the ICU includes airway protection, noninvasive ventilation, mechanical ventilation, cardiovascular monitoring and support, gastrointestinal and nutritional management, and psychological supportive care. Airway assessment is important in patients who have a depressed level of consciousness, usually because of neurologic problems or systemic sepsis, and in patients who have acute respiratory failure. Detailed discussion of the management of acute hypoxemic respiratory failure is presented in Chap. 38. In general, patients with arterial hypoxemia require supplemental high-flow, high-concentration oxygen. If hypoxemia is refractory to supplemental oxygen, then mask continuous positive airway pressure (CPAP) of 5 to 10 cm H_2O may improve arterial hypoxemia and decrease respiratory rate in alert patients who are able to protect their airway.[123] Mask CPAP has been used for up to 11 days. Pneumothorax occurs infrequently, in approximately

5% of patients.[121] Mask CPAP also allows speech and therefore ongoing discussion regarding prognosis and therapeutic options. Noninvasive ventilation using BiPAP also may preclude the need for intubation and mechanical ventilation. Endotracheal intubation and mechanical ventilation are indicated in patients who require airway protection, or who do not respond to CPAP or BiPAP. Assist-control ventilation with positive end-expiratory pressure is usually necessary for PCP patients who require mechanical ventilation.

In patients who meet the criteria of acute lung injury (ALI),[75] lung-protective ventilation with a tidal volume of 6 mL/kg of ideal body weight is recommended because this decreases the mortality of ALI from 40% to 30% (ARDSnet). It is recommended to use the ARDSnet protocol, which includes titration of positive end-expiratory pressure (PEEP) and $F_{I_{O_2}}$ according to a simple algorithm. Use of higher PEEP generally is not recommended because of the risk of barotrauma (especially in PCP) and because a randomized, controlled trial of higher PEEP versus "usual" PEEP (ALVEOLI trial, in press at present time) found no significant improvement in mortality.

Critically ill AIDS patients may develop cardiovascular instability. Systemic arterial catheterization is appropriate for continuous arterial pressure monitoring and arterial blood gas determinations. Hypotension may be caused by hypovolemia, autonomic neuropathy, pentamidine, or septic shock. Hypovolemia may be caused by increased insensible fluid losses, diarrhea, and inadequate intake. Autonomic neuropathy occurs in some AIDS patients and appears to explain the occasionally sudden fatal hypotension and bradycardia.[122] The hypotension that may occur during infusion of pentamidine can be minimized by administering the drug slowly over 4 hours, as described earlier. Hypotension in critically ill AIDS patients may be the result of septic shock owing to bacterial sepsis (e.g., pneumococcus, *H. influenzae, Staphylococcus,* or enteric gram-negative bacilli), PCP, or other systemic fungal infection such as histoplasmosis. Patients who have PCP, similar to patients who have bacterial sepsis, have tachycardia, decreased systemic vascular resistance, increased cardiac output, and hypotension.[123] The clinical approach to management is similar to that for other critically ill patients, detailed in Chap. 46. The evaluation of adrenal insufficiency and use of corticosteroids for septic shock[124] are relevant; furthermore, patients with PCP or suspected PCP should be treated with hydrocortisone, as discussed earlier.

HIV-positive patients who have severe sepsis in the ICU may be eligible for consideration of treatment with recombinant human activated protein C (rhAPC). This treatment option is discussed in more detail in Chap. 46. A large, pivotal randomized clinical trial showed that rhAPC decreased mortality of severe sepsis from 31% to 25%.[125] RhAPC is approved for treatment of patients who have severe sepsis and who are at high risk of death (defined as an APACHE II score >25 or organ system failure involving two or more organs). End-stage disease and end-stage HIV were exclusions in the pivotal trial. However, we recommend consideration of rhAPC in HIV-positive patients admitted to the ICU who have at least an otherwise moderately good prognosis.

Enteropathy, malnutrition, and weight loss are very common gastrointestinal problems in AIDS patients. Up to 30% of AIDS patients have multiple gastrointestinal pathogens.[126]

TABLE 48-6 Causes of Common Gastrointestinal Problems in AIDS Patients

Problem	Organisms
Esophagitis	*Candida,* CMV, HSV
Gastroenteritis	*Cryptosporidium, Microsporidium, Giardia lamblia, Isospora belli, Salmonella,* MAC, CMV
Enterocolitis	*Shigella, Campylobacter, Entamoeba histolytica,* CMV, *Cryptosporidium,* MAC, *Clostridium difficile*
Sexually transmitted proctitis	*N. gonorrhea, Chlamydia trachomatis, Treponema pallidum,* HSV

ABBREVIATIONS: CMV = cytomegalovirus; HSV = herpes simplex virus; MAC = *Mycobacterium avium complex.*

The causes of common gastrointestinal problems in AIDS patients are listed in Table 48-6, and their treatment is outlined in Table 48-4. Esophagitis may be caused by *Candida,* CMV, and herpes simplex virus (HSV). *Candida* esophagitis usually presents with dysphagia, but marked odynophagia suggests either HSV or CMV esophagitis. Oropharyngeal and esophageal *Candida* infection rarely gives rise to deep visceral involvement or disseminated candidiasis. Diarrhea occurs in about 50% of AIDS patients and is caused by gastrointestinal infections, AIDS-associated enteropathy, and much less commonly, gastrointestinal neoplasms. Gastroenteritis may be secondary to *Cryptosporidium*, *Giardia*, *Isospora*, *Salmonella*, MAC, and CMV. *Cryptosporidium* and *Microsporidia* may cause severe diarrhea, and although specific antimicrobial therapy for cryptosporidiosis has not been proved effective, clinical and microbiologic resolution has been reported anecdotally in association with HAART-induced immune reconstitution. Enterocolitis may be the result of infection with *Shigella, Campylobacter, Entamoeba histolytica,* and CMV. Finally, sexually transmitted proctitis caused by gonorrhea, syphilis, *Chlamydia,* or HSV may produce severe rectal symptoms accompanied by frequent small-volume stools associated with blood and mucus. *Clostridium difficile* colitis also should be considered in patients treated recently with antibacterial agents. Others have diarrhea caused by AIDS-associated enteropathy,[127] which may represent an unidentified infectious cause, possibly HIV or an autoimmune disorder.

AIDS patients with esophageal symptoms and thrush may be treated empirically with fluconazole 100 to 200 mg daily. If there is no response, then esophagoscopy and biopsy should be performed. Investigation of diarrhea includes examination of stool for ova and parasites, stool culture and *C. difficile* toxin assay, and occasionally, flexible sigmoidoscopy and upper gastrointestinal endoscopy.[128] The treatment of critically ill AIDS patients who have diarrhea includes bowel rest, antimicrobial therapy for isolated pathogens[126,129] (see Table 48-4), intravenous fluid and electrolytes, symptomatic antidiarrheal therapy, and nutritional therapy. Antimotility agents should be avoided when certain enteric pathogens (e.g., *Salmonella, Shigella, E. histolytica,* and *C. difficile*) are suspected. Total parenteral nutrition may be necessary in critically ill patients who have significant diarrhea because enteral nutrition frequently exacerbates the diarrhea. Malnourished AIDS patients who are critically ill and do not have diarrhea often respond

adequately to enteral nutrition supplemented as appropriate with potassium, magnesium, calcium, and phosphate.

AIDS patients, family, and friends also may suffer important emotional and psychological problems that require counseling, psychological support, and the empathy of health care workers. In many communities with a high prevalence of AIDS patients, active peer support groups may be extremely helpful. In addition, family physicians and referring specialists who have long-term care relationships with patients can provide valuable support to the critical care team.

ICU Eligibility of AIDS Patients

The two fundamental issues determining ICU eligibility in a patient with AIDS are the patient's prognosis and the patient's wishes regarding life support. Concerning prognosis, it is necessary to assess both the prognosis of the acute illness necessitating life support and the prognosis of the underlying HIV disease. Prior to the development of AIDS, the prognosis of HIV disease generally was dictated by the CD4 count and the remaining antiretroviral treatment options available. A prognostic staging system had been suggested for patients with AIDS.[130] Various clinical and laboratory abnormalities were scored, and higher scores were associated with shorter survival times. Although this information had been useful in the assessment of eligibility of AIDS patients for life support in the ICU,[131] its applicability in the setting of HAART is unclear.

As in any other critical illness, it is of utmost importance to involve the patient or those close to the patient, whenever possible, in discussions regarding the appropriateness of ICU admission and life support. Often the issue of life support has been considered previously, and the patient has already made his or her wishes known to primary physicians, friends, or relatives.[132] ICU admission and life support generally are inappropriate for patients with life-threatening complications for which there is no particularly effective therapy (e.g., high-grade lymphoma). It is reasonable, however, to offer ICU admission and life support to patients with an acceptable quality of life who have a potentially reversible acute illness.[133]

In every instance, clear goals of ICU admission should be established with the patient, family, and treating physicians. Obviously, a lucid, well-informed patient and his or her family may refuse life support. Finally, it must be emphasized that the outlook of AIDS and its related conditions has improved considerably. For this reason, rigid policies regarding ICU admission are undesirable, and detailed evaluation of each situation on a case-by-case basis is required. For patients who still have antiretroviral therapy options and in whom there is some expectation of partial immune reconstitution, there is no CD4 count that by itself would be considered justification for exclusion of the patient from admission to the ICU. It also should be noted that the initiation of HAART may be associated with clinical improvement in patients with opportunistic diseases for which there is no proven specific effective therapy (e.g., microsporidiosis, cryptosporidiosis, PML, and macrolide-resistant disseminated MAC infection).

Acknowledgment

This work was supported in part by the National Health and Research Development Programme, Health and Welfare, Ottawa, Canada, and the National Institutes of Health. We thank Kelly Hsu for assistance in preparation of the manuscript.

KEY POINTS

- *The possibility of intravascular infection should be considered in all critically ill patients with bacteremia or fungemia of uncertain origin, particularly when there are known intravascular or endocardial abnormalities or intravascular devices; fever or hemodynamic instability of unclear origin; or signs of inflammation related to an indwelling intravascular device.*
- *Blood cultures are the most important diagnostic test for this group of infections because most intravascular infections will result in persistent bacteremia or fungemia.*
- *Successful therapy often requires prolonged administration of microbicidal agents plus removal of devices.*
- *Certain microbes, including staphylococci, enterococci, aerobic gram-negative bacilli, and yeasts, are especially likely to cause intravascular infectious disease.*

Patients hospitalized in ICUs may have an intravascular infectious disorder as their primary problem, as a complication of their main disorder, or as a nosocomial infection occurring during their stay. Specific populations common to the ICU, including hemodialysis patients, injection drug users, HIV-infected patients, and those with congenital heart disease, are at increased risk of intravascular infection. Furthermore, violation of anatomic barriers by indwelling intravascular devices and by surgery, as well as impairment of cellular or humoral immune function related to critical illness, contributes to invasion by a variety of microbial pathogens. Infections of intravascular foreign bodies or native vascular structures themselves are likely to be associated not only with symptoms and signs of local inflammation but also with evidence of disseminated disease due to metastatic spread of infectious agents. This chapter provides the clinician caring for patients in an ICU with an approach to the patient with suspected or proved intravascular infectious disorders. We will emphasize the underlying clinical situations that predispose to intravascular infection, the pathogenesis of the disorders, the symptoms and signs of disease, and the appropriate diagnostic procedures, particularly those that provide assistance in the choice of antimicrobial therapy and selection of ancillary medical and surgical procedures. Table 49-1 lists the intravascular infections of native vessels and those associated with intravascular devices, respectively.

Intravascular Infections in the Absence of Any Foreign Device

INFECTIVE ENDOCARDITIS ON A NATIVE VALVE

PATHOGENESIS

The pathogenesis of infective endocarditis (IE) usually involves transient bloodstream invasion by microorganisms, followed by adherence of the organism to the endocardial surface and multiplication of the microorganism within a layer of platelets and fibrin that is relatively inaccessible to host phagocytic defenses. The likelihood that a patient with or without underlying valvular heart disease may develop IE depends on the species and concentration of microorganisms in the blood, the duration of the bloodstream invasion, the presence or absence of antimicrobial agents in serum at the time of bacteremia/fungemia, and the characteristics of the endocardium. Clearly, some microorganisms are much more likely to adhere to endocardium than others. *Staphylococcus aureus,* enterococci, and other streptococci are most adherent. Enteric gram-negative bacilli and anaerobic microorganisms are less so. Since *S. aureus* is adherent and invasive, is found commonly on the skin, and causes skin infection that can result in transient bacteremia, this organism is associated with acute bacterial endocarditis, even in patients without significant underlying valvular heart disease. *Viridans*-type streptococci, which are normal flora of the upper airway, may gain access to the bloodstream from trauma to the teeth or gingiva (as in dental work) and cause IE nearly always in a patient with a significant predisposing valvular abnormality. Many distinctions between acute and subacute endocarditis are blurred. Enteric gram-negative organisms, because they are much less adherent to endocardium, cause fewer cases of endocarditis relative to the frequency of bacteremia caused by these organisms. However, gram-negative organisms that have a greater propensity to adhere to surfaces, such as *Pseudomonas aeruginosa,* and that can gain access to the circulation via contaminated intravenous injections (as in drug abusers) or infection at other body sites produce a significant proportion of cases. The most common nosocomial pathogenesis of IE in critically ill patients is from central venous catheters, with peripheral IVs and urologic instrumentation also identified as sources.[1–4]

CLINICAL AND LABORATORY FEATURES

Table 49-2 lists the most common signs and symptoms encountered in patients with native-valve IE. Table 49-3 lists the most commonly encountered laboratory abnormalities. Because most reports stress community-acquired disease, patients developing IE while hospitalized in an ICU may not manifest identical findings. Fernandez-Guerrero and colleagues[1] reported fever in 100% of patients with hospital-acquired IE. A murmur was present in only 20% of patients with vascular catheter–associated IE but was present in 75% of patients with IE following a urologic procedure. Still, fever and a heart murmur are the most common findings in IE; both are found in at least 80% of patients with community-acquired left-sided IE. The incidence is less in patients with right-sided disease only.[5]

A number of peripheral manifestations may be present in patients with IE. A number of skin lesions occur, petechiae

TABLE 49-1 Intravascular Infection of Native Vessels and Implanted Intravascular Devices

Site	Infectious Disorder	Comment
Medium and large arteries	Mycotic aneurysm	Abdominal aortic aneurysms; various sites complicating endocarditis
Intracranial	Cavernous sinus thrombosis	Follows facial cellulitis, *Staphylococcus aureus* common etiology
Heart and major vessels	Native-valve endocarditis	Usually occurs at site of prior endocardial damage
	Prosthetic-valve endocarditis	Risk of infection on mitral equals aortic valve risk
	Permanent pacemaker infection	Risks include diabetes, malignancy, corticosteroid use, bacteremia, or skin erosion over generator box
	Arterial graft infection	Increased risk if graft crosses groin; risk greatest in first year after placement
Head and neck venous structures	Postanginal sepsis	*Fusobacterium, Bacteroides* common; metastatic disease frequent
Pelvic veins	Pelvic vein thrombophlebitis	Following septic abortion, pelvic inflammatory disease in women
Portal veins	Pylephlebitis	Complication of intra-abdominal abscess; perforated appendix, peridiverticular abscess, etc.

being most common. These are 1- to 2-mm red, nonblanching macules that become darker and fade within 2 to 3 days. These are seen in less than 50% of patients but, when present, are seen most often on the conjunctiva, soft palate, and distal portions of the extremities.[6] Vascular hemorrhages in the optic fundus are referred to as *Roth spots.* Splinter hemorrhages are vascular hemorrhages occurring under the nails, and often they are difficult to distinguish from traumatic lesions. Splinter hemorrhages due to trauma are more common and are more typically an isolated finding. Osler nodes are erythematous, tender subcutaneous papules that occur on the finger pads (Fig. 49-1 and Color Figure 49-1). They are 2 to 5 mm in diameter and may be multiple. Janeway lesions are painless, erythematous macules, larger than Osler nodes, that occur on the palms and soles (Fig. 49-2 and Color Figure 49-2). It is unclear whether Osler nodes and Janeway lesions are due to septic emboli directly or to immunologic phenomena.

Systemic emboli occur in approximately 40% of patients with left-sided valvular infection. In the central nervous system (CNS), embolic occlusion of peripheral arteries results in the stroke syndrome. Emboli to the spleen and kidney often cause abdominal pain. Emboli to mesenteric arteries may cause ischemic bowel disease or frank infarction of bowel. Emboli to muscles are common but usually clinically unapparent. Embolic disease can occur after the institution of antibiotics; patients at increased risk for this complication include those with embolic disease prior to the institution of antibiotics, those with larger vegetations, those with mitral valve involvement, and those infected with staphylococci.[7] Drug abusers with right-sided IE frequently have evidence of septic pulmonary emboli on chest x-ray.[5]

Patients with IE also may present with heart failure due to valve malfunction, embolic myocardial infarction, myocarditis, or systemic toxicity owing to sepsis syndrome. Renal insufficiency is also a prominent sequela of untreated IE, whether occurring on a native or prosthetic valve.

Disorders of the CNS are prominent in patients with IE. Between 10% and 50% of patients with IE will develop some neurologic abnormality. Mental status changes such as confusion, delirium, and psychosis are most common. Focal neurologic symptoms and signs may be caused by an embolic stroke, a bleeding mycotic aneurysm, meningitis, or cerebral artery vasculitis. Overall, approximately 30% of patients with IE will have evidence of a focal neurologic event during their illness.

Anemia is common in patients with IE. Leukocytosis occurs in about 40% of patients. Changes in the renal sediment, particularly proteinuria and microscopic hematuria, usually are present in patients with IE. In long-standing disease, rheumatoid factor is present in about one-half of patients.

TABLE 49-2 Frequency of Symptoms and Signs at Presentation of Infective Endocarditis

Symptoms	Frequency, %	Signs	Frequency, %
Fever	85	Fever	95
Malaise	25	Murmur	85

DIAGNOSIS

Blood cultures are the most important laboratory tests in the diagnosis of IE. The vast majority of blood cultures obtained when a patient is not receiving antimicrobial therapy will be positive. In approximately 5% to 10% of patients with presumed IE, no etiologic organism is isolated initially. The causes of culture-negative endocarditis are prior antibiotics and endocarditis due to fastidious organisms, including anaerobes, nutritionally deficient streptococci, *Coxiella burnetii, Legionella pneumophila, Chlamydia psittaci, C. pneumoniae,* members of the HACEK group, and various fungi. *HACEK* is an acronym for a group of small, fastidious, gram-negative bacilli that includes *Haemophilus* spp., *Actinobacillus actinomycetemcomitans, Cardiobacterium hominis, Eikenella corrodens,* and *Kingella kingae*.[8] Longer incubation of cultures, special culture techniques to aid in isolation of fastidious microorganisms, and use of serologic studies for *Coxiella, Bartonella,* and *Chlamydia* may aid in diagnosis. Other potentially useful laboratory techniques currently under study for intravascular infections and endocarditis include the urinary histoplasmosis antigen, polymerase chain reaction (PCR) using universal bacterial (16S) and fungal (18S, 28S, and 5.8S) RNA primers,[9] and serology for lipid S, a component of the gram-positive cell wall.[10]

FIGURE 49-2 Osler's nodes: randomly distributed tender nodules on the palm of the hand in a patient with *Staphylococcus aureus* endocarditis. (See Color Plate 49-2.)

Echocardiography is useful in identifying vegetations or local complications of IE. Transthoracic echocardiography has around 60% sensitivity in detecting vegetations in IE. Transesophageal echocardiography (TEE) has emerged as a major tool in the diagnosis and management of native-valve endocarditis (NVE). The sensitivity of TEE in the diagnosis of NVE is 90% to 99%, with a specificity of 90%. Therefore, when NVE is likely clinically but blood cultures are sterile, a TEE may be obtained to assist in diagnosis.[11–13] A TEE also should be obtained in patients with an equivocal transthoracic echocardiogram (TTE) or those with a complicated course. One study has suggested that if the pretest probability of IE is between 4% and 60%, it is cost-effective to proceed to TEE without TTE.[15] Durack and colleagues[12] have proposed criteria for diagnosis of infective endocarditis, and they have been proved useful by other investigators.[13] Finally, intracardiac echocardiography is an emerging diagnostic tool that has been used to identify pacemaker lead vegetations even in patients whose TEE is unremarkable.[16]

MANAGEMENT

Patients encountered in the ICU with fever, cardiac murmurs, or other findings suggesting the possibility of IE always should be evaluated for the possibility of valve infection; this evaluation should include multiple blood cultures and echocardiography. While this evaluation proceeds, two central questions arise: Which clinical situations warrant empirical antimicrobial therapy, and what empirical therapy should be selected? In general, physicians managing patients with *possible* IE should initiate therapy when one of the following situations is present: (1**)** the patient is critically ill, (2) antimicrobial therapy appears be necessary for some other infectious disorder, (3) early valve replacement is contemplated because of valve malfunction, and (4) IE is suspected clinically and one or more blood cultures are positive for an etiologic microorganism.

In patients with undiagnosed fever or other findings suggesting IE as a diagnostic consideration but without any of these indications for immediate therapy, withholding antimicrobials is reasonable until blood cultures and the results of other investigations provide support for the diagnosis.

In centers with lower rates of methicillin-resistant *S. aureus* (MRSA), it is still reasonable to initiate therapy with IV nafcillin at 2 g every 4 hours plus IV ampicillin at 2 g every 4 hours and gentamicin. Gentamicin doses should be at lower levels (1 mg/kg q8h) because synergistic killing with β-lactam agents does not require conventional gentamicin dosage. In the many hospitals and communities where increasing rates of infection with MRSA have been identified, empirical therapy with vancomycin rather than nafcillin should be considered. However, this regimen may not be adequate for IE secondary to vancomycin-resistant enterococci (VRE), which are being reported from many centers. Newer agents, such as linezolid and quinupristin-dalfopristin (*faeceium* isolates only), may be useful alternatives if VRE are identified and other agents, especially ampicillin, are also unavailable because of resistance profiles.[14]

TABLE 49-4 Etiology and Valve Involvement in Native-Valve Endocarditis

Microorganism	Percentage

Enterococci	7
Staphylococcus aureus	25
Staphylococcus epidermidis	6
Gram-negative bacilli	6
Fungi	1
Culture negative	7
Distribution of valvular lesions:	
Aortic	35–50
Mitral	50
Tricuspid	10
Pulmonic	1

In a febrile patient without the usual risk factors for coronary artery disease admitted with acute myocardial infarction, careful consideration of a diagnosis of IE should be undertaken prior to the administration of thrombolytics because catastrophic CNS bleeds from ruptured mycotic aneurysms have been reported.[17]

In patients with an established diagnosis of IE, management entails a careful choice of antimicrobial therapy based on identification of the etiologic microorganism and ongoing consideration of surgical measures that may be necessary. Table 49-4 lists the most common etiologic microorganisms causing community-acquired NVE and the valves involved. Staphylococci, enterococci, and *Candida* are the most common microorganisms responsible for nosocomial IE.[1] Table 49-5 describes the recommended antimicrobial regimens for treatment of IE. Certain principles are followed when treating patients with IE. Parenteral antibiotics are preferred over oral agents because of more sustained antibacterial activity associated with IV antibiotics and erratic absorption associated with many oral drugs. Bactericidal agents are superior to bacteriostatic drugs. Long-term antimicrobial therapy almost always is required for cure. However, 2 weeks of antibiotics may be adequate in selected patients with uncomplicated *viridans* streptococcal IE or staphylococcal IE of the tricuspid valve.[18,19] Determination of minimal inhibitory concentrations (MICs) and minimal bactericidal concentrations (MBCs) of antimicrobial agents necessary to inhibit or kill the microorganism, respectively, are useful in choosing treatment regimens in patients with streptococcal or enterococcal infections. The serum bactericidal test (Schlicter test) is a measurement of antibacterial activity of the patient's serum, at peak and trough antimicrobial concentrations, against the patient's microorganisms. This test remains somewhat controversial. However, some investigators believe that a peak serum inhibitory concentration (SIC) of 1:8 or greater is more likely to be associated with successful treatment of IE.

Valve replacement may be life-saving in patients with IE. Indications for urgent valve replacement include severe heart failure, valvular obstruction, fungal endocarditis, ineffective antimicrobial therapy, and the presence of an unstable prosthetic device.[20] A point system to aid in evaluation of the need for surgical intervention in IE has been described.[21] The various complications that develop during IE are assigned a weighted point value according to their importance as indicators for valve replacement. A total of five or more points indicates the need for urgent surgery. Table 49-6 lists the conditions associated with need for valve replacement and their relative point ratings. Severe heart failure is considered heart failure that does not respond to maximal medical therapy (see Chaps. 22 and 23). Moderate heart failure is failure that is still present after routine but not maximal medical therapy.

PROGNOSIS

The outcome of treatment for IE is heavily influenced by the relative pathogenicity of the infecting organism, the location of the infected valve, and the presence of complications of the infection. *S. aureus* typically produces a severe and destructive endocarditis that is fatal in more than a third of patients when the infection occurs on the aortic or mitral valve. In patients with tricuspid valve endocarditis, as typically occurs in intravenous drug users, the prognosis is substantially better.[5] Recent data indicate that patients with large (>1 cm) vegetations have an increased morbidity and mortality.[22] Other factors associated with worse prognosis include mitral valve involvement, severe cardiac failure, shock, major arterial emboli, myocardial abscess formation, and associated major organ system failure. As noted earlier, several of these would constitute indications for surgical intervention.

ANTIMICROBIAL PROPHYLAXIS

Prevention of IE in susceptible individuals has been emphasized for many years because of the significant morbidity and mortality associated with the disease. Prophylactic antimicrobial therapy is based on evidence suggesting that bacteremia commonly occurs during certain procedures and that certain cardiac abnormalities place patients at an increased risk for the development of IE following bacteremia. Procedures most frequently associated with bacteremia and for which prophylaxis is recommended include dental extractions, periodontal surgery, lower gastrointestinal procedures, and genitourinary procedures. Bronchoscopy, endoscopy, and barium enemas are also associated with bacteremia but much less commonly, and none of these procedures routinely justifies antimicrobial prophylaxis. Most of the common procedures carried out in ICUs, including endotracheal intubation, urethral catheterization, and insertion of central vascular catheters percutaneously, pose little risk of bacteremia and do not require prophylaxis (except for urethral catheterization in the presence of a urinary tract infection).

Cardiac abnormalities that appear to especially predispose patients to IE following bacteremia include significant aortic and mitral valve deformity/disease, unrepaired ventricular septal defects, patent ductus arteriosus, coarctation of the aorta, prosthetic heart valves, and previously infected native valves. Patients with atrial septal defects, cardiac pacemakers, and atherosclerotic lesions are at much less risk. Mitral valve prolapse with a systolic murmur and/or redundancy of the valve seen on echocardiogram may be an indication for prophylaxis.

The specific antimicrobial agents chosen for prophylaxis depend on the specific procedure to be performed, the cardiac abnormality present, and the presence or absence of penicillin allergy (Table 49-7). In critically ill patients with underlying cardiac abnormalities who are undergoing procedures with a risk of bacteremia, a parenteral regimen usually is appropriate.

TABLE 49-5 Antimicrobial Therapy for Infective Endocarditis and Other Intravascular Infections[a]

Organism	Recommended Therapy	Penicillin-Allergic
1. Penicillin-sensitive streptococci (MIC □ 0.1)	Penicillin G 10–20 million units IV qd for 4 wks *plus* aminoglycoside[c] for first 2 wks (streptomycin 7.5 mg/kg [< or = 500 mg] IM q12h *OR* Gentamicin 1.0 mg/kg IM or IV q8h	Cefazolin 2 g IV q8h for 4 wks[b] *plus* aminoglycoside for 2 weeks Ceftriaxone 2 g IV qd for 4 wks
2. Relatively "resistant" streptococci (Penicillin MIC-0.2–0.5)	Penicillin G 20 million units/d for 4 wks plus aminoglycoside[d] for 4 wks	Cefazolin 2 g IV q8h for 4 weeks[b] *plus* aminoglycoside for 4 wks
3. Resistant streptococci and enterococci (MIC > 0.5)	Penicillin G 20–30 million units IV qd for 6 wks (ampicillin 12 g IV qd is alternative) *plus* aminoglycoside[d] for 6 wks[b]	Vancomycin 30 mg/kg qd for 6 wks[a]
4. Staphylococci (methicillin-sensitive)—in absence of prosthetic valve	Nafcillin 2.0 g IV q4h for 4–6 wks[e] *or* nafcillin 2 g IV q4h *or* gentamicin 1 mg/kg q8h for 2 wks[h]	Cefazolin 2 g IV q8h for 4–6 wks[b]
5. Methicillin-resistant staphylococci—in absence of prosthetic valve	Vancomycin 30 mg/kg IV per day +/− rifampin 300 mg PO q8h for 6 wks	Same
6. Staphylococci (methicillin-sensitive)	Nafcillin 2.0 g IV q4h for 6–8 wks *plus* rifampin 300 mg[f] PO q8h for 6–8 wks *plus* aminoglycoside for 2 wks	Cefazolin 2 g IV[b] q8h for 6–8 wks *plus* rifampin[f] plus aminoglycoside for 2 wks
7. Staphylococci (methicillin-resistant)—in presence of prosthetic valve	Vancomycin 30 mg/kg 24h IV for 6–8 wks, rifampin 300 mg q8h for 6–8 wks[f] *plus* aminoglycoside for 2 wks	Same
8. *Corynebacterium*	Penicillin G 20–30 million units IV qd for 6 wks *plus* aminoglycoside for 6 wks	Vancomycin 30 mg/kg qd IV for 6 wks
9. Gram-negative bacilli Enterobacteriaceae	Therapy should be directed by in vitro susceptibilities	Same
Pseudomonas	Therapy should be directed by in vitro susceptibilities, though usual regimen includes tobramycin (8 mg/kg per day) plus extended-spectrum penicillin	Same, though ceftazidime *plus* tobramycin (8 mg/kg per day) frequently used
HACEK group	Ampicillin 2.0 g IV q4h is commonly used, though therapy should be directed by in vitro susceptibilities (aminoglycoside frequently used in combination)	Third-generation cephalosporins (e.g., ceftriaxone 2g IV qd for 4 wks)
10. Rickettsia *Coxiella burnetti*	Tetracycline 500 mg PO q6h for at least 1 yr *plus* trimethoprim 480 mg plus sulfamethoxazole 2400 mg qd until there is no evidence clinically of disease or phase I antibody titer is < .1:128	Same
11. Fungal	Amphotericin B plus surgery	Same

[a] Duration of treatment given applies to native-valve infective endocarditis only.
[b] If patient sensitivity to penicillin is of the immediate hypersensitivity type, vancomycin is recommended.
[c] Aqueous crystalline penicillin G should be used alone in patients over 65 years of age or in those who have renal disease or hearing impairment.
[d] Choice of aminoglycoside should depend on in vitro susceptibilities.
[e] Addition of an aminoglycoside is optional.
[f] Use of rifampin in coagulase-negative staphylococcal infection is recommended. The value of rifampin in coagulase-positive staphylococcal infections is controversial.
[g] Vancomycin is indicated for penicillin-resistant strains; consult when treating vancomycin-resistant strains.
[h] Optional in uncomplicated right-sided IE in intravenous drug users.

MYCOTIC ANEURYSM

PATHOGENESIS AND MICROBIAL ETIOLOGY

Mycotic aneurysms are aneurysmal dilations of arteries caused by infection of the vessel wall with consequent weakening of the vessel's structure. These aneurysms occur most commonly in patients with IE and in that instance usually involve vessels of smaller caliber. The pathogenesis probably involves embolic localization of a valvular vegetation with extension of suppuration from the lumen circumferentially into the vessel wall. Another proposed mechanism is embolization of the vasa vasorum by infected material from the valve. In the absence of underlying IE, mycotic aneurysm may occur following transient bacteremia with seeding of a previously damaged site in a large artery, most commonly an

TABLE 49-6 Point System for Assessing the Need for Cardiac Surgery in Infective Endocarditis

Complication	POINT RATING[a] Native-Valve IE	Prosthetic-Valve IE

ulcerated atherosclerotic plaque in the abdominal aorta. Mycotic aneurysms also may occur in intravenous drug abusers who both damage and contaminate the wall of a large artery by direct intra-arterial injections of drugs; mycotic aneurysms of the lower extremity, particularly the femoral artery, are most common in this population.

Endocarditis-associated mycotic aneurysms are caused by the same microorganisms causing the IE—streptococci, staphylococci, and occasionally, gram-negative enteric bacilli, the latter being more common among drug abusers. *S. aureus* and *Salmonella* spp. are the most frequent causes of mycotic aneurysms of the abdominal aorta and usually are not associated with IE.

CLINICAL FEATURES

Intracranial mycotic aneurysms are encountered most commonly in patients who already carry a diagnosis of IE. These aneurysms usually are asymptomatic unless they rupture. In that circumstance, symptoms and signs are consistent with subarachnoid or intracerebral hemorrhage, with sudden onset of severe headache, decrease in the level of consciousness, and focal neurologic signs. Mycotic aneurysms of visceral arteries have a variable presentation based on the organ involved. In the case of the small bowel, there may be colicky abdominal pain and symptoms of small-bowel obstruction. In the case of hepatic arterial aneurysms, an important differential diagnostic consideration is ascending cholangitis because of fever, right upper quadrant pain, and jaundice. Mycotic aneurysms of the external iliac artery may present with pain in the lower anterior abdomen, quadriceps wasting, diminished deep tendon reflexes, and arterial insufficiency of the ipsilateral lower extremity.[23]

Patients with mycotic aneurysms of the abdominal aorta present with pain and fever, often of weeks' or months' duration. In as many as one-third of patients with abdominal aortic aneurysms, there is extension into the lumbar or thoracic vertebrae with resulting osteomyelitis. Aortoenteric fistula may occur if an aneurysm erodes into bowel lumen. On physical examination, in addition to fever, there may be a palpable mass in the abdomen.

DIAGNOSIS

In patients with IE, clinical suspicion of a mycotic aneurysm usually arises after an episode of new neurologic symptoms in the case of intracranial aneurysms or local findings suggestive of aneurysms, as noted earlier. Clinical suspicion of a leaking intracerebral aneurysm should prompt contrast- and non–contrasted-enhanced computed tomographic (CT) examinations initially; however, an angiogram generally is necessary to exclude or confirm the diagnosis. The diagnosis of mycotic aneurysm of the abdominal aorta is also made on the basis of clinical suspicion, demonstration of bacteremia, and radiologic examination. CT scan of the abdomen may indicate a perivascular collection of fluid or actual blood in an aneurysm or pseudoaneurysm. Arteriography also may be helpful in demonstrating an aortic mycotic aneurysm, and bone films may show erosion of adjacent vertebral bodies.

MANAGEMENT

The management of mycotic aneurysm depends on the organ involved. In the case of intracranial mycotic aneurysms, there

TABLE 49-7 Endocarditis Prophylaxis

Procedure	Standard Regimen	Standard Oral Regimen for PCN-Allergic Patients	Alternative Parenteral Regimens
Dental or respiratory tract procedure	Amoxicillin 3.0 g PO 1 h before, then 1.5 g 6 h later	Erythromycin 1.0 g PO 2 h before, then 500 mg 6 h later *or* clindamycin 300 mg PO 1 h before, then 150 mg 6 h later	Ampicillin 2.0 g IV or IM 30 min before, then 1.0 g 6 h later *or* clindamycin 300 mg IV 30 min before, then 150 mg 6 h later *or* vancomycin 1.0 g IV over 1 h
Gastrointestinal or genitourinary tract procedure	Ampicillin 2.0 g IV or IM *plus* gentamicin 1.5 mg/kg of body weight IV or IM given 30 min before, repeat 8 h later		Vancomycin 1.0 g IV slowly over 1 h, *plus* gentamicin 1.5 mg/kg of body weight IV or IM, given 1 h before, repeat 8 h later

TABLE 49-8 Recommended Duration of Antimicrobial Therapy for Patients with Various Intravascular Infections

	PATIENTS WITHOUT INTRAVASCULAR FOREIGN BODIES
Infectious Disorder	Duration of Treatment
Cavernous sinus thrombosis	2 weeks following the resolution of all signs of the disease (usually 4 weeks)
Mycotic aneurysm	4–6 weeks; 2–4 weeks after resection of the aneurysm
Postanginal sepsis	4 weeks or 10 days following resolution of local symptoms and signs
Pelvic vein thrombophlebitis	4 weeks (consider anticoagulation)
Pylephlebitis	4–6 weeks; if associated with liver abscess, consider additional treatment until abscess is resolved

is debate regarding the most appropriate therapy. For peripheral intracranial aneurysms, clipping probably is indicated. For deep lesions, for which a surgical approach is felt to be hazardous, antimicrobial therapy alone is advisable because many aneurysms will resolve spontaneously with medical treatment. A history of bleeding, large aneurysm size, and persistence of the aneurysm following antimicrobial therapy are all factors that increase the advisability of surgery for accessible lesions. In the case of abdominal aortic aneurysms, surgical resection of the involved aorta is almost always necessary. Antimicrobial therapy for mycotic aneurysms and other intravascular infections without foreign bodies is outlined in Tables 49-5 and 49-8.

CAVERNOUS SINUS THROMBOSIS

Cavernous sinus thrombosis usually results from direct spread of bacteria from a contiguous focus of infection. Extension of bacteria may occur by several routes, including septic thrombophlebitis of the angular and ophthalmic veins from facial cellulitis, along the lateral sinus and petrosal sinuses from middle ear infections, via the pterygoid venous plexus from a peritonsillar abscess, following a dental infection from osteomyelitis of the maxilla or from a cervical abscess, and along the venous plexus surrounding the internal carotid artery from the middle ear or jugular bulb.

S. aureus is the cause of cavernous sinus thrombosis in about 60% to 70% of patients. Streptococci, anaerobes, and other aerobes account for most of the rest.[24] Patients with cavernous sinus thrombosis generally present with the early onset of external ophthalmoplegia with decreased sensation around the eye. The physical examination reveals periorbital edema and chemosis, and as the illness develops, meningismus, altered mental status, and cranial nerve palsies, especially of cranial nerves III, IV, V, and VI, become evident. Examination of the fundus often reveals striking venous congestion. The differential diagnosis of cavernous sinus thrombosis includes orbital cellulitis and rhinocerebral phycomycosis (mucormycosis). The distinction between cavernous sinus thrombosis and orbital cellulitis is sometimes difficult. Bilateral involvement and fifth nerve palsy, a fixed, dilated pupil, and signs of meningitis are all more likely in cavernous sinus thrombosis than in orbital cellulitis.

Although the diagnosis may be evident on clinical grounds alone, several imaging modalities can be useful. Ultrasound examination of the orbit can be useful in defining a periorbital abscess that may require surgical intervention. CT examination with contrast or MRI also can aid in this, will be useful in demonstrating sinusitis or underlying osteomyelitis, and may establish the diagnosis of cavernous sinus thrombosis as well. Carotid angiography and orbital venography also have been used to establish the diagnosis but are not recommended because they are unlikely to influence management. Following CT scan, a lumbar puncture is warranted, but it is usually sterile (80%)[24] with a parameningeal inflammatory pattern: pleocytosis and elevated protein without significant hypoglycorrhachia. Blood cultures are mandatory and often are positive (70%)[24]; if sinus or abscess drainage is performed, fluid should be cultured for both aerobic and anaerobic bacteria. When rhinocerebral mucormycosis is a consideration, usually in a diabetic patient with blackish nasal discharge in addition to the rest of the syndrome, surgical exploration with biopsy and histologic examination for fungi is needed to establish the diagnosis.

Successful management of cavernous sinus thrombosis depends on early, effective antimicrobial therapy. Even with the best medical and surgical therapy, the outcome is often unsatisfactory. For this reason, adjunctive therapies such as corticosteroids and anticoagulation have been tried without success, and they cannot be recommended. The regimens shown in Tables 49-5 and 49-8 can be used when a bacterial etiology has been established. Prior to bacteriologic confirmation, empirical therapy depends on the underlying infection suspected.

POSTANGINAL SEPSIS

In 1936, in an article entitled, "On Certain Septicemias Due to Anaerobic Organisms," Lemierre[25] described a group of patients with pharyngitis complicated by bacteremia due to anaerobic microorganisms. Subsequently, this disorder, usually referred to as *postanginal sepsis,* has been described frequently.[26] The pathogenesis is thought to involve bacterial invasion of the mucosa of the posterior pharynx with extension of suppurative thrombophlebitis (ST) into the internal jugular veins. Bacteremic spread of the infection is common, with lung, liver, and joints the most common sites of metastatic disease. Clinically, patients present with sore throat, chills, fever, and occasionally jaundice. On physical examination, in addition to the toxicity and fever, there may be palpable tender thrombosis of the jugular vein as well as evidence of septic arthritis, pleuropulmonary disease, or jaundice. An enhanced CT scan usually will demonstrate internal jugular vein thrombophlebitis and is useful to localize purulent collections requiring drainage. Chest radiograph may show scattered infiltrates owing to septic pulmonary emboli. *Fusobacterium necrophorum* has been isolated most commonly from blood, although *Bacteroides fragilis* and other mouth anaerobes have been reported as well.

Management includes early recognition and treatment of the disorder with effective antimicrobial therapy. Antibiotics should be directed against anaerobic bacteria, with drugs such as metronidazole, chloramphenicol, imipenem-cilastatin, or ticarcillin-clavulanic acid. Prompt surgical intervention to

drain any purulent material present locally or distantly is required in addition to antibiotics.

SEPTIC PELVIC VEIN THROMBOPHLEBITIS

Pelvic vein thrombophlebitis develops most often 1 to 2 weeks after delivery or gynecologic surgical intervention or in the setting of pelvic suppuration, such as following septic abortion or post–Cesarean section endometritis. Symptoms include fever, chills, anorexia, nausea, vomiting, and abdominal pain.[27] On physical examination, there may be tenderness in the lower quadrants, and tender venous structures may be palpated in one-third of patients.[28] Eighty percent of pelvic vein thromboses complicating pregnancy and delivery occur on the right side, perhaps because of compression of the right ovarian vein at the pelvic brim by the enlarged uterus. In 5% of episodes, thrombosis is apparent only on the left, and in 14%, it is bilateral. Spread distally to femoral veins is unusual.

The most serious complication of suppurative pelvic vein thrombosis is pulmonary embolization. When this occurs, the patient presents with respiratory distress associated with pulmonary opacities that often are pleural-based. Even though the process is associated with thrombosis and bacterial suppuration in the venous lumen, bacteremia is unusual, with an overall prevalence of only 30%. Microorganisms isolated from the blood, or from the veins if surgery is carried out, include those that are normally present in the pelvis, particularly *Peptostreptococcus* spp., *Peptococcus* spp., *B. fragilis,* aerobic gram-negative bacilli such as *Escherichia coli, Klebsiella,* and *Enterobacter,* group A and group B β-hemolytic streptococci, and rarely, staphylococci.

The diagnosis can be difficult because the findings are similar to a wider range of other pelvic and lower abdominal inflammatory conditions. Probably the best imaging modality to support the diagnosis is contrast-enhanced CT scan; ultrasound examination also may be useful if the intravascular thrombus can be demonstrated.

Successful treatment frequently requires both antimicrobial therapy and heparinization; indeed, in the appropriate clinical context, fever that is failing to respond to apparently appropriate antimicrobials and that responds to the addition of intravenous heparin can be regarded as support for the diagnosis.[29] Complications are mainly those related to suppurative pulmonary emboli.

PYLEPHLEBITIS

Pylephlebitis is septic thrombosis of the portal vein and its branches. It is a rarely seen complication of intra-abdominal suppuration and was first described in patients with appendicitis or diverticulitis. The illness evolves in three phases. In the first phase, symptoms and signs of the original intra-abdominal disorder such as acute appendicitis or perforated diverticulum predominate. The second phase involves portal bacteremia, with resulting invasion and thrombosis of portal veins. In the third phase, abscesses form in the liver owing to proximal spread of the suppurative material. Late signs and symptoms include fever, abdominal pain, jaundice, and right upper quadrant tenderness. The liver is enlarged in one-half of patients. Laboratory studies reveal an elevated white blood cell count with increased numbers of immature granulocytes and abnormal liver function tests, particularly elevations of the alkaline phosphatase and aspartate aminotransferase (AST) levels. Bacteremia is not a consistent finding. CT scan is especially useful in demonstrating this disorder, showing clot in the portal veins and occasionally gas in portal vein radicals in the liver. The microorganisms responsible reflect large bowel flora and include aerobic gram-negative bacilli such as *E. coli, Klebsiella,* and *Enterobacter;* anaerobic microorganisms such as *Peptococcus, Peptostreptococcus, B. fragilis,* and *Fusobacterium;* and gram-positive aerobic species such as staphylococci and enterococci.

Successful therapy requires surgical correction of the primary problem, as well as high-dose antibacterial therapy directed against the offending pathogens. Pyogenic liver abscesses resulting from this disorder usually are best treated with prolonged medical therapy alone, unless they are few and relatively large, in which case percutaneous drainage may be useful. Surgical drainage of multiple small abscesses is very difficult, often requires a transperitoneal approach, and is not recommended. The effectiveness of antibacterial therapy may be judged by physical examination, resolution of fever and leukocytosis, and improvement of abnormalities demonstrated by ultrasound or CT scan.

Infections of Intravascular Prosthetic Devices

PROSTHETIC VALVE ENDOCARDITIS

PATHOGENESIS AND MICROBIOLOGY

Prosthetic heart valves may become infected early following implantation or later during the life of the device. Overall, about 2% of patients with prosthetic heart valves become infected, one-third in the first few months after valve implantation and two-thirds later. In early prosthetic valve endocarditis (PVE), the presumed pathogenesis involves inoculation of the operative site at the time of surgery or the localization of microorganisms on the new device following transient bacteremia associated with indwelling lines used in the perioperative period. Factors associated with an increased risk of PVE include IE of the native valve prior to valve resection and replacement, use of a mechanical valvular device in contrast to a tissue heterograft or homograft, a history of intravenous drug abuse, male gender (possibly because of the greater likelihood of superficial cellulitis as a result of shaving prior to surgery), and longer cardiopulmonary bypass time.[30]

In late PVE, i.e., disease appearing more than 12 months after replacement, the pathogenesis more closely resembles that of native-valve disease.[31] Extension of local tissue disease via lymphatics to the bloodstream or direct inoculation of microorganisms via capillary beds, as occurs during dental work, results in transient bacteremia with localization on the prosthetic device. Nosocomial PVE is acquired most commonly via intravascular devices but may be initiated by cutaneous and other infections as well.[32]

Microorganisms most commonly responsible for PVE are listed in Table 49-9. *Staphylococcus epidermidis* is the most common cause of early PVE. *S. aureus* and gram-negative bacilli are also prominent etiologic microorganisms during this period. Other less commonly encountered microorganisms are enterococci, other streptococci, and yeast. Microorganisms found in patients with late PVE tend to be similar to those seen in native-valve disease. *Viridans* streptococci

TABLE 49-9 Etiology of Prosthetic-Valve Endocarditis

Microorganism	Early PVE, %	Late PVE, %
Staphylococci		
S. epidermidis	30	20
S. aureus	20	11
Streptococci		
Group D streptococci	5	12
Viridans streptococci	4	25
Gram-negative bacilli	20	12
Corynebacterium (not *C. diphtheriae*)	8	3
Fungi	10	5
Other or culture-negative	3	12

are common, as is *S. aureus; S. epidermidis* and gram-negative bacilli are less common. Nosocomial PVE is most commonly due to staphylococci, *epidermidis* followed by *aureus;* enterococci, gram-negative bacilli, *Candida,* and *viridans* streptococci are less common pathogens.[32]

CLINICAL FEATURES

The signs, symptoms, and clinical laboratory abnormalities seen in PVE generally are similar to those encountered in patients with NVE, except that patients with PVE have a higher prevalence of cardiac complications. Clinical evidence of these cardiac complications may include new and changing regurgitant murmurs caused by paravalvular leak from dehiscence of the valve ring, intraventricular and atrioventricular conduction defects resulting from extension of a paravalvular abscess into the interventricular septum, and muffling of prosthetic heart sounds or new stenotic murmurs related to malfunction of the valve caused by a vegetation. Fang and colleagues [31] reported on patients with nosocomial PVE having peripheral stigmata in 20%, splenomegaly in 5%, stroke in 3%, and a new or changing murmur in 31%.

DIAGNOSIS

Diagnostic difficulty arises in the immediate postoperative period when bacteremia occurs in a patient with a new prosthetic valve. In this setting, blood cultures yielding staphylococci, "diphtheroids," and yeasts are more likely to represent true prosthetic valve infection than is gram-negative bacilli bacteremia, which more likely results from indwelling venous catheter infection.

In patients with late PVE caused by staphylococci or streptococci, bacteria usually are recovered consistently from blood cultures, provided that the patient has not received prior antimicrobial therapy. Generally, three sets of blood cultures obtained over a brief period from different venipuncture sites are sufficient to identify the etiology of prosthetic valve infection. Echocardiography helps identify vegetations and local suppurative complications, as well as determine ventricular function and valvular integrity, although the metallic devices tend to result in distorted echo signals, confusing the interpretation. TEE is superior to TTE in visualizing the mitral valve; visualization of aortic valve prostheses with TEE is less clear. The reported sensitivity and specificity of TEE for detection of morphologic abnormalities are 86% and 88%, respectively.[11] Patients with neurologic symptoms associated with PVE also should undergo a contrast-enhanced CT scan of the head to detect embolic hemorrhagic infarcts and abscesses. Since a CT scan does not reliably exclude mycotic aneurysm, cerebral angiography also may be indicated when CT findings do not explain the neurologic symptoms adequately.

MANAGEMENT

The same principles described for the treatment of NVE apply for the treatment of PVE.[33] The antimicrobial agents used in the treatment of PVE are outlined in Table 49-5. In general, initial antimicrobial therapy is chosen on the basis of identification and susceptibility tests of the infecting microorganism. When the infecting microorganism has not been identified, initial therapy should include vancomycin and gentamicin to cover the likely possibilities of *S. epidermidis, S. aureus,* and streptococci. This combination would cover most nosocomial pathogens as well; however, the choice of antibiotics also should be determined by the usual organisms encountered at the specific hospital environ. In addition, previous or current antibiotic use should be considered when choosing an empirical regimen, especially for nosocomial PVE. Ill, bacteremic patients who may have IE should be treated without delay. In addition, if heart surgery is scheduled because of valve deterioration or antimicrobial therapy is required for some other indication in a patient with suspected endocarditis, therapy should be initiated without waiting for the results of blood cultures. Relative indications for valve replacement in PVE include early PVE, nonstreptococcal late PVE, and periprosthetic leak. Patients with PVE should be treated for 6 to 8 weeks in most instances whether or not the valve is removed. If microorganisms can be cultured at the time of valve replacement, we recommend 6 to 8 additional weeks of therapy beginning at that time.

CARDIAC PACEMAKER INFECTIONS

Four major varieties of pacemakers are presently in use: transvenous and epicardial temporary pacemakers with external generators and transvenous and epicardial pacemakers of the permanent variety with implanted generator boxes. The pathogenesis and management of infections of temporary transvenous pacemakers are essentially identical to those for other percutaneous central vascular catheters and are not discussed further here (see Chap. 50). The most common complication affecting permanently implanted pacemakers is mechanical failure (failure to pace or sense correctly), but infection is the next most common. Approximately 4% of pacemakers become infected at some point after placement. Generator box infections, infection of the electrode along its subcutaneous course, and bacteremic infection of the intravascular portion of the electrode, with or without associated endocarditis, each contribute approximately one-third to the overall infection problem. Diabetes mellitus, cancer, and corticosteroid therapy all have been noted to predispose to infection of the device. Skin erosion adjacent to a generator pouch also predisposes to direct invasion of the apparatus. As with PVE, pacemaker infections can be classified as early or late; early infections occur in the first 3 to 6 months. Early infections generally can be attributed to wound contamination by skin organisms at the time of implantation, whereas late infection, particularly of the intravascular electrode, often results from transient bacteremia with adherence of organisms

to the surface of the device. Particularly in the case of staphylococcal infections, adherence to the foreign material is facilitated by an exopolysaccharide glycocalyx produced by the organism. This material also forms a protective layer over the biofilm on the foreign body, contributing to impairment of the local antibacterial activity of polymorphonuclear leukocytes and reducing the effectiveness of antimicrobial therapy.

S. epidermidis and *S. aureus* are the most common microorganisms isolated from patients with generator pocket or electrode infections. In one large study of pacemaker infections, *S. epidermidis* accounted for 44% of episodes and *S. aureus*, 29%.[34] They are also the most common organisms isolated from the blood of patients with pacemaker infections in the absence of obvious generator pocket or electrode disease. Other etiologic microorganisms that have been reported include *Corynebacterium* spp., gram-negative aerobic bacilli, and occasionally, fungi.

Chills, fever, and other constitutional symptoms without another evident source constitute the usual presentation of pacemaker infection. The diagnosis is made by inspecting the generator pocket and the subcutaneous electrodes and obtaining blood cultures. Generator pocket and subcutaneous electrode infections usually evidence local inflammation without bacteremia or with transient bacteremia. Persistent bacteremia in a patient with an intravascular pacemaker suggests intravascular electrode infection or IE. Since most pacemakers are implanted in the right ventricle, the associated endocarditis is usually not accompanied by systemic embolic phenomena but may produce septic pulmonary emboli or multifocal pneumonia, as in right-sided endocarditis of other causes. TEE is more sensitive than TTE with regard to detecting pacemaker-related vegetations. As mentioned previously, intracardiac echocardiography is an emerging technology that also may prove useful in identifying pacemaker lead vegetations.[16]

There are three main considerations in developing a therapeutic plan for the management of pacemaker infection. One is the identity of the suspected or proved infecting microorganisms, second is the particular component of the apparatus that is involved, and the third is the presence or absence of bacterial infection at sites other than the pacemaker itself. Infected pacemakers must be removed when the generator box is infected, when there is persistent bacteremia, and when there is evidence of IE. A few authors have suggested that patients with permanent transvenous pacemakers that have been present for a long duration and who have bacteremia without evidence of generator box infection or IE can be tried on antibacterial therapy in the hope that the infection on the device may be cured without replacement. If treatment of pacemaker infection is attempted without removal of the device, 4 to 6 weeks of intravenous antimicrobial therapy probably is necessary as an initial trial. In the case of fungal agents or mycobacteria, a longer duration of therapy is necessary and is more likely to be unsuccessful. If the decision is made to remove the pacemaker, then the new transvenous generator should be located in a deeper pocket. Antimicrobial therapy is chosen on the basis of the microorganism isolated from the skin and subcutaneous tissue or bloodstream and is described in Tables 49-5 and 49-10. Two weeks of antimicrobial therapy after removal of the device probably is sufficient in the case of most generator pocket infections resulting from pyogenic microorganisms unless there is metastatic disease or secondary NVE, in which case the usual duration of treatment for NVE is used after the device is removed. Transvenous lead infections also require device removal and parenteral antimicrobial therapy. It is sometimes difficult to extricate the transvenous electrode tip from the right side of the heart. Tricuspid valve or ventricular wall tears have occurred. If percutaneous electrode removal is impossible, thoracotomy is required.

TABLE 49-10 Recommended Duration of Antimicrobial Therapy for Infections of Intravascular Devices

Infectious Disorder	Recommended Duration of Treatment
Pacemaker infection, generator box, and/or bacteremia	2 weeks after device removed, 4–6 weeks if not removed
Ventricular assist device	No uniform recommendations at this time; prolonged antibiotics and removal of device if possible
Prosthetic heart valves replacement	6–8 weeks; if culture positive at valve, 6–8 additional weeks beginning at that time
Arterial vascular grafts	6–8 weeks

VENTRICULAR ASSIST DEVICE INFECTIONS

Ventricular assist devices (VADs) are becoming more common in ICU patients. VADs often serve as bridges to cardiac transplantation. Because they are an intravascular device, VADs may become colonized and serve as a site for recurrent bacteremias or fungemias. It has been estimated that 25% to 50% of VAD placements are complicated by infection.[35] VAD-associated infections often involve the pump driveline, the pocket, or both. Commonly reported etiologic organisms include *S. aureus*,[35,36] *S. epidermidis*,[35,36] *P. aeruginosa*,[35] and *Candida* species.[35,36] If this complication should develop, replacement is one consideration; however, others would argue that this approach will fail more often than not owing to reinfection of the subsequent device and that these patients should receive priority for transplantation. However, lack of donor organs often leaves the former as the only available option.

ARTERIAL GRAFT INFECTIONS

Arterial grafts have an infection rate that has varied between 2% and 6% in different studies,[37–39] with a mortality rate as high as 50%. The pathogenesis of graft infection is analogous to that of prosthetic valve disease, with some patients presumably developing infectious disorders of the graft owing to inoculation of microorganisms at the time of surgery and others developing infection later owing to adherence of microorganisms that have gained access to the circulation. Grafts remain susceptible to infection for a rather long period because of the slow process of pseudointima formation in the graft lumen. Overall, graft infections present a mean of 8 months after implantation, but late disease may occur as long as 7 to 10 years after graft placement.[40] Autogenous vein grafts are the least susceptible to infection. Knitted Dacron grafts appear to be more susceptible, and woven Dacron grafts have a risk of infection somewhere in between. Grafts that cross the femoral area seem to be at greatest risk for infection, possibly due to contamination by bowel flora at the time of implantation.

TABLE 49-11 Microorganisms Responsible for Infections of Implanted Intravascular Devices

Organisms	PVE[a]	Pacemaker, %	Vascular Graft, %
S. epidermidis	27	42	10
S. aureus	14	35	15
Streptococci (includes enterococci)	26	—	30
Gram-negative rods	14	—	30
Diphtheroids and gram-positive rods	7	—	3
Fungi	9	—	2
Unknown	3	23	10

[a] Prosthetic-valve endocarditis.

The microbial etiology of vascular graft infection is shown in Table 49-11. Gram-positive microorganisms, particularly *S. aureus*, are the most common cause of graft infections, particularly in the groin or popliteal area. Gram-negative enteric microorganisms such as *E. coli, Proteus*, or *Pseudomonas* are more often the cause of abdominal graft suppuration.

Graft infections generally present with variable systemic constitutional symptoms, nonspecific laboratory evidence of an inflammatory process (leukocytosis, elevated erythrocyte sedimentation rate [ESR]), and findings at the graft site that vary depending on the location of the graft. Early infections (occurring less than 4 months after graft placement) more often present as sepsis or wound infection, whereas late infections present with graft malfunction or cutaneous sinus formation. Intraluminal infection may present as fever and nonspecific constitutional complaints resulting from bacteremia. Patients with a vascular graft who have persistent bacteremia with no other known source must be approached as if they have a graft infection. Extraluminal infection may present with evidence of local graft infection with erythema, tenderness, and swelling over the graft site; with systemic inflammatory symptoms without definite localizing findings; or with graft occlusion. Rapid swelling suggests disruption of the suture line with bleeding and false aneurysm formation and frequently implies graft infection. The most common presentation of groin or leg graft site infection is a localized abscess or draining sinus. Graft thrombosis should be suspected when signs and symptoms of peripheral arterial insufficiency develop. Exteriorization of the graft secondary to breakdown of tissue overlying the graft is rare but, when present, is pathognomonic of infection.

With infection of abdominal aortic grafts, swelling of tissues surrounding the graft may produce a mass effect, sometimes with evidence of ureteral obstruction or hydronephrosis. In addition, symptoms and signs of lower extremity ischemia may occur. The development of an aortoduodenal fistula between an infected aortic graft and the duodenum is a catastrophic complication. Patients in this group present with hematemesis or circulatory collapse.

Not infrequently, a diagnosis of graft infection must be based predominantly on the clinical features noted earlier because blood cultures are negative. The most useful imaging procedure is scanning with indium- or technetium-labeled white blood cells, which can demonstrate the inflammatory process along the course of the vascular graft.[41] CT scan or MRI is perhaps preferable if soft-tissue edema resulting from infection surrounding the graft or false aneurysm formation can be demonstrated. Vascular imaging may be combined with percutaneous fine-needle aspiration of perigraft fluid that can be Gram-stained and cultured. When the graft is removed for presumed infection, the graft itself and swabs from the graft bed should be cultured for both aerobes and anaerobes and examined for fungi.

Management of an infected intravascular graft almost always requires specific antimicrobial therapy chosen on the basis of the presumed or demonstrated infecting microorganism, as well as graft removal. When antimicrobial therapy alone is attempted, graft infection usually persists. If a graft provides the only blood supply to a distal organ or extremity, then some variety of revascularization must be carried out at the time of graft removal. An example is the use of an axillofemoral graft to bypass an infected aortic bifurcation prosthesis.

Specific antimicrobial regimens and suggested duration of therapy are indicated in Tables 49-5 and 49-10.

An Approach to Patients with Fever and Suspected Intravascular Infection

Intravascular infection is usually suspected in a critically ill patient when fever or other clinical or laboratory features of sepsis are present without a satisfactory alternative explanation. Blood cultures are mandatory in all such patients as an initial step, and all permanent or temporary intravascular devices should be inspected carefully for local evidence of infection.

Patients with otherwise unexplained positive blood cultures in the presence of an intravascular device must be presumed to have an infection of the device. When the device is a temporary one, such as a peripheral intravenous line, central venous catheter, or temporary pacemaker, it should be removed. In most cases, IV antimicrobial agents appropriate for the organism should be given for 1 to 2 weeks. If pus can be expressed from the puncture site or there is persistent bacteremia, surgical exploration of the peripheral veins is indicated. Tunneled central venous catheters call for a more selective approach (see Chap. 50). When positive blood cultures are attributed to an infected permanent intravascular device, the initial clinical decision is whether the device should be removed. Indications for permanent intravascular device removal depend on the variety of the device and have been discussed previously.

Positive blood cultures in the absence of an intravascular device and without an evident infection such as cellulitis, pneumonia, urinary tract infection, cholangitis, or intra-abdominal abscess predisposing to bacteremia most commonly result from an occult abscess or an intravascular suppuration. When sufficient clinical suspicion suggests the possibility of an intravascular infection such as a mycotic aneurysm, NVE, postanginal sepsis, pelvic vein thrombophlebitis, or pylephlebitis, appropriate special diagnostic studies outlined earlier should be performed promptly, and appropriate antimicrobial therapy for the bacteremia should be initiated. In addition, when the diagnosis has been established, appropriate surgical intervention frequently is required, as noted earlier.

Another group of critically ill patients in whom intravascular infection must be considered consists of those with fever and persistently sterile blood cultures, either while receiving antimicrobial therapy or not. When antimicrobial agents are being administered for some other reason, making a diagnosis of the precise etiology of intravascular infection may be especially difficult. Even if antimicrobial therapy can be discontinued, blood cultures may still take as long as 2 weeks to become positive again. In the patient with a prosthetic heart valve, blood-culture–negative IE is a consideration. In those with permanent pacemakers or vascular grafts, infection with a fastidious organism that is difficult to detect by usual methods is also a possibility, as is infection of a part of the device that is extravascular. The approach to these infections involves blood cultures designed to detect more fastidious organisms (see above), serologic studies for infections not detected by culture, and imaging studies aimed at acquiring nonmicrobiologic support for the diagnosis of infection. An echocardiogram demonstrating a vegetation on a valve, an arteriogram showing a mycotic aneurysm, or a scan with labeled white blood cells demonstrating increased uptake around a vascular graft may be sufficient to raise the index of suspicion high enough to proceed to more definitive therapy.

Patients with fever, negative blood cultures, and temporary devices in place should be examined carefully for evidence of local inflammation at the site of the device, and if present, the device should be removed and cultured semiquantitatively: A colony count of less than 15 when the intracutaneous portion of a vascular catheter is rolled on an agar plate virtually excludes sepsis due to infection of that line, whereas higher bacterial counts provide some support for the diagnosis.[42]

A common practice in some centers involves changing the central venous line over a guidewire in the febrile patient whose central vascular catheter exit site does not look infected and who is not bacteremic; if the line tip culture is positive, then the central venous line is replaced in a sterile site. Data to support or refute this practice are not compelling; therefore, one must weigh the risk of the catheter being the source of sepsis against the risk associated with placement of a new catheter or doing without it. A more complete discussion of the problem of suspected temporary intravascular device infection is given in Chap. 50.

Finally, even in the patient with fever of unknown source, negative blood cultures, and no intravascular device in place, an intravascular infection remains an important diagnostic consideration. Mycotic aneurysms, culture-negative NVE, pelvic vein septic thrombophlebitis, and pylephlebitis are all examples. The key points in the diagnostic approach are a careful history and physical examination and consideration of the clinical context. Examples include a woman with fever without bacteremia following delivery, in whom a pelvic vein thrombophlebitis, a new or previously demonstrated pathologic heart murmur (raising the possibility of culture-negative IE), or known intravenous drug abuse suggesting the possibility of mycotic aneurysm must be considered.

Chapter 50

INFECTIOUS COMPLICATIONS OF INTRAVASCULAR ACCESS DEVICES USED IN CRITICAL CARE

J. M. CONLY

KEY POINTS

- *Intravascular access device–associated infections may be either local or bacteremic, and the risk of developing an infection varies with the patient population, the type of device, the microbe, and the patient-microbe-device interaction.*
- *The status of all indwelling vascular access devices should be reviewed daily by the critical care team, with attention to the duration of placement, appearance of the exit site, and continued clinical indication for the intravascular device.*
- *Central venous catheters account for over 90% of all intravascular device–related bacteremias.*
- *Most intravascular device–related bacteremias are caused by endogenous skin flora at the catheter insertion site that migrate along the transcutaneous portion of the catheter with subsequent colonization of the catheter tip.*
- *Coagulase-negative staphylococci and* Staphylococcus aureus *account for just over 50% of all intravascular device–related bacteremias, followed in frequency by gram-negative bacilli and yeast.*
- *Diagnosis of intravascular device–related infection, either local or bacteremic, is best approached using a combination of clinical and laboratory criteria.*
- *Although treatment of central line infections due to coagulase-negative staphylococci may be successful without catheter removal, infections caused by* S. aureus *necessitate catheter removal.*
- *Central intravascular catheter infections are essentially preventable infections. Successful prevention entails attention to a careful needs assessment for the device, careful site selection, maximal barrier precautions and aseptic technique on insertion, insertion by the most skilled operators, rigorous catheter-site care, and interrupting the integrity of the system as little as possible.*

The use of intravascular access devices has become an integral part of modern patient care, and nowhere is this more evident than the ICU. Progress over the last two to three decades has provided an increasing array of devices other than the original peripheral and single-lumen central catheters. Included in the list of devices currently in use are multilumen central venous catheters (CVCs); tunneled CVCs such as the Hickman, Broviac, Cook, and Quinton catheters; flow-directed pulmonary artery catheters (PACs), peripherally inserted central and midline catheters, peripheral arterial catheters, and totally implantable devices. These indwelling intravascular devices provide a route for the administration for fluids, blood products, nutritional products, and medications; allow the monitoring of hemodynamic functions; and permit bloodletting and the maintenance of emergency access. However, vascular access devices may be associated with several complications, including local and bacteremic infections related to the device, thrombosis, thrombophlebitis, and septic thrombophlebitis. Infectious complications are the most frequent and among the most serious of these complications. The magnitude of CVC-related infectious complications can be appreciated when one realizes there are an estimated 15 million days of exposure to CVCs in patients in ICUs in the United States each year.[1] Bacteremias caused by intravascular devices are associated with increased morbidity, prolonging hospitalization a mean of 7 days, and have a reported attributable mortality of up to 35% in studies that are not controlled for severity of illness.[1–4]

Epidemiology

The risk of developing device-related infection (either local or bacteremic) varies considerably with the patient population, the type of device and its intended use, the microorganisms involved, and the patient-microbe-device interaction. The risk factors for device-associated infection that have been identified for the host, the microbe, the device, and the interaction among them are listed in Table 50-1. In addition, representative incidence-density rates for device-associated bacteremias are shown in Table 50-2.

Of the many intravascular devices available, the peripheral venous catheter is by far the most commonly used. Most peripheral venous catheters currently are made of polyurethane, Teflon, or steel and are associated with a very low risk of bacteremia, with less than 1 episode of bacteremia per 500 devices.[5,6] There is little difference currently in the risk of bacteremia regardless of whether polyurethane, Teflon, or steel needles are used if the same level of asepsis is applied at the time of placement.

Peripheral arterial catheters are in widespread use in ICUs for blood pressure monitoring and for obtaining arterial samples for blood gas determination. The incidence of bacteremia related to peripheral arterial devices is about 1%,[7–9] and the rate of significant colonization (≥15 colony-forming units [cfu] on semiquantitative culture) is about 5%.[7–11] Insertion by cutdown, catheterization lasting 4 days or longer, and inflammation at the catheter exit site are associated with a higher risk of significant catheter colonization.

CVCs are estimated to account for over 90% of all catheter-related bacteremias. Prospective studies of noncuffed, short-term single or multilumen catheters inserted into either internal jugular or subclavian sites have found bacteremia rates of 1% to 5% and rates of significant colonization of the catheters (≥15 cfu on semiquantitative culture) ranging between 5% and 30%[12–18] depending on the use and duration of the catheter plus the patient population. Peripherally inserted central catheters (PICCs) have somewhat lower catheter-related bacteremia rates, ranging between 1% to 2%.[19] Many of the factors that may influence the risk of catheter colonization and/or catheter-related bacteremia are listed in

TABLE 50-1 Risk Factors for Catheter-Related Infection

Patient-related factors
Age (age ≤1 year or ≥60 years)
Loss of skin integrity (burns)
Presence of neutropenia (absolute neutrophil count ≤1000)
Chemotherapy and radiotherapy
Distant focus of infection
Severity of underlying illness
Device-related risk factors
Type of device material (steel, polyurethane, Teflon, and silicone more resistant to bacterial adherence than polyethylene and polyvinylchloride)
Frequency of surface irregularities
Thrombogenecity of catheter materials (predisposes to bacterial colonization)
Use of antibiotic or antiseptic impregnated catheters (reduces risk)
Microbe-related risk factors
Adherence properties (adherence to fibronectin or directly to polymer materials)
Extracellular slime substance (antiphagocytic and may potentiate pathogenecity by acting as a barrier to antimicrobial penetration)
Host-microbe–device interaction risk factors
Type of placement (cutdown higher risk than percutaneous)
Emergent placement (higher risk than elective placement)
Site of placement (jugular greater risk than subclavian)
Duration of use (longer duration increases the risk)
Use of aseptic technique at the time of insertion (use of maximal barrier precautions—mask, sterile gown and gloves, and large drape—decreases risk)
Dense cutaneous colonization at device entry site (higher density of bacteria per unit area increases risk)
Dressing material (gauze dressing associated with lower risk for central lines)
Skill of puncturist (greater operator skill decreases risk)
Type of skin antiseptic used for insertion (chlorhexidine preparations may be associated with less risk)
Use of topical antimicrobial ointment (may decrease risk)
Frequency of entry into the system (greater frequency of entry represents greater risk)

Table 50-1. The presence of a distant focus of infection, bacteremia, tracheostomy, loss of skin integrity, emergent placement, internal jugular placement, absence of appropriate barrier precautions, transparent dressings, a high frequency of entry into the system, and multilumen catheters increase the risk of significant catheter colonization.[1,12–15,20–27]

The use of less stringent barrier precautions, the use of 10% povidone-iodine or 70% alcohol alone as compared with 2% chlorhexidine as an antiseptic, the use of transparent dressings (in some but not all randomized studies), duration of catheterization of 4 days or more, and heavy cutaneous insertion-site colonization all have been associated with an increased risk of catheter-related bacteremia for central catheters.[12–15,20,28–30] Antibiotic-coated and antiseptic-impregnated[31–33] CVCs reduce catheter colonization and bloodstream infection, but a recent meta-analysis suggests that the benefit is only during the first week after insertion.[34] Replacement of existing catheters over a guidewire is associated with a significantly lower rate of mechanical complications than replacement by insertion at a new site but more frequently results in infection of the newly placed catheter.[35]

PACs, which are used frequently in the management of hemodynamically unstable, critically ill patients, carry many of the same risk factors and rates of bacteremia as CVCs. Most PACs consist of a polyurethane catheter that passes through a percutaneous indwelling Teflon introducer sheath. Prospective studies have identified several risk factors associated with significant catheter colonization, including placement with less stringent barrier precautions, internal jugular vein placement, prolonged catheterization (≥4 days), and heavy microbial colonization at the catheter insertion site.[20,36,37] Exposure of a PAC to bacteremia from a distant focus of infection, catheterization for 4 days or more, and difficulty with insertion also have been found to increase the risk of bacteremia. The incidence of bacteremia from PACs is about 1%.[37]

Pathogenesis

Microorganisms can gain entry (Fig. 50-1) to the intravascular device (usually an intravascular catheter) and the intravenous delivery system in several ways to cause device- or catheter-related bacteremia, including contamination of infusate, contamination of the catheter hub–infusion tubing junction, hematogenous seeding of the catheter tip, and colonization at the cutaneous catheter exit site.

Contamination of infusate may be *intrinsic*, occurring at the manufacturing level, or *extrinsic*, occurring via the administration sets, the extension tubing, the use of outdated intravenous solutions, or a break in aseptic technique allowing faulty admixtures. The potential for proliferation of organisms in various infusate fluids after intrinsic contamination has been well documented with strains of *Klebsiella, Enterobacter*, and *Serratia*.[38,39] *Candida* species have a propensity to grow in hypertonic glucose solutions used in parenteral solutions, and the commercially available lipid emulsions support

TABLE 50-2 Representative Rates for Intravascular Device-Associated Bacteremia

Type of Device	Setting	Incidence Density Rate
Peripheral		
Short-term, infusion lock	Med/surg wards	<1/1000 catheter-days
Arterial, PICC	Med/surg ICU	2/1000 catheter-days
Central		
Non-cuffed venous	Med/surg ICU, CCU	5–7/1000 catheter-days
(single- or multilumen)	Pediatric ICU	11.4/1000 catheter-days
	Burn units	30.2/1000 catheter-days
Cuffed venous (Hickman, Broviac)	Med/surg wards	2.0/1000 catheter-days
Pulmonary arterial	Med/surg ICU	4.8/1000 catheter-days

PICC = peripherally inserted central catheter.

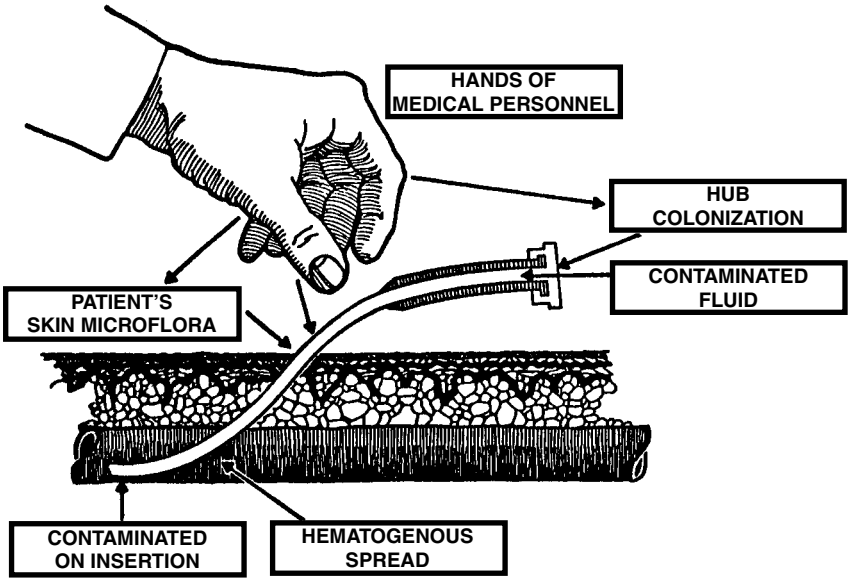

FIGURE 50-1 Potential sources for contamination of intravascular devices.

the growth of most organisms.[40] Nosocomial bacteremias secondary to contaminated infusate usually have occurred in epidemics or clusters but with improvement in manufacturing standards are now exceedingly rare. Extrinsic contamination of infusate causing central catheter–related bacteremia is also a very uncommon problem, with an estimated incidence of less than 1 per 1000 cannula-related septicemias. Most are reported in epidemics occurring as a result of the exposure to a common source of microbial contamination such as multidose vials, administration sets, or contaminated water-bath warmers. The risk of fluid becoming extrinsically contaminated is related to the duration of infusion through the administration set. Most hospitals now have policies that require replacement of the entire delivery system every 72 hours, which represents one of the most important control measures for reducing the complications of contaminated infusates. Similar to intrinsic contamination, hematogenous seeding of the catheter tip with consequent bacteremia is considered to be a rare event.

Most cannula-related bacteremias are thought to result from local endogenous microflora colonizing skin at the insertion site and/or the transcutaneous wound[29,41,42] that migrate along the subcutaneous tunnel, colonize the subcutaneous portion of the catheter, and then finally colonize the tip of the catheter. Another mechanism is colonization of the internal surface of the catheter hub, with subsequent colonization of the internal surface of the catheter and eventual colonization of the catheter tip.[43–45] This could occur as a result of obligate manipulations of the connection during tubing replacements or improper connection. After the hub has been contaminated, the microbes would be carried intraluminally, reach the catheter tip, and colonize the fibrin sheath. The origin of these microorganisms colonizing the hub is often the hands of those manipulating the hub rather than the flora of the patient's skin. This latter mechanism of catheter tip colonization is considered an important contributor to intraluminal colonization of long-term catheters.[43–45]

Studies of central line infections (short indwelling insertion times) using molecular subtyping techniques to differentiate the different strains of infecting and colonizing organisms have demonstrated that approximately 80% of the microorganisms from distal catheter tips are concordant with organisms present on the skin at the catheter insertion site. The source of the remaining organisms was either contamination of the catheter hub, hematogenous colonization from remote sites, or unknown sources. Of episodes of catheter-related bacteremia, concordance of organisms at the catheter insertion site, the catheter tip, and the blood varied between 86% and 100%.

It also has been shown in several studies[15,20,41] that heavy colonization at the catheter insertion site is strongly associated with significant catheter colonization, which in turn is associated with catheter-related bacteremia. Using quantitative insertion-site cultures, the presence of $\geq 10^3$ cfu/mL per 25 cm^2 has been strongly associated with the presence of significant catheter colonization.

Once microorganisms gain access to the catheter tip, they act as a nidus for further colonization because of a loosely formed fibrin sheath that develops around the distal portion of the cannula. This sheath acts as a reservoir within which microorganisms can multiply and be shielded from the body's normal host defense mechanisms. The presence of grossly visible thrombus formation on the catheter tip is also highly correlated with the presence of bacterial colonization.

Microbiology

The species of the microorganism causing a bacteremia is frequently an important clue suggesting the intravascular device as the source of the bacteremia. Coagulase-negative staphylococci (mainly *Staphylococcus epidermidis*) and *Staphylococcus aureus* are the most frequently encountered organisms causing cannula-related infections. These two species account for well over 50% of all cannula-related infections. Enteric gram-negative bacilli are the next most frequent group of causative organisms, followed by yeast, especially *Candida albicans*. Other less commonly identified organisms include *Pseudomonas* species, *Corynebacterium jeikeium*, and *Malassezia furfur*.

TABLE 50-3 Frequently Encountered Microorganisms Associated with Device-Associated Bacteremia

Source	Microorganisms
Peripheral venous catheters	Coagulase-negative *Staphylococci* *S. aureus* *Candida* species *Bacillus* species *Malassezia* furfur
Peripheral arterial catheters	*Klebsiella-Enterobacter* species *Serratia* species Coagulase-negative *Staphylococci* *S. aureus*
Central venous and arterial catheters	Coagulase-negative *Staphylococci* *S. aureus* *Candida* species *Corynebacterium jeikeium* *Klebsiella-Enterobacter* species *Trichophyton beiglii* *Malassezia furfur*

Several studies have suggested that coagulase-negative staphylococci may have an intrinsic propensity to adhere to plastic catheters that results in a selective advantage for these organisms in causing device-associated infections.[46]

Unusual isolates such as *Enterobacter* species, *Burkholderia cepacia, Flavobacterium* species, and *Stenotrophomonas* and *Acinetobacter* species are uncommonly found as a cause for CVC-associated infection and should suggest the possibility of a contaminated infusion product or a common environmental reservoir.[47,48] A summary of the organisms commonly associated with device-associated bacteremia is given in Table 50-3.

Definitions and Diagnosis of Device-Related Infections

There is currently no uniform method for defining local device-related infection or device-related bacteremia. Establishing a firm diagnosis of device-related bacteremia may be very difficult. Basing the diagnosis and subsequent definition of device-related infection on clinical or laboratory criteria alone has its own intrinsic limitations. In addition, the definitions used for clinical purposes may differ from those used for surveillance.[49]

Several laboratory techniques are available to assist the diagnosis of catheter-related infection. These include qualitative culture of vascular catheters in broth, semiquantitative culture of catheters on solid media, and quantitative culture of catheters in broth, removing organisms by flushing or sonication. Qualitative culture in broth is not specific, is prone to contamination, and probably should not be done. The use of semiquantitative cultures of catheter tips or of the intracutaneous portion of the catheter or central-line sheath using the roll-plate method described by Maki and colleagues[50] defines significant colonization as 15 cfu or more. Using this laboratory definition and applying it to diagnosing catheter-related bacteremia, a specificity of 76% to 96% and a positive predictive value of 16% to 31% have been reported. Owing to its simplicity, the roll-plate method has been adopted widely in many hospital microbiology laboratories. The use of quantitative cultures of broth, in which the catheter has been flushed or sonicated, may be more sensitive but is too time-consuming and laborious for routine use.

Quantitative blood cultures have been used as a laboratory method to assist in the diagnosis of catheter-related bacteremia when catheter removal is not possible.[51,52] Blood cultures are obtained simultaneously from the central catheter (a retrograde "drawback" culture) and from a peripheral venipuncture. A 10-fold or higher differential count from blood obtained from the central catheter is considered to be indicative of catheter-related bacteremia. The use of quantitative cultures is laborious, and concerns over contamination of drawback cultures have limited the usefulness of this technique. Recent studies have evaluated endoluminal brush sampling and differential blood culture growth rates, which may provide acceptable accuracy without requiring removal of indwelling catheters, but the accuracy of these techniques needs to be confirmed in other studies.[53–56]

Using clinical criteria alone to make a diagnosis of catheter-related infection also may be difficult. Whereas the presence of culture-positive purulent exudate at the catheter insertion site in the presence of bacteremia with the same organism would define a catheter-related bacteremia, making the diagnosis is much more difficult with bacteremia in the absence of any inflammation at the catheter insertion site. Signs of local inflammation at the catheter insertion site are present in only about 50% of the cases of catheter-related bacteremia. Several clinicoepidemiologic features are helpful in distinguishing catheter-related bacteremia from bacteremia caused by another source. These findings, which may be present alone or in combination, include the following:

1. Absence of an alternative source for bacteremia on clinical examination
2. Patient not considered at high risk for bacteremia
3. Presence of local purulence at the catheter exit site
4. Presence of *Candida* endophthalmitis in patients who are receiving total parenteral nutrition
5. A septic picture that is refractory to antimicrobial theapy
6. Bloodstream infection caused by staphylococci or *Candida* species
7. Dramatic improvement of a febrile syndrome following catheter removal
8. Clusters of bacteremia due to *Enterobacter* species for seemingly unapparent reasons (suggesting common-source contamination of IV fluids)

Many definitions for catheter-related infections have been used, but none is considered standard or uniform. However, any definition used should incorporate both clinical and laboratory criteria in an attempt to increase the utility of the definition. Examples of definitions for local and bacteremic catheter-related infections that may be used are given below. For local infections, definitions include

- Purulent discharge at the exit site, either spontaneous or expressed on palpation of the site, regardless of whether an organism is cultured from the site
- Erythema, tenderness, and/or induration (any two of the three) at the exit site with serous or serosanguineous discharge, either spontaneous or expressed on palpation, in the

presence of a positive exit-site culture (moderate to heavy growth of a single or predominant organism)

Definitions for bacteremic infection include those for *definite* infection:

- A single positive peripheral blood culture from a patient with clinical and microbiologic data disclosing no other source of the bacteremia in the presence of a semiquantitative or quantitative culture of a catheter segment (proximal or distal) from which the same organism (species, antibiogram) was isolated
- Differential quantitative blood cultures with a 10-fold or greater colony-count difference between blood cultures drawn from the catheter and simultaneously from a peripheral venous blood culture
- A single positive peripheral blood culture from a patient with isolation of the same organism (species, antibiogram) from purulent, serous, or serosanguineous discharge from the catheter exit site or along the path of a subcutaneously tunneled catheter or from the subcutaneous pocket containing a reservoir of a totally implantable device

Definitions for *probable* infection include

- Two or more positive blood cultures for the same organism (species, antibiogram) from any source (peripheral or retrograde intravascular device cultures) from a patient with clinical and microbiologic data disclosing no other source for the bacteremia except the intravascular device
- One positive blood culture for *S. aureus* or *Candida* species from any source (peripheral or retrograde intravascular device culture) in a patient with clinical and microbiologic data disclosing no other source for the bacteremia except the intravascular device
- One positive blood culture for any organism commonly associated with intravascular device–related infection (coagulase-negative staphylococci, *Bacillus* species, *Corynebacterium* species, and *M. furfur*) from any source (peripheral or retrograde culture) in an immunocompromised patient or a neutropenic patient (neutrophils <500 cells/μL) with clinical and microbiologic data disclosing no other source for the bacteremia except a *centrally* placed intravascular device

Management of Infection

The management of intravascular device–associated infections depends on several variables, including the type of infection (local or bacteremic), the microorganism(s) involved, the type of device (peripheral or central catheter, totally implanted device), and the severity of illness of the patient. A guideline was published recently that outlines these variables in detail and provides detailed recommendations for the management of intravascular catheter–related infections.[57] Local infections at the catheter insertion site may be treated with catheter removal, local care, and topical and/or systemic antimicrobial agents as appropriate. If a spreading cellulitis develops, extending along the course of the catheter, then systemic antimicrobials and catheter removal are indicated. The antimicrobials chosen should be based on microbiologic cultures obtained from the discharge present at the insertion site.

The management of bacteremic infections is more complex and depends on the microorganism, the type of device, and the clinical status of the patient. Any peripheral (venous or arterial) or noncuffed central catheters (venous or pulmonary arterial) that are being used in the short term and are suspected of being the source of a bacteremic infection in a patient with no other obvious source should be removed, the administration set changed, and the catheter tip and intracutaneous portion of the insertion sheath sent for culture. The catheter should be removed regardless of whether there is evidence of inflammation at the insertion site because over 50% of the catheter-related bacteremias occur without any evidence of local site inflammation.

An option for the management of CVC-related bacteremia due to coagulase-negative staphylococci, without removal of the catheter, is the use of systemic antimicrobials and the antibiotic-lock technique,[57] but the risk of recurrent bacteremic infection is approximately 20%.[58] Thus this option must be considered carefully on an individual basis. In general, if the indication for the central catheter remains, a new catheter should be inserted into a new site if the catheter is proved to be or is strongly suspected as the source of the infection. In the absence of inflammation or local purulence at the catheter insertion site, and when the evidence suggesting the line as the source for infection is not compelling, it is reasonable to do a guidewire catheter exchange at the same site, but the catheter that is removed should be cultured, and if it is positive, the newly inserted catheter should be removed and another catheter inserted in a different site.[35]

Device-related bacteremia that is suspected to arise from cuffed central long-term indwelling catheters (Hickman, Broviac, or Cook catheter) or totally implanted devices does not necessarily require removal of the device.[57] If there is obvious local purulence, bacteremia due to *S. aureus* or *Candida* species, a spreading tunnel-associated cellulitis, septic thrombophlebitis, tricuspid valve endocarditis, or a persisting bacteremia despite appropriate parenteral antimicrobial therapy, removal of the device is required, often with surgical dissection. Retention of a cuffed long-term central catheter with catheter-related *S. aureus* bacteremia has been associated with a higher relapse rate of bacteremia and higher sepsis-related mortality.[59] In the setting of bacteremia due to other microorganisms and in the absence of complications, a course of parenteral antimicrobial therapy with or without antibiotic-lock therapy without removal of the cuffed central catheter or implantable device may be sufficient in as many as two-thirds of cases.[57,60,61] Following treatment, these patients should be monitored carefully for recurrences of bacteremic infection.

Definitive antimicrobial therapy for device-associated bacteremia depends on appropriate identification and susceptibility testing of the infecting microorganism. Empirical therapy prior to the identification and susceptibility results will be influenced by local microbiologic patterns of line-related infection and susceptibilities. However, a combination of an IV antistaphylococcal penicillin (vancomycin if methicillin-resistant *S. aureus* is prevalent) and an aminoglycoside or a third-generation cephalosporin will provide coverage for most gram-positive and gram-negative microorganisms. Any catheter-related bacteremic infections caused by S. *aureus* should be treated for 14 days with parenteral therapy to avoid metastatic infectious complications. The optimal duration of therapy for infections caused by organisms other than

TABLE 50-4 Strategies for Prevention of Vascular Device–Related Infections

Process or System	Preventive Strategy	Rationale
Device itself	Institute careful needs assessment prior to insertion of any intravascular device.	Avoid unnecessary insertions. Use of peripheral catheter, midline, or PICC line should be considered if appropriate.
	Choose least thrombogenic material for type of device being inserted based on the needs assessment.	Polyvinylchloride > polyurethane > silicone > steel with respect to thrombogenecity and colonization with certain microorganisms.
	Consider use of antiseptic-antimicrobial bonded devices or use of subcutaneous cuffs impregnated with antimicrobial agent.	Significant reductions in catheter infection rates (50%–80%) have been found in several randomized controlled trials using chlorhexidine silver-bonded catheters, silver-impregnated cuffs, and antibiotic-coated catheters.
	Minimize the number of lumens and the number of accesses whenever possible.	This strategy is somewhat controversial, since several but not all studies have demonstrated an increased risk of catheter infection with multilumen lines. A greater number of lumens will increase the frequency of entry to the system, which is associated with a greater risk of catheter-related infection.
Device insertion	Choose site associated with least risk for local and systemic device-related infection.	Risk of local and systemic catheter-related infection is independently associated with density of flora at the catheter insertion site; femoral > jugular/subclavian > antecubital fossa.
	Use aseptic technique.	Good hand washing and use of maximal barrier precautions (masks, sterile drapes, gloves, gown) are associated with less risk of catheter-related bacteremia than minimal barrier precautions (mask, sterile gloves, small drapes).
	Insertion is done by skilled operators.	Organized, specifically trained IV teams have been associated with lower catheter infection rates, but the key ingredient is a highly skilled operator with excellent technique. Difficulty of insertion has been associated with higher local catheter-related infection rates.
	Place device in as controlled an environment as possible.	Emergency catheter insertions are associated with a higher risk of infection than elective placement.
	Use prophylactic antibiotics at time of insertion.	Prospective randomized controlled trials have shown no benefit, and prophylactic antibiotics are not generally recommended.
Catheter site care	Use cutaneous antiseptic with maximal efficacy, ease of application, and compliance with recommendations for usage.	Chlorhexidine (0.5% tincture or 2% aqueous) may offer best approach to cutaneous antisepsis considering all criteria for use. Povidone iodine, although effective, is often used improperly despite best efforts to improve compliance.
	Apply topical antiseptics/antimicrobials at the insertion site.	Clinical trials to date have shown only marginal or no benefit but may be of benefit in selected settings.
	Choose dry gauze or other permeable dressings for site care.	Transparent semipermeable dressings have been associated with both a significantly increased density of flora at the catheter insertion site and local catheter-related infection rates. Some prospective studies have demonstrated a significantly increased risk of catheter-related bacteremia.
Catheter care	Minimize the number of interruptions to the integrity of the line.	With TPN there is an increased risk of catheter-related infection with line violations. The system should be kept closed as much as possible.
Delivery system	Minimize the number of interruptions to the integrity of the delivery system.	With TPN the risk of catheter-related infections increases significantly with interruptions to the integrity of the system.
	Change administration set every 72 hours.	Changes of the administration sets at 72-hour intervals have not been shown to be associated with any increased risk of catheter-related infection compared to changes at 24-hour intervals.

PICC = peripherally inserted central catheter; TPN = total parenteral nutrition.

S. aureus is unknown, but 7 to 14 days has been suggested.[57] Catheter-related candidemia may be treated with a short course of amphotericin B (3 to 7 mg/kg total dose) or fluconazole (200 to 400 mg/day for 10 to 14 days). In the susceptible patient population most often found in the ICU, a thorough evaluation for metastatic candidal infection, including careful funduscopic examination, is necessary. The finding of persistently positive blood cultures after catheter removal and initiation of antifungal therapy or the finding of metastatic candidal lesions would necessitate more prolonged therapy.

Preventive Strategies

Attention to detail in all aspects of the placement and care of intravascular devices is necessary to minimize the risks

of device-related infection. This attention to detail is particularly important in the ICU, where the use of lines is intensive and patients, by nature of their underlying illnesses, are at high risk of device-related infections. The processes to which preventive strategies may be applied may be divided conveniently into the catheter itself, the catheter insertion, catheter site care, catheter care, and the delivery system (Table 50-4). The details on which attention should be focused, as well as the accompanying rationale for the specific strategy, are presented. Detailed guidelines for the prevention of intravascular device–related infections are available from the Centers for Disease Control and Prevention.[49]

Although new scientific approaches to establishing improved techniques for catheter care are necessary and new technologic advances such as microbe-resistant materials will help to reduce the incidence of catheter-related infection, there is no substitute for meticulous care and attention to detail in care of the lines.

Chapter 51
PNEUMONIA

R. BRUCE LIGHT

KEY POINTS

- *Pneumonia is one of the leading causes of respiratory failure leading to admission to the intensive care unit and is by far the most common nosocomial infection in critically ill patients.*
- *Mortality rate may exceed 50% for severe community-acquired pneumonia (CAP) requiring admission to the intensive care unit and varies from 30% to 60% in nosocomial cases.*
- *The initial approach to diagnostic testing and empiric therapy is guided by the clinical presentation of the pneumonia, which can be categorized as follows: CAP, acute CAP, aspiration pneumonia/lung abscess, and chronic pneumonia; nosocomial pneumonia; and pulmonary infiltrate in immunocompromised host.*
- *Investigation of acute pneumonia should always include a blood culture and Gram stain and culture of lower respiratory tract secretions. Smear and culture for* Legionella *species and serologic testing for other atypical pathogens should be done when atypical pneumonia features are present and in otherwise undiagnosed cases of severe pneumonia.*
- *Fiberoptic bronchoscopy with quantitative bacteriology of a protected brush specimen or bronchoalveolar lavage specimen is the procedure of choice for diagnosis of acute CAP and nosocomial pneumonia that respond poorly to treatment and resist diagnosis by noninvasive means.*
- *Empiric intravenous antimicrobial therapy should be begun immediately in all critically ill patients with an acute pneumonia. Antimicrobial coverage should include all pathogens of more than trivial probability and should always include* Streptococcus pneumoniae, Staphylococcus aureus, *and* Enterobacteriaceae. *In cases of severe pneumonia of unknown cause, a fluoroquinolone should be included to cover* Legionella *species, and dual antimicrobial coverage for* Pseudomonas *species should be given to patients at special risk of carrying this organism.*
- *Empiric antimicrobial therapy initially can be withheld in less severely ill patients in whom the diagnosis of infectious pneumonia is in doubt and in patients with a chronic pneumonia presentation, pending definitive diagnosis.*
- *Pulmonary infiltrates in an immunocompromised host may be caused by any of the infectious agents affecting the normal population, by opportunistic infections, or by noninfectious processes. The required approach combines empiric therapy, selected on the basis of the particular infectious agents for which the patient is at special risk, with a timely stepwise diagnostic approach that moves from noninvasive testing to fiberoptic bronchoscopy to open lung biopsy at a rate determined by the rate of progression of the patient's undiagnosed pneumonia.*

Pneumonia remains the leading infectious cause of death in the developed world. It is also the most frequent infection leading to admission to most intensive care units (ICUs) and by far the most important nosocomial infection complicating the treatment of patients admitted to ICUs for other problems. Roughly 5% to 10% of patients hospitalized for community-acquired pneumonia (CAP) require ICU admission, with a mortality rate of 30% to 50%.[1–3] Pneumonia is also the most important nosocomial infection leading to ICU admission and a frequent complication of treatment in an ICU, occurring in 5% to 50% of patients requiring mechanical ventilation.[4] A systematic approach and an aggressive attitude toward diagnosis and treatment of pneumonia therefore are fundamental to good critical care practice.

The discussion that follows categorizes the major pneumonia syndromes as CAP, nosocomial pneumonia, and pulmonary infiltrates in the immunocompromised host. Whereas the etiologies of pneumonia in these three categories overlap to some degree, the underlying pathogeneses, etiologic differential diagnoses, and approaches to empiric antimicrobial therapy differ considerably.

Community-Acquired Pneumonia

Pneumonia in patients presenting from outside the hospital can lead to ICU admission for a variety of reasons: hypoxemic or hypercapnic respiratory failure, depressed level of consciousness caused by hypoxia or sepsis, or hypotension related to relative hypovolemia or septic shock. Although supportive management for these problems is generally similar for all types of pneumonia and the principles of circulatory and respiratory management differ little from those for shock and respiratory failure of other causes, there are major differences among the different forms of pneumonia in the approach to diagnosis and empiric antimicrobial therapy. The great majority of CAPs are caused by common bacterial pathogens such as *Streptococcus pneumoniae*, *Staphylococcus aureus*, and *Haemophilus influenzae*. However, in most series of pneumonia severe enough to require ICU admission, a significant minority of cases is caused by a number of less common pathogens with widely differing antimicrobial susceptibilities.[1–7] Approximate percentages for the major causes of CAP are shown in Table 51-1. The distribution of etiologies varies widely among different geographic areas.

PATHOGENESIS

Pathogenic mechanisms of pneumonia vary greatly among the different etiologic agents, depending on the relative virulence of the organism, which host defenses are most important in preventing infection with that organism, and the common route of entry of the organism into the lung. The three major routes of entry are aspiration of oropharyngeal or gastric contents into the lung, inhalation of aerosols or particles containing organisms, and hematogenous spread of organisms into the lung from another infected site.

Aspiration accounts for the vast majority of pulmonary infections, with the particular clinical syndrome being determined by the quantity of material aspirated, the nature of the bacteria in the aspirated material, and the efficiency of the host's pulmonary defense mechanisms. The upper airway of normal human beings is frequently colonized by *S. pneumoniae*, *H. influenzae*, and, occasionally, *S. aureus*, in addition to the normal microflora consisting of mixed aerobic and anaerobic bacteria. Colonization by enteric gram-negative

TABLE 51-1 Infectious Etiologic Agents Implicated in Severe Community-Acquired Pneumonia Requiring Intensive Care Support

Etiologic Agent	Cases Admitted (%)[a]
Acute community-acquired pneumonia	85
Streptococcus pneumoniae	40
Staphylococcus aureus	10
Enterobacteriaceae	10
Legionella pneumophila	10
Haemophilus influenzae	5
Mycoplasma pneumoniae	5
Chlamydia psittaci	2
Coxiella burnetii	1
Viral	2
Aspiration pneumonia/lung abscess	10
Chronic pneumonia syndrome	5
Mycobacterium tuberculosis	3
Endemic dimorphic fungi	2

[a] The percentage shown are approximate only, based on published studies from different geographic locations and population bases. Because these percentages represent cases requiring hospital admission and care in the intensive care unit, pneumonias that more commonly cause severe illness or that occur more commonly in patients with significant underlying disease (*S. aureus*, enteric gram-negative bacilli, *Legionella* spp., etc.) are over-represented compared with unselected community-acquired pneumonia. Also note that most published series include 20% to 50% for which no etiologic diagnosis was made and that are not included in this table.

bacilli, such as *Escherichia coli* or *Klebsiella pneumoniae*, is much less frequent, occurring in fewer than 1% of persons in the community at large, although it is more frequent in alcoholics, persons with poor oral hygiene, and the institutionalized elderly.[8,9] Even people who have normal upper airway reflexes aspirate small quantities of oropharyngeal material during sleep.[10] Normally, the organisms so aspirated are cleared by the bronchial mucociliary clearance mechanism, and any residual debris is cleared by the phagocytic cells present in alveoli and on the bronchial mucosa. However, if the aspirate contains organisms with significant potential for virulence, and if the aspiration occurs in a human host with impaired pulmonary clearance mechanisms, the organism can proliferate in the pulmonary parenchyma and cause pneumonia. Pneumonia caused by relatively high-grade pathogens such as *S. pneumoniae*, *S. aureus*, and enteric gram-negative bacilli generally occurs as an acute infection without clinically obvious major aspiration (i.e., the aspiration is subclinical) in patients with damaged or deficient host defenses. Examples include pneumonia after a viral respiratory infection (which impairs ciliary clearance mechanisms), pneumonia in alcoholics or others with intermittently depressed level of consciousness (greater opportunity for subclinical aspiration), and pneumonia in patients with impaired mucociliary clearance (chronic obstructive pulmonary disease, or chronic bronchitis) or relative immunologic impairment (diabetes mellitus, uremia, or hypogammaglobulinemia).

The normal microflora of the upper airway has limited virulence and therefore causes pulmonary infection mainly when aspiration is more florid, when the aspirated oropharyngeal material is present in greater quantity, or when there is severe local impairment of tracheobronchial clearance. Examples of these conditions include risk factors for major aspiration, such as uncontrolled epileptic seizures or abnormal motor control of the upper airway; periodontal disease; and bronchial obstruction caused by foreign body aspiration or neoplasm. The infection produced by these relatively nonpathogenic bacteria is usually an indolent one producing a subacute, but necrotizing, pneumonia, with eventual liquefaction of pulmonary parenchyma and abscess formation.

Because the numbers of microorganisms reaching the lung usually are extremely small when the route of entry is inhalation, only organisms that are highly efficient pathogens produce infection by this mechanism. This does not include most of the common bacterial pathogens but does include most respiratory viruses, *Legionella* species, *Mycoplasma pneumoniae*, *Chlamydia* species, *Coxiella burnetii*, *Mycobacterium tuberculosis*, and most of the endemic fungal pneumonias. These pathogens are inhaled and deposited within alveoli, evading tracheobronchial mucociliary clearance. For the most part they share the ability to resist phagocytosis or to survive intracellularly within phagocytes, requiring the development of a humoral and cell-mediated immune response to limit infection.

For hematogenous spread of infection to the lung, the organisms must gain access to the venous circulation; the organisms lodge in the pulmonary microvasculature of the lung and proliferate. The pneumonia is usually diffuse or multinodular throughout both lung fields. In most cases, there is an established infection elsewhere, which is then carried to the lung, or organisms are injected directly into the bloodstream, as with intravenous drug abusers and persons given contaminated intravenous fluid infusions. The common pathogens are *S. aureus* and aerobic gram-negative bacilli such as *Pseudomonas aeruginosa*. A few rare pulmonary infections caused by very virulent organisms that gain entry directly through damaged skin are also transmitted to the lung hematogenously; such pulmonary involvement may occur in tularemia, brucellosis, and melioidosis.

PATHOPHYSIOLOGY

The proliferation of microorganisms within the pulmonary parenchyma elicits the host's full acute inflammatory response, with exudation of protein-rich fluid and influx of large numbers of phagocytic cells into alveoli and airways. The local mechanical consequences of this include impaired distribution of ventilation and a decrease in lung compliance, which contribute to increased work of breathing and the symptom of dyspnea. Ventilation/perfusion mismatch is increased somewhat, particularly in predominantly interstitial pneumonias; in most acute bacterial pneumonias, the major mechanism for arterial hypoxemia is intrapulmonary shunt caused by maintenance of pulmonary arterial blood flow to consolidated lung.[11,12] There is also evidence that metabolically active inflammatory cells within the consolidated lung consume oxygen, thus further decreasing pulmonary venous oxygen content and arterial oxygenation.[12–14]

The local inflammatory response includes activation of mononuclear phagocytic cells, which are the main source of interleukin 1, cachectin, and other cytokines that act as hormones mediating the acute-phase response. These effects

result in fever, leukocytosis, and the many other metabolic changes of infection. In more severe cases, bacteremia or microbial antigenemia may activate the inflammatory response systemically, leading to frank septic shock (see Chap. 46).

CLINICAL AND RADIOGRAPHIC FEATURES

The basic features common to most forms of pneumonia include (a) the presence of a systemic inflammatory response manifest as fever, elevation of the white blood cell count, and, in severe cases, other features of the sepsis syndrome; (b) pulmonary symptoms such as cough, sputum production, or hemoptysis, dyspnea, and pleuritic chest pain (if the pleura is involved); (c) physical findings consistent with an inflammatory pulmonary parenchymal process, such as tachypnea, rales, or signs of consolidation (bronchial breathing, dullness to percussion, increased vocal fremitus over the consolidated lung region); (d) evidence of abnormal lung function, such as arterial hypoxemia and hypocapnia (in a hyperventilating, dyspneic patient) or hypercapnia (in a patient with acute-on-chronic respiratory failure); and (e) a radiographic pulmonary infiltrate consistent with pneumonia.

There are major differences in the time course, frequency, and pattern of these findings among the many forms of pneumonia caused by the multiplicity of etiologic agents. Characterizing the patient's presentation based on the clinical, epidemiologic, and radiographic features—information generally available for most patients when they are initially seen—is a useful starting point in the assessment of pneumonia. These clinical presentations include:

1. Acute CAP
2. Aspiration pneumonia
3. Chronic pneumonia

ACUTE COMMUNITY-ACQUIRED PNEUMONIA

Bacterial Pneumonia

The typical history for CAP caused by conventional bacteria, most commonly *S. pneumoniae*, is acute onset of fever, with chills or rigors, associated with dyspnea and a cough productive of purulent or bloody sputum, sometimes with pleuritic chest pain. Patients with no chronic underlying disease often report a preceding upper respiratory tract infection, but most pneumonias occur in the presence of a predisposing illness, such as alcohol abuse, chronic lung disease, chronic cardiac or renal failure, or malignancy. In more severely debilitated patients or the institutionalized elderly, a specific history may be unavailable; new or worsened confusion and tachypnea noted by attendants is often the only history in these instances.

Physical examination shows a tachypneic, apprehensive patient with tachycardia, fever, and diaphoresis. Crackles are heard over the involved lung fields on auscultation. There may be signs of pulmonary consolidation (bronchial breathing, dullness to percussion, or increased tactile fremitus).

The chest radiograph usually demonstrates airspace consolidation with a lobar or a bronchopneumonic pattern. A dense lobar infiltrate, particularly with an air bronchogram, very strongly suggests acute bacterial pneumonia (Fig. 51-1); bronchopneumonic and patchy infiltrates are less specific.

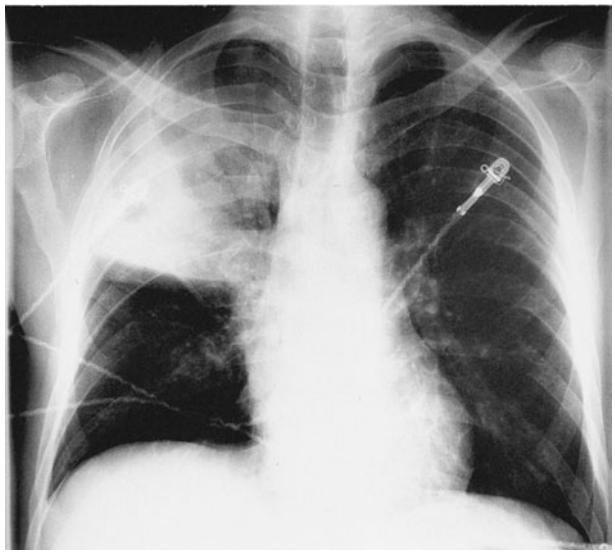

FIGURE 51-1 Dense localized infiltrate consistent with acute bacterial pneumonia. Note the air bronchogram, the downward-bulging transverse fissure, and the cavitation within the infiltrate, suggesting necrotizing infection with a mucoid organism such as *Klebsiella pneumoniae*, which proved to be the pathogen in this case.

Interstitial infiltrates virtually exclude the usual bacterial pneumonias, although diffuse reticulonodular patterns or multicentric pneumonia sometimes occur with hematogenous pneumonia (e.g., in intravenous drug abusers; Fig. 51-2).

The polymorphonuclear leukocyte count is usually elevated and shifted leftward but may be depressed in severely ill patients with shock or may even be within the normal range in debilitated or elderly patients.

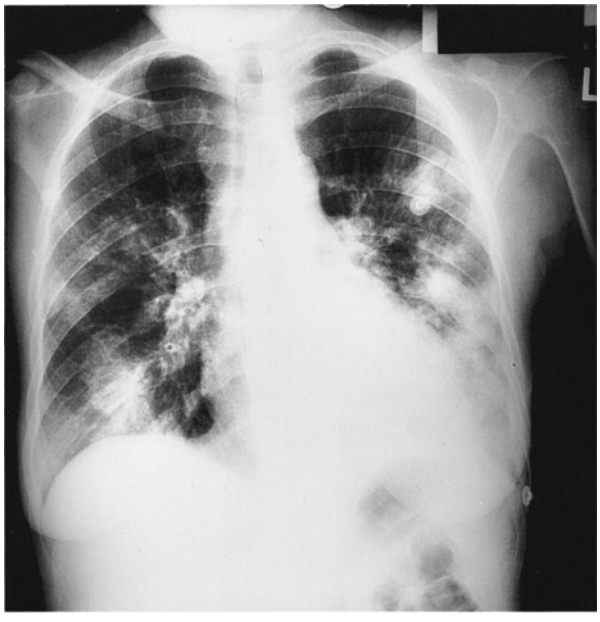

FIGURE 51-2 Multicentric hematogenous *Staphylococcus aureus* pneumonia in an intravenous drug abuser with severe cellulitis at an injection site. Note the multicentric regions of airspace consolidation.

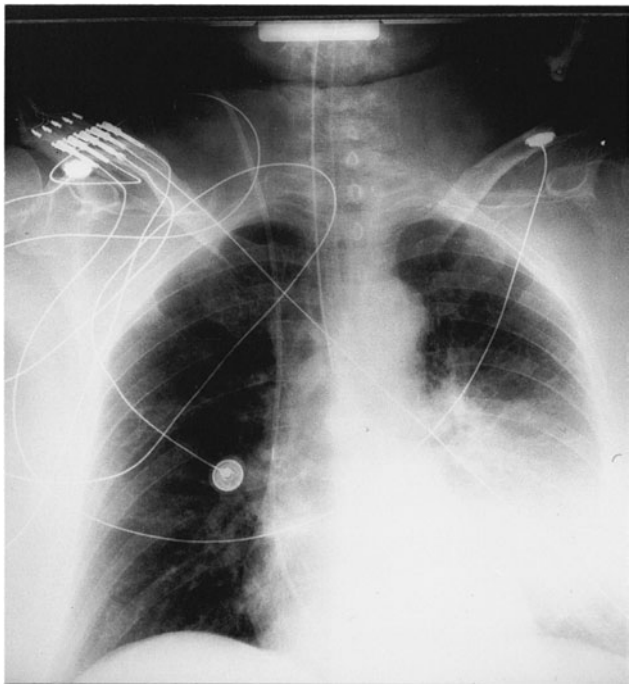

FIGURE 51-3 Ill-defined, large airspace density in the left lower lobe of a patient with community-acquired *Legionella pneumophila* pneumonia.

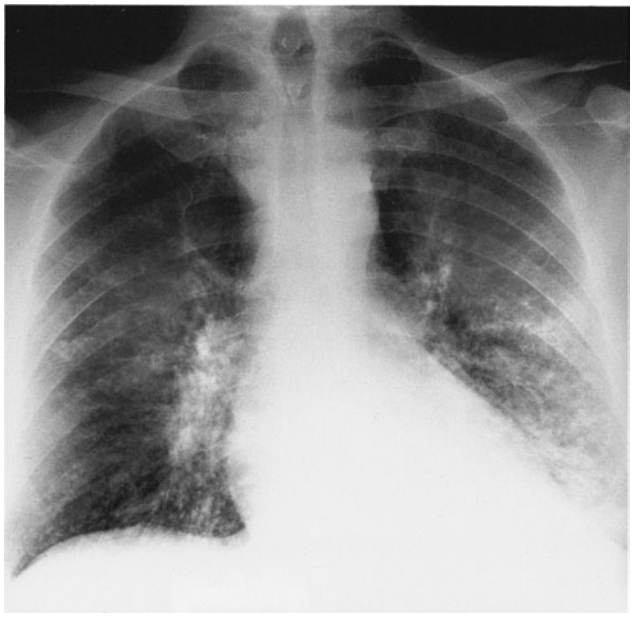

FIGURE 51-4 Diffuse interstitial and alveolar infiltrates in a patient with acute *Mycoplasma pneumoniae* pneumonia complicated by acute respiratory failure.

Legionnaire's Disease

Whereas early descriptions of community-acquired Legionnaire's disease emphasized many clinical features that set it apart from usual bacterial pneumonia,[15] we now know that Legionnaire's disease can present in ways clinically indistinguishable from disease caused by pneumococcus.[16] Clinical features that may suggest the diagnosis include dry cough, preceding diarrhea or other gastrointestinal (GI) symptoms, and encephalopathy not explained by other features of the illness. Epidemiologic clues include exposure to aerosols of *Legionella*-contaminated water in cooling towers or potable water distribution systems, underlying chronic lung disease, and immunologic impairment, particularly that caused by corticosteroid therapy. In patients requiring intensive care, the course is usually one of rapidly progressive pneumonia, sometimes with the aforementioned clinical features, or extrapulmonary involvement complicated by acute hypoxemic respiratory failure. The radiologic abnormalities are variable; most characteristic is peripheral rounded airspace consolidation with ill-defined margins (Fig. 51-3); however, patchy infiltration is also common.[17]

Mycoplasma pneumoniae *Pneumonia*

The term *atypical pneumonia* was coined to describe the pneumonia syndrome caused by *M. pneumoniae*, a pneumonia usually occurring in people in the second and third decades of life without major underlying disease predisposing to acute bacterial pneumonia. The clinical syndrome consists of a prodromal upper respiratory tract infection followed by an increasingly persistent dry cough associated with low-grade fever, frequently with extrapulmonary symptoms such as diarrhea, myalgia, arthralgia, and skin rash. In severe cases, the patient is tachypneic and cyanotic, but examination of the chest generally shows only widespread crackles without signs of pulmonary consolidation. The pharynx may be red; bullous myringitis is occasionally present, and a rash is sometimes seen. The chest radiograph most typically shows a unilateral segmental infiltrate but may show patchy or interstitial infiltrates bilaterally. In patients requiring intensive care for respiratory failure caused by this infection, diffuse bilateral interstitial and alveolar infiltrates are usual (Fig. 51-4). Other extrapulmonary features can also lead to the need for intensive care, in particular encephalomyelitis or myocarditis (manifest more commonly as prolonged QT interval or ventricular arrhythmias than as congestive heart failure). A moderately "septic" appearance and hemodynamic assessment is usual; however, frank septic shock is not, and hypotension is more often caused by volume depletion.

In the more severe cases seen in the ICU, the polymorphonuclear leukocyte count is elevated and shifted leftward, and thrombocytopenia may be present. Hemolytic anemia may be present because of the presence of high-titer cold agglutinins, which may also produce erroneous red cell indices, or "error flags," on automated cell counters because of red cell agglutination. Moderate elevation of hepatic transaminase levels is common. Although most patients do not produce sputum, in those who do it is usually purulent grossly and on microscopic examination; organisms are conspicuously absent on Gram stain.

Chlamydia psittaci

The major epidemiologic clue to psittacosis is exposure to infected birds, often pets (budgerigars and other related species which may or may not be visibly ill) in homes or pet stores, or commercial birds, such as turkeys, which may shed the organism when killed and eviscerated in processing plants.[18] The pneumonia follows exposure by 1 to 2 weeks. High fever and a persistent dry cough are frequently associated with a variety of atypical features: myalgias, headache, GI symptoms, and

occasionally a macular rash. On auscultation of the lungs, crackles over involved lung regions, without signs of pulmonary consolidation, are usual. Extrapulmonary physical findings are not infrequent: hepatomegaly, splenomegaly, pleural and pericardial friction rubs, and, in the rare case with complicating endocarditis, pathologic cardiac murmurs. In severe cases, dyspnea and hypoxia are prominent; encephalopathy, with confusion, obtundation, or even coma, may occur. The pulmonary infiltrate is generally a patchy infiltrate in all lung fields, with lower lobe predominance, but this is too variable to be a major differential point. Other routine laboratory studies are equally nonspecific, demonstrating only the usual hematologic and biochemical changes common in patients with serious infections.

Other *Chlamydia* species may also cause pneumonia (*C. pneumoniae* commonly, *C. trachomatis* rarely) but generally do not cause acute CAP sufficiently severe to require intensive care, unless the disease occurs in patients with severe underlying debility.

Q Fever Pneumonia

Coxiella burnetii is a rickettsia-like organism that is transmitted to human beings by inhalation of aerosols or suspended particulate matter from a wide variety of domestic and wild animals, including sheep, goats, cattle, domestic fowl, mice, rabbits, and parturient cats.[19] Usually the infected animal is not ill. The illness begins with fever and chills, associated with myalgia and severe diffuse headache in most cases. Some persons with Q fever have GI symptoms. Cough is usually not severe and is nonproductive; however, in cases likely to be referred for intensive care, dyspnea and hypoxemia are prominent. Peripheral segmental infiltrates or rounded opacities are the most common radiographic findings, but no radiologic pattern excludes the diagnosis. Leukocytosis, elevated hepatic transaminase levels, and electrolyte disturbances are common but not specific.

Viral Pneumonia

In adults, the major viral causes of pneumonia that produce illnesses severe enough to lead to ICU admission are influenza viruses A and B. Rarely, severe pneumonia can be caused by respiratory syncytial virus (RSV) or cytomegalovirus (CMV), especially in the debilitated elderly or the immunocompromised; by *Varicella zoster* virus in healthy adults with primary chicken pox or secondary to disseminated herpes zoster in the immunocompromised; by Epstein-Barr virus in nonimmunocompromised adults with unusually severe infectious mononucleosis; or by adenovirus in susceptible young adults in close contact (e.g., military recruits). Severe influenza occurs during epidemic periods of the year ("flu season," usually winter or early spring), particularly in nonimmunized patients who are elderly or have significant underlying disease. A "flu-like" illness, with fever, myalgia, headache, sore throat, and harsh cough with burning retrosternal chest pain, is followed by increasing dyspnea and prostration. Physical findings include pharyngitis, crackles and wheezes in all lung fields, tachypnea, and cyanosis. The chest radiograph generally shows diffuse interstitial infiltrates (Fig. 51-5) unless there is also a complicating acute bacterial pneumonia, which is a common circumstance.[20]

In autumn 2002, an apparently novel, highly contagious form of severe pneumonia appeared in southern China and over the ensuing months was transmitted by air travelers throughout the world, leading to multiple local outbreaks of different degrees of severity.[21] Termed *severe acute respiratory syndrome* (SARS), the illness has been shown to be caused by a coronavirus of animal origin transmitted to humans.[22] Typically, after close contact with an infected individual, there is an incubation period of 2 to 10 days followed by abrupt onset of fever with rigors.[23] Three to 5 days after the onset of fever, there follows the development of dyspnea associated with headache, malaise, and dry cough. Physical examination at this time is unremarkable except for crackles and signs of consolidation on chest examination. The white blood cell count is generally unremarkable except for moderate lymphopenia. The chest radiograph may be unremarkable in less severe cases, but in definite cases shows airspace opacities of variable (focal or patchy) distribution. In the more severe cases, pulmonary infiltrates progress over 5 to 10 days to full-blown acute respiratory distress syndrome (ARDS) radiologically and histopathologically, which requires intensive care for mechanical ventilatory support. Mortality rate worldwide has averaged about 15%, ranging from 1% to 5% in younger, previously well, people to higher than 50% in the elderly or debilitated. At the time of this writing, ongoing transmission of this infection appears to be halted; however, the potential for re-emergence of the disease clearly exists, requiring physicians to remain alert to this possibility when faced with rapidly advancing undiagnosed pneumonia in a returned traveler.

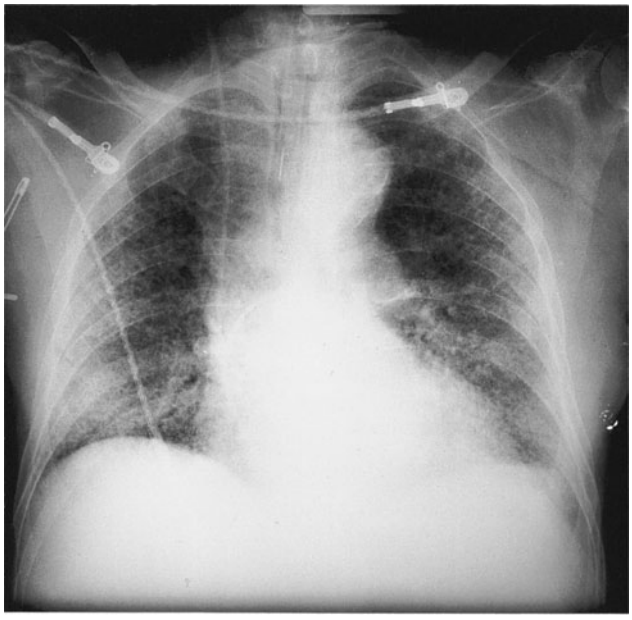

FIGURE 51-5 Diffuse interstitial infiltrates caused by influenza A pneumonia in an elderly, but otherwise well, individual.

Pneumocystis carinii *Pneumonia*

Although this infection is an opportunistic pneumonia occurring only in the severely immunocompromised, the current prevalence of the human immunodeficiency virus (HIV) among people who previously were well requires the physician to consider it as a possible diagnosis in patients presenting with diffuse pneumonia even in the absence of a prior diagnosis of HIV infection. It presents as a relatively

insidious illness characterized by low-grade fever, dry cough, and increasing dyspnea, usually with diffuse infiltrates on the chest radiograph (see Chap. 48). Although *Pneumocystis carinii* pneumonia (PCP) would be the immediate consideration with this presentation in a patient with known advanced HIV infection, the diagnosis is less obvious when this diagnosis has not been made, particularly when the patient is not known to be at increased risk for HIV infection (high-risk sexual activity, prior transfusion with potentially HIV-contaminated blood products, illicit intravenous drug use, or exposure to multiply-used nonsterile needles, etc.).

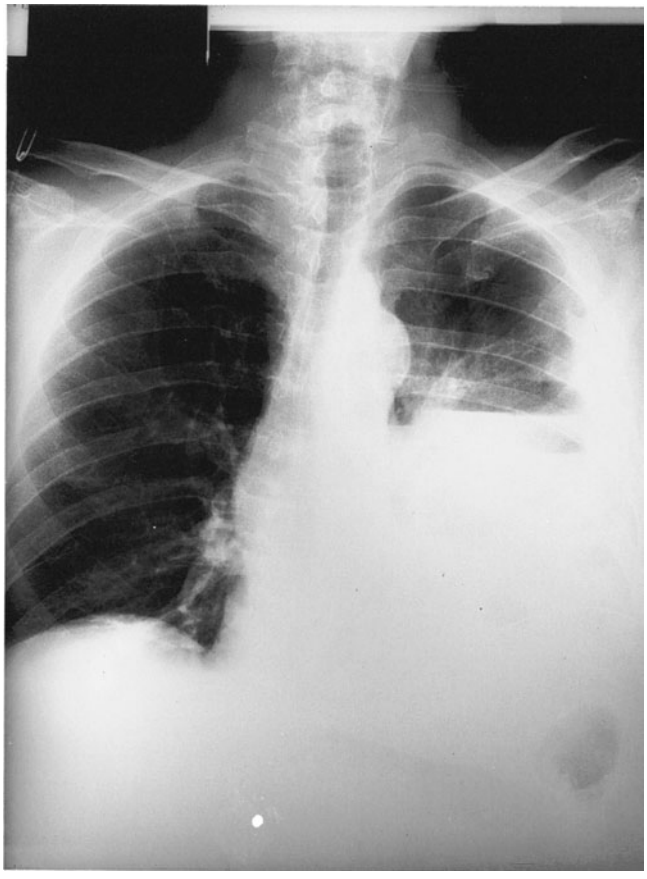
ASPIRATION PNEUMONIA

Frank aspiration of oropharyngeal or gastric contents can produce any of a number of different clinical presentations, depending on the amount and nature of the material aspirated.[24] Large-particle aspiration causes airway obstruction with acute asphyxia (the "cafe coronary"), atelectasis, unilateral or localized hyperinflation, or, subacutely, bacterial pneumonia or lung abscess caused by impaired mucociliary clearance in the airway obstructed by a foreign body. Small-particle or liquid aspiration usually causes a low-grade chemical pneumonitis, with a pulmonary infiltrate that clears over a few days without treatment. When the aspirated liquid is gastric acid, a more severe chemical burn is the result, with rapid exudation of fluid into the lung. Consequences can include acute hypovolemic hypotension and, if the region of damaged lung is relatively large, acute hypoxemic respiratory failure.

In most cases of witnessed pulmonary aspiration, the number and pathogenicity of aspirated bacteria are low, and no infection requiring immediate antimicrobial therapy is present. In addition, no evidence indicates that administering antimicrobials at this point decreases the risk of subsequent infective pneumonia, which, when it occurs, becomes evident 3 days to 1 week after the episode of aspiration.[24,25] A major exception to this rule is aspiration of gastric contents that have become heavily contaminated with mixed enteric organisms. This occurs in the setting of bowel obstruction with accumulation of large amounts of feculent upper GI fluid, which may be aspirated. It may also occur after upper abdominal surgery or in the presence of upper GI bleeding or paralytic ileus, particularly when there is absence of the normal low gastric pH on account of achlorhydria or treatment with antacids or histamine-blocking agents. Aspiration of feculent gastric contents can result in a fulminant necrotizing pneumonia caused by mixed aerobic and anaerobic enteric bacteria. Prompt broad-spectrum antimicrobial therapy is mandatory.

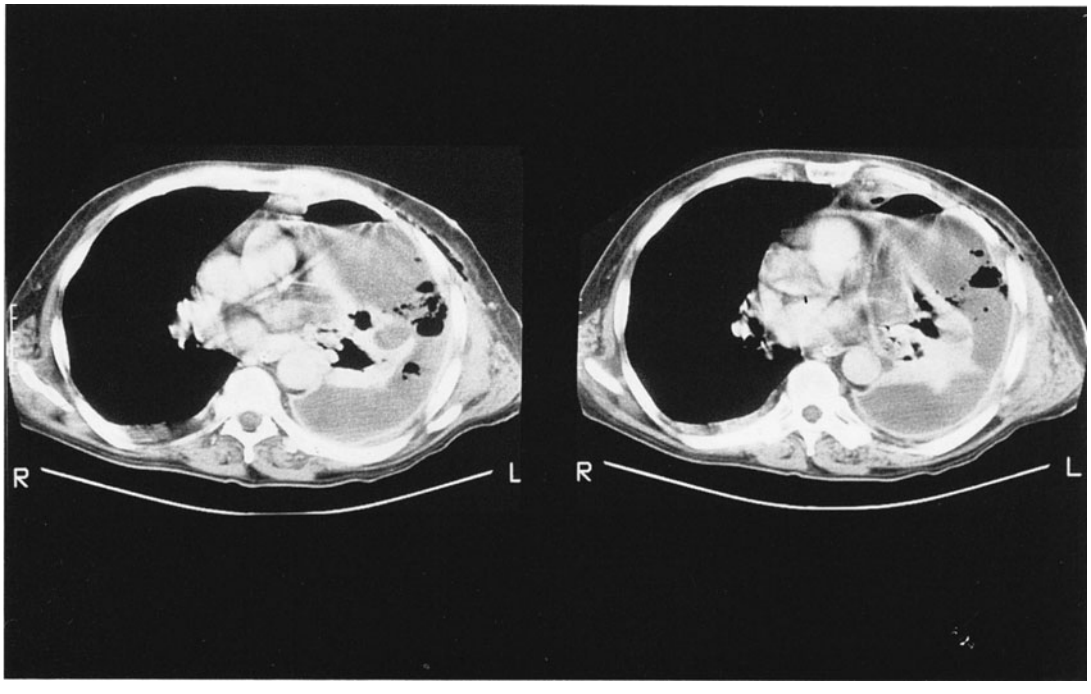
A much more common syndrome related to pulmonary aspiration is pneumonia or lung abscess caused by the predominantly anaerobic normal microflora of the mouth. Persons at particular risk are those who have a propensity toward aspiration because of a continuously or intermittently depressed level of consciousness (alcohol or drug abuse, epileptic seizures, stupor or coma of any cause), an impaired swallowing mechanism (esophageal or neurologic disease), or an impairment of tracheobronchial clearance mechanisms (endobronchial lesion or foreign body). After the aspiration episode, a low-grade pneumonia, manifest as cough, fever, and malaise, begins within a few days to 1 week. A chest radiograph at this time usually shows a patchy infiltrate, which may be unilateral or bilateral, occurring a little more commonly in the right lung and predominantly in lung zones that would be dependent in the supine patient (posterior segments of the upper and lower lobes). If the patient does not seek medical attention at this stage, the illness evolves over 1 to 4 weeks, with a persistent fever with night sweats, malaise, anorexia, and weight loss. The onset of production of large amounts of foul-smelling, watery sputum signals the development of a lung abscess, manifest on a chest radiograph as a cavity (or multiple smaller cavities), often with an air–fluid level, surrounded by a pulmonary infiltrate (Fig. 51-6). Involvement of the pleura often results in empyema, as demonstrated by clinical examination and radiographic findings consistent with a pleural effusion related to the region of pulmonary consolidation. Most patients with this syndrome are subacutely, rather than acutely, ill, but very large empyema collections or relatively extensive pneumonia can produce respiratory failure. In particular, the onset of respiratory insufficiency caused by re-expansion pulmonary edema after drainage of large empyemas may require intensive supportive therapy.

Leukocytosis may be mild or marked; many patients are anemic, especially those with a more protracted course. Electrolyte disturbances, in particular hyponatremia, are common. A variety of biochemical abnormalities related to lengthy illness and malnutrition may be present, including hypoalbuminemia, hypophosphatemia, and hypomagnesemia. None of these is particularly valuable in categorizing the syndrome.



CHRONIC PNEUMONIA

Pneumonia in intensive care practice is predominantly an acute problem; in a significant minority of cases, however, a chronic progressive pulmonary process presents with impending or established respiratory failure or with circulatory consequences of the inflammatory process. It is critically important to recognize the presentation as subacute or chronic, because the approaches to diagnosis and empiric therapy are entirely different from those employed in patients with acute pneumonia. Because the differential diagnosis can be extremely large, including many relatively exotic infectious diseases and a number of noninfectious entities, a systematic and aggressive diagnostic approach is more rewarding than wide-spectrum empiric therapy, the initial approach generally adopted for acute pneumonias.



The usual definition of chronic pneumonia is progressive pulmonary symptoms (cough, dyspnea, and pain) for a period of 3 weeks to several months, associated with radiographic evidence of an inflammatory pulmonary parenchymal process. The patient generally appears chronically, rather than acutely, ill and is often malnourished or cachectic. Hematologic and routine biochemical testings show the usual evidence of a longstanding inflammatory process: mild leukocytosis, lymphopenia, and anemia, more often with thrombocytosis than with thrombocytopenia; hypoalbuminemia; and multiple mild electrolyte abnormalities. Depending on the cause of the process and the specific other organs involved, a wide variety of other findings may be present.

DIAGNOSIS

Pneumonia is often an obvious diagnosis, particularly when respiratory symptoms associated with a new pulmonary

A

B

FIGURE 51-6 Aspiration-associated anaerobic pneumonia and empyema. A. Chest radiograph demonstrates multiple fluid levels with incompletely drained empyema fluid and underlying atelectasis or consolidation. B. Computed tomogram of the thorax shows multiple loculations of empyema fluid and, predominantly, atelectasis of the underlying lung. This patient required decortication to achieve adequate drainage and re-expansion of the lung.

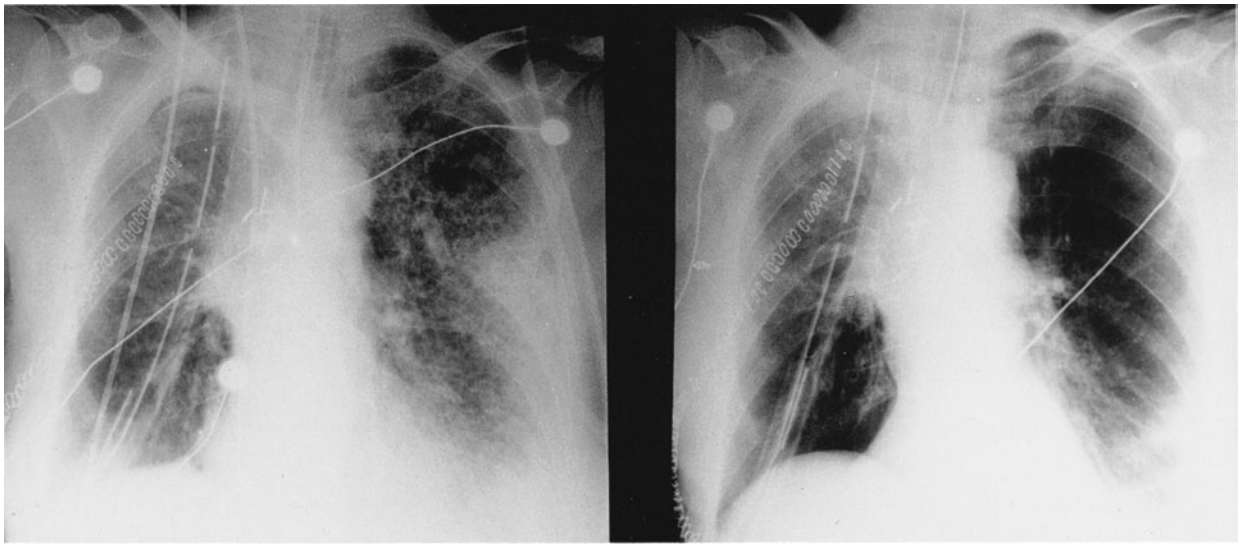


FIGURE 51-7 Example of delay of radiologic diagnosis of pneumonia attributable to volume depletion. These chest radiographs were obtained just 4 hours apart. *Right.* At the time this radiograph was obtained, the patient had severe dyspnea, crackles in the left lung, and hypoxemia requiring urgent intubation; until then she had been treated vigorously with diuretics for presumed cardiac failure, although no radiologic evidence and only equivocal clinical evidence were present. *Left.* After fluid resuscitation for hypotension (and demonstration of a low pulmonary wedge pressure), extensive pulmonary infiltrates quickly became evident in the left lung. These were attributed to acute *Escherichia coli* nosocomial pneumonia.

infiltrate and systemic signs of infection occur in a previously well patient. However, in patients with underlying lung or cardiac disease, the diagnosis may be more difficult. Increased dyspnea and cough with low-grade fever in a patient with an underlying chronic lung disease associated with long-term abnormalities on chest radiograph may be caused by pneumonia but may also represent a viral bronchitis or even an infection or inflammatory process elsewhere in the body. In a patient with known congestive cardiac failure, respiratory deterioration with a moderate leukocytosis and asymmetric radiographic findings of pulmonary edema may be due simply to heart failure, but the radiographic asymmetry may be caused by an underlying pneumonia. These less certain situations can be approached in one of two ways, depending on a clinical assessment of the relative likelihood that superimposed pneumonia is present, the severity of the illness, and the potential consequences of a wrong judgment. When pneumonia seems less likely and the patient is relatively stable, it is often reasonable to treat the underlying condition and withhold antimicrobial therapy with the expectation that the patient will improve without it. In the patient with congestive heart failure, steady clearing of the pulmonary edema, including the asymmetric region, without increasing systemic signs of infection helps to exclude the diagnosis of pneumonia; but failure of the local infiltrate to clear with diuresis, persistent productive cough, fever, and leukocytosis mandate further investigation and empiric treatment for pneumonia. In a more severely ill patient in whom it is felt that any delay in treatment for pneumonia would adversely affect outcome, it is more prudent to initiate empiric antimicrobial therapy at the outset and to stop that therapy later if the clinical course does not support the initial impression of possible pneumonia.

Cough with sputum production, fever, and leukocytosis without a convincing pulmonary infiltrate on chest radiograph is usually caused by viral bronchitis or, in the patient with chronic lung disease, an exacerbation of chronic bronchitis caused by a viral infection, or increased endobronchial bacterial microflora. However, in occasional cases, pneumonia may be present but not visible on the radiograph. This is usually caused by intravascular volume depletion delaying the appearance of the infiltrate (Fig. 51-7) or by a technically inadequate radiograph. Repeating the radiograph with a better technique or after volume resuscitation usually clarifies these situations.

When one has made a clinical diagnosis of pneumonia, the next major issues are making an etiologic diagnosis and prescribing antimicrobial therapy. These tasks can be made difficult by the fact that, although most pneumonias are caused by a small number of common pathogens, a significant minority is caused by a wide range of less common pathogens that require different approaches to investigation and treatment. The differential diagnosis also includes a large number of noninfectious causes of pulmonary infiltrates associated with an acute inflammatory response. For acute pneumonias, these include pulmonary atelectasis, chemical pneumonitis from aspiration or toxic inhalation, pulmonary infarction from pulmonary embolism, lung contusion in trauma cases, and a range of immunologically mediated acute pneumonitis syndromes. Noninfectious causes of subacute and chronic pneumonias are even more common. Many of these diagnoses can be suspected on the basis of the clinical context; in severe cases otherwise consistent with an infectious etiology, one usually should proceed with investigation and initial empiric therapy for infection until such an etiology is excluded.

The first step in the diagnostic assessment is to try to categorize the pneumonia presentation as outlined under Clinical and Radiographic Features. The diagnostic and immediate therapeutic approach to each is different: severe acute CAP mandates empiric antimicrobial therapy and investigation directed at identifying the offending organism; aspiration pneumonia or lung abscess is generally treated empirically with

agents directed at the predominantly anaerobic, normal oral microflora, with investigation aimed mainly at uncovering an underlying anatomic cause for the pneumonia; and the chronic pneumonia syndrome, which has an extremely large differential diagnosis including infectious and noninfectious entities, usually does not require empiric therapy but does mandate a systematic and often invasive approach to establishing the diagnosis.

ACUTE COMMUNITY-ACQUIRED PNEUMONIA

All patients with a clinical diagnosis of pneumonia leading to ICU admission should have a blood culture, a Gram stain, and culture of lower respiratory tract secretions. If a significant pleural effusion is present it should be aspirated. In nonintubated patients, the immediately available lower respiratory tract sample is sputum, which is a mixture of materials from the lung and the upper respiratory tract and that has many well-known limitations in diagnosis: The patient may not be able to produce a good specimen; the specimen may contain potentially pathogenic organisms that come from the upper respiratory tract but are not the cause of the pneumonia; and contaminating organisms from the upper airway may overgrow the real pathogen on the culture plate and prevent its detection. Despite these problems, sputum examination remains a good place to start, mainly because in a significant minority of cases, and particularly in the most severe cases of bacterial pneumonia, the Gram stain, with subsequent confirmation by culture, can be diagnostic.

The utility of the Gram stain can be maximized by microscopic evaluation of the degree to which the sample is contaminated by upper respiratory secretions.[26] A specimen with large numbers of polymorphonuclear leukocytes, more than 25 per high-power field, and few large epithelial cells, fewer than 10 per high-power field, is reasonably likely to represent a good-quality lower respiratory tract specimen and can usefully be examined further to determine the predominant bacterial morphotype present. Those specimens with large numbers of epithelial cells and few leukocytes are mostly saliva; they are unlikely to yield useful diagnostic information and should be discarded after another and better specimen has been obtained. In a patient with a clinical presentation consistent with acute bacterial pneumonia, a microscopically acceptable specimen that contains large numbers of bacteria of a single morphotype and few bacteria of other types is strong evidence that this is the cause of the pneumonia. A fairly definitive result such as this occurs in fewer than 33% of cases; however, it occurs more commonly in the most severe cases—those with extensive pneumonia caused by *S. pneumoniae*, *S. aureus*, and enteric facultatively aerobic gram-negative bacilli—and in cases in which an endotracheal tube has been placed, which permits the collection of a less heavily contaminated lower respiratory tract specimen.

Preliminary results of blood and sputum cultures are usually available at 24 to 48 hours. Whereas a positive blood culture for a recognized pneumonia pathogen is definitive, sputum cultures must be interpreted in light of the original Gram stain of the specimen, bearing in mind that potential pathogens grown from a specimen that contained mainly upper respiratory tract material may not be the cause of the pneumonia and that, if the patient received antimicrobials before providing the specimen, susceptible pathogens such as *S. pneumoniae* might not be detected.

In most cases of acute bacterial pneumonia, the investigations described above are all that is needed. Patients with severe bacterial pneumonia leading directly to ICU admission very frequently have positive blood or respiratory secretion cultures, whereas those who are less ill at the time of hospital admission usually improve with empiric antimicrobial therapy (whether or not a positive culture is obtained). Further investigation is needed in patients whose condition deteriorates or fails to improve and in whom the initial investigation has failed to provide an etiologic diagnosis to guide changes in therapy. The first step in a newly intubated patient is to repeat the Gram stain and culture of lower respiratory tract secretions. In deteriorating nonintubated pneumonia patients, the procedure of choice is fiberoptic bronchoscopy using a protected brush to collect a specimen from the consolidated lung segment or bronchoalveolar lavage (BAL) of the region. Because many of these patients have significantly compromised respiratory function, the procedure should be performed by an experienced bronchoscopist with other personnel present to continually monitor the patient's respirations, blood pressure and pulse, and oxygenation. A pulse oximeter to monitor arterial oxygen saturation continuously is mandatory. In patients who have significant arterial hypoxemia to begin with, it is usually best to insert an endotracheal tube and provide supplemental oxygen and assisted ventilation to facilitate bronchoscopy. The specimens obtained should be Gram stained and cultured quantitatively for conventional bacteria; the finding of more than 10^5 colony-forming units/mL from a BAL specimen (or 10^3 colony-forming units/mL from a protected brush) of a recognized pathogen is diagnostic of infection.[27–29] The specimen also should be stained and cultured for *Legionella* species, mycobacteria, and fungi and, where available, cultured for viruses. In most cases, it is also wise to do cytologic examination of the specimen.

Among the major pneumonia pathogens not detectable by routine Gram stain and culture of respiratory secretions, the one with the greatest propensity to present with an illness indistinguishable from usual acute bacterial pneumonia is *Legionella pneumophila*. For this reason, some hospital laboratories in areas of high prevalence routinely culture all submitted lower respiratory tract secretions for this organism. If this culture is not done routinely, it should be ordered specifically for all patients in whom an etiologic diagnosis is not immediately evident from the Gram stain. A direct fluorescent antibody stain for *Legionella* is also available. This can be done on sputum, endobronchial aspirates, or bronchoscopy specimens, but, particularly with sputum, the sensitivity of the test is not high, and false-positive results can result from cross-reaction of the fluorescent antibody with other gram-negative species. A urinary antigen detection test for *Legionella* is available in many centers and has excellent specificity; however, particularly early in the course of the illness, the sensitivity is not sufficiently high to exclude the diagnosis.[16]

In cases of severe pneumonia that resist diagnosis, particularly when the clinical course suggests the possibility of infection with an "atypical pneumonia " pathogen, additional investigations should be ordered according to the epidemiologic features of the case. In appropriate cases, culture of respiratory secretions and stool for viruses is worthwhile. Acute and 2- to 4-week blood specimens for serologic examination will establish the diagnosis in *M. pneumoniae*, *Chlamydia* speceis, *C. burnetii*, and the major viruses causing pneumonia

(influenzae A and B, adenovirus, RSV, and CMV). Single high-titer–specific antibody levels can also be used to make most of these diagnoses earlier in the clinical course. Serology is also valuable in diagnosing some rare bacterial infections, such as *Francisella tularensis* pneumonia and brucellosis. Legionnaire's disease also can be detected serologically, but, because the antibody response to the organism may be slow, convalescent blood specimens should be drawn at 2 weeks and 6 weeks.

Direct enzyme immunoassay antigen detection performed on respiratory secretions is widely available for diagnoses of influenza A and RSV and is very useful in establishing a diagnosis quickly. At the time of this writing, rapid diagnostic testing for the SARS coronavirus is still under development; the diagnosis still relies on clinical case definitions associated with investigation of the outbreak (probable case: exposure to a known case or travel to an area of local transmission, fever, respiratory symptoms, and pulmonary infiltrate on chest radiograph without an alternative diagnosis).

Suspicion of PCP, generally based on the clinical and radiographic features and history of factors placing the patient at increased risk of HIV infection, should prompt early consideration of fiberoptic bronchoscopy with BAL. Serologic testing for HIV is usually also a part of this investigation.

ASPIRATION PNEUMONIA

The approach to aspiration-associated acute bacterial pneumonia caused by the usual pyogenic aerobic organisms is the same as that for pneumonia caused by subclinical aspiration. However, most aspiration CAPs, particularly those progressing to lung abscess, are caused by organisms constituting the normal flora of the oropharynx. These are predominantly anaerobic. Culture of sputum or endotracheal aspirates will always demonstrate some of these organisms because of the inevitable contamination of these specimens with saliva, and the microbiology laboratory will report the result of aerobic cultures as containing "normal flora." Anaerobic culture of such specimens is not worthwhile because they also would demonstrate "normal flora" in virtually all patients whether or not these organisms were pathogenically important. When the clinical presentation suggests aspiration pneumonia and conventional sputum or endobronchial aspirate cultures show only "normal flora," in most cases it is reasonable to make a clinical diagnosis of pneumonia caused by mixed oropharyngeal anaerobic bacteria and to treat accordingly. In less obvious cases, in which bronchoscopy is done to establish an etiologic diagnosis, it is reasonable to perform aerobic and anaerobic cultures on protected brush or BAL specimens because they are less likely to be contaminated by saliva. Bronchoscopy at some time in the treatment course is indicated in many patients with anaerobic pneumonia or lung abscess, particularly those with no clearly increased risk of significant aspiration, to exclude a predisposing endobronchial lesion.

CHRONIC PNEUMONIA

Some of the many infectious and noninfectious diseases that may present as a chronic pneumonia are listed in Table 51-2. Patients with an undiagnosed chronic pneumonia are less common in the ICU environment because the chronicity of progressive symptoms usually leads patients to seek medical attention before intensive care is required. In those who do present in respiratory failure, there are usually extensive bilateral pulmonary infiltrates, and the radiologic pattern is sometimes helpful in suggesting the diagnosis. However, almost every "characteristic" radiologic pattern can be caused by several different disease processes.

TABLE 51-2 Infectious and Noninfectious Etiologies of Chronic Pneumonia

Bacterial and mycobacterial infections
Tuberculosis
Chronic cavitary bacterial pneumonia (*Klebsiella pneumoniae, Pseudomonas aeruginosa*, others)
Actinomycosis
Nocardiosis
Melioidosis
Aspiration-induced anaerobic pneumonia and lung abscess
Fungal infections
Blastomycosis
Coccidioidomycosis
Paracoccidioidomycosis
Histoplasmosis
Cryptococcosis
Chronic necrotizing aspergillosis
Noninfectious causes
Systemic vasculitides
Malignancy
Interstitial pneumonitis (fibrosing alveolitis) and other idiopathic infiltrative pulmonary diseases
Cryptogenic organizing pneumonia
Lymphomatoid granulomatosis
Sarcoidosis
Toxic exposures and drug reactions

Among infectious causes of chronic pneumonia, reactivating pulmonary fibrocaseous tuberculosis generally demonstrates characteristic upper lobe predominance, with cavities and pleural thickening and scarring, but only rarely causes significant hypoxemia, generally when spillage of infected material from tuberculous cavities into otherwise normal lung produces acute airspace inflammation termed *acute tuberculous pneumonia* (Fig. 51-8). Somewhat less rarely, miliary tuberculosis or chronic hematogenous tuberculosis usually presents with a diffuse miliary or reticulonodular pattern on a chest radiograph (Fig. 51-9), often with respiratory failure, particularly when the disease produces a systemic inflammatory response complicated by the ARDS.[30] Infections that can mimic upper lobe tuberculosis reactivation include chronic necrotizing bacterial pneumonia (usually caused by *K. pneumoniae*, occasionally by *P. aeruginosa* or *S. aureus*), melioidosis, and some fungal infections. Miliary or reticulonodular disease (with or without ARDS) causing respiratory failure also occasionally occurs with fungal pneumonias, in particular blastomycosis[31] (Fig. 51-10), malignancy, and noninfectious granulomatous diseases.

The initial step in the investigation of a patient with a chronic pneumonia is recognizing that the pace and pattern of the disease do not fit with one of the acute bacterial or atypical pneumonias. Appropriately directed, additional history taking for exposure to tuberculosis or residence in an area endemic for one of the dimorphic fungi can be obtained, and extrapulmonary symptoms or signs associated with the noninfectious diseases listed in Table 51-2 can be sought. Lower respiratory tract secretions should be sent for routine Gram stain and culture for bacteria, and several

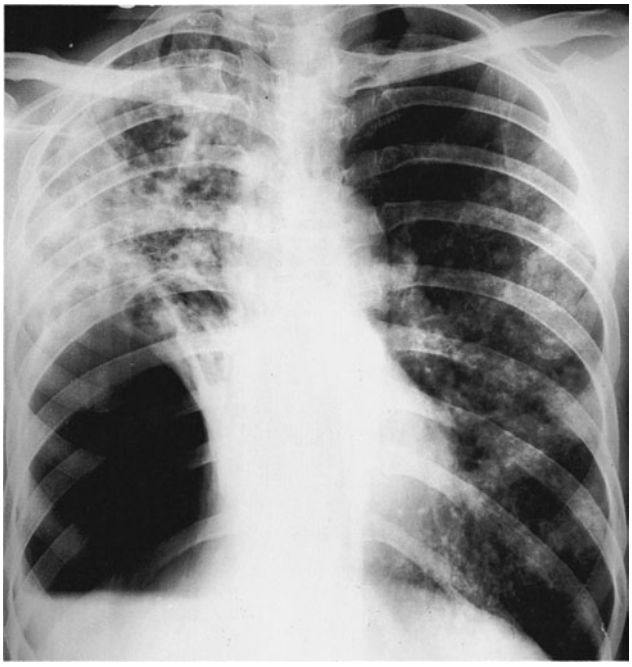

FIGURE 51-8 Tuberculous pneumonia. Fairly discrete acinar shadows are present in the left lung, remote from the confluent airspace disease on the right. ***(Courtesy of Dr. Richard Long, Edmonton, Canada.)***

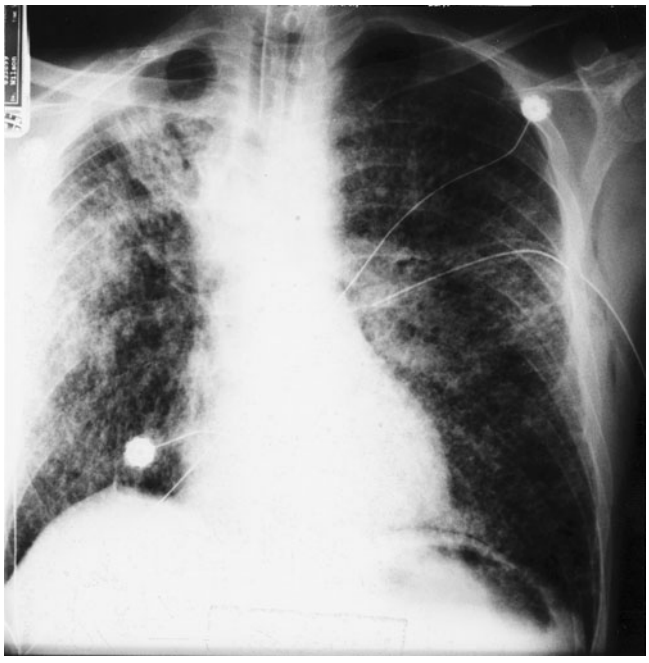

FIGURE 51-10 Severe pulmonary blastomycosis with a miliary pattern. This patient had an associated septic arthritis of the right knee caused by blastomycosis, the likely source of hematogenous dissemination to the lung.

specimens should be examined and cultured for mycobacteria and fungi. In patients who have spent time in the Far East, examination for ova and parasites should be done to exclude infection with *Paragonimus westermani*. Cytologic studies for malignancy should be done in most cases. If sputum or endobronchial secretions are used, these should be sent repeatedly (three to five specimens) to maximize yield. In patients from whom satisfactory secretions cannot be obtained, fiberoptic bronchoscopy with BAL is most satisfactory.

Other noninvasive tests for infectious agents, such as serologic testing and skin tests, which are often of some diagnostic value in less severely ill patients, are not helpful in critically ill patients. However, for some of the noninfectious diseases, in particular systemic vasculitides and other immunologically mediated diseases with pulmonary involvement, testing for the specific autoantibodies associated with these syndromes can be very useful (see Chap. 104).

Many of the causes of the chronic pneumonia syndrome also cause extrapulmonary manifestations. The nature of these associated findings is frequently of considerable help in suggesting the correct diagnosis; examples include skin or bone involvement with pulmonary blastomycosis, sinusitis with Wegener granulomatosis, lymphocytic meningitis with coccidioidomycosis or tuberculosis, granulomatous oral lesions with paracoccidioidomycosis, and glomerulonephritis with Goodpasture syndrome and other immunologically mediated systemic diseases. When other organ systems are involved, it is often less risky for a patient with significantly compromised respiratory function to undergo biopsy of the extrapulmonary site of involvement rather than of the lung.

If a diagnosis is not promptly established by the initial examination of lower respiratory tract secretions, if the clinical constellation of findings is not characteristic enough to establish a diagnosis on these grounds, and if no extrapulmonary site of involvement suitable for biopsy is present, most critically ill patients with chronic pneumonia immediately should undergo open lung biopsy. The range of potential diagnoses and risks associated with empiric therapy for most of the diagnostic entities is simply too large to attempt management without establishing a definitive diagnosis. In a patient who has reached a stage of the disease requiring intensive care,

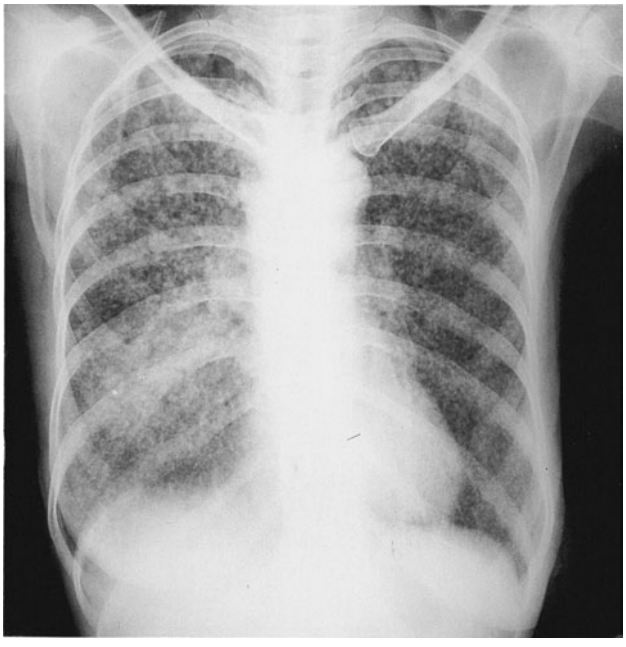

FIGURE 51-9 Miliary tuberculosis. Discrete small nodules (1 to 3 mm) are uniformly distributed throughout the lungs. ***(Courtesy of Dr. Richard Long, Edmonton, Canada.)***

TABLE 51-3 Initial Antimicrobial Therapy for Acute Pneumonia of Known Etiology in Critically Ill Patients[a]

	Recommended Antimicrobial Therapy	Alternative Antimicrobial Agents
Streptococcus pneumonia and other streptococci		
Penicillin susceptible	Penicillin G 1 million U IV q 4 h	Cefazolin, clindamycin, or vancomycin
Intermediate susceptibility (MIC 0.1–1.0 μg/mL)	Penicillin G 3 million U IV q 4 h or cefotaxime 2 g IV q 8 h	Clindamycin, fluoroquinolone, vancomycin
Penicillin resistant (MIC > 2 μg/mL)	Vancomycin 1 g IV q 12 h	Linezolid, fluoroquinolone
Staphylococcus aureus		
Methicillin sensitive	Nafcillin 2 g IV q 4 h	Cefazolin, clindamycin, or vancomycin
Methicillin resistant	Vancomycin 500 mg IV q 6 h	Linezolid, cotrimoxazole (if susceptible)
Haemophilus influenzae		
β-Lactamase negative	Ampicillin 2 g IV q 6 h	Cefuroxime, cotrimoxazole
β-Lactamase positive	Cefuroxime 1.5 g IV q 8 h	Cotrimoxazole
Moraxella catarrhalis	Cefuroxime 1.5 g IV q 8 h	Cotrimoxazole
Klebsiella, Escherichia coli, etc.	Cefotaxime 2 g IV q 6 h *and* gentamicin 4.5 mg/kg q 24 h	Piperacillin/tazobactam or carbapenam *and* gentamicin, cotrimoxazole, or ciprofloxacin
Enterobacter spp.	Meropenem 500 mg IV q 8 h *and* ciprofloxacin 400 mg IV q 12 h	Cotrimoxazole
Pseudomonas aeruginosa	Ceftazidime 2 g IV q 8 h *and* tobramycin 4.5 mg/kg q 24 h	Carbapenem or anti-pseudomonal penicillin and tobramycin or ciprofloxacin
Anaerobic pneumonia/ lung abscess	Penicillin 2 million U IV q 4 h *and* metronidazole 750 mg IV q 8 h	Clindamycin, chloramphenicol
Legionella pneumophila	Ciprofloxacin 400 mg IV q 12 h ± rifampin 600 mg IV daily	Macrolide and rifampin
Mycoplasma pneumoniae	Azithromycin 500 mg IV once daily	Tetracycline, macrolide or fluoroquinolone
Chlamydia psittaci (psittacosis)	Doxycycline 100 mg IV q 12 h	Macrolide, fluoroquinolone
Coxiella burnetii (Q fever)	Doxycycline 100 mg IV q 12 h	Macrolide with rifampin
Yersinia pestis (plague)	Gentamicin 5 mg/kg IV once daily	Ciprofloxacin, doxycycline
Francisella tularensis (tularemia)	Gentamicin 5 mg/kg IV once daily	Ciprofloxacin, doxycycline
Bacillus anthracis (anthrax)	Ciprofloxacin 400 mg IV q 12 h *and* clindamycin 600 mg IV q 8 h	Doxycycline, rifampin, penicillin G (if susceptible)
Influenza A or respiratory syncytial virus (severe with respiratory failure)	Ribavirin aerosol 1 g/d over 12–18 h	
Varicella zoster	Acyclovir 10 mg/kg q 8 h	

[a] All drug dosages cited are for patients with normal renal function; dosage adjustment for renal insufficiency is required for several of the agents listed. Monitoring of blood drug levels is strongly advised for the aminoglycosides.
ABBREVIATIONS: IV, intravenously; MIC, minimum inhibitory concentration.

the necessary time for further observation of the course or attempts at empiric trials of therapy is lacking.

ANTIMICROBIAL THERAPY

ACUTE COMMUNITY-ACQUIRED PNEUMONIA

When a specific etiologic diagnosis for pneumonia has been established on the basis of the blood culture or Gram stain and culture of secretions from the respiratory tract, antimicrobial therapy directed specifically at that pathogen can be prescribed (Table 51-3). The regimens suggested in this chapter are applicable when in vitro testing demonstrates that the organism is susceptible to the listed antimicrobial agents; resistant strains would require appropriate alternative therapy. However, in most cases of pneumonia, the etiologic diagnosis is not available at the outset, and empiric therapy must be directed at the most probable microbial etiologies in the particular patient being treated. Because patients requiring intensive care are usually in a relatively precarious state that makes the consequences of undertreatment unacceptable, it is a principle of therapy in this class of patient that antimicrobial treatment should be very conservative; that is, it should cover all etiologic possibilities except the quite remote ones. Some suggested empiric regimens are presented in Table 51-4; these are loosely congruent with, but not identical to, some recent recommendations from expert panels[1–3] that thus far have been unable to reach a consensus, mainly because definitive comparative studies of antimicrobial regimens do not exist.

For most cases of severe acute pneumonia, a third-generation cephalosporin combined with quinolone or a macrolide is appropriate because it works against most conventional bacteria likely to be acquired in the community and atypical pathogens such as *Legionella* and *Mycoplasma*. A respiratory quinolone or macrolide alone is not advised in the more severely ill ICU population because of the emergence of significant resistance to these agents in *Streptococcus pneumoniae* and some other species.

When the clinical context suggests the possibility of infection caused by *C. burnetii* or *C. psittaci*, a tetracycline such as doxycycline 100 mg intravenously (IV) every 12 hours should be included in the regimen. Rifampin 600 mg IV or orally can be added for patients with fulminant atypical pneumonia and for patients with pneumonia caused by *L. pneumophila*

TABLE 51-4 Empiric Antimicrobial Therapy for Critically Ill Patients with Acute Community-Acquired Pneumonia[a]

Clinical Setting	Recommended Antimicrobial Therapy	Alternative Agents
Acute community-acquired pneumonia (including nursing home patients and those with COPD or alcohol abuse)	Cefotaxime 2 g IV q 8 h *or* other third-generation cephalosporin	β-Lactam/β-lactamase inhibitor, carbapenem, respiratory fluoroquinolone
Legionellosis or suspected atypical pneumonia	Ciprofloxacin 400 mg IV q 12 h *or* azithromycin 500 mg IV once daily	
Anaerobic aspiration pneumonia/lung abscess	Penicillin G 2 million U IV q 4 h *and* metronidazole	Clindamycin, carbapenam, β-lactam/β-lactamase inhibitor
Severe/fulminant pneumonia	Piperacillin/tazobactam 3.375 g IV q 6 h *and* ciprofloxacin 400 mg IV q 12 h	Carbapenem or third-generation cephalosporin *and* ciprofloxacin or macrolide

[a] Dosages cited are for patients with normal renal function; dosage adjustment for renal insufficiency is required for several of these agents.
ABBREVIATIONS: COPD, chronic obstructive pulmonary disease; IV, intravenously.

or Q fever that is responding poorly to the initial treatment regimen.

ASPIRATION PNEUMONIA

Most cases of witnessed or otherwise recent aspiration of oropharyngeal or gastric contents associated with a new pulmonary infiltrate represent an acute chemical pneumonitis rather than an infection. These cases usually resolve without antimicrobial therapy, with deep breathing and coughing, or with chest physiotherapy, when required. There is no convincing evidence that early administration of antimicrobials decreases subsequent incidences of complicating bacterial pneumonia, although there is evidence that such treatment may be associated with subsequent pneumonia caused by a relatively antimicrobial-resistant organism.[24,25] Aspiration that has resulted in pneumonia, lung abscess, or empyema caused by oropharyngeal anaerobic bacteria has usually been treated, at least initially, with penicillin. However, in a critically ill patient with this syndrome, therapy should usually begin with penicillin 2 million U IV every 4 hours and metronidazole 750 mg IV every 6 hours or with clindamycin 900 mg every 8 hours. Aspiration can also be complicated by later development of aerobic acute bacterial pneumonia; in these cases, the regimens listed in Tables 51-3 and 51-4 apply. Much less commonly, aspiration can produce an acute, rapidly progressive necrotizing pneumonia. This infection usually involves anaerobes and facultatively aerobic enteric gram-negative bacilli. The clinical context is often major aspiration in a patient without gastric acid (and therefore a large gastric bacterial population) or with an accumulation of feculent material in the stomach caused by adynamic ileus, upper GI bleeding, or bowel obstruction. Treatment must include adequate coverage for anaerobes, including *Bacteroides fragilis*, and aerobic gram-negative organisms. As in other acute gram-negative pneumonias, it is unwise to rely on an aminoglycoside alone for aerobic gram-negative coverage. Acceptable initial regimens include piperacillin/tazobactam 3.375 g IV every 6 hours with gentamicin 4.5 mg/kg every 24 hours, clindamycin 900 mg IV every 8 hours with cefotaxime 2 g IV every 6 hours, and meropenem 1 g every 8 hours with gentamicin 4.5 mg/kg IV every 24 hours. Ciprofloxacin can be substituted for the aminoglycoside when toxicity is a concern.

CHRONIC PNEUMONIA

Empiric therapy is seldom indicated for patients presenting with a chronic pneumonia. The pace of the illness is generally such that a delay of hours or a few days in establishing the diagnosis is not critical, and the large differential diagnosis makes selection of empiric treatment difficult. One occasional exception to this rule is extensive pneumonitis or pulmonary hemorrhage in a patient with sufficient extrapulmonary evidence to support a clinical diagnosis of a systemic inflammatory disease such as lupus erythematosus, Goodpasture syndrome, polyarteritis, or Wegener granulomatosis (see Chap. 104).

A full discussion of specific therapies for all the infectious and noninfectious causes of chronic pneumonia is beyond the scope of this chapter; however, treatment regimens for the more common fungal pneumonias are listed in Table 51-5. Drugs used in the treatment of critical illness or respiratory failure caused by tuberculosis are listed in Table 51-6. In general, in seriously ill patients, use of four antituberculous drugs initially (isoniazid, rifampin, pyrazinamide, and streptomycin; ethambutol substituted for streptomycin, if necessary, or added if drug resistance is suspected) is recommended.[32] Addition of a corticosteroid (methylprednisolone 125 mg IV every 12 hours) can also be considered in the nonimmunocompromised patient with severe tuberculosis in an attempt to speed resolution of the exudative

TABLE 51-5 Treatment Regimens for Fungal Pneumonia Associated with Critical Illness in the Nonimmunocompromised Host

Etiologic Agent	Recommended Antimicrobial Therapy
Blastomyces dermatitidis	Amphotericin B 0.5–1.0 mg/kg IV daily to total dose of 2–2.5 g
Histoplasma capsulatum	As above
Coccidioides immitis (without CNS involvement)	Amphotericin B 0.5–0.8 mg/kg IV daily to total dose of 3–4 g
Cryptococcus neoformans	Amphotericin B 0.4–0.6 mg/kg IV daily *and* flucytosine 75–100 mg/kg daily in 4 divided doses (adjusted according to monitored blood levels)

ABBREVIATIONS: CNS, central nervous system; IV, intravenously.

TABLE 51-6 Drugs Used in the Treatment of Critical Illness due to Tuberculosis

Drug	Daily Dose	Route	Comments
Isoniazid	10 mg/kg up to 300 mg (given with pyridoxine 50 mg)	PO, IM, IV	Hepatotoxic—monitor liver enzymes
Rifampin	20 mg/kg up to 600 mg	PO, IV	Hepatotoxic—monitor liver enzymes
Pyrazinamide	30 mg/kg up to 2 g	PO	Monitor liver enzymes and serum uric acid
Streptomycin	15 mg/kg up to 1 g	IM	Nephrotoxic—monitor renal function; neurotoxic to cranial nerve VIII
Ethambutol	25 mg/kg	PO	

ABBREVIATIONS: IM, intramuscular; IV, intravenous; PO, oral.

inflammatory response, but controlled studies to support this practice are lacking.

SUPPORTIVE THERAPY

In most respects, supportive therapy for patients with pneumonia resembles that for other patients with infections requiring intensive care. The most frequent reason for a patient with pneumonia to require intensive care is respiratory failure. An approach to management of this problem is detailed in Chapter 38. Most patients have intravascular volume depletion at presentation and require some intravenous volume expansion with crystalloid solutions. However, septic pneumonia patients are also at increased risk of developing more generalized pulmonary edema, as in ARDS (see Chap. 38). Hypotension that does not respond to reasonable volume expansion is usually due to septic shock, the management of which is detailed in Chapter 46.

As in other critically ill patients, a multiplicity of metabolic, hematologic, and blood electrolyte abnormalities occur and may require correction. Especially important in the pneumonia patient is hyponatremia caused by inappropriate vasopressin secretion, leading to impaired water excretion by the kidney; this is common and makes administration of hypotonic intravenous solutions potentially hazardous.[33] The correction of metabolic alkalosis of any cause also may be important because this may be associated with an improvement in arterial oxygenation caused by improved ventilation/perfusion matching related to potentiation of regional hypoxic pulmonary vasoconstriction.[34]

Because patients with acute pulmonary infections frequently shed potentially pathogenic organisms into their immediate environment, the risk of exposure of caregivers and other patients to these pathogens must be considered. Many of the common acute respiratory pathogens causing pneumonia are normal flora of the respiratory tract (e.g., *S. pneumoniae*, *H. influenzae*, and *Moraxella catarrhalis*) and therefore require no special precautions during patient care. However, some bacterial pathogens do pose significant risk to other patients if transmitted via aerosol or on the hands or equipment of caregivers. These include *S. aureus* (especially methicillin-resistant *S. aureus*) and multiply-resistant gram-negative bacilli. When these organisms are cultured or suspected patients should be cared for in separate rooms, where possible, using appropriate infection control precautions[35] (see Chap. 4). Some viral infections also pose a risk to staff and other patients. Examples include influenzae A and B (for which staff vaccination is highly effective), RSV, and acute *Varicella zoster*.

During the SARS outbreak of March 2002, transmission of infection to caregivers accounted for the majority of cases in some centers, with several fatalities among those infected. Most transmissions occurred by direct contact or by respiratory droplet spread from undiagnosed infected patients to staff not using personal protective precautions. When active case identification was put in place, potential cases were rapidly put in isolation, and caregivers were protected by using N95 masks, eye protection, gloves, gowns, and strict hand washing for all patient contact, transmission was quickly halted. Patients requiring ventilatory support in the ICU were particularly important vectors of infection, mainly related to droplet spread of the virus during endotracheal intubation and other respiratory care procedures. The following measures to minimize risk to staff during intubation for SARS-related respiratory failure are suggested:

1. Anticipate the need for ventilatory support to ensure that intubation occurs in a well-prepared, nonemergent controlled setting.
2. Intubation should be performed by the most skilled individual available.
3. Minimize staff in procedure room.
4. Intubate in a closed-door, well-ventilated, and preferably negative-pressurized room.
5. Minimize coughing and other droplet-generating respiratory efforts by the patient by using good preintubation sedation; consider using muscle relaxation to facilitate intubation.
6. Personnel in the room should have N95 masks checked for correct fit, face shields, gowns, and gloves.
7. Meticulous hand washing should occur after any procedure, particularly after removing protective clothing.
8. Surfaces in the procedure room should be disinfected before the area is used for another purpose.
9. Continue these infection control procedures during subsequent ICU care for respiratory failure.

Nosocomial Pneumonia

Nosocomial pneumonia differs significantly from CAP in aspects of pathogenesis and in the range of usual microbial pathogens seen.[36,37] Approaches to diagnosis are generally

TABLE 51-7 Bacterial Causes of Nosocomial Pneumonia in Patients Requiring Intensive Care

Organism	Frequency (% of Cases)[a]
Enterobacteriaceae (*Klebsiella, Escherichia coli, Enterobacter, Proteus, Acinetobacter, Serratia,* etc.)	30–50
Staphylococcus aureus	10–30
Pseudomonas aeruginosa	10–20
Streptococci (including *Streptococcus pneumoniae*)	10–15
Legionella spp.	5–15
Haemophilus influenzae	2–10
Moraxella (Branhamella) catarrhalis	2–10
Anaerobes	2–5

[a] Ranges shown are derived from several studies from different geographic areas and different patient populations. The incidence of each infection greatly depends on local circumstances.

similar to those for CAP; however, the approach to antimicrobial therapy differs considerably, reflecting the different spectrum of pathogens. In addition, because nosocomial pneumonia by definition occurs in patients already under medical care for illnesses requiring hospitalization, the possibility of preventing its occurrence exists and is an important aspect of the day-to-day care of the critically ill patient (see Chaps. 4 and 10).

PATHOGENESIS AND MICROBIOLOGY

The most common microbial causes of nosocomial pneumonia are listed in Table 51-7. This table was constructed from data gathered in a number of surveys of different patient populations, and it must be emphasized that hospital populations are not identical with respect to risk for pneumonia caused by each of these pathogens. As in CAP, the basic event leading to pneumonia is usually subclinical aspiration of oropharyngeal material, an event for which hospitalized patients are at increased risk on account of disease and medical intervention. These increased risks include depressed level of consciousness caused by head injury, metabolic disease, or sedative and anesthetic drugs, and impaired laryngeal reflexes and esophageal sphincter function caused by neurologic disease or instrumentation of the airway or esophagus. Although endotracheal intubation with a cuffed tube may prevent frank aspiration of gastric contents, it is no barrier to the minor degrees of aspiration required to transfer potential pathogens from the upper to the lower respiratory tract. The patient's ability to deal effectively with contamination of the lower respiratory tract may also be compromised. Mucociliary clearance may be impaired by damage to the tracheal mucosa by endotracheal tubes, metabolic disease, or drugs; immunologic defenses may be impaired by underlying disease or by immunosuppressive therapy.

The explanation for the nature of the common pneumonia pathogens is the pattern of colonization of the upper airway, which determines which organisms gain access to the lung when aspiration occurs. In previously well patients admitted to ICUs with acute illness that compromises airway defenses, pneumonia in the few days after admission is caused most often by organisms that are frequent colonizers of the upper airway in normal persons: *S. aureus, Streptococcus* species, and, to a lesser extent, *H. influenzae* and *M. catarrhalis*.[38] Patients with underlying chronic lung disease are frequently colonized with these same pathogens, but nontypeable *H. influenzae* and *M. catarrhalis* are more frequent in patients with underlying lung disease than in normal persons and therefore cause early nosocomial pneumonia more frequently in these patients.[39,40] Patients who have other chronic debilitating diseases or those who have been in the hospital for a number of days are at increased risk of having upper airway colonization and subsequent pneumonia caused by enteric facultatively aerobic gram-negative bacilli such as *K. pneumoniae*, *E. coli*, and *Enterobacter* species, whereas patients with underlying structural lung disease, the immunosuppressed, and those who have been treated with antimicrobials or who have had a lengthy stay in an ICU are at increased risk for colonization or infection with more antimicrobial-resistant hospital-acquired pathogens such as *P. aeruginosa*, *Stenotrophomonas maltophilia*, or *Acinetobacter* species.[41] The source of staphylococci or *Enterobacteriaceae* causing these infections is most often the patient's own endogenous microflora; however, many of the more resistant pathogens may be transmitted to patients by contact spread from the hands of caregivers or, particularly with water-borne organisms such as *Pseudomonas* or *Acinetobacter*, by contaminated respiratory therapy equipment.

Among the pathogens in the atypical pneumonia group, only viruses and *L. pneumophila* are notable causes of nosocomial pneumonia. Influenza A and RSV are sporadically reported to cause outbreaks of pneumonia in the hospital, generally by respiratory or hand-to-hand spread from other infected individuals, and there is reason to believe that CMV can also occasionally cause pneumonia leading to respiratory failure in immunocompetent hospitalized patients; the pathogenesis of nosocomial infection in this population is unknown. In the March 2002 SARS coronavirus outbreak, much of the disease transmission was nosocomial, mainly by direct contact or droplet spread from patients with undiagnosed SARS to health care workers not using any personal protection against infection, and from them to other patients by the same mechanisms.[21] For nosocomial infection with *Legionella* species, the pathogenesis is inhalation of aerosols containing the organism. In outbreak situations, this can usually be traced to presence of the organism in hospital water supplies, with dissemination by showers and baths and the like, or to cooling tower contamination. Ground excavation near an outside air intake has also been implicated. It is likely that many hospitalized patients are exposed to *Legionella*, given its widespread presence in hospital water supplies; however, most cases continue to occur among the immunosuppressed hospitalized population, particularly those on corticosteroid treatment for prevention of organ transplant rejection. This is presumably because a patient with suppressed cell-mediated immunity has a reduced capacity to clear even small inhaled inocula of this intracellular pathogen, with which a patient with intact cell-mediated immunity can cope easily.

DIAGNOSIS

The clinical features and radiographic findings associated with nosocomial pneumonia are similar to those of CAP but may be greatly confounded by other disease processes common in hospitalized patients, particularly those in intensive care. The diagnosis is suggested by the presence of a

pulmonary infiltrate consistent with pneumonia on chest radiograph, increased amount and purulence of lower respiratory tract secretions (sputum or endobronchial aspirates), deterioration in gas exchange and increased dyspnea, and an increase in temperature or leukocyte count. There are problems with the sensitivity and specificity of this clinical definition. Postmortem studies of critically ill patients with extensive lung disease of other causes have indicated that many patients have clinically unsuspected bacterial pneumonia at the time of death. However, there is evidence that, in the general ICU patient population, other processes, such as chemical pneumonitis caused by aspiration, atelectasis, and purulent tracheobronchitis, can produce many of or all the same clinical findings as pneumonia, and that pneumonia can be significantly overdiagnosed in this context.[42] In intubated, ventilated patients in particular, quantitative bacteriologic evaluation of bronchoscopic specimens of secretions from the lower respiratory tract has been advocated as a way of overcoming this problem, and this approach is discussed comprehensively in Chapter 43.

For most patients, a careful clinical assessment combined with conventional microbiologic studies for the diagnosis of nosocomial pneumonia in ward patients and in intubated ICU patients remains a reasonable first approach. Some patients have clinical presentations with such marked pyrexia, leukocytosis, deterioration in lung function, and advancing infiltrates that the diagnosis is fairly certain. It remains only to obtain the appropriate specimen to establish the etiology; in most such cases, this is sputum or endobronchial aspirates, a blood culture, and needle aspirate of pleural fluid if a significant amount is present. It is mainly in patients with less florid presentations, with marginal changes in the major diagnostic parameters and with infiltrates that could be atelectasis or pneumonia, in whom the diagnosis is substantially in doubt. In these cases, the usual best policy is to obtain endobronchial secretions for Gram stain and culture, provide chest physiotherapy and or frequent posturing of the patient and endobronchial suctioning, and withhold antimicrobial treatment initially. Over the ensuing hours to days, the result of the culture will become available; the additional information regarding the progress of the pulmonary process, the systemic inflammatory response without antimicrobial treatment, the presence and quantitation of leukocytes and bacteria on Gram stain, and the results of initial cultures will aid in making the judgment about whether an infection requiring antimicrobial treatment is present. In cases in which substantial uncertainty remains, fiberoptic bronchoscopy with a protected specimen brush or BAL with quantitative bacteriology is a reasonable next step.

MANAGEMENT

The principles of supportive management for nosocomial pneumonia are identical to those outlined for CAP. However, there are several differences in antimicrobial therapy because of the considerably different range of etiologic agents seen. Atypical pneumonia is much less common in hospitalized patients and, when it occurs, is most often caused by *Legionella* species. Bacterial pneumonias make up the vast majority of cases and are much more likely to be caused by *S. aureus* or enteric gram-negative bacilli and, in particular subgroups of patients, by relatively antimicrobial-resistant gram-negative bacilli. Suggested empiric antimicrobial regimens for hospital-acquired pneumonia are listed in Table 51-8 and those for specific proven pathogens are listed in Table 51-3.

The pathogens causing hospital-acquired pneumonia are much more likely to cause a destructive necrotizing pneumonia than are the common community-acquired pathogens and therefore are more likely to result in formation of abscesses and empyema, pneumothorax, and permanent fibrosis of involved lung regions. These pathogens also are more difficult to eradicate permanently from the lung with antimicrobial therapy. Accordingly, duration of antimicrobial therapy is generally longer, usually at least 3 weeks to as many as 6 or 8 weeks, depending on the initial response, presence of abscess cavities, and susceptibility of the organism. Treatment should always be parenteral initially and for most enteric gram-negative organisms should usually include two different agents effective against the pathogen, generally a β-lactam drug and an aminoglycoside or a quinolone. After 7 to 10 days, if a good clinical response has been observed, completion of the treatment course with an appropriate oral agent is reasonable. Oral agents considered suitable for gram-negative

TABLE 51-8 Empiric Antimicrobial Therapy for Nosocomial Pneumonia Associated with Critical Illness[a]

Clinical Setting	Recommended Antimicrobial Therapy	Alternative Antimicrobial Therapy
Acute nosocomial pneumonia (postoperative or complicating medical illness)	Cefotaxime 2 g IV q 8 h *and* gentamicin 4.5 mg/kg IV q 24 h	Co-trimoxazole IV; ciprofloxacin or ofloxacin IV ± a β-lactam
Nosocomial pneumonia with increased risk of resistant aerobic gram-negatives (i.e., prior broad-spectrum antibiotics, acute leukemia, endemic resistant organisms, etc.)	Piperacillin/tazobactam 3.375 g IV q 6 h and ciprofloxacin 400 mg IV q 12 h or gentamicin 4.5 mg/kg IV q 24 h	Carbapenem or ceftazidime *and* gentamicin or quinolone
Severe pneumonia after aspiration	Clindamycin 900 mg IV q 8 h *and* cefotaxime 2 g IV q 8 h	Clindamycin and cotrimoxazole IV, metronidazole and cefotaxime
Suspect legionellosis (endemic, organ transplant, steroid use, or undiagnosed fulminant pneumonia)	*Add* ciprofloxacin 400 mg IV q 12 h ± rifampin 600 mg IV daily to one of the above regimens	Azithromycin ± rifampin
Suspect methicillin-resistant *Staphylococcus aureus*	*Add* vancomycin 500 mg IV q 6 h	

[a] Doses cited are for patients with normal renal function; dosage adjustments for renal insufficiency are required for several of the listed agents. Monitoring of blood drug levels is strongly advised for aminoglycosides. Gentamicin is shown as the preferred aminoglycoside; however, where resistance to this agent is common, selection of an alternative aminoglycoside may be necessary.

pneumonias include cotrimoxazole, amoxicillin/clavulanic acid, cefuroxime axetil, cefixime, and, for resistant organisms such as *Pseudomonas* species, ciprofloxacin.

As in outpatients, pulmonary aspiration in hospital patients can result in a simple chemical pneumonitis or atelectasis that does not require antimicrobial therapy. Hospitalized patients are much more likely to have been receiving antimicrobial agents for other indications, agents that decrease gastric acidity, and are more likely to have conditions predisposing to development of large numbers of pathogenic bacteria in the oropharynx and the stomach (e.g., recent surgery, adynamic ileus, or tube feeding). This increases the risk of an acute necrotizing bacterial pneumonia in these patients. Accordingly, if there is evidence to support an active infectious process after presumed or witnessed aspiration, antimicrobial therapy directed at GI anaerobes and relatively resistant enteric gram-negative bacilli should be given.

Antimicrobial selection for hospital-acquired pneumonia, to a much greater extent than that for CAP, must be based on knowledge of which pathogens are prevalent in the environment in a particular hospital or even in a particular unit within the hospital, because antimicrobial resistance patterns vary greatly in different locations. The recommendations listed in the tables must therefore be used with caution and with knowledge of local conditions.

PREVENTION

The considerable morbidity rate associated with nosocomial pneumonia, particularly in critically ill patients, has led to much interest in developing methods to prevent these infections.[43,44] Prevention would clearly depend on breaking the pathogenetic chain leading from colonization of the upper respiratory and GI tracts with potential pathogens to aspiration of these colonizers into the lower respiratory tract; establishment of lower respiratory tract colonization; and then failure of the pulmonary clearance mechanisms and immune system to contain the organism, leading to invasion of the pulmonary parenchyma. Attempts to break the chain at each of the points mentioned have been tried by various investigators, with limited success.

Minimizing the potential for the transmission of relatively antimicrobial-resistant pathogens between patients clearly is the first priority. Basic measures to accomplish this include hand washing before and after patient contact by all caregivers, avoiding the sharing of bedside or respiratory therapy equipment between patients, and isolation of patients known to be infected or colonized with multiply-resistant bacterial pathogens.

Interventions to prevent upper airway and gastric colonization by enteric gram-negative bacilli have recently been tried in many centers. Based on evidence that stomach acid helps minimize such colonization and that administration of H_2 blockers or antacids for prophylaxis against upper GI bleeding increases colonization, use of sucralfate, an agent that protects the mucosa and prevents bleeding without increasing stomach pH, has been advocated, and studies from some centers have been demonstrated that its use decreases the rate of nosocomial pneumonia in intubated patients. However, others have been unable to confirm that gastric colonization is a risk for airway colonization and pneumonia or that use of sucralfate rather than antacids or histamine blockers is protective. Although the controversy on this issue continues, it should be pointed out that sucralfate is cheap, nontoxic, and probably as effective as other agents, so if bleeding prophylaxis is used, sucralfate may be preferable to an H_2 blocker or antacid, except in patients at special risk for upper GI bleeding. Other suggested strategies to limit bacterial proliferation in the stomach and subsequent spread to the respiratory tract include using small bowel feeding tubes instead of gastric tubes, intermittent feeding to maintain gastric acidity, and acidification of feeds, but none of these has been convincingly shown to be effective.

Different prophylactic antimicrobial regimens, topical and systemic, have also been used to prevent colonization and pneumonia. These regimens have often been shown to be effective in limiting the incidence of pneumonia in ICU patients, but there continues to be concern that their use may eventually lead to an increase in the prevalence of antimicrobial resistance. Also, in most reported studies, the decreased rate of pneumonia was not associated with a decrease in mortality rate or in use of ICU resources. For these reasons, none of the currently available prophylactic antimicrobial regimens can be recommended.

Decreasing the risk of aspiration in seriously ill patients involves mainly commonsense measures. For a nonintubated patient who has difficulty in swallowing or decreased level of consciousness, nursing the patient on his or her side with the head slightly down may be helpful. Frequent and careful suctioning and mouth care are also important. In patients with endotracheal or nasogastric tubes and those with otherwise disturbed esophageal sphincter function, the upright position and sleeping with the head of the bed up reduces the risk of gastroesophageal reflux and aspiration. When the nasogastric tube is in place solely for feeding purposes, and it has been established that gastric emptying is adequate, the large-bore tube can be changed to a soft small-bore tube, which is less likely to interfere with the esophageal sphincter and is also more comfortable. In orally intubated patients, use of an orogastric tube rather than a nasogastric tube is also preferred.

For intubated patients, exemplary nursing care can have a substantial role in decreasing the risk of pneumonia. Frequent turning of patients while they are in bed and minimizing the use of deep sedation or muscle relaxants help avoid dependent secretion accumulation in the lungs. Use of oscillating beds to accomplish this has had mixed success with respect to efficacy and tolerance by patients, so their routine use is not currently recommended. Frequent gentle suctioning of the endotracheal tube and careful monitoring of endotracheal cuff seal and pressure are also likely to help minimize secretion accumulation and prevent pneumonia.[45] Good mouth care, suctioning of the oropharynx before endotracheal tube cuff deflation or before turning of the patient, no-touch sterile suctioning technique, and early detection and correction of gastroesophageal reflux problems are other measures that have yet to be studied in a systematic way with regard to infection rate; but they almost certainly account for much of the extremely wide variation in nosocomial pneumonia rates in different ICUs.

An active infection control program is also critical to minimizing nosocomial pneumonia risk.[46] Careful monitoring of infection rates and the occurrence of pathogens with a propensity for nosocomial spread is needed to detect potential reservoirs for cross-infection of patients and to guide

TABLE 51-9 The More Common Opportunistic Pulmonary Infections of the Immunocompromised Host[a]

Immunodeficiency	Predominant Pulmonary Infections	Most Frequent Clinical Settings
Humoral immunodeficiency	Pyogenic bacterial pneumonias	Hypogammaglobulinemia, chronic lymphocytic leukemia, multiple myeloma
Phagocytic cell deficiency	Bacterial pneumonia, fungal pneumonias, aspergillosis, candidemia with pulmonary involvement, cryptococcosis	Chemotherapy-induced granulocytopenia, acute myelogenous leukemia
Cell-mediated immunodeficiency	*Pneumocystis carinii* pneumonia, legionellosis, nocardiosis, CMV pneumonia, cryptococcosis, mycobacteriosis	Lymphoma or acute lymphocytic leukemia undergoing chemotherapy, high-dose corticosteroid therapy, organ transplantation, advanced HIV infection

[a] These categories are not mutually exclusive. For example, bone marrow transplant recipients develop mainly bacterial and fungal infections associated with phagocytic cell deficits early after transplantation but develop infections related to chronic suppression of cell-mediated immunity after recovery from transplantation.
ABBREVIATIONS: CMV, cytomegalovirus; HIV, human immunodeficiency virus.

institution of infection control measures. In general, an ICU with a pneumonia rate higher than approximately 10% in patients ventilated for longer than 48 hours, with a sustained increase in pneumonia rate over baseline, or with a predominance of water-borne gram-negative organisms such as *Pseudomonas* species or *Acinetobacter* species or any other single species as a cause of most cases of pneumonia, probably has a potentially correctable infection control problem.

Pulmonary Infiltrates in the Immunocompromised Host

Immunocompromised patients with fever and new pulmonary infiltrates usually come to the attention of the intensive care physician when they develop imminent or established acute respiratory failure or when a period of endotracheal intubation with mechanical ventilatory support is needed to facilitate an invasive diagnostic procedure. That both of these events occur relatively frequently says a great deal about the many special problems posed by this group of patients: The differential diagnosis of pulmonary inflammatory processes is wide, establishing a definitive diagnosis is often difficult, empiric antimicrobial therapy is often ineffective, and the patient's condition can deteriorate rapidly.

The nature of the immunologic abnormality that is present in a given case has a major bearing on the nature of the infective processes likely to be present. The major categories of immunologic abnormality include (a) deficient humoral immunity (these are patients with agammaglobulinemia and multiple myeloma or chronic lymphocytic leukemia, without intensive chemotherapy), (b) deficient phagocytic cell function or number (patients with chemotherapy-induced granulocytopenia make up the majority in this group), and (c) deficient cell-mediated immune function (includes patients on corticosteroids or other immunosuppressive drugs for the control of a variety of inflammatory diseases, control of rejection after organ transplantation, and less intensive chemotherapy for a variety of malignancies; it also includes patients with advanced HIV infection, which is discussed in more detail in Chap. 48). Many patients have mixed immune dysfunctions, especially those on rigorous chemotherapeutic regimens for cancer. Table 51-9 lists the major pulmonary infections most strongly associated with each type of immune dysfunction.

CLINICAL FEATURES

In addition to the information regarding the nature of the immunodeficiency noted above, clues to the etiologic diagnosis may be available from details of the history and physical examination.

The timing of the onset of the illness, with respect to previous chemotherapy and duration of immunosuppression, is often very helpful. After cytotoxic chemotherapy resulting in granulocytopenia, acute bacterial infections predominate in the first 2 to 3 weeks. Subsequently, especially with illnesses occurring in the face of broad-spectrum antimicrobial therapy, opportunistic fungal infections are increasingly common. After bone marrow and other transplantation procedures, bacterial infections also predominate early, with viral and fungal infections occurring weeks to months later. In this patient population, CMV pneumonia is of particular importance, occurring with increased frequency in patients known to be seropositive for CMV; in bone marrow recipients, CMV pneumonitis is also more common in older patients, those who have received total-body irradiation, and those with severe graft-versus-host disease.[47,48] Some noninfectious causes of pulmonary infiltrates also follow a somewhat predictable time course: radiation pneumonitis usually occurs 4 to 10 weeks after treatment; pulmonary edema caused by acute toxic myocarditis after high-dose doxorubicin therapy usually occurs a few days to a few weeks after treatment, whereas cardiomyopathy from doxorubicin and daunorubicin is increasingly frequent with increasing cumulative dose; and interstitial pneumonitis caused by bleomycin is common at cumulative doses larger than 450 U, although damaging pulmonary reactions to this cytotoxic drug and to others can occur with much smaller doses.[49]

Although the pace at which the pulmonary process progresses is to some degree characteristic for each etiologic agent, this is highly variable and greatly dependent on the nature and severity of the underlying immunologic deficit. *Aspergillus* species, for example, produce an indolent localized pneumonia in patients treated with immunosuppressive drugs and corticosteroids if phagocytic cell function is relatively preserved, but in patients with severe combined immunodeficiency and in some with long-term granulocytopenia from chemotherapy for myelogenous leukemia, the illness may be fulminant.[50] *Pneumocystis carinii* causes a severe, rapidly progressive diffuse pneumonia in patients with lymphoma or leukemia but usually is an insidious illness in those with HIV. It is also worth bearing in mind that an apparent change in the pace of progression of disease may signal the presence of more than one process, for example, an acute bacterial infection superimposed on a more slowly progressive disease, such as interstitial pneumonitis.

The physical examination is only occasionally revealing in this patient group. Examination of the chest almost never adds to the radiologic assessment. However, extrapulmonary findings may be very helpful in the differential diagnosis and may provide a potential alternative site for diagnostic testing. Central nervous system involvement (meningitis or encephalitis) indicates systemic fungal infections, tuberculosis, bacteremia with metastatic foci, or disseminated viral infections and mandates computed tomography of the brain followed by lumbar puncture. Disseminated aspergillus infection, in addition to involving the lung and brain, may produce necrotizing skin lesions. *Ecthyma gangrenosum* signals bacteremia, usually with *P. aeruginosa* and usually producing a diffuse multinodular pneumonia. Staphylococcal bacteremia and pneumonia may be associated with widespread cutaneous pustules, whereas the rare case of disseminated candidiasis with pulmonary involvement may be associated with a papular rash, myalgias, or "cotton wool" exudates on funduscopic examination.

RADIOGRAPHIC FEATURES

The chest radiographic appearance of the pulmonary infiltrate can be a useful guide to a differential diagnosis but is seldom specific enough to establish the diagnosis. The most important differentiation to be made is whether the infiltrate is a localized or a diffuse process.

Diffuse infiltrates, if they are of infectious origin, imply infection with a pathogen that has reached the lung hematogenously in large numbers or has spread rapidly along the respiratory mucosa early in the course of the infection. Examples include viral infections such as CMV, which is actually a systemic infection; hematogenous bacterial pneumonia (*P. aeruginosa* most commonly); miliary or chronic hematogenous tuberculosis; and candidemia with secondary candidal pneumonitis. PCP also is typically a diffuse pneumonia (Fig. 51-11). Noninfectious processes producing diffuse infiltrates are those in which the entire lung is exposed equally to the damaging agent through the bloodstream or the lymphatics (Table 51-10). Examples include drug-associated lung injury, leukemic infiltration or lymphangitic carcinomatosis of the lung, and idiopathic interstitial pneumonitis.[51]

Localized infiltrates caused by infections are generally those in which the organism has gained access to the lung by aspiration of oropharyngeal material or by inhalation of the pathogen. Examples include most cases of acute bacterial pneumonia, including nocardial pneumonia and *L. pneumophila* pneumonia, and most cases of opportunistic fungal pneumonia, such as those caused by *Aspergillus*, *Mucor*, and *Cryptococcus* species. The appearance of the infiltrate sometimes provides a diagnostic clue. *Legionella pneumophila* often produces airspace consolidation with a peripheral, ill-defined, rounded density, often with rapid subsequent progression (see Fig. 51-4).[16] Localized infiltrates caused by *Aspergillus* usually begin as enlarging nodular infiltrates or as patchy bronchopneumonia in the granulocytopenic patient (Fig. 51-12), with the development of central necrosis, cavitation, and "air crescent" signs associated with marrow recovery.[52] Hematogenous spread of infection causing a localized infiltrate also occurs occasionally, although this most often produces multiple, locally spreading infiltrates that may not be anatomically adjacent; hematogenous bacterial infections, especially septic thromboembolia, are examples of this. The major noninfectious entities producing localized infiltrates are atelectasis, pulmonary embolism with infarction, and metastatic neoplastic disease.

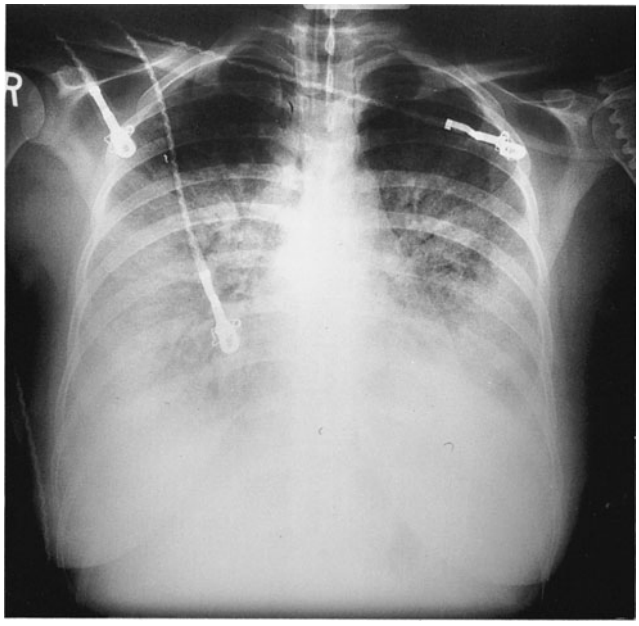

FIGURE 51-11 Severe *Pneumocystis carinii* pneumonia in a patient with acute myelogenous leukemia undergoing induction chemotherapy. Note the lower lobe and perihilar predominance of the mainly alveolar infiltrate, with areas of frank consolidation; in the right lower lobe, note an air bronchogram.

APPROACH TO DIAGNOSIS AND MANAGEMENT

Diagnosis and management must be considered together, particularly for patients requiring support in an ICU. There are usually two phases to the approach. In the first phase, a presumptive diagnosis or group of potential diagnoses is formulated and empiric therapy is begun while relatively noninvasive diagnostic testing is implemented. Many patients respond to initial therapy or, if they do not, have a tenable diagnosis established on the basis of the initial investigation, leading to a revision of the initial therapeutic regimen. In the second phase, which is marked by the increasingly clear need

TABLE 51-10 Noninfectious Causes of Pulmonary Infiltrates in the Immunocompromised Host and the Clinical Settings in Which They Are Most Frequently Seen

Noninfectious Diagnosis	Clinical Settings
Diffuse pulmonary infiltrates	
Interstitial pneumonitis due to cytotoxic drug therapy	Bleomycin (>150 mg total) or not related to dose Reaction to bleomycin, cyclophosphamide, methotrexate, and others
Cardiogenic pulmonary edema	Pre-existing cardiac disease Chemotherapy with daunorubicin or doxorubicin
Lymphangitic carcinomatosis	Carcinoma poorly responsive to therapy
Leukemic infiltration of lung	Uncontrolled acute leukemia
Acute low-pressure pulmonary edema (diffuse alveolar damage)	Leukemic cell lysis after chemotherapy Leukoagglutination reaction after transfusion
Focal pulmonary infiltrates	
Pulmonary metastasis	Untreated or poorly responsive primary carcinoma
Atelectasis	Endobronchial lesion Chest wall or upper abdominal pain Depressed cough or respiration (narcotics)
Pulmonary infarction (pulmonary thromboembolism)	Hypercoagulable state owing to carcinoma or paraproteinemia, immobility, venous obstruction
Radiation pneumonitis	Recent (4–12 wk) radiotherapy with lung exposure

for a definitive diagnosis because of the failure of empiric therapy or the pace and severity of progression of disease, increasingly invasive diagnostic testing is performed until the diagnosis is established and definitive therapy begun. The key to appropriate management is to take great care to neither abandon the frequently correct initial diagnosis and treatment too soon (thereby subjecting many patients to the risk of an unnecessary lung biopsy) nor wait too long to proceed to a definitive diagnostic procedure (making the diagnosis too late to reverse the disease).

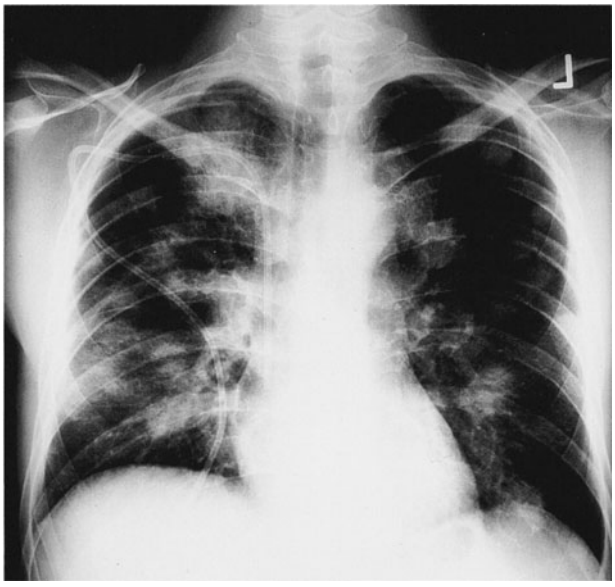

FIGURE 51-12 Pulmonary aspergillosis in a patient with acute myelogenous leukemia and protracted granulocytopenia. Note the multiple, dense, alveolar infiltrates forming large expanding nodules.

The major considerations governing the initial empiric antimicrobial approach and the selection of diagnostic procedures are (a) the underlying disease and the timing of the pulmonary process with respect to it, (b) the presence of major clues to the diagnosis from the initial clinical evaluation, (c) the radiologic pattern, and (d) the physiologic stability of the patient and the rate of progression of the disease. Patients with pulmonary infiltrates that fit a commonly seen clinical and radiologic pattern quite well and who are physiologically stable can be treated empirically pending the results of initial diagnostic testing. Those who have less certain clinical and radiologic patterns and who are unstable or getting worse quickly require prompt and definitive diagnostic testing.

Patients with diffuse infiltrates should receive intravenous wide-spectrum antimicrobials directed at hematogenous bacterial pneumonia, at least until initial culture results are available. Piperacillin/tazobactam 3.375 g IV every 6 hours and ciprofloxacin 400 mg IV every 12 hours is usually acceptable. Cotrimoxazole (20 mg/kg trimethoprim with 100 mg/kg sulfamethoxazole per day in four divided doses) may be added to cover *P. carinii* (unless the patient has been receiving cotrimoxazole prophylaxis, in which case the diagnosis is essentially excluded). Investigations include blood cultures, respiratory and stool specimens for viral culture, culture of blood for CMV, respiratory secretions for Gram stain and culture, and examination for acid-fast bacilli and fungi. In patients with predominantly cell-mediated immune impairment (lymphoma, steroid, or immunosuppressive drug therapy or organ transplant) who have not received cotrimoxazole and have negative blood cultures, PCP is the leading infectious possibility. Unlike what is seen in HIV patients with PCP, the number of organisms in the lung is not large; hence sputum examination for the organism is not useful. Early bronchoscopy with BAL or a protected specimen brush is advised.[53] The specimen obtained should be examined

TABLE 51-11 Initial Antimicrobial Therapy for Opportunistic Lung Infections in Critically Ill Immunocompromised Patients

Pulmonary Infection	Antimicrobial Regimen
Pneumocystis carinii pneumonia	Cotrimoxazole 5 mg/kg TMP and 25 mg/kg SMX IV q 6 h *or* clindamycin 600 mg IV q 8 h with primaquine 30 mg PO once daily
Nocardia asteroids, pneumonia, or abscess	Cotrimoxazole 2.5 mg/kg TMP and 12.5 mg/kg SMX IV q 6 h *or* imipenem 500 mg IV q 6 h ± amikacin 5 mg/kg IV q 8 h
Aspergillosis	Voriconazole 6 mg/kg q 12 h × 2, then 4 mg/kg IV q 12 h *or* amphotericin B 0.6–1.0 mg/kg IV q 24 h
Candida pneumonia due to associated candidemia	Amphotericin B 0.5–0.8 mg/kg IV q 24 h *or* fluconazole 400 mg IV q 24 h
CMV pneumonia	Ganciclovir 2.5 mg/kg IV q 8 h *and* CMV immunoglobulin 400–500 mg/kg on alternate days (4–10 doses)
Varicella zoster, disseminated, with pneumonia	Acyclovir 10 mg/kg IV q 8 h

ABBREVIATIONS: CMV, cytomegalovirus; IV, intravenously; PO, orally; SMX, sulfamethoxazole; TMP, trimethoprim.

for the full range of pathogens mentioned above. Cytologic examination of cells for evidence of CMV, culture of respiratory secretions, and blood for CMV will help in establishing that diagnosis. Bronchoscopic methods have excellent diagnostic yield for infectious diagnoses in this setting but are somewhat less useful in defining noninfectious etiologies for diffuse infiltrates.[54] Accordingly, for patients who are at lesser risk for PCP and CMV, for those in whom the initial investigation excludes these possibilities, and for those with rapidly progressive diffuse lung disease, open lung biopsy should be considered. Open lung biopsy remains controversial in this setting: Although a definitive diagnosis can be established in most patients and therapy can be adjusted appropriately, in severely ill patients this often does not lead to survival. Further, significant morbidity caused by the procedure is not uncommon. Nevertheless, there is evidence that in selected cases open biopsy can be very useful by offering the best chance of survival to the subset of patients with reversible disease.[55,56] In the face of progressing disease, if a biopsy is to be done, it is important to make the decision to proceed before the patient has progressed to frank respiratory failure.

The diagnosis of localized pulmonary infiltrates caused by conventional bacterial pneumonia can usually be established with sufficient certainty by blood cultures, Gram stain and culture of respiratory secretion and culture, direct fluorescent antibody staining and culture of respiratory secretions for *L. pneumophila*, and the clinical response to empiric antimicrobial therapy, usually piperacillin/tazobactam and ciprofloxacin, unless it is known that the patient is colonized with a pathogen resistant to these antimicrobials. If the diagnosis is not immediately forthcoming or the patient does not respond promptly to empiric therapy, bronchoscopy should be done and BAL or protected brush specimens sent for examination for bacteria; acid-fast bacilli; direct fluorescent antibody, and culture for *Legionella*; fungal elements; and cytologic examination. If there is no contraindication, transbronchial biopsy may increase the yield for invasive fungal infection and for malignancy. However, as many as 50% of cases of invasive fungal infections may not be detected by bronchoscopic methods and require open lung biopsy for diagnosis. Culture of aspergilli from nasal scrapings or sputum can be helpful in this regard. Although culture of aspergilli is not indicative of disease in normal persons, in severely immunocompromised patients with granulocytopenia and acute leukemia, such positive cultures are strongly associated with invasive disease.

When the diagnosis has been established, definitive therapy is begun and other agents started empirically are discontinued unless other indications for their use remain. A discussion of the full range of therapies for noninfectious etiologies of pulmonary infiltrates is beyond the scope of this chapter; drug regimens for the major infectious causes of opportunistic pneumonia are presented in Table 51-11.

Chapter 52

BACTERIAL INFECTIONS OF THE CENTRAL NERVOUS SYSTEM

ALLAN R. TUNKEL
W. MICHAEL SCHELD

KEY POINTS

- *More than 80% of adults with bacterial meningitis present clinically with fever, headache, meningismus, and signs of cerebral dysfunction; elderly patients, however, may present with insidious disease manifested only by lethargy or obtundation, variable signs of meningeal irritation, and no fever.*
- *Occasionally, a patient with acute bacterial meningitis has a low cerebrospinal fluid (CSF) white cell count despite high bacterial concentrations in CSF; therefore, a Gram stain and culture should be performed on every CSF specimen, even if the cell count is normal.*
- *Neuroimaging techniques have little role in the diagnosis of acute bacterial meningitis. However, computed tomography (CT) should be performed before lumbar puncture when a space-occupying lesion of the central nervous system (CNS) is suspected. Clinical features at baseline associated with an abnormal CT image (in patients with suspected meningitis) are age of at least 60 years, immunocompromise, a history of CNS disease, a history of seizure within 1 week before presentation, and specific neurologic abnormalities.*
- *Empirical antimicrobial therapy, based on the patient's age and underlying disease status, should be initiated as soon as possible in patients with presumed bacterial meningitis; therapy should never be delayed while diagnostic tests such as CT are awaited.*
- *Adjunctive dexamethasone therapy has been shown to decrease the morbidity rate in infants and children with acute* Haemophilus influenzae *type b meningitis and, if commenced with or before antimicrobial therapy, is also beneficial for pneumococcal meningitis in childhood. A recent study has associated adjunctive dexamethasone with decreased morbidity and mortality rates in adults with pneumococcal meningitis when administered before the first dose of antimicrobial therapy.*
- *Only about 50% of patients with brain abscess present with the classic triad of fever, headache, and focal neurologic deficit; the clinical presentation of brain abscess in immunosuppressed patients may be masked by the diminished inflammatory response.*
- *The diagnosis of brain abscess has been revolutionized by the development of CT; magnetic resonance imaging may offer advantages over CT in the early detection of cerebritis, cerebral edema, and satellite lesions.*
- *Aspiration of brain abscess under stereotaxic CT guidance is useful for microbiologic diagnosis, drainage, and relief of increased intracranial pressure.*
- *A short course of corticosteroids may be useful in patients with brain abscess who have deteriorating neurologic status and increased intracranial pressure.*
- *Cranial subdural empyema should be suspected in patients with headache, vomiting, fever, change in mental status, and rapid progression of focal neurologic signs.*
- *Spinal epidural abscess may develop acutely or chronically, with symptoms and signs of focal vertebral pain, nerve root pain, motor or sensory defects, and paralysis; the transition to paralysis may be rapid, indicating the need for emergent evaluation, diagnosis, and treatment.*
- *Surgical therapy is essential for the management of subdural empyema because antibiotics do not reliably sterilize these lesions.*
- *Rapid surgical decompression should be performed in patients with spinal epidural abscess who have increasing neurologic deficit, peristent severe pain, or increasing temperature or peripheral white blood cell count.*
- *Lateral gaze palsy may be an early clue to the diagnosis of cavernous sinus thrombosis because the abducens nerve is the only cranial nerve traversing the interior of the cavernous sinus.*
- *The noninvasive diagnostic procedure of choice for suppurative intracranial thrombophlebitis is magnetic resonance imaging, which can differentiate between thrombus and normally flowing blood.*

Bacterial infections of the central nervous system (CNS) are frequently devastating. The brain possesses several defense mechanisms (e.g., intact cranium and blood-brain barrier) to prevent entry of bacterial species; but once microorganisms have gained entry to the CNS, host defense mechanisms are inadequate to control the infection. Antimicrobial therapy is limited by the poor penetration of many agents into the CNS and by the ability of antibiotics to induce inflammation in the CNS via their bacteriolytic action, thereby contributing to brain damage. We review meningitis, brain abscess, subdural empyema, epidural abscess, and intracranial thrombophlebitis, with an emphasis on recent developments in diagnosis and therapy as they pertain to the care of the critically ill patient.

Meningitis

EPIDEMIOLOGY AND ETIOLOGY

The rates of morbidity and mortality from bacterial meningitis remain unacceptably high despite the availability of effective antimicrobial therapy. In a surveillance study of all cases of bacterial meningitis in 27 states of the United States from 1978 to 1982, the overall annual attack rate of bacterial meningitis was approximately 3.0 cases per 100,000 population, although there was variability according to geographic area, sex, and race;[1] incidences for the various meningeal pathogens are listed in Table 52-1. Bacterial meningitis is also a significant problem in hospitalized patients. In a review of 493 episodes of bacterial meningitis in adults 16 years or older from the Massachusetts General Hospital from 1962 through 1988, 40% of cases were nosocomial in origin, and these episodes carried a high mortality rate (35% for single episodes of nosocomial meningitis).[2] With the introduction of *Haemophilus influenzae* type b conjugate vaccines in the

SOURCE: Adapted from Schlech et al[1] and Shuchat et al.[4]

United States and elsewhere, dramatic declines in the incidence of invasive *H. influenzae* type b disease have been reported; these conjugate vaccines have been licensed for routine use in all children beginning at age 2 months.[3] In a study that evaluated the epidemiology of bacterial meningitis in the United States during 1995 in laboratories serving all the acute care hospitals in 22 counties in four states (Georgia, Tennessee, Maryland, and California),[4] the incidence of bacterial meningitis decreased dramatically as a result of the vaccine-related decline in meningitis caused by *H. influenzae* type b (see Table 52-1).

Before the development of effective vaccines against it, *H. influenzae* type b was isolated in almost half of all cases of bacterial meningitis in the United States, but this microorganism currently accounts for only 7% of cases. About 40% to 60% of cases were seen in children ages 2 months to 6 years; of these, 90% were due to capsular type b strains. Disease is most likely initiated after nasopharyngeal acquisition of a virulent organism with subsequent systemic invasion. *Haemophilus influenzae* is unusual after age 6 years; isolation of the organism in this older group should suggest the possible presence of certain predisposing factors, including sinusitis, otitis media, epiglottitis, pneumonia, head trauma with a cerebrospinal fluid (CSF) leak, diabetes mellitus, alcoholism, splenectomy or asplenic states, and immune deficiency (e.g., hypogammaglobulinemia).[5]

Meningitis due to *Neisseria meningitidis* is most often found in children and young adults and may occur in epidemics. Nasopharyngeal carriage of virulent organisms accounts for initiation of infection.[6] The incidence of meningococcal serogroup C disease has been increasing in North America, with several recent outbreaks reported in the United States and Canada.[7,8] Infection is more likely in persons who have deficiencies in the terminal complement components (C5, C6, C7, C8, and perhaps C9), the so-called membrane attack complex; the incidence of neisserial infections is more than 8000-fold greater in this group than among other persons.[9]

Pneumococcal meningitis is observed most frequently in adults (>30 years) and is often associated with distant foci of infection, such as pneumonia, otitis media, mastoiditis, sinusitis, and endocarditis; this organism currently accounts for 47% of cases of bacterial meningitis in the United States.[4] Serious pneumococcal infections may be observed in persons with predisposing conditions, such as splenectomy or asplenic states, multiple myeloma, hypogammaglobulinemia, and alcoholism. *Streptococcus pneumoniae* is the most common meningeal isolate in head trauma patients who have basilar skull fracture with subsequent CSF leakage.[10]

Listeria monocytogenes accounts for only about 8% of all cases of bacterial meningitis but carries a high mortality rate.[4] Infection with *Listeria* is more likely in neonates, the elderly, alcoholics, cancer patients, and immunosuppressed adults (e.g., renal transplant patients).[11,12] *Listeria* meningitis is found infrequently in patients with human immunodeficiency virus infection,[13] despite its increased incidence in patients with deficiencies in cell-mediated immunity. However, up to 30% of adults and 54% of children and young adults with listeriosis have no apparent underlying condition. Listeriosis has been associated with several food-borne outbreaks involving contaminated cole slaw, milk, cheese, and processed meats.

Meningitis due to aerobic gram-negative bacilli is observed in specific clinical situations.[14] *Escherichia coli* is isolated in 30% to 50% of infants younger than 2 months with bacterial meningitis. *Klebsiella* species, *E. coli*, and *Pseudomonas aeruginosa* may be isolated in patients who have had head trauma or neurosurgical procedures, in the elderly, in immunosuppressed patients, and in patients with gram-negative septicemia. Despite the low frequency of meningitis due to this group of organisms, the mortality rates are very high (~84% with *P. aeruginosa*, until recently).

Specific clinical situations also predispose to the development of meningitis due to staphylococcal species.[15] *Staphylococcus epidermidis* is the most common cause of meningitis in persons with CSF shunts. Meningitis due to *Staphylococcus aureus* is frequently found (when compared with other pathogens) soon after neurosurgery. Underlying diseases among persons with no prior CNS disease who develop *S. aureus* meningitis include diabetes mellitus, alcoholism, chronic renal failure requiring hemodialysis, and malignancies. Conditions that increase *S. aureus* nasal carriage rates (e.g., injection drug abuse, insulin-requiring diabetes, and hemodialysis) may also predispose to staphylococcal infection of the CNS.

Group B streptococcus (*Streptococcus agalactiae*) is a common cause of meningitis in neonates.[16] The risk of transmission from the mother to her infant is increased when the inoculum of organisms and number of sites of maternal colonization are large; horizontal transmission has also been documented from the hands of nursery personnel to the infant. Risk factors for group B streptococcal meningitis in adults include age older than 60 years, diabetes mellitus, parturient status in women, cardiac disease, collagen vascular disease, malignancy, alcoholism, hepatic failure, renal failure, and corticosteroid therapy.[17–19] No underlying illnesses were found in 43% of patients in one review.[18]

CLINICAL PRESENTATION

The classic clinical presentation in adults with bacterial meningitis includes fever, headache, meningismus, and signs of cerebral dysfunction;[20] these symptoms and signs are found in more than 80% of cases. Also seen are nausea, vomiting, rigors, profuse sweating, weakness, and myalgias. The meningismus may be subtle or marked or accompanied (rarely) by the Kernig and/or Brudzinski sign. The Kernig sign is elicited by flexing the thigh on the abdomen with the knee flexed; the leg is then passively extended, and, if there is meningeal inflammation, the patient resists leg extension.

The Brudzinski sign is present when passive flexion of the neck leads to flexion of the hips and knees. However, these signs are elicited in fewer than 20% of cases of bacterial meningitis in adults. Cerebral dysfunction is manifested by confusion, delirium, or a declining level of consciousness ranging from lethargy to coma. Cranial nerve palsies (especially involving cranial nerves III, IV, VI, and VII) and focal cerebral signs are uncommon (10% to 20% of cases). Seizures occur in about 30% of all cases. Papilledema is rare (<5%) and should suggest an alternate diagnosis, such as an intracranial mass lesion. Late in the disease, patients may develop signs of increased intracranial pressure, including coma, hypertension, bradycardia, and third-nerve palsy; these findings are ominous prognostic signs.

Certain symptoms and signs may suggest an etiologic diagnosis in patients with bacterial meningitis.[20] Persons with meningococcemia present with a prominent rash, principally on the extremities (~50% of cases). Early in the disease course, the rash may be erythematous and macular, but it quickly evolves into a petechial phase, with further coalescence into a purpuric form. The rash often matures rapidly, with new petechial lesions appearing during the physical examination. A petechial, purpuric, or ecchymotic rash may also be seen in other forms of meningitis (i.e., those due to echovirus type 9, *Acinetobacter* species, *S. aureus*, and, rarely, *S. pneumoniae* or *H. influenzae*), in Rocky Mountain spotted fever or *S. aureus* endocarditis, and in overwhelming sepsis (due to *S. pneumoniae* or *H. influenzae*) in splenectomized patients. An additional suppurative focus of infection (e.g., otitis media, sinusitis, or pneumonia) is present in 30% of patients with pneumococcal or *H. influenzae* meningitis but is rarely found in meningococcal meningitis. Meningitis due to *S. pneumoniae* is relatively likely after head trauma in persons who have basilar skull fractures in which a dural fistula is produced between the subarachnoid space and the nasal cavity, paranasal sinuses, or middle ear.[10] These persons commonly present with rhinorrhea or otorrhea due to a CSF leak; a persistent defect is a common explanation for recurrent bacterial meningitis.

Certain subgroups of patients may not manifest the classic signs and symptoms of bacterial meningitis. Usually in a neonate there is no meningismus or fever, and the only clinical clues to meningitis are listlessness, high-pitched crying, fretfulness, refusal to feed, or irritability. Elderly patients, especially those with underlying conditions such as diabetes mellitus or cardiopulmonary disease, may present with insidious disease manifested only by lethargy or obtundation, variable signs of meningeal irritation, and no fever. In this subgroup, altered mental status should not be ascribed to other causes until bacterial meningitis has been excluded by CSF examination. A patient after neurosurgery or a patient who has undergone head trauma also presents a unique clinical situation because these patients already have many of the symptoms and signs of meningitis from their underlying disease processes.[10] One must have a low threshold for CSF examination in these patients should they develop any clinical deterioration.

DIAGNOSIS

The diagnosis of bacterial meningitis rests on the CSF examination.[20] The opening pressure is elevated in virtually all cases; values above 600 mm H_2O suggest cerebral edema, the presence of intracranial suppurative foci, or communicating hydrocephalus. The fluid may be cloudy or turbid if the white blood cell count is elevated (>200/μL). If the lumbar puncture is traumatic, the CSF may appear bloody initially, but it should clear as flow continues. Xanthochromia, a pale-pink to yellow-orange color of the supernatant of centrifuged CSF, is found in patients with subarachnoid hemorrhage, usually within 2 hours after hemorrhage.

The CSF white cell count is usually elevated in untreated bacterial meningitis, ranging from 100 to at least 10,000 per microliter, with a predominance of neutrophils. About 10% of patients present with a lymphocytic predominance (>50%) in CSF. Some patients have a very low CSF white cell count (0 to 20/μL) despite high bacterial concentrations in CSF; these patients have a poor prognosis. Therefore, a Gram stain and culture should be performed on all CSF specimens, even those with a normal cell count. A CSF glucose concentration of less than 40 mg/dL is found in about 60% of patients with bacterial meningitis, and a CSF:serum glucose ratio of less than 0.31 is observed in 70% of cases. The CSF glucose level must always be compared with a simultaneous serum glucose concentration. The CSF protein concentration is elevated in virtually all cases of bacterial meningitis, presumably because of disruption of the blood-brain barrier.

CSF examination by Gram stain permits a rapid, accurate identification in 60% to 90% of cases of bacterial meningitis; the likelihood of detecting the organism by Gram stain correlates with the specific bacterial pathogen and the concentration of bacteria in CSF. False-positive findings may occur as a result of contamination in the collection of tubes or during staining. Cultures of CSF are positive in 70% to 80% of cases. These percentages may be lower in patients who have received prior antimicrobial therapy.

Several rapid diagnostic tests have been developed to aid in the diagnosis of bacterial meningitis.[21] Tests using staphylococcal coagglutination or latex agglutination are rapid and sensitive, although many of the kits do not include tests for group B meningococcus, and other kits probably are poor detectors of this antigen because of the limited immunogenicity of group B meningococcal polysaccharide. Performance of one of these rapid diagnostic tests (preferably latex agglutination) should be considered on all CSF specimens from patients in whom bacterial meningitis is suspected when the Gram stain is negative. Recently, the routine use of CSF bacterial antigen tests for the etiologic diagnosis of bacterial meningitis has been questioned; positive results have not modified therapy and false-positive and false-negative results may occur. Measurement of serum C-reactive protein or pro-calcitonin may also be useful in discriminating between bacterial and viral meningitis because elevated serum concentrations of these proteins have been observed in patients with acute meningitis.[22] In patients with acute meningitis in whom the CSF Gram stain is negative, serum concentrations of C-reactive protein or pro-calcitonin that are normal or below the limit of detection have a high negative predictive value in the diagnosis of bacterial meningitis. Polymerase chain reaction has been used to amplify DNA from patients with meningococcal meningitis; it showed a sensitivity and specificity of 91% in one study.[23] Further refinements in polymerase chain reaction may render it useful in the diagnosis of bacterial meningitis when the CSF Gram stain and cultures are negative.

Neuroimaging techniques have little role in the diagnosis of acute bacterial meningitis, except to rule out the presence

of other pathologic conditions or to identify a parameningeal source of infection. However, computed tomography (CT) or magnetic resonance imaging (MRI) may be useful in patients who have a persisting fever several days after initiation of antimicrobial therapy, prolonged obtundation or coma, new or recurrent seizure activity, signs of increased intracranial pressure, or focal neurologic deficits. MRI is better than CT for evaluation of subdural effusions, cortical infarctions, and cerebritis, although it is more difficult to obtain an MRI in a critically ill patient, which limits its usefulness in many patients with meningitis.

TREATMENT

ANTIMICROBIAL THERAPY

The initial approach to the patient with suspected bacterial meningitis is to perform a lumbar puncture to determine whether the CSF findings are consistent with that diagnosis.[20,24] Patients should receive empirical antimicrobial therapy based on their age and underlying disease status, if no etiologic agent is identified by Gram stain or rapid diagnostic tests. In patients with a focal neurologic examination, CT should be performed immediately to exclude an intracranial mass lesion because lumbar puncture is relatively contraindicated in that setting. However, obtaining a CT scan generally entails some delay, so empirical antimicrobial therapy should be started immediately, before the CT scan and lumbar puncture are done and after obtaining blood cultures, because of the high mortality rate in patients with bacterial meningitis in whom antimicrobial therapy is delayed. Although many clinicians routinely perform CT before lumbar puncture, this is probably not necessary in most patients. In a recent retrospective study of 301 adults with suspected meningitis,[25] the clinical features at baseline that were associated with an abnormal finding on CT of the head were an age of at least 60 years, immunocompromise, a history of CNS disease, a history of seizure within 1 week before presentation, and the following neurologic abnormalities: an abnormal level of consciousness, an inability to answer two consecutive questions correctly or to follow two consecutive commands, gaze palsy, abnormal visual fields, facial palsy, arm drift, leg drift, and abnormal language. These results need to be validated but are a reasonable guide in determining which patients require CT before lumbar puncture.

Our choices for empirical antibiotic therapy in patients with presumed bacterial meningitis, based on age, are presented in Table 52-2.[20,24] For neonates younger than 1 month, the most likely infecting organisms are *E. coli*, *S. agalactiae*, and *L. monocytogenes*; for those ages 1 to 23 months, infection may be due to *S. pneumoniae*, *N. meningitidis*, *S. agalactiae*, *E. coli*, or *H. influenzae*. From age 2 to 50 years, most cases of meningitis are due to *N. meningitidis* and *S. pneumoniae*. In older adults (≥50 years), the meningococcus and the pneumococcus are possible causes, as are *L. monocytogenes* and gram-negative bacilli. For all patients in whom *S. pneumoniae* is a possible causative pathogen, vancomycin should be added to empirical therapeutic regimens because highly penicillin- or cephalosporin-resistant strains of *S. pneumoniae* may be likely (see below). One other situation deserves comment: In patients after neurosurgery or patients with CSF shunts or foreign bodies, likely infecting organisms include staphylococci (*S. epidermidis* or *S. aureus*), diphtheroids, and gram-negative bacilli (including *P. aeruginosa*). Antimicrobial therapy in these situations should consist of vancomycin plus ceftazidime or cefepime pending culture results.

Once an infecting microorganism has been isolated, antimicrobial therapy can be modified for optimal treatment.[20,24] Our antibiotics of choice are listed in Table 52-3. Dosages for adults are listed in Table 52-4. For bacterial meningitis due to *S. pneumoniae* or *N. meningitidis,* penicillin G and ampicillin are equally efficacious. However, although in past years pneumococci remained uniformly susceptible to penicillin (minimal inhibitory concentration $\leq 0.06\ \mu g/mL$), worldwide reports have now documented relatively and highly resistant strains of pneumococci, with minimal inhibitory concentrations of 0.1 to 1.0 $\mu g/mL$ and at least 2 $\mu g/mL$, respectively. In view of these recent trends, and because sufficient CSF concentrations of penicillin are difficult to achieve with standard high parenteral doses (initial CSF concentrations of $\sim 1\ \mu g/mL$), penicillin can never be recommended as empirical antimicrobial therapy when *S. pneumoniae* is considered a likely infecting pathogen. Further, susceptibility testing must be performed on all CSF isolates. For relatively resistant strains, a third-generation cephalosporin (e.g., cefotaxime or ceftriaxone) should be used; for highly resistant strains, vancomycin in combination with a third-generation cephalosporin is the antimicrobial regimen of choice. Vancomycin used alone may not be optimal therapy for patients with pneumococcal meningitis. In one report of 11 consecutive patients with culture-proven pneumococcal meningitis caused by relatively penicillin-resistant strains,[26] four patients experienced a therapeutic failure with vancomycin, necessitating a change in therapy. These data indicate the need

TABLE 52-2 Empirical Therapy of Purulent Meningitis

Age	Standard Therapy	Alternative Therapies
<1 mo	Ampicillin plus cefotaxime	Ampicillin plus an aminoglycoside[b]
1–23 mo	Vancomycin plus a third-generation cephalosporin[a]	Vancomycin plus ampicillin plus chloramphenicol
2–50 y	Vancomycin plus a third-generation cephalosporin[a]	Meropenem
>50 y	Vancomycin plus ampicillin plus a third-generation cephalosporin[a]	Vancomycin plus ampicillin plus aztreonam; vancomycin plus trimethoprim-sulfamethoxazole; meropenem

[a] Cefotaxime or ceftriaxone.
[b] Gentamicin, tobramycin, or amikacin.

TABLE 52-3 Antimicrobial Therapy of Bacterial Meningitis

Organism	Antibiotic of Choice
Streptococcus pneumoniae	
Penicillin MIC < 0.1 μg/mL	Penicillin G or ampicillin
Penicillin MIC 0.1–1.0 μg/mL	Third-generation cephalosporin[a]
Penicillin MIC ≥ 2.0 μg/mL	Vancomycin plus a third-generation cephalosporin[a]
Neisseria meningitidis	Penicillin G or ampicillin; or a third-generation cephalosporin[a]
Haemophilus influenzae	
β-Lactamase–negative	Ampicillin
β-Lactamase–positive	Third-generation cephalosporin[a]
Enterobacteriaceae	Third-generation cephalosporin[a]
Pseudomonas aeruginosa	Ceftazidime or cefepime[b]
Streptococcus agalactiae	Penicillin G or ampicillin[b]
Listeria monocytogenes	Ampicillin or penicillin G[b]
Staphylococcus aureus	
Methicillin sensitive	Nafcillin or oxacillin
Methicillin resistant	Vancomycin
Staphylococcus epidermidis	Vancomycin[c]

[a] Cefotaxime or ceftriaxone.
[b] Addition of an aminoglycoside should be considered.
[c] Addition of rifampin may be indicated.
ABBREVIATION: MIC, minimal inhibitory concentration.

for careful monitoring, perhaps even including measurement of CSF vancomycin concentrations, in adult patients who are receiving vancomycin alone for pneumococcal meningitis. We recommend the combination of vancomycin plus a third-generation cephalosporin (cefotaxime or ceftriaxone) for documented pneumococcal meningitis pending results of susceptibility testing. Some investigators have recommended the addition of rifampin (if the organism is susceptible) to vancomycin for the treatment of meningitis caused by highly resistant pneumococcal strains,[27] although there are no firm data to support this. Meropenem, a carbapenem antimicrobial agent, yields microbiologic and clinical outcomes similar to those of cefotaxime or ceftriaxone in the treatment of patients with bacterial meningitis.[28] The newer fluoroquinolones (e.g., moxifloxacin, gatifloxacin) have in vitro activity against resistant pneumococci and have shown activity in experimental animal models of resistant pneumococcal meningitis but should not be used as first-line therapy in patients with bacterial meningitis, pending results of ongoing clinical trials. Trovafloxacin was recently shown to be therapeutically equivalent to ceftriaxone with or without vancomycin for the treatment of pediatric bacterial meningitis,[29] although this agent is no longer used because of concerns of liver toxicity.

TABLE 52-4 Recommended Doses of Antibiotics for Intracranial Infections in Adults with Normal Renal Function

Antibiotic	Total Daily Dose in Adults (Dosing Interval)
Amikacin	15 mg/kg (q 8 h)
Ampicillin	12 g (q 4 h)
Aztreonam	6–8 g (q 6–8 h)
Cefepime	6 g (q 8 h)
Cefotaxime	8–12 g (q 4–6 h)
Ceftazidime	6 g (q 8 h)
Ceftriaxone	4 g[a] (q 12–24 h)
Chloramphenicol	4–6 g[b] (q 6 h)
Ciprofloxacin	800–1200 mg (q 8–12 h)
Gentamicin, tobramycin	5 mg/kg (q 8 h)
Meropenem	6 g (q 8 h)
Metronidazole	30 mg/kg (q 6 h)
Nafcillin, oxacillin	9–12 g (q 4 h)
Penicillin G	24 million U (q 4 h)
Rifampin[c]	600 mg (q 24 h)
Trimethoprim-sulfamethoxazole	10–20 mg/kg[d] (q 6–12 h)
Vancomycin	2–3 g (q 8–12 h)

[a] Actual dose studied was 50 mg/kg every 12 hours.
[b] Higher dose recommended for pneumococcal meningitis.
[c] Oral administration.
[d] Dosage based on trimethoprim component.

Meningococcal strains that are relatively resistant to penicillin have also been reported from several areas (in particular Spain); however, most patients harboring these strains have recovered with standard penicillin therapy, so their clinical significance is unclear. In the United States, approximately 3% of meningococcal strains have shown intermediate resistance to penicillin.[30] Some authorities would treat meningococcal meningitis with a third-generation cephalosporin (cefotaxime or ceftriaxone) pending results of in vitro susceptibility testing.

Treatment of *H. influenzae* type b meningitis has been hampered by the emergence of β-lactamase–producing strains of the organism, which accounted for approximately 25% to 33% of all isolates in the United States.[1] Chloramphenicol resistance also has been reported in the United States (<1% of isolates) and Spain (≥50% of isolates). In addition, a study found chloramphenicol to be bacteriologically and clinically inferior to certain β-lactam antibiotics (ampicillin, ceftriaxone, and cefotaxime) in childhood bacterial meningitis, and most of these cases were due to *H. influenzae* type b.[20] From these findings and those of other studies, the third-generation cephalosporins (e.g., cefotaxime and ceftriaxone) seem to be at least as effective as ampicillin plus chloramphenicol for therapy of *H. influenzae* meningitis. Cefuroxime, a second-generation cephalosporin, has also been evaluated for therapy of *H. influenzae* meningitis. Although initial studies documented an efficacy for this drug similar to that of ampicillin plus chloramphenicol, recent case reports have documented delayed CSF sterilization and the development of epiglottitis in patients receiving cefuroxime for meningitis. In addition, a prospective randomized study of ceftriaxone versus cefuroxime for the treatment of childhood bacterial meningitis documented the superiority of ceftriaxone; patients receiving this drug had milder hearing impairment and more rapid CSF sterilization than did those receiving cefuroxime.[31] We currently recommend a third-generation cephalosporin for empirical therapy when *H. influenzae* is considered a likely infecting pathogen.

The treatment of bacterial meningitis in adults that is caused by gram-negative enteric bacilli has been revolutionized by the third-generation cephalosporins,[20] with cure rates of 78% to 94%. Ceftazidime or cefepime is also active against *P. aeruginosa* meningitis; ceftazidime, alone or in combination with an aminoglycoside, resulted in cure of 19 of 24 patients with *Pseudomonas* meningitis in one report. Intrathecal or intraventricular aminoglycoside therapy should be considered

if there is no response to systemic therapy, although this therapy is now rarely needed. The fluoroquinolones (e.g., ciprofloxacin or pefloxacin) have been used in some patients with gram-negative bacillary meningitis, but at this time they can be considered only for patients with meningitis due to multidrug-resistant gram-negative bacilli or for patients in whom conventional therapy has failed.

The third-generation cephalosporins are inactive against meningitis caused by *L. monocytogenes,* an important meningeal pathogen; this is a major drawback of these agents. Therapy in this situation should consist of ampicillin or penicillin G; addition of an aminoglycoside should be considered in documented infection, at least for the first several days of treatment.[12,20] Alternatively, trimethoprim-sulfamethoxazole can be used. Patients with *S. aureus* meningitis should be treated with nafcillin or oxacillin; vancomycin should be reserved for patients allergic to penicillin and patients with disease caused by methicillin-resistant organisms.[15] Infection with *S. epidermidis,* the most likely isolate in a patient with a CSF shunt, should be treated with vancomycin, with rifampin added if the patient fails to improve. Shunt removal is often essential to optimize therapy.

The durations of therapy for bacterial meningitis should be 10 to 14 days for most causes of non-meningococcal meningitis and 3 weeks for meningitis due to gram-negative enteric bacilli.[20,32] Seven days of therapy appear adequate for meningococcal meningitis; several reports have suggested that 7 days of therapy is effective also for *H. influenzae* meningitis. Patients with *S. agalactiae* meningitis should be treated for 14 to 21 days, and patients with meningitis caused by *L. monocytogenes* should be treated for at least 21 days. However, therapy must be individualized; on the basis of clinical response, some patients may require longer courses of treatment.

ADJUNCTIVE THERAPY

Despite the availability of effective antimicrobial therapy, the morbidity and mortality rates of bacterial meningitis remain unacceptably high. Recent studies have focused on the pathogenesis and pathophysiology of bacterial meningitis, in the hope of developing innovative strategies for adjunctive treatment.[20,24] Recent work in experimental animal models of meningitis has suggested a potentially useful role for anti-inflammatory agents (e.g., corticosteroids and nonsteroidal anti-inflammatory agents) in decreasing the inflammatory response in the subarachnoid space, which may be responsible for the development of neurologic sequelae. Adjunctive dexamethasone therapy has been evaluated over the past decade in a number of published trials, mostly in infants and children with *H. influenzae* type b meningitis.[20,24] A meta-analysis of clinical studies published from 1988 to 1996 confirmed the benefit of adjunctive dexamethasone (0.15 mg/kg every 6 hours for 2 to 4 days) in infants and children with *H. influenzae* type b meningitis and, if commenced with or before parenteral antimicrobial therapy, suggested benefit for pneumococcal meningitis in childhood.[33] Administration of dexamethasone before or with initiation of antimicrobial therapy is recommended for optimal attenuation of the subarachnoid space inflammatory response; patients must be carefully monitored for the possibility of gastrointestinal hemorrhage. In a recently published prospective, randomized, double-blind trial in adults with bacterial meningitis, adjunctive treatment with dexamethasone was associated with a reduction in the proportion of patients who had unfavorable outcome and in the proportion of patients who died; the benefits were most striking in the subset of patients with pneumococcal meningitis.[34] The use of adjunctive dexamethasone, however, is of particular concern in patients with pneumococcal meningitis caused by highly penicillin- or cephalosporin-resistant strains who are treated with vancomycin because a diminished inflammatory response may significantly decrease CSF vancomycin penetration and delay CSF sterilization, perhaps leading to a worse outcome. In the study cited above, only 72% of the 108 CSF cultures that were positive for *S. pneumoniae* were submitted for susceptibility testing, and all were susceptible to penicillin. However, based on the results of this trial and the apparent absence of serious adverse outcomes in the patients who received dexamethasone, routine use of adjunctive dexamethasone is warranted in most adults with pneumococcal meningitis.[35] In patients with meningitis caused by pneumococcal strains resistant to penicillin and/or cephalosporins, careful observation and follow-up are critical to determine whether dexamethasone therapy is associated with an adverse outcome. When dexamethasone is used, the timing of administration is crucial. Administration of dexamethasone before or concomitant with the first dose of antimicrobial therapy is recommended for optimal attenuation of the subarachnoid space inflammatory response. Dexamethasone is not recommended in patients who have already received antimicrobial therapy. If the meningitis is found not to be caused by *S. pneumoniae* in adults, dexamethasone therapy should be discontinued.

Other adjunctive therapies may be useful in critically ill patients with bacterial meningitis.[20] Patients who are stuporous or comatose (precluding assessment of worsening neurologic function) and who show signs of increased intracranial pressure (e.g., altered level of consciousness; dilated, poorly reactive or nonreactive pupils; and ocular movement disorders) may benefit from the insertion of an intracranial pressure monitoring device. Increased intracranial pressure can be lowered by elevating the head of the bed to 30 degrees to maximize venous drainage with minimal compromise of cerebral perfusion, by the use of hyperosmolar agents, and by hyperventilation. However, the routine use of hyperventilation (to maintain the partial arterial pressure of CO_2 between 27 and 30 mm Hg) has been questioned in patients with bacterial meningitis. Infants and children with bacterial meningitis and normal initial CT scans can be treated with hyperventilation to decrease elevated intracranial pressure because it is unlikely that cerebral blood flow will be decreased to ischemic thresholds. However, in children in whom CT shows cerebral edema, cerebral blood flow is likely to be normal or decreased, so hyperventilation might decrease intracranial pressure at the expense of cerebral blood flow, possibly reducing flow to ischemic thresholds. The use of hyperosmolar agents (e.g., mannitol, glycerol) may be useful in reducing increased intracranial pressure in patients with bacterial meningitis. In one recent study in infants and children with bacterial meningitis, oral glycerol appeared to help prevent neurologic sequelae,[36] although further studies are needed before adjunctive glycerol can be routinely recommended. A detailed discussion of the management of raised intracranial pressure is found in Chap. 65. Seizures must be treated promptly to avoid status epilepticus, which might lead to

anoxic brain injury (see Chap. 64). Another important adjunctive measure in patients with bacterial meningitis is fluid restriction to combat hyponatremia caused by excess secretion of antidiuretic hormone, although this measure is not appropriate in the presence of shock or dehydration because hypotension may predispose the patient to cerebral ischemia. Many patients, particularly children, with bacterial meningitis are hyponatremic (serum sodium level < 135 mEq/L) at presentation; the degree and duration of hyponatremia may contribute to neurologic sequelae. The management of hyponatremia is discussed in greater depth in Chap. 76.

PREVENTION

A final point concerns chemoprophylaxis of contacts of meningitis cases, which is indicated for contacts of patients with *N. meningitidis* or *H. influenzae* type b meningitis.[20] For meningococcal meningitis, chemoprophylaxis usually is administered only to intimate contacts (e.g., household contacts, day-care contacts, nursery school contacts, contacts who eat or sleep in the same dwelling, and close contacts such as in a military barracks or boarding school); it is not indicated for other groups (e.g., office coworkers or classmates) unless there has been intimate contact. However, one study has suggested that school-aged children may be at increased risk of secondary infection when classrooms are crowded and/or when contact during lunch or recess is frequent. Prophylaxis is not necessary for medical personnel caring for cases unless there has been intimate contact (e.g., mouth-to-mouth resuscitation, or those who perform endotracheal intubation or endotracheal tube management). All contacts (children and adults) of a patient with *H. influenzae* meningitis should receive chemoprophylaxis if exposure has occurred in a household or day-care center containing children 4 years or younger (other than the index case), provided that the exposure to *H. influenzae* type b was in the week before presentation. The recommended drug of choice for chemoprophylaxis, for contacts of patients with either type of meningitis, is rifampin. For contacts of patients with *H. influenzae* meningitis, rifampin at a daily dose of 20 mg/kg (not exceeding 600 mg) for 4 consecutive days is most effective. For contacts of meningococcal cases, one rifampin dose of 10 mg/kg (not exceeding 600 mg) twice a day for 2 days is effective. One dose of ciprofloxacin (500 or 750 mg) may also be effective for eradicating nasopharyngeal carriage of meningococci; ciprofloxacin is not recommended in pregnant women or in persons younger than 18 years because of concerns of cartilage damage. Ciprofloxacin may well supplant rifampin for chemoprophylaxis in adults. On one study, ceftriaxone (250 mg intramuscularly in adults or 125 mg in children) was shown to eliminate the meningococcal serogroup A carrier state in 97% of patients for up to 2 weeks and is probably the safest alternative for meningococcal chemoprophylaxis in pregnant women. Azithromycin (500 mg orally once) was also shown to be as effective as a four-dose regimen of rifampin in the eradication of meningococci from the nasopharynx.[37]

Brain Abscess

EPIDEMIOLOGY AND ETIOLOGY

Brain abscess is one of the most serious complications of head and neck infections. Even in the antibiotic era, mortality from brain abscess was not appreciably different from that in the era before antibiotics (about 40% to 60%) until the past decade, when mortality decreased to between 5% and 10%.[38] This improvement is likely due to recent developments in diagnosis and treatment, which are discussed below. There is a large geographic variability in the incidence of brain abscess, with approximately 4 to 10 cases seen annually on active neurosurgical services in developed countries.

Bacteria can reach the brain by several different mechanisms. The factors predisposing to brain abscess and the etiologic agents in each circumstance are presented in Table 52-5.[38-40] The most common pathogenic mechanism of brain abscess formation is spread from a contiguous focus of infection, most often in the middle ear, mastoid air cells, or paranasal sinuses. Early studies associated 40% of brain abscesses with otitis media, but this number has been decreasing in recent years. However, if antibiotic therapy of otitis is neglected, there is an increased risk of intracranial complications. Brain abscess secondary to otitis media is bimodally distributed, with peaks in children (acute otitis media) and in persons older than 40 years (chronic otitis media). Most cases of brain abscess due to otitis media occur in the temporal lobe and cerebellum. The etiologic agents in brain abscess secondary to otitis media include a broad range of bacterial species, including streptococci, *Bacteroides fragilis,* and members of the *Enterobacteriaceae*.

TABLE 52-5 Predisposing Conditions and Microbiology in Brain Abscess

Predisposing Condition	Usual Bacterial Isolates
Otitis media or mastoiditis	Streptococci (anaerobic or aerobic), *Bacteroides* sp., *Enterobacteriaceae*
Sinusitis (frontoethmoidal or sphenoidal)	Streptococci, *Bacteroides* sp., *Enterobacteriaceae, Staphylococcus aureus, Haemophilus* sp.
Dental sepsis	Mixed *Fusobacterium, Bacteroides,* and *Streptococcus* sp.
Penetrating trauma or postneurosurgical state	*Staphylococcus aureus,* streptococci, *Enterobacteriaceae, Clostridium* sp.
Congenital heart disease	Streptococci, *Haemophilus* sp.
Lung abscess, empyema, bronchiectasis	*Fusobacterium, Actinomyces,* and *Bacteroides* sp. *Nocardia asteroides;* streptococci
Bacterial endocarditis	*Staphylococcus aureus,* streptococci
Immunosuppressed host	*Nocardia,* Enterobacteriaceae

SOURCE: Adapted from Tunkel et al.[38]

Paranasal sinusitis continues to be an important condition predisposing to brain abscess, most commonly in persons ages 10 to 30 years. The frontal lobe is the predominant abscess site; when brain abscess complicates sphenoid sinusitis, the temporal lobe or sella turcica is usually involved.[38–40] Streptococci are the predominant bacterial species involved in brain abscess secondary to sinusitis, although anaerobes, *S. aureus*, and gram-negative bacilli have been isolated.

Dental infections are a less common source of brain abscess; infections of molar teeth seem most often to be the cause. The frontal lobe is usually involved, but temporal lobe extension has also been described.

A second mechanism of brain abscess formation is hematogenous dissemination to the brain from a distant focus of infection. These abscesses are usually multiple and multiloculated, and they have a higher mortality rate than do abscesses that arise secondary to contiguous foci of infection.[38–40] The most common sources in adults are chronic pyogenic lung diseases, especially lung abscess, bronchiectasis, empyema, and cystic fibrosis. Anaerobes (*Fusobacterium* and *Bacteroides* species) and streptococci are likely infecting pathogens in this situation, as are *Nocardia* and *Actinomyces* species. Brain abscess may also occur hematogenously from wound and skin infections, osteomyelitis, pelvic infection, cholecystitis, and other intra-abdominal infections. Another predisposing factor leading to hematogenously acquired brain abscess is cyanotic congenital heart disease (accounting for 5% to 10% of all brain abscess cases, with higher percentages in some pediatric series), most commonly due to tetralogy of Fallot and transposition of the great vessels.[41] Brain abscess is rare during bacterial endocarditis (<5% of cases in most series), despite the presence of persistent bacteremia.[42] Hereditary hemorrhagic telangiectasia is a predisposing factor almost always observed in patients with coexisting pulmonary arteriovenous malformations; perhaps it allows septic emboli to cross the pulmonary circulation without capillary filtration. Brain abscesses have also developed after esophageal dilatation and sclerosing therapy for esophageal varices.

Trauma is a third pathogenic mechanism in the development of brain abscess, whether secondary to an open cranial fracture with dural breach, to neurosurgery, or (especially in children) to a foreign body injury.[38–40] The incidence of brain abscess formation after head trauma ranges from 3% to 17% in military populations, where it is usually secondary to retained bone fragments or contamination of initially "sterile" missile sites with bacteria from skin, clothes, and the environment. Predisposing traumatic conditions in the civilian population include compound depressed skull fractures, dog bites, rooster pecking, and, especially in children, injury from lawn darts and pencil tips. Likely infective microorganisms after trauma include staphylococci, streptococci, gram-negative bacilli, and anaerobes.

Brain abscess is cryptogenic in about 20% of patients. Many of these cases are secondary to unrecognized dental foci of infection. In this subgroup of patients, broad antimicrobial therapy is indicated pending culture results (see section on Treatment, below).

Overall, the most commonly isolated bacterial species in brain abscess are streptococci (aerobic, anaerobic, and microaerophilic), which are present in 60% to 70% of cases.[38–40] These bacteria (especially the *Streptococcus milleri* group) normally reside in the oral cavity, appendix, and female genital tract and have a proclivity for abscess formation. *Staphylococcus aureus*, which was isolated in 25% to 30% of cases in the era before antibiotics, currently accounts for 10% to 15% of isolates, although the frequency of isolation of *S. aureus* is increased in certain clinical situations (e.g., cranial trauma and endocarditis). Attention to proper culture techniques has increased the rate of isolation of anaerobes, with *Bacteroides* species isolated in 20% to 40% of cases, often in mixed culture. Enteric gram-negative bacilli (*Proteus* species, *E. coli, Klebsiella* species, and *Pseudomonas* species) are isolated in 23% to 33% of patients. Other bacterial species occur less commonly (<1% of cases) and include *H. influenzae*, *S. pneumoniae*, *L. monocytogenes*, and *Nocardia asteroides* (*Nocardia* is more often isolated in patients with T-lymphocyte or mononuclear phagocyte defects). Nocardial brain abscesses have increased in incidence with the increasing numbers of immunosuppressed patients, although up to 48% of patients with nocardiosis have no underlying conditions. Brain abscesses due to *Actinomyces* species are commonly associated with pulmonary and odontogenic infections.

CLINICAL PRESENTATION

The clinical course of brain abscess may be indolent or fulminant; 75% of patients have symptoms for less than 2 weeks. Most of the clinical manifestations are due to the presence of space-occupying lesions within the brain.[38–40] The most common symptom is headache, present in more than 70% of patients. The headache is usually moderate to severe and hemicranial, but it may be generalized. Other findings include nausea and vomiting (~50% of cases), nuchal rigidity (~25%), and papilledema (~25%). Mental status changes ranging from lethargy to coma occur in the majority of cases. Seizures, usually generalized, occur in 25% to 35% of patients. Fever appears in only 45% to 50% of cases; afebrile patients tend to be older and to have a longer duration of illness and a higher mortality rate. Only about 50% of patients present with the classic triad of fever, headache, and focal neurologic deficit. Patients with frontal lobe abscess often present with headache, drowsiness, inattention, and deterioration in mental status; the most common focal neurologic signs are hemiparesis, with unilateral motor signs, and a motor speech disorder. The clinical presentation of cerebellar abscess may include ataxia, nystagmus, vomiting, and dysmetria. Persons with abscess of the temporal lobe may present with ipsilateral headache and aphasia, if the lesion is in the dominant hemisphere. A visual field defect (e.g., an upper homonymous quadrantanopia) may be the only presenting sign of a temporal lobe abscess. Persons with brain stem abscesses usually present with facial weakness, fever, headache, hemiparesis, dysphagia, and vomiting. Clues to the site of origin of the infection should also be sought; these include otorrhea, orbital cellulitis, purulent nasal discharge, dental sepsis, and postoperative or posttraumatic cranial infection; such findings occur in about 60% of cases. It is important to note that the clinical presentation of brain abscess in immunosuppressed patients may be masked by the diminished inflammatory response.

DIAGNOSIS

The diagnosis of brain abscess has been revolutionized by CT, which not only is an excellent means to examine the brain parenchyma but also is superior to standard radiologic procedures for examination of the paranasal sinuses, mastoid cells,

and middle ear.[38–40] The sensitivity of CT is 95% to 99% for brain abscess; it also yields information concerning the extent of surrounding edema, the presence or absence of a midline shift, the presence of hydrocephalus, and the possibility of imminent ventricular rupture. The characteristic appearance of brain abscess on CT is a hypodense center with a uniform peripheral ring enhancement after the injection of contrast material; this is surrounded by a variable hypodense area of brain edema. A similar appearance is seen with neoplasms, granulomas, cerebral infarction, or resolving hematoma. Contrast enhancement of the ependymal lining suggests ventriculitis. Other CT findings include nodular enhancement and areas of low attenuation without enhancement; the latter finding is observed during the early stage of cerebritis, before abscess formation; as the abscess progresses, contrast enhancement is observed. In later stages, as the abscess becomes encapsulated, contrast no longer differentiates the lucent center, and the CT appearance is similar to that in the early stage of cerebritis. The use of delayed films may be helpful because the presence of contrast material in the center of the lesion suggests cerebritis. The absence of contrast material likely indicates a well-encapsulated lesion. This difference is important therapeutically because cerebritis may respond to medical therapy alone, whereas most encapsulated lesions require surgical intervention. CT is also useful for following the course of brain abscess, although, after aspiration, improvement in the CT appearance may not be seen for up to 5 weeks or longer. Complete resolution may take 4 to 5 months.

Scintigraphy with ^{111}In-labeled leukocytes has also been evaluated in the diagnosis of brain abscess.[43] Radiolabeled leukocytes migrate to, and accumulate in, an area of active inflammation, thereby differentiating brain abscess from other cerebral mass lesions, although false-positive scans can be observed in necrotic tumors and false-negative scans in patients receiving corticosteroids. This modality is most useful as a complement to CT.

MRI has an important role in the diagnosis of brain abscess, for which it has several advantages over CT.[38] MRI is more effective for the early detection of cerebritis. Also, in cases of cerebral edema, MRI shows a stronger contrast between an edematous and a normal brain and more clearly shows the spread of inflammation into the ventricles and subarachnoid space. MRI also permits earlier detection of satellite lesions. T1-weighted images characteristically demonstrate a peripheral zone of mild hypointensity (representative of edema formation) related to adjacent brain, which surrounds a central zone of more marked hypointensity (indicative of the necrotic center of the abscess); these two regions are separated by a capsule that appears as a discrete rim, which is isointense to mildly hyperintense. On T2-weighted images, there is an area of marked hyperintensity in the zone of edema when compared with adjacent brain, whereas the central core is isointense to hyperintense compared with gray matter; the capsule appears as a well-defined hypointense rim at the margin of the abscess. Contrast-enhanced MRI, using the paramagnetic agent gadolinium diethylenetriamine penta-acetic acid, has the advantage of clearly differentiating the central abscess, the surrounding contrast-enhancing rim, and the cerebral edema surrounding the abscess. MRI is the current diagnostic procedure of choice for detection of brain abscess, although it is not always feasible in critically ill patients.

A major advance in the use of CT is the availability of stereotaxic CT-guided aspiration of the abscess to facilitate bacteriologic diagnosis. However, aspiration during the early cerebritis stage may be complicated by hemorrhage. At the time of aspiration, a specimen should be sent for Gram stain (and other special stains, e.g., Ziehl-Nielsen, modified acid-fast, and silver stains, when appropriate), routine culture, and anaerobic culture. The use of this modality in the treatment of brain abscess is discussed under Surgical Therapy in the section on Treatment.

Lumbar puncture is contraindicated in patients with suspected or proven brain abscess because of the risk of life-threatening cerebral herniation after removal of CSF. When lumbar puncture is performed, the CSF profile is nonspecific, with a predominantly mononuclear pleocytosis and an elevated protein concentration. Hypoglycorrhachia is present in only 25% of cases, and fewer than 10% of CSF cultures are positive. Microorganisms usually are not demonstrated on Gram stain, unless the abscess has ruptured into the subarachnoid space or there is accompanying meningitis.

TREATMENT

ANTIMICROBIAL THERAPY

Perhaps related to the alteration of the blood-brain barrier in the area of the brain abscess, there is increased penetration of normally excluded antibiotics into the brain. However, this increased penetration into the brain does not predict penetration into cerebral abscesses. Brain abscess concentrations of antibiotics have been measured, and several generalizations can be made:[38] (a) metronidazole can be expected to achieve inhibitory levels for sensitive anaerobic microorganisms; (b) chloramphenicol concentrations in the brain are likely to be high relative to serum; and (c) concentrations of various penicillins and cephalosporins in brain tissue and abscess are usually poor, although when given in large parenteral doses, these agents achieve therapeutic concentrations for sensitive microorganisms.

When a diagnosis of brain abscess is made, whether presumptively on the basis of radiologic studies or through aspiration of the abscess, antimicrobial therapy should be initiated. Aspiration may provide an etiologic diagnosis on Gram stain examination, but when aspiration is impractical or delayed, we recommend empirical therapy based on the likely etiologic agent, if a predisposing condition can be identified (Table 52-6).[38] Because of the high rate of isolation of streptococci (particularly the *S. milleri* group) from brain abscesses of various etiologies (see Table 52-5), high-dose penicillin G (20 to 24 million U/day) or another drug that is active against this organism (e.g., a third-generation cephalosporin, either cefotaxime or ceftriaxone) should be included in the initial therapeutic regimen. Penicillin is also active against most anaerobic species, with the notable exception of *B. fragilis*, which is isolated in a high percentage (20% to 40%) of brain abscess cases. When *B. fragilis* is suspected, we recommend the addition of metronidazole (7.5 mg/kg every 6 hours). The advantages of metronidazole over other agents include its bactericidal activity against *B. fragilis* (the others are frequently bacteriostatic for this organism) and the high concentrations it attains in brain abscess pus, even with concomitant corticosteroid administration. In addition, one retrospective review has suggested that metronidazole may improve mortality rates in patients with brain abscess.[44] In cases in which *S. aureus* is a likely infecting pathogen (e.g., cranial trauma or prior neurosurgery), nafcillin should be used.

TABLE 52-6 Empirical Antimicrobial Therapy for Brain Abscess

Predisposing Condition	Antimicrobial Regimen
Otitis media or mastoiditis	Metronidazole plus a third-generation cephalosporin[a]
Sinusitis	Vancomycin plus metronidazole plus a third-generation cephalosporin[a]
Dental sepsis	Penicillin plus metronidazole
Cranial trauma or postneurosurgical state	Vancomycin plus a third-generation cephalosporin[a]
Congenital heart disease	Third-generation cephalosporin[a]
Unknown	Vancomycin plus metronidazole plus a third-generation cephalosporin[a]

[a] Cefotaxime or ceftriaxone; ceftazidime or cefepime is used if *Pseudomonas aeruginosa* is suspected.

Vancomycin, which penetrates into brain abscess fluid,[45] is reserved for patients who are allergic to penicillin or in whom methicillin-resistant organisms are likely or have been isolated. The penetration of clindamycin, erythromycin, and the first-generation cephalosporins into brain abscesses is usually inadequate to achieve therapeutic concentrations, thus precluding their use in this setting. For empirical therapy when members of the *Enterobacteriaceae* are suspected (e.g., in cases of abscess of otitic origin), a third-generation cephalosporin or trimethoprim-sulfamethoxazole should be used.

One regimen that has theoretical advantages and covers a broad range of possible infecting bacterial pathogens is metronidazole, vancomycin, and a third-generation cephalosporin (cefotaxime or ceftriaxone; see Table 52-6). In addition to activity against gram-negative bacilli, these third-generation cephalosporins have excellent antistreptococcal activity and possess antistaphylococcal action. However, it is important to note that there are no clinical trials comparing this regimen with traditional penicillin-containing formulas. If *P. aeruginosa* is a likely infecting pathogen, ceftazidime or cefepime is the agent of choice. However, if ceftazidime is the third-generation cephalosporin used in empirical therapy of brain abscess, the regimen must also include penicillin G to treat a possible streptococcal infection because ceftazidime has unreliable activity against gram-positive organisms.

Once an infecting pathogen is isolated, antimicrobial therapy can be modified (Table 52-7).[38] Antimicrobial therapy with large-dose intravenous antibiotics should be continued for 6 to 8 weeks and is often followed by oral antibiotic therapy for 2 to 6 months, if an appropriate agent is available. A shorter course (3 to 4 weeks) may be adequate for patients undergoing excision of the abscess. Surgical therapy (see below) is often required for treatment of brain abscess, although certain subgroups of patients can be managed without surgery.[46,47] These include patients with medical conditions that increase the risks from surgery, patients with multiple abscesses or an abscess in a deep or dominant location, patients with coexisting meningitis or ependymitis, patients in whom antimicrobial therapy results in early abscess reduction and clinical improvement, and patients with an abscess smaller than approximately 3 cm.

SURGICAL THERAPY

Most patients require surgical management for optimal treatment of brain abscess. The two procedures judged equivalent by outcome are aspiration of the abscess after burr hole placement and complete excision after craniotomy.[38,48,49] Drainage and marsupialization are rarely used. The choice of procedure must be individualized for each patient. Aspiration may be performed using stereotaxic CT guidance, which affords the surgeon rapid, accurate, and safe access to virtually any intracranial point. Aspiration can also be used for swift relief of increased intracranial pressure. Incomplete drainage of multiloculated lesions is a major disadvantage of aspiration;

TABLE 52-7 Antimicrobial Therapy for Brain Abscess

Organism	Standard Therapy	Alternative Therapies
Streptococcus milleri and other streptococci	Penicillin G	Third-generation cephalosporin,[a] vancomycin
Bacteroides fragilis	Metronidazole	Chloramphenicol, clindamycin
Fusobacterium sp., *Actinomyces*	Penicillin G	Metronidazole, chloramphenicol, clindamycin
Staphylococcus aureus	Nafcillin	Vancomycin[c]
Enterobacteriaceae	Third-generation cephalosporin[a]	Aztreonam,[b] trimethoprim-sulfamethoxazole, fluoroquinolone, meropenem
Haemophilus sp.	Third-generation cephalosporin[a]	Aztreonam,[b] trimethoprim-sulfamethoxazole
Nocardia asteroides	Trimethoprim-sulfamethoxazole	Minocycline, third-generation cephalosporin,[a] imipenem (all[b])

[a] Cefotaxime or ceftriaxone.
[b] Limited data available for use of these agents; firm recommendations are not possible at this time.
[c] Use vancomycin if methicillin-resistant S. *aureus* is isolated.

these lesions frequently require excision. Other risks of aspiration are that it may allow the abscess to rupture into the ventricle, and that pus may leak into the subarachnoid space, resulting in ventriculitis or meningitis.

Complete excision after craniotomy is most often employed in patients in a stable neurologic condition. Surgery is also indicated for abscesses exhibiting gas on radiologic evaluation and for posterior fossa abscesses. In patients with worsening neurologic deficits, including deteriorating consciousness or signs of increased intracranial pressure, surgery should be performed emergently. Excision is contraindicated in the early stages, before a capsule is formed. All brain abscesses larger than 2.5 cm in diameter should be aspirated or excised for optimal management.[50]

ADJUNCTIVE THERAPY

Intracranial pressure monitoring has become important in the intensive care management of brain abscess patients who have cerebral edema (see Chap. 65). The use of these monitoring devices has diminished the likelihood of transtentorial herniation, brain stem compression, and further injury from cerebral ischemia.

Corticosteroids have been used as one method to manage increased intracranial pressure, although their use remains controversial.[38] These agents may retard the encapsulation process, reduce antibiotic entry into the CNS, increase necrosis, and alter the appearance of ring enhancement on CT as inflammation subsides, thereby obscuring information from sequential studies. Steroids (at a dexamethasone dose for adults of 4 to 6 mg every 6 hours) are most useful in the patient with deteriorating neurologic status and increased intracranial pressure, for whom steroids may prove lifesaving. When used to treat cerebral edema, steroids should be used for the shortest time possible and withdrawn when the mass effect no longer poses a significant danger to the patient. The management of increased intracranial pressure is discussed in Chap. 65.

Subdural Empyema and Epidural Abscess

EPIDEMIOLOGY AND ETIOLOGY

The term *subdural empyema* refers to a collection of pus in the space between the dura and arachnoid. This process accounts for about 20% of all localized intracranial infections.[51–53] The disease was essentially lethal before the advent of antimicrobial therapy; with current methods of diagnosis and treatment, mortality rates are 10% to 20%. The most common predisposing conditions are otorhinologic infections, especially infection of the paranasal sinuses, which are affected in 50% to 80% of cases.[51,52,54] The pathogenesis involves spread of infection to the subdural space through valveless emissary veins in association with thrombophlebitis or by extension of an osteomyelitis of the skull with accompanying epidural abscess. The mastoid cells and middle ear are the source in 10% to 20% of patients, especially in geographic areas where many cases of otitis media are not treated promptly with antibiotics. Other predisposing conditions include skull trauma, neurosurgical procedures, and infection of a pre-existing subdural hematoma. The infection is metastatic in a minority of cases (~5%), principally from the pulmonary system. In infants, meningitis is an important predisposing condition for the development of subdural empyema, which occurs in about 2% of infants with bacterial meningitis. Different bacterial species have been isolated from cranial subdural empyemas[53–55] (Table 52-8), including streptococci (35% to 40% of cases), staphylococci (~15%), aerobic gram-negative bacilli (~3%), and anaerobes (33% to 100%, when careful culturing is performed); these organisms constitute the microbial flora that are frequently isolated from patients with chronic sinusitis and cranial abscesses.

Spinal subdural empyema is a rare condition occurring secondary to metastatic infection from a distant site.[56] *Staphylococcus aureus* is the most frequent isolate, whereas streptococci are found less frequently.

The term *epidural abscess* refers to a localized infection between the dura mater and the overlying skull or vertebral column. Cranial epidural abscess can cross the cranial dura along emissary veins, so subdural empyema often is also present. Therefore, the etiology, pathogenesis, and bacteriology of intracranial epidural abscess are usually identical to those described for subdural empyema (see above), with the initial focus of infection in the middle ear, paranasal sinuses, or mastoid cells.

In contrast, spinal epidural abscess usually follows hematogenous dissemination from foci elsewhere in the body to the epidural space or, by extension, from vertebral osteomyelitis.[57,58] Hematogenous spread occurs in 25% to 50% of cases, secondary to infections of the skin (furuncles, cellulitis, or infected acne), urinary tract infections, periodontal abscesses, pharyngitis, pneumonia, or mastoiditis. Mild blunt spinal trauma may provide a devitalized site susceptible to transient bacteremia. Infection of the epidural space has also been reported after penetrating injuries, extension of decubitus ulcers or paraspinal abscesses, back surgery, lumbar puncture, and epidural anesthesia. Bacteremia may be an

TABLE 52-8 Bacteriology of Cranial Subdural Empyema and Spinal Epidural Abscess

Organism	Cranial Subdural Empyema (%)	Spinal Epidural Abscess (%)
Staphylococci (including *S. aureus* and *S. epidermidis*)	15	65
Streptococci (aerobic, anaerobic, and microaerophilic)	36	8
Aerobic gram-negative bacilli	3	17
Other anaerobes	18	2
Other	8	2
Unknown	20	6

SOURCE: Data summarized from Kaufman et al,[53] Yoshikawa et al,[55] Danner and Hartman,[58] and Koppel et al.[59]

important predisposing factor because the incidence of spinal epidural abscess is increased in patients who use injection drugs[59] or have intravenous catheters. The infecting microorganism in the vast majority of cases is *S. aureus* (50% to 95% in various series; see Table 52-8). Other isolates include aerobic and anaerobic streptococci (~8% of cases) and gram-negative aerobic bacilli (~18%), especially *E. coli* and *P. aeruginosa*.

CLINICAL PRESENTATION

Persons with subdural empyema can present in a rapidly progressive, life-threatening clinical condition.[51–53] Symptoms and signs relate to the presence of increased intracranial pressure, meningeal irritation, or focal cortical inflammation. In addition, 60% to 90% of patients have evidence of the antecedent infection (e.g., sinusitis or otitis). Headache, initially localized to the infected sinus or ear is a prominent complaint and can become generalized as the infection progresses. Vomiting is common as intracranial pressure increases. Early in the infection, about 50% of patients have altered mental status, which can progress to obtundation if the patient is not treated. Fever with a temperature above 39°C is present in most cases. Focal neurologic signs appear in 24 to 48 hours and progress rapidly, with eventual involvement of the entire cerebral hemisphere. Hemiparesis and hemiplegia are the most common focal signs, although ocular palsies, dysphasia, homonymous hemianopsia, dilated pupils, and cerebellar signs have been observed. Seizures (focal or generalized) are observed in more than 50% of cases. Signs of meningeal irritation (e.g., meningismus) are found in approximately 80% of patients, although fewer have Kernig or Brudzinski sign. If the patient remains untreated, neurologic deterioration occurs rapidly, with signs of increased intracranial pressure and cerebral herniation. Papilledema develops in fewer than 50% of patients. This fulminant picture may not be seen in patients with subdural empyema after cranial surgery or trauma, in patients who have received prior antimicrobial therapy, in patients with infected subdural hematomas, or in patients with infections metastatic to the subdural space.

Spinal subdural empyema usually manifests as radicular pain and symptoms of spinal cord compression, which may occur at multiple levels.[56] Clinically, this lesion is difficult to distinguish from a spinal epidural abscess (see the section on Diagnosis, below).

The onset of symptoms in cranial epidural abscess may be insidious and overshadowed by the primary focus of infection (e.g., sinusitis or otitis media).[51] Headache is a usual complaint, but the patient may otherwise feel well unless the clinical course is complicated (e.g., by development of subdural empyema or involvement of deeper intracranial structures). Because the dura is closely opposed to the inner surface of the cranium, the abscess usually enlarges too slowly to produce sudden major neurologic deficits (in contrast to subdural empyema) unless there is deeper intracranial extension. However, there may eventually be development of focal neurologic signs and focal or generalized seizures. In the absence of treatment, papilledema and other signs of increased intracranial pressure develop as the abscess enlarges. An epidural abscess near the petrous bone may present as Gradenigo syndrome, characterized by involvement of cranial nerves V and VI, with unilateral facial pain and weakness of the lateral rectus muscle.[50]

Spinal epidural abscess may develop within hours to days (after hematogenous seeding) or may grow slowly over months (associated more often with vertebral osteomyelitis).[57–61] Most abscesses pass through the following stages: focal vertebral pain; root pain; defects of motor, sensory, or sphincter function; and paralysis. Pain is the most consistent symptom and is accompanied by local tenderness at the affected level in more than 90% of cases. Subsequently, radicular pain develops; it is followed by progression to weakness and paralysis. Fever occurs in most patients during the course of the illness. Headache and neck stiffness may also occur. Respiratory function may be impaired if the cervical spinal cord is involved. The usually irreversible manifestations of cord involvement include muscle weakness, sensory deficits, and disturbances of sphincter control. At this juncture there may be rapid transition to paralysis (usually within 24 hours from onset of weakness), indicating the need for emergent evaluation, diagnosis, and treatment.

DIAGNOSIS

Subdural empyema should be suspected in any patient with meningeal signs and a focal neurologic deficit. Lumbar puncture is contraindicated in this setting because of the risk of cerebral herniation. When lumbar puncture is performed, CSF findings are nonspecific and include elevated opening pressure, moderate neutrophilic pleocytosis, and an increased protein concentration. Unless the course is complicated by bacterial meningitis, CSF Gram stain and cultures are negative. Skull radiographs may demonstrate evidence of concurrent sinusitis or osteomyelitis.

The diagnostic procedures are CT with contrast enhancement or MRI.[51,62] The typical CT appearance is a crescentic or elliptical area of hypodensity below the cranial vault or adjacent to the falx cerebri. Loculations may also be seen. Depending on the extent of disease, there is often an associated mass effect with displacement of midline structures. After the administration of contrast material, a fine, intense line of enhancement can be seen between the subdural collection and the cerebral cortex. However, false-negative CT scans do occur. MRI provides greater clarity of morphologic detail and may detect empyema not clearly seen on CT; it is of particular value in identifying subdural empyemas located at the base of the brain, along the falx cerebri, or in the posterior fossa. On the basis of signal intensity, MRI can differentiate extra-axial empyemas from most sterile effusions and chronic hematomas. Based on these findings, MRI is considered the modality of choice for the diagnosis of subdural empyema. CT and MRI are also useful for demonstrating sinusitis and otitis, although CT is better than MRI at imaging bone and should be used in cases of penetrating injury or osteomyelitis. MRI is the diagnostic procedure of choice for spinal subdural empyema because it more accurately defines the extent of the lesion than does CT.[60,61]

CT and MRI are also the diagnostic procedures of choice for cranial epidural abscess because both demonstrate a superficial, circumscribed area of diminished density.[51] The possibility of adjacent subdural empyema or other intracranial involvement can also be assessed. MRI or CT should be performed in cases of suspected spinal epidural abscess. MRI is recommended as the diagnostic procedure of choice because

it can visualize the spinal cord and epidural space in sagittal and transverse sections and can identify accompanying osteomyelitis, intramedullary spinal cord lesions, and joint space infection; the response to therapy also can be assessed readily with this technique.

TREATMENT

The therapy of subdural empyema and epidural abscess optimally requires a combined medical and surgical approach. Surgical therapy is essential for three reasons: because antibiotics do not reliably sterilize these lesions without concurrent drainage; because cultures of purulent material guide antimicrobial therapy; and because surgical decompression is useful in controlling increased intracranial pressure.

ANTIMICROBIAL THERAPY

Once purulent material is aspirated, antimicrobial therapy should be initiated; it should be based on a Gram stain and on the site of primary infection[51,63] (Table 52-9). For suspected *S. aureus*, nafcillin (1.5 to 2.0 g every 4 hours) should be used, with vancomycin (1.0 g every 12 hours) reserved for patients allergic to penicillin and for cases where methicillin-resistant organisms are suspected. Metronidazole (15 mg/kg loading dose and then 7.5 mg/kg every 6 to 8 hours) is used when anaerobes (e.g., *B. fragilis*) are suspected. For aerobic gram-negative bacilli, a third-generation cephalosporin (cefotaxime or ceftriaxone) should be used, with ceftazidime or cefepime reserved for cases in which *P. aeruginosa* is likely. Parenteral antibiotics should be continued for 3 to 6 weeks, depending on the patient's clinical response. Longer periods of intravenous therapy (and perhaps oral therapy) may be required if an associated osteomyelitis is present.

Presumptive antimicrobial therapy for spinal epidural abscess must include a first-line antistaphylococcal agent (nafcillin or vancomycin); coverage for gram-negative organisms should be included for any patient with a history of a spinal procedure or of injection drug abuse.[58,60] In addition, pending culture results, empirical antimicrobial therapy in patients who have undergone a spinal procedure should include vancomycin for presumed involvement by *S. epidermidis.*

SURGICAL THERAPY

The optimal surgical approach for subdural empyema is controversial, and there are several unanswered questions with regard to management.[51] First, should drainage be performed by craniotomy or via burr holes? Previous studies have documented a lower mortality rate in patients undergoing craniotomy, although it may be that a larger percentage of gravely ill patients were treated with burr holes because of the greater surgical risk. Burr hole therapy may be more efficacious in the early stages of subdural empyema, when the pus is liquid, because thickening occurs as the disease progresses, making aspiration more difficult. If burr holes are to be placed, they should be multiple to allow extensive irrigation. However, craniotomy may be essential for posterior fossa subdural empyema, and it is also needed in 10% to 20% of patients initially treated with trephination. Thus, burr hole drainage, even with catheter irrigation, may not adequately drain the empyema. When craniotomy is performed, wide exposure should be afforded to allow adequate exploration of all areas where subdural pus is suspected. Second, should antibiotics be instilled locally to irrigate the subdural space? Although antibiotic irrigation has become common, there are no data on the potential benefits of this practice. Third, should drains, or catheters, be left in the subdural space? This decision is best made by the neurosurgeon intraoperatively; however, with drains in place, the risk of nosocomial superinfection must be kept in mind. Further, surgical correction of the antecedent otorhinologic infection may also be necessary. In patients with spinal epidural abscess, laminectomy with decompression and drainage may need to be performed as a surgical emergency to minimize the likelihood of permanent neurologic sequelae. However, in a literature review of 38 patients with spinal epidural abscess treated with antimicrobial therapy alone, 23 recovered, two died, one worsened, and the rest remained the same or improved.[64] However, there have been no prospective, randomized trials comparing the efficacy of antimicrobial agents plus surgery with antimicrobial therapy

TABLE 52-9 Empirical Antibiotic Therapy for Subdural Empyema, Epidural Abscess, and Septic Intracranial Thrombophlebitis

Condition	Site of Primary Infection	Antibiotics
Cranial subdural empyema, cranial epidural abscess, or septic intracranial thrombophlebitis	Paranasal sinusitis, otitis media, or mastoiditis	Vancomycin plus metronidazole plus a third-generation cephalosporin[a]
	Cranial surgery	Vancomycin plus a third-generation cephalosporin[a]
	Hematogenous from distant and/or unknown site	Vancomycin plus metronidazole plus a third-generation cephalosporin[a]
Spinal epidural abscess or spinal subdural empyema	Extension of osteomyelitis or paravertebral infection	Vancomycin plus a third-generation cephalosporin[a]
Spinal epidural abscess	Hematogenous spread	Vancomycin plus a third-generation cephalosporin[a]
Spinal subdural empyema	Hematogenous spread	Vancomycin

[a] Cefotaxime or ceftriaxone should be used. If *Pseudomonas aeruginosa* is suspected, ceftazidime or cefepime is indicated instead.

alone. Rapid surgical decompression should be performed in patients with increasing neurologic deficit, persistent severe pain, or increasing temperature or peripheral white blood cell count.[65]

ADJUNCTIVE THERAPY

Patients may also require various adjunctive measures to control increased intracranial pressure. Preoperative use of mannitol, hyperventilation, and/or dexamethasone may be effective in controlling intracranial pressure before surgical decompression. However, corticosteroids should be tapered rapidly after surgical therapy because of the increased risk of secondary infection. We believe a short course of corticosteroids is appropriate in cases in which surgical intervention is delayed or contraindicated. Anticonvulsants should be used in patients with seizures.

Suppurative Intracranial Thrombophlebitis

EPIDEMIOLOGY AND ETIOLOGY

Septic intracranial thrombophlebitis involves venous thrombosis and suppuration. It may begin within veins and venous sinuses or may follow infection of the paranasal sinuses, middle ear, mastoid, face, or oropharynx, and it may involve additional vessels by propagation or discontinuous spread. Septic thrombophlebitis may also occur in association with epidural abscess, subdural empyema, or bacterial meningitis. Occasionally, there is metastatic spread from distant sites of infection. Conditions that increase blood viscosity or coagulability, such as dehydration, polycythemia, pregnancy, oral contraceptive use, sickle cell disease, malignancy, and trauma, increase the likelihood of thrombosis.

The antecedent conditions that predispose to the development of intracranial venous sinus thrombosis depend on the close proximity of various structures to the dural venous sinuses[66,67] (Fig. 52-1). The usual predisposing conditions for cavernous sinus thrombosis are paranasal sinusitis (especially frontal, ethmoidal, or sphenoidal) and infection of the face or mouth. Likely infecting bacterial pathogens depend on the initial source: staphylococci, streptococci, gram-negative bacilli, and anaerobes, if the antecedent condition is sinusitis, and predominantly *S. aureus* in the case of facial infections. Otitis media and mastoiditis are infections associated with lateral sinus thrombosis and infection of the superior and inferior petrosal sinuses. Infections of the face, scalp, subdural space, and epidural space and meningitis are associated with suppurative thrombophlebitis of the superior sagittal sinus. The likely infecting microorganisms depend on the associated primary condition (see Table 52-5).

In cavernous sinus thrombosis, *S. aureus* is the most important infecting microorganism, having been isolated in more than 66% of cases. This relates to the importance of this organism in infections of the face and scalp and in acute sphenoid sinusitis. Less common isolates include streptococci (isolated in about 17% of cases), pneumococci and gram-negative bacilli (5% each), and *Bacteroides* species (2%).

CLINICAL PRESENTATION

The clinical manifestations of suppurative cortical thrombophlebitis depend on the location of involvement. With involvement of the cortical venous system, the appearance of neurologic deficits depends on the adequacy of collateral venous drainage.[68] Persons with inadequate collateral flow present with impairment of consciousness, focal or generalized seizures, symptoms of increased intracranial pressure,

and focal neurologic signs (e.g., hemiparesis). Aphasia is common if the dominant cerebral hemisphere is involved.

The findings in dural venous sinus thrombosis also depend on location.[66,67] In cavernous sinus thrombosis, the most common complaints are periorbital swelling (73% of cases) and headache (52%). Headache is more common if the antecedent condition is sinusitis rather than a facial infection. Other symptoms include drowsiness, diplopia, eye tearing, photophobia, and ptosis. Fever is present in more than 90% of patients. Other common signs are proptosis, chemosis, periorbital edema, and weakness of the extraocular muscles (due to involvement of cranial nerves III, IV, and VI). Because the abducens nerve is the only cranial nerve traversing the interior of the cavernous sinus, lateral gaze palsy may be an early neurologic finding. Papilledema or venous engorgement and a change in mental status are observed in 65% and 55% of patients, respectively. Meningismus is present in about 40% of cases, usually secondary to retrograde spread of the thrombophlebitis. About 25% of patients have dilated or sluggishly reactive pupils, decreased visual acuity (frequently progressing to blindness), and dysfunction of cranial nerve V. As the infection spreads to the opposite cavernous sinus through the intercavernous sinuses, findings are duplicated in the opposite eye. Persons with septic cavernous sinus thrombosis may present with acute or chronic illness.[67] In the acute presentation (generally secondary to facial infection), the time between primary infection and cavernous sinus thrombosis is short (<1 week), and the patient presents in a significantly toxic state, with rapid development of the symptoms and signs described above; there is also rapid progression to bilateral eye signs. In contrast, there is a more indolent form of cavernous sinus thrombosis, usually secondary to dental infection, otitis media, or paranasal sinusitis. In these patients, the orbital manifestations are often unimpressive, and involvement of the contralateral eye is a late and inconsistent finding.

Patients with septic lateral sinus thrombosis complain predominantly of headache (>80% of cases); earache, vomiting, and vertigo also may occur because otitis media is a common predisposing condition.[66,68] Fever and abnormal ear findings are observed in most patients (79% and 98%, respectively), and there may be seventh nerve palsy, facial pain and altered facial sensation, papilledema, and mild nuchal rigidity. Thrombosis of the superior sagittal sinus produces an abnormal mental status, motor deficits, nuchal rigidity, and papilledema. Seizures occur in more than 50% of these patients. Patients with sinusitis as a predisposing condition tend to have a subacute onset of symptoms. Involvement of the inferior petrosal sinus may produce ipsilateral facial pain and lateral rectus muscle weakness (Gradenigo syndrome).

DIAGNOSIS

The noninvasive diagnostic procedure of choice for suppurative intracranial thrombophlebitis is MRI.[69] This technique visualizes blood vessels and differentiates between thrombus and normally flowing blood. It can also demonstrate the evolution and resolution of the entire veno-occlusive process. CT, with and without use of intravenous contrast material, also permits diagnosis of venous sinus thrombosis,[67] although it is considerably less sensitive and reliable than MRI. CT usually visualizes unilateral or bilateral multiple irregular filling defects in the enhancing cavernous sinus, with or without orbital inflammatory change. An additional benefit of MRI and CT is the ability to fully evaluate the paranasal sinuses and to provide information concerning subdural and epidural infection, cerebral infarction, cerebritis, hemorrhage, and cerebral edema.

Other laboratory studies are usually nonspecific.[66,67] Lumbar puncture demonstrates a mild pleocytosis (mononuclear, neutrophilic, or mixed) and an elevated protein concentration (consistent with a parameningeal focus of infection), although, in septic thrombosis of the superior sagittal sinus, there may be findings consistent with frank meningitis; often the causative organism is isolated on CSF culture. Blood cultures may be positive, especially in patients with a rapidly progressive course. Chest radiographs may show evidence of septic pulmonary emboli after propagation of thrombus into the inferior petrosal sinus and jugular vein. Sinus radiographs may document involvement of the paranasal sinuses, although conventional radiographs are inferior to MRI and CT in the detection of sphenoid sinusitis.

TREATMENT

ANTIMICROBIAL THERAPY

Appropriate antimicrobial therapy of septic intracranial thrombophlebitis depends on the antecedent clinical condition. The likely organisms are similar to those observed in cranial subdural empyema and epidural abscess; empirical antibiotic therapy should be directed toward those organisms[68] (see Table 52-9). If the antecedent condition is paranasal sinusitis, empirical therapy should be directed toward gram-positive organisms (staphylococci and streptococci), aerobic gram-negative bacilli, and anaerobes. In cavernous sinus thrombosis, an antistaphylococcal agent should always be included (because of the high incidence of *S. aureus* isolates) in the empirical therapeutic regimen pending culture results. Nafcillin should be used, with vancomycin reserved for penicillin-allergic patients and cases in which methicillin-resistant organisms are suspected.

SURGICAL THERAPY

Surgical intervention may be required for optimal therapy. Surgical drainage of infected sinuses is necessary when antimicrobial therapy alone is ineffective. This is especially important in patients with cavernous sinus thrombosis secondary to sphenoid sinusitis; some investigators have recommended operative intervention for patients who develop cavernous venous thrombosis as a complication of sinusitis. Internal jugular vein ligation has been used for lateral sinus vein thrombosis, and thrombectomy has also been used in some situations, but the efficacy of these procedures is poorly defined. Surgical therapy may also be required for other infections (e.g., dental abscess).

ADJUNCTIVE THERAPY

The use of anticoagulants (e.g., heparin) is controversial, although there is literature to support their use in prevention of the spread of thrombus from the cavernous sinus to other dural venous sinuses and cerebral veins.[66] Recent evidence has indicated that anticoagulation (in combination with antibiotics) decreases mortality rate and is most beneficial early in the treatment of cavernous sinus thrombosis to reduce the morbidity rate among survivors.[70] However, the hazards of

intracranial hemorrhage (bleeding from sites of cortical venous infarction or from sites on the intracavernous walls of the carotid artery) must be recognized. In the absence of specific contraindications, anticoagulation is most likely to be useful early in the course of cavernous sinus thrombosis.

Chapter 53
ENCEPHALOMYELITIS

JOHN C. GALBRAITH
ROBERT VERITY
D. LORNE TYRRELL

KEY POINTS

- *Herpes simplex virus (HSV) is the most common cause of fatal sporadic encephalitis. Early recognition and early treatment with acyclovir significantly improve outcome.*
- *A diagnosis of encephalomyelitis should be suspected in patients with fever, headache, behavioral changes, unexplained focal neurologic signs, seizures, or altered mental status without an obvious alternative explanation.*
- *Focal neurologic abnormalities are demonstrable either clinically or with neurodiagnostic evaluation in 90% of cases of HSV encephalitis (HSVE).*
- *If focal neurologic signs are present, computed tomography or magnetic resonance imaging should be performed before lumbar puncture. Diagnostic imaging is helpful in ruling out other treatable causes of altered mental status and also may identify patients with increased intracranial pressure in whom lumbar puncture may be dangerous.*
- *Unless contraindicated, an early lumbar puncture should be performed. This measure is especially important to rule out bacterial meningitis.*
- *The cerebrospinal fluid (CSF) is almost always abnormal in encephalomyelitis, usually demonstrating increased leukocytes, generally between 10 and 500 cells per microliter. The CSF glucose value is usually normal, and the protein content is usually normal or slightly elevated. Although a completely normal CSF does not rule out encephalomyelitis, it should heighten suspicion for a toxic or metabolic encephalopathy.*
- *Treatment with acyclovir must be commenced early when HSVE is suspected clinically. Polymerase chain reaction detection of HSV in CSF is the gold standard for the diagnosis of HSVE. However, a negative result on polymerase chain reaction does not always exclude HSVE and does not, by itself, provide justification for the termination of acyclovir treatment.*
- *Arboviruses are the most common cause of encephalitis worldwide. Their frequency varies dramatically, depending mainly on the season and geographic locale. West Nile virus has recently emerged as an important cause of encephalitis in North America.*
- *Although viruses are the most common cause of encephalomyelitis, nonviral causes should be carefully ruled out because they are often readily treatable.*
- *The threat of bioterrorism has increased the likelihood that unusual organisms may be etiologic agents.*
- *Intensive supportive care is indicated in patients with encephalitis because these patients may make remarkable recoveries even after prolonged unconsciousness.*

Encephalitis and *myelitis* refer to inflammation of the brain and spinal cord, respectively. These processes may occur together, often with meningeal involvement; hence, the terms *meningoencephalitis* and *meningoencephalomyelitis*. Encephalomyelitis may result from direct invasion of a microorganism into the central nervous system (CNS) or from an autoimmune process that results in demyelination; the latter process is often triggered by a recent vaccination or infection. Up to 20% of all encephalitides result from autoimmune reactions; they have been variously termed *postinfectious, parainfectious* (when they occur simultaneously with an infection), and *postvaccinial* (when they occur after a vaccination). Regardless of the pathogenesis, the clinical manifestations and differential diagnosis of these processes overlap to such a degree that they may be considered together.

Approach to the Patient with Suspected Encephalomyelitis

There are a multiplicity of etiologies for encephalomyelitis[1] (Table 53-1). Unfortunately, most patients do not present with symptoms and signs pathognomonic of a certain cause, but rather with nonspecific problems of fever, headache, and behavioral changes or altered mental status. Therefore, one must have a clear approach in the workup of such patients. This should begin with a careful history and physical examination. The clinical features alone are not generally sufficient to establish an etiologic diagnosis, but they do influence the likelihood of some diagnoses. For instance, age can be a factor because neonates are the group at highest risk for meningoencephalitis from herpes simplex virus type 2 (HSV-2). Enteroviruses and bacterial infections, including infections with group B streptococcus and *Listeria monocytogenes*, should also be considered in the differential diagnosis of progressive encephalopathy in neonates. At the other end of the age spectrum, *Varicella zoster* virus (VZV) is a leading cause of encephalitis in the elderly.

The setting of disease may provide helpful clues. Arbovirus encephalitis depends more or less on the season, locale, degree of insect exposure, and current prevalence of disease in a given community. Most outbreaks of eastern equine encephalitis are preceded by enzootics of disease in local horses and pheasants. West Nile virus infections are heralded by outbreaks and deaths among birds. Epidemics of St. Louis encephalitis are often preceded by serologic changes in chickens. Tick exposure in specific geographic areas should heighten the suspicion for Lyme disease, Rocky Mountain spotted fever, or ehrlichiosis. Similarly, exposure to certain animals may be suggestive of rabies or leptospirosis.

The progression of disease often suggests certain causes. Encephalitis developing 1 to 2 weeks after immunization or a viral syndrome is more likely postinfectious, whereas an acute fulminant course is more in keeping with herpes simplex virus encephalitis (HSVE) or eastern equine encephalitis. A slowly progressive neurologic disease is more characteristic of Creutzfeldt-Jakob disease, variant Creutzfeldt-Jakob disease, subacute sclerosing panencephalitis (SSPE), or encephalopathy due to acquired immunodeficiency syndrome (AIDS). A chronic or fluctuating course suggests mycobacterial or fungal infections, although mucormycosis may progress very rapidly. The diagnosis of CNS tuberculosis is difficult and requires a high index of suspicion.

TABLE 53-1 Causes of Encephalomyelitis[a]

Viral	Nonviral
Herpetoviridae	Bacterial meningitis, brain abscess
Herpes simplex virus	Parameningeal infection
Varicella zoster virus	Infective endocarditis
Cytomegalovirus	*Mycobacterium*
Epstein-Barr virus	*Listeria*
Human herpesvirus type 6	*Anthrax*
Herpes B virus	Brucellosis
Togaviridae	*Mycoplasma*
Alphaviruses	*Coxiella burnetii*
Eastern equine encephalitis virus	*Rickettsia*
Western equine encephalitis virus	*Borrelia*
Venezuelan equine encephalitis virus	*Leptospira*
Flaviviridae	*Treponema pallidum*
St. Louis encephalitis virus	*Cryptococcus*
Murray Valley encephalitis virus	*Nocardia*
Japanese B encephalitis virus	*Actinomycosis*
Dengue fever virus	*Coccidioides*
West Nile Virus	Mucormycosis
Tick-borne complex	*Histoplasma*
Bunyaviridae	*Toxoplasma*
California (La Crosse) encephalitis virus	*Plasmodium falciparum*
Picornaviridae	*Trypanosoma*
Echovirus	*Acanthamoeba*
Coxsackievirus	*Naegleria*
Poliovirus	Connective tissue diseases, vasculitis
Hepatitis A virus	
Arenaviridae	
Lymphocytic choriomeningitis virus	
Lassa fever virus	
Rhabdoviridae	
Rabies virus	
Retroviridae	
Human immunodeficiency virus	
Human T-cell lymphotropic virus (myelitis)	
Paramyxoviridae	
Measles virus	
Mumps virus	
Nipah virus	
Myxoviridae	
Influenza virus	
Rubivirus	
Rubella virus	
Adenoviridae	
Adenovirus	
Filoviridae	
Marburg virus	
Ebola virus	

[a] Conditions that may resemble encephalitis include tumor, toxic or metabolic encephalopathy, intracranial hemorrhage or hematoma, and cerebrovascular disease.

A subacute neurologic process with certain associated systemic symptoms may suggest immunologic disorders (e.g., systemic lupus erythematosus or sarcoidosis) or a neoplastic disease such as lymphoma, leukemia, and breast or lung carcinoma.

The immune status of the patient is also important when considering the various etiologic possibilities. Patients who are immunocompromised frequently develop unusual forms of encephalitis. Hypogammaglobulinemic patients may develop chronic encephalitis with enteroviruses. Rhinocerebral mucormycosis most often occurs in diabetics with ketoacidosis and in neutropenic leukemics who have been on broad-spectrum antibiotics. Toxoplasmosis is the most common cause of encephalitis in AIDS patients. Other causes of encephalitis in AIDS include cytomegalovirus (CMV) and other herpesviruses, fungi (especially *Cryptococcus*), *Mycobacterium*, and uncommon pathogens such as *Nocardia*, *Listeria*, *Acanthamoeba*, and papovavirus.

Physical examination lends little to the diagnostic approach except in cases in which a characteristic rash is present, as in varicella, measles, Lyme disease, or Rocky Mountain spotted fever. A cutaneous eschar may aid in the diagnosis of anthrax. Evidence of disease outside the CNS can suggest certain causes. For example, most patients with CNS disease

associated with *Mycoplasma pneumoniae* have antecedent or concurrent respiratory tract infection. Pulmonary symptoms may accompany lymphocytic choriomeningitis or legionella infections. A thorough neurologic examination is important because the presence of focal neurologic signs heightens the likelihood of treatable infectious causes and mandates the commencement of empirical antimicrobial therapy. Although it is noteworthy that encephalitis caused by HSV is associated with focal neurologic findings in the vast majority of patients, these findings are nonspecific. Even when present in patients with fever, they could represent other CNS diseases, such as parameningeal infection, subdural empyema, brain abscess, cerebral malaria, hemorrhage, vascular disease, or tumor.

The presence of focal neurologic abnormalities clearly mandates urgent diagnostic imaging with computed tomography (CT) or magnetic resonance imaging (MRI). Although the sensitivity of these techniques is limited in diagnosing encephalitis, they are essential and invaluable in ruling out other CNS processes that could be confused clinically with encephalitis and that require a different specific therapy. In addition, CT or MRI can identify patients with increased intracranial pressure (ICP) in whom lumbar puncture is contraindicated.

A lumbar puncture is an important step in the diagnostic evaluation of encephalitis and should be performed early unless there is a specific contraindication. It is especially important to rule out bacterial meningitis. If there is concern about increased ICP and possible herniation, a cisternal puncture should be considered. Cerebrospinal fluid (CSF) should be sent for cell count, chemistry, viral studies (including polymerase chain reaction [PCR] for HSV and other viruses), and stains and culture for fungi and bacteria (including mycobacteria). Completely normal findings on lumbar puncture significantly decrease the likelihood of encephalitis and raise the possibility of toxic or metabolic encephalopathy. Reye syndrome must be distinguished from encephalitis. This syndrome has been associated with several viral infections, especially influenza and VZV, together with salicylate use. It occurs most often in children who are usually afebrile but have altered mental status and hepatomegaly. CSF protein and cell counts are normal, but the blood ammonia level is almost always elevated. Other clues to the diagnosis of Reye syndrome include elevated liver enzyme levels in serum and hypoglycemia. Patients with normal CSF examinations should be monitored carefully; if the index of suspicion for encephalitis remains high, further neurodiagnostic evaluation, including a second lumbar puncture, should be considered. Further evaluation of patients with encephalitis includes an electroencephalogram (EEG) and CT or MRI. Ancillary studies, such as serology, should be performed depending on the specific characteristics of each case. If no specific diagnosis is established, then brain biopsy should be considered. In patients with suspected HSVE, it is important to commence empirical treatment early with acyclovir. Ongoing surveillance for alternative diagnoses must be maintained.

AIDS patients are unique. The approach to management in these patients requires a complete neurodiagnostic assessment and serologic testing for *Toxoplasma.* If the encephalitis is compatible with toxoplasmosis, then empirical treatment with pyrimethamine and sulfadiazine is begun. Clinical and radiographic improvements are expected to occur within 10 days of the start of therapy. However, if there is evidence of disease progression, then brain biopsy for definitive diagnosis should be performed. At least one pathogen is occasionally isolated in AIDS patients with CNS disease. There are other possibilities to consider in the patient who is infected with human immunodeficiency virus (HIV) and presents with CNS mass lesions, including CNS lymphoma and progressive multifocal leukoencephalopathy (see Chap. 48).

Myelitis

The diagnostic and therapeutic approach to myelitis without encephalitis is somewhat different. Polio should be suspected in cases in which there is a history of recent immunization or contact with a recently immunized individual. The pattern of myelitis caused by poliovirus and other enteroviruses is primarily lower motor neuron disease; characteristically, there is an asymmetric flaccid paralysis with preserved sensation and bladder function. The diagnosis is established by isolation of virus from stools, the throat, or the CSF, in addition to serologic confirmation. It is noteworthy that Japanese virus encephalitis and West Nile virus infection can also produce a polio-like myelitis.

Patients with transverse myelitis usually present with limb weakness and a sensory level with loss of bowel and bladder control. This syndrome may result from a variety of infectious diseases; however, in most cases, there is no identifiable cause. It is important to exclude the potentially treatable causes, such as tuberculosis, syphilis, herpes zoster, schistosomiasis, and HIV infection. The numerous parainfectious etiologies of transverse myelitis include measles, mumps, rubella, influenza, and *M. pneumoniae* infection, and the management of these causes is strictly supportive. Regardless of the exact etiology, early neurodiagnostic evaluation with myelography and CT or MRI is important to rule out spinal cord compression, epidural abscess, or hemorrhage.

A syndrome known as *tropical spastic paraparesis* is associated with human T-lymphotropic virus type I infection. Tropical spastic paraparesis is characterized by spastic paraparesis or paraplegia with pyramidal signs, occasional mild distal sensory loss, and occasional sphincter incontinence. Human T-lymphotropic virus type I is endemic in certain geographic regions, including Africa, southern Japan, and the Caribbean basin.

Herpes Simplex Virus Encephalitis

EPIDEMIOLOGY AND PATHOGENESIS

HSVE is the most common fatal nonepidemic encephalitis. It accounts for 5% to 10% of all reported cases of encephalitis.[2] The exact incidence is unknown, but the disease has been estimated to have an incidence of 1 in 250,000 population per year.[3] It is seen in all age groups, in both sexes, and in all seasons.[4] The patient is seldom immunocompromised, and one cannot predict who is at risk for HSVE. HSVE is particularly important because it has a very high mortality rate if untreated, whereas early therapy with acyclovir significantly improves the outcome.[5]

A temporal lobe syndrome is the most common clinical presentation for HSVE, but atypical presentations may occur, with involvement of parietal or frontal lobes. The predilection of the disease for the frontal or temporal lobes has led to

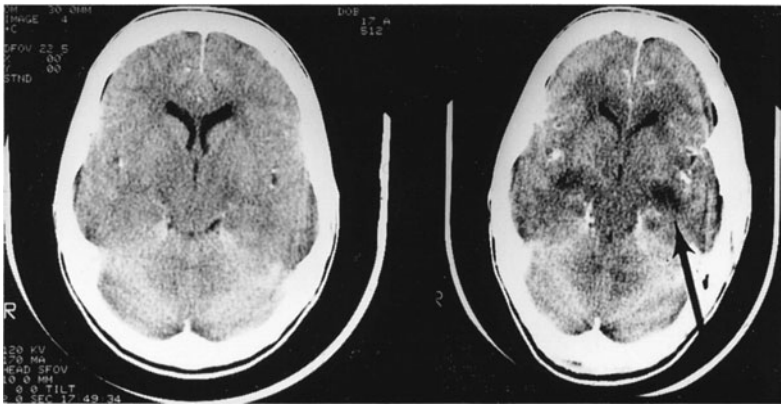

FIGURE 53-1 Computed tomographic scan of the head in a patient with herpes simplex virus encephalitis demonstrating bilateral hippocampal hypodensities. Involvement of the temporal lobes is classic for herpes simplex virus encephalitis.

the speculation that HSVE results from the retrograde spread of infection from the nasopharynx along the olfactory pathway to the basal portion of the frontal and temporal lobes. Alternatively, latent virus in the trigeminal ganglia may become activated and may reach the CNS along a neurotropic route.[6] Either of these pathogenetic mechanisms may explain why HSV-1 more commonly causes adult encephalitis than HSV-2. Serologic evaluation indicates that approximately 70% of HSVE is due to reactivation of latent HSV, whereas approximately 30% is due to primary infection. The median age for patients developing primary HSVE is 15 years, whereas the median age for recurrent infection is 50 years.[5]

CLINICAL AND LABORATORY FEATURES

There are no pathognomonic clinical symptoms or signs of HSVE that distinguish it from encephalitis of other etiologies. The clinical presentation may be abrupt or insidious. There may be an influenza-like prodrome. Clinical findings include fever (90%), headache (81%), alteration of consciousness (97%), personality changes (85%), dysphasia (76%), autonomic dysfunction (60%), ataxia (40%), hemiparesis (38%), seizures (38%), cranial nerve defects (32%), visual field loss (14%), and papilledema (14%). Eighty-five percent of patients have clinical findings indicative of focal neurologic disease.[4]

Adult HSVE may occur in the presence or absence of mucocutaneous HSV lesions. Although a history of recurrent HSV lesions was obtained in 22% of patients with HSVE, this history was also found with equal frequency in patients with encephalitis of other etiologies.[4]

Examination of the CSF shows an abnormality in 90% to 97% of cases.[4,7] Usually there is a lymphocytic predominance with 10 to 500 leukocytes per microliter, although early in the course of illness, polymorphonuclear cells (PMNs) may predominate. Red blood cells are present in 75% to 80% of samples, indicating the hemorrhagic nature of this encephalitis. The glucose level is generally normal, and the protein content is only moderately elevated. Viral cultures are almost always negative. PCR analysis to detect HSV DNA in CSF is the gold standard for the diagnosis of HSVE,[8] especially in the early phase of the disease. It has a sensitivity of 96% and a specificity of 99%.[9] Later in the course of the disease, intrathecal antibody detection may be used to confirm the diagnosis, although this is seldom used in practice.[10] When the index of suspicion remains high for HSVE even though PCR has not produced a positive result, a full course of acyclovir is recommended.[11]

Neurodiagnostic tests, such as EEG, brain scan, CT, and MRI, are useful in confirming and localizing the CNS lesion. EEG has been shown to be more sensitive than brain scan or CT early in the course of HSVE.[4] In 80% to 90% of cases, the initial EEG is abnormal, with predominantly spiked and slow wave patterns localized to the area of the brain involved. Paroxysmal lateral epileptiform discharges are characteristic of HSVE but are neither pathognomonic nor common.[12] Sodium pertechnetate ^{99}Tc brain scans are abnormal in only about 50% of cases of HSVE and demonstrate radionuclide uptake in the involved area of the brain. Similarly, CT scans are abnormal early in the course of illness in only about 50% of cases of HSVE. Abnormalities include localized edema, low-density lesions, mass effect, contrast enhancement, and hemorrhage (Fig. 53-1).[4] MRI may be the most sensitive neurodiagnostic test and has excellent delineation of the temporobasal lobe of the brain[13] (Fig. 53-2). MRI is more specific than the EEG and has been advocated by some as the preferred imaging test in the evaluation of suspected HSVE,[14–16] although single-photon emission CT has shown abnormalities in the temporo occipital area of two HSVE patients with normal MRI.[17]

DIAGNOSIS AND MANAGEMENT

For optimal patient care, acyclovir treatment must be commenced early when HSVE is clinically suspected. The diagnosis can be confirmed subsequently by PCR detection of HSV DNA in the CSF. Although PCR detection is an extremely useful technique, false-positive and false-negative results have been reported.[10,18,19] Brain biopsy should be considered in very select circumstances, when the diagnosis remains uncertain despite all available investigations, and particularly when the patient is deteriorating clinically despite empirical therapy. When the diagnosis is not established, it is important to continue diagnostic investigations to rule out other disorders that mimic HSVE, such as bacterial abscess, tuberculosis, cryptococcosis, toxoplasmosis, rickettsial infections, anthrax, and neoplastic or vascular diseases. If a brain biopsy specimen is taken, the pathology and microbiology laboratories should be notified. Specimens should be submitted for the detection and culture of bacteria (including mycobacteria), viruses, and fungi and for histopathology.[20,21]

FIGURE 53-2 T2-weighted magnetic resonance image of the head demonstrating increased signal intensity involving the medial aspects of the temporal lobes in the region of the hippocampus. Increased signal intensity is present bilaterally but is more marked on the right side than on the left. These findings are highly suggestive for herpes simplex virus encephalitis.

The recommended treatment of HSVE is acyclovir at a dose of 10 mg/kg every 8 hours for 10 to 14 days.[22] Relapse of HSVE has been described after successful treatment and may necessitate a second course of therapy.[23,24] In most cases, the relapses occurred within 2 weeks of completing antiviral therapy. The precise etiology and the frequency of relapses remain unclear, although it appears to be more common in children than in adults.

The toxicity of acyclovir is minimal. Uncommonly, precipitation of crystals in renal tubules can occur in poorly hydrated patients. This is manifested by a rise in serum creatinine and blood urea levels, which can be reversed by increased hydration, dosage adjustment, or discontinuation of therapy. Patients at a higher risk of nephrotoxicity include those with pre-existing renal disease and those concurrently receiving nephrotoxic drugs. The dosage of acyclovir should be adjusted in patients with renal failure[25] (Table 53-2).

TABLE 53-2 Dose of Intravenous Acyclovir for Herpes Simplex and Varicella-Zoster Encephalitis According to Renal Function

Creatinine Clearance (mL/min per 1.7 m^2)	Dose Schedule
>50	10 mg/kg q 8 h
25–50	10 mg/kg q 12 h
10–25	10 mg/kg q 24 h
0–10	5 mg/kg q 24 h
Hemodialysis (3 times/wk)	5 mg/kg q 24 h
Postdialysis	6.0 mg/kg after dialysis

SOURCE: Adapted with permission from Deeter and Khanderia.[25]

Patients who receive acyclovir for suspected HSVE should also receive broad-spectrum antibiotics, such as cloxacillin, cefotaxime, and metronidazole, for the first 48 to 72 hours until CSF and other cultures for bacteria are reported negative.

The precise factors that determine the therapeutic response are unknown. Patients who are younger than 30 years and present with a Glasgow coma score higher than 10 have the best outcome.[5] Patients who present with a Glasgow coma score below 6, irrespective of age, have a very poor prognosis. Other markers of poor outcome include bilateral abnormalities on the EEG and the presence of identifiable lesions on the original CT scan.

Long-term complications of HSVE infection are common and include residual dysphasias, paresis, paresthesias, behavioral changes, and a Korsakoff-like amnesia. Even with acyclovir treatment, the mortality rate is 28%, and only 38% of patients recover with little or no residuum.[5,26]

Herpes Simplex Virus Type 2

HSV-2 as a cause of encephalitis is seen primarily, although not exclusively, in neonates. In adults it is more frequently seen as a cause of aseptic meningitis concurrent with primary genital infection.

Neonatal infection occurs with the frequency of 26 per 100,000 deliveries, and, although infection may be localized to the skin, it is more often disseminated.[27] Infection is acquired by passage of infants through the birth canal of infected mothers, especially mothers with primary infection. It is recommended that all women in labor be examined for genital HSV-like lesions and, if lesions are present (and if the membranes are intact), that a cesarean section be performed.[28] Unfortunately, most neonatal exposure to HSV results from excretion of virus by asymptomatic mothers at delivery. Asymptomatic shedding in pregnant women has been documented to be not infrequent. One can neither predict nor prevent these exposures. Because HSV-2 causes 90% of primary genital herpes and 99% of recurrent infections, neonatal HSV infections are usually caused by HSV-2. HSV-2 causes more morbidity than HSV-1 in neonatal encephalitis.[29] Approximately 50% of neonates with encephalitis are premature, and clinical illness typically begins 1 to 3 weeks after birth. Although CNS disease can occur in isolation, more commonly there is evidence of diffuse disease with accompanying skin lesions, hepatitis, pneumonitis, or disseminated intravascular coagulation.[6]

The diagnosis should be suspected in any infant who becomes encephalopathic during the first weeks of life. Skin vesicles are, if present, the easiest source of viral isolation and confirmation of diagnosis, but up to 20% of newborns with HSV infection never have skin involvement.[30] These infants often excrete virus from peripheral sites in the absence of skin lesions; hence, conjunctival, throat, and CSF specimens should be submitted for viral studies. As with HSV-1, PCR testing for HSV-2 DNA in CSF is important to confirm the diagnosis. Further diagnostic evaluation may include EEG, brain scan, CT, ultrasonography, and MRI, alone or in combination, depending on the circumstances. Early empirical treatment with acyclovir is important in decreasing mortality and morbidity rates. Without treatment, the mortality rate is

50% to 85% and the morbidity rate is 100%. A new larger-dose regimen of acyclovir at 20 mg/kg every 8 hours for 21 days is the current recommended dose for neonatal HSVE.[31] With this larger-dose treatment, the mortality rate has decreased to 5% in neonates and about 40% of survivors develop normally.

Varicella Zoster Virus

Primary VZV infection (chickenpox) is only rarely complicated by encephalitis, aseptic meningitis, transverse myelitis, or Guillain-Barré syndrome. There are two forms of encephalitis with primary VZV.[32,33] The cerebellar form is seen in children and occurs with a frequency of 1 per 1000 cases of chickenpox. It is characterized by ataxia, nystagmus, headache, nausea, vomiting, and nuchal rigidity. This illness is usually self-limited, lasting 2 to 4 weeks, and most children have a complete recovery. The mortality rate is only 0.5%.[34] A more severe form of encephalitis occurs mostly in adults and infants, with an incidence of one to two episodes per 10,000 cases of VZV. It most often begins about 1 week after the varicella rash and is manifested by altered sensorium, seizures, and focal neurologic signs; it has a mortality rate of 5% to 10%.[33]

After chickenpox ends, the virus becomes latent, but it may reactivate later in the form of shingles (herpes zoster). Viral invasion of the CNS is not uncommon with zoster, occurring in 35% of patients in one study.[35] However, CNS complications of zoster such as meningoencephalitis or myelitis are rare. Zoster encephalitis may take the form of a stroke. This is more commonly observed in the elderly and can occur weeks to months after an episode of herpes zoster, typically involving the first division of the trigeminal nerve. It is thought that VZV directly invades cerebral arteries by extension along intracranial branches of the trigeminal nerve. Diagnosis is usually supported by angiography. The mortality rate is 20% to 25%, and there is a strong probability of permanent neurologic sequelae.[33]

Chronic zoster encephalitis is seen almost exclusively in immunocompromised patients, especially those with AIDS. The presentation is subacute, with headache, fever, mental status changes, seizures, and focal neurologic signs. The onset may occur months after the zoster rash, making the diagnosis more difficult. The clinical course is often progressive deterioration and death.[33]

A fulminant necrotizing zoster encephalitis with concomitant lymphoma related to Epstein-Barr virus (EBV) and CMV ventriculitis in an AIDS patient has been reported.[36] This highlights the potential for simultaneous infection with multiple pathogens in immunodeficient patients.

The diagnosis of VZV encephalitis may be suspected on the basis of the characteristic lesions of varicella or zoster. The virus may be identified from vesicular scrapings on immunofluorescence, electron microscopy, or culture.[27] The virus grows slowly, usually requiring 2 to 3 weeks for a positive culture. Serologic recognition of the presence of specific immunoglobulin M (IgM) may be useful for diagnosing primary chickenpox. It has been noted that primary varicella encephalitis and zoster encephalitis can occur in the absence of any rash.[37,38] As with HSVE, PCR analysis of CSF VZV DNA and VZV antibody may be used to confirm the diagnosis.[39] Intravenous acyclovir is the drug of choice for VZV encephalitis, at doses of 10 mg/kg every 8 hours. In one study, foscarnet was added and a favorable outcome was reported in one patient with zoster encephalitis who was not responding to acyclovir alone.[40]

Cytomegalovirus

CMV encephalitis (CMVE) is not uncommon in immunocompromised patients.[41,42] The presentation is typically subacute, with lethargy, confusion, cranial nerve palsies, and coma being prominent clinical features. A large majority of these patients has AIDS, and most have a history of another CMV disease, especially retinitis. CSF viral cultures are typically negative. PCR detection for the presence of CMV DNA in CSF has a sensitivity of 79% and a specificity of 95%.[42] Unfortunately, it does not always correlate with histologic evidence of encephalitis in immunocompromised patients.[43] A high level of CMV DNA in the CSF may be an indicator of significant CMV encephalitis. MRI is more sensitive than CT and characteristically demonstrates periventricular enhancement. The diagnosis is especially challenging in AIDS patients because the clinical presentation is widely variable and because there may be coexisting processes including HIV encephalopathy, toxoplasmic encephalitis, CNS lymphoma, or coinfection with HSV or VZV.[41,42]

CMVE is rare in immunocompetent individuals but has been reported.[42,44] Patients tend to be relatively young, 20 to 64 years. The pathogenesis is unclear. The typical clinical picture is similar to that of HSVE, with severe headache, fever, and focal neurologic signs. CSF examination shows a mild pleocytosis, and the EEG may be markedly abnormal. Differentiation from HSVE requires specific virologic studies. In contrast to AIDS patients, in whom progressive deterioration is the rule, immunocompetent patients with CMVE usually recover but may have long-term sequelae.

Ganciclovir, a nucleoside analogue, is the accepted antiviral agent of choice for CMV.[25,42] The standard dose is 5.0 mg/kg intravenously every 12 hours, given for 2 to 3 weeks. Dosage must be adjusted in patients with renal dysfunction. Possible adverse effects include granulocytopenia, thrombocytopenia, anemia, and elevated serum concentrations of bilirubin, alkaline phosphatase, and creatinine. In AIDS patients adding foscarnet to ganciclovir may be more efficacious.[45]

Epstein-Barr Virus

Neurologic complications occur in fewer than 1% of cases of mononucleosis but are the leading cause of death in infections with EBV.[6] CNS manifestations can include aseptic meningitis, Guillain-Barré syndrome, Bell palsy, transverse myelitis, or encephalitis.[27]

EBV encephalitis typically is acute in onset and may be diffuse or focal, with abnormalities localized usually to the cerebellum or temporal lobe. The diagnosis may be readily evident if the encephalitis occurs in the setting of fever, pharyngitis, lymphadenopathy, and positive EBV serology. CSF changes usually demonstrate a mononuclear pleocytosis with fewer than 200 cells per microliter. Atypical lymphocytes may be seen in the CSF. The protein content may be normal or mildly elevated, and the glucose level is usually normal.[27] PCR detection of EBV DNA is a reliable method of

diagnosing EBV encephalitis or myelitis.[46] Although EBV encephalitis may be severe, it is usually self-limited, and almost all survivors recover without sequelae. Successful treatment with intravenous ganciclovir has been reported in immunocompromised patients with EBV encephalitis.[47,48]

Arboviruses

Arboviruses are a group of enveloped RNA viruses that are transmitted by insects. There are numerous viruses in this group that are known to cause encephalitis; together, they are the most common cause of encephalitis worldwide.[6] The relative predominance of the different arboviruses depends on the geographic locale, season, and weather conditions (Table 53-3). In temperate climates, infections tend to be seasonal, occurring mainly in the summer when arthropod populations are high. Human beings are incidental hosts and do not play a part in the natural history of the arboviruses that cause encephalitis. Asymptomatic and mild infections are most common. Serologic evidence indicates that the proportion of infections manifested as disease depends on the specific virus and on the age of the host. In eastern equine encephalitis, 1 in 10 to 40 infections results in encephalitis, whereas in Murray Valley encephalitis, only 1 in 1000 infections results in encephalitis. For West Nile virus, approximately 1 in 150 infections result in meningoencephalitis.[49,50] Historically, California serogroup encephalitis was the most frequently reported arbovirus infection in the United States; the number of cases reported has remained relatively constant since the 1970s. In 1994 a case of Powassan encephalitis was reported in Massachusetts. This tick-borne flavivirus illness occurs infrequently, with only 24 confirmed cases having been reported in North America between 1958 and 1994.[51] More recently, West Nile virus has arrived on the North American continent, and annual cases of West Nile virus meningoencephalitis may surpass those of California serogroup encephalitis.

The pathogenesis of arbovirus encephalitis is believed to begin with an initial viremia followed by localization in the CNS. The virus likely crosses the blood-brain barrier by infected cells that migrate through the blood vessels of the brain. Once within the CNS, the virus may replicate in neurons or glial elements.

The clinical features of the different arbovirus encephalitides are presented in Table 53-4. In general, arbovirus encephalitides follow the typical pattern of acute onset of fever, headache, and meningismus, with progression to an alteration in mental status. Examination of the CSF usually shows fewer than 500 leukocytes per microliter; most leukocytes are mononuclear, although early on there may be a PMN predominance. The protein content is usually normal or slightly elevated. The glucose level is characteristically normal. Virus isolation is rare; hence, distinguishing among the different viruses requires careful consideration of epidemiologic and clinical variables in addition to serology.[52–56] There is an enzyme immunoassay that detects virus-specific IgM antibodies in blood or CSF of patients with suspected Japanese B encephalitis.[57] Similarly, the diagnosis of West Nile virus encephalitis can be established by the presence of IgM antibody in blood or CSF.[50] Molecular assays are also rapidly becoming more available.

At present, there is no proven antiviral therapy for arboviral encephalitis. In vitro activity of interferon α against West Nile virus and other flaviviruses has been demonstrated. Open clinical trials using interferon α for patients with St. Louis encephalitis and Japanese encephalitis have produced promising results. During an Israeli outbreak of West Nile virus infection in 2000, large-dose ribavirin was given without detectable benefit. Immunoglobulin from patients previously

TABLE 53-3 Epidemiology of the Major Arboviruses

Disease	Virus	Vector	Reservoir	Geographic Location	Approximate Number of U.S. Cases/Year
Eastern equine encephalitis	Togavirus (alphavirus)	Mosquito	Birds	North, Central, and South America (especially Atlantic and Gulf states)	0–12
Western equine encephalitis	Togavirus (alphavirus)	Mosquito	Birds	North, Central, and South America (in U.S. in regions west of the Mississippi; in Canada in prairie provinces)	3–50
Venezuelan equine encephalitis	Togavirus (alphavirus)	Mosquito	Horses	Florida, Texas, Central, and South America	0–5
St. Louis encephalitis	Flavivirus	Mosquito	Birds (especially chickens)	North, Central, and South America	20–2500
West Nile meningoencephalitis	Flavivirus	Mosquito	Birds (especially Corvidae family)	North and Central America, Africa, parts of Asia and southern Europe	20–2500
Japanese B encephalitis	Flavivirus	Mosquito	Pigs and birds	Asia (especially southern and eastern Asia)	0
Murray Valley encephalitis	Flavivirus	Mosquito	Birds	Australia, New Guinea	0
California (La Crosse) encephalitis	Bunyavirus	Mosquito	Rodents	Midwestern U.S.	50–200

TABLE 53-4 Clinical Aspects of Arbovirus Infection

Disease	Clinical Features	Morbidity and Mortality Rates in Patients Who Develop Encephalitis
EEE	Mainly affects children and the elderly Abrupt onset with fulminant course Seizures are common; diffuse signs	50–75% mortality rate; 30% of survivors have severe sequelae: mental retardation, behavior changes, seizures, and paralysis
Western equine encephalitis	Mainly affects infants and the elderly Subclinical infections are common Similar to EEE but milder (except in infants)	3–7% mortality rate; fewer sequelae than with EEE
Venezuelan equine encephalitis	Many subclinical infections <4% develop encephalitis Myalgias are prominent	10–20% mortality rate
St. Louis encephalitis	<1% infected people develop encephalitis Most severe in elderly May have tremor, seizures, paresis, syndrome of inappropriate antidiuretic hormone, urinary symptoms	5–15% mortality rate; mortality rate increase with age; neurasthenia may be a persistent problem
Japanese B encephalitis	Most common arbovirus worldwide Mainly among children <2% of infected develop encephalitis A vaccine is available	10–50% mortality rate, especially among children; up to 70% of survivors have neuropsychiatric sequelae
Murray Valley encephalitis	Patients frequently present in coma Rapid disease progression in infants	20–50% mortality rate; 40–100% of survivors have neurologic sequelae
California (La Crosse) Encephalitis	Mainly affects boys (ages 3–10 y) Fulminant onset with seizures Rapid recovery after 2–5 d	<2% mortality rate; up to 15% have behavioral problems or recurrent seizures
West Nile meningoencephalitis	Incubation period 2–14 d 1 in 150 people infected develop encephalitis More severe in the elderly 1–7 d febrile prodrome May have polio-like flaccid paralysis	4–14% mortality rate for patients admitted to the hospital; higher in the elderly

ABBREVIATIONS: EEE, eastern equine encephalitis.

infected with West Nile virus has been given to some patients and is being considered for clinical trials.[50] The mortality and morbidity rates depend on the specific arbovirus and the age and health of the patient.

Enteroviruses

Enteroviruses are very common causes of meningitis but cause only a small proportion of cases of encephalitis. They rank behind arboviruses, HSV, and lymphocytic choriomeningitis virus as causes of encephalitis that proved to be viral in the United States. Enteroviruses are distributed worldwide, and infections are most prevalent in the summer and autumn months in the temperate climates. At least 50% to 80% of nonpolio enteroviral infections are completely asymptomatic.[58] When encephalitis develops, the signs and symptoms may vary, from lethargy, drowsiness, and personality changes to seizures, paresis, and coma. The clinical findings suggest generalized involvement in most cases, but focal abnormalities, including partial motor seizures, hemichorea, and acute cerebellar ataxia, have been reported. Enteroviral encephalitis can mimic HSVE, and distinguishing CNS enteroviral infection from other bacterial and viral causes of encephalitis can be clinically difficult.

CSF examination typically shows 10 to 500 leukocytes per microliter, with a lymphocytic predominance, although neutrophils may predominate early in infection. The CSF protein content is normal or slightly elevated, and the glucose level is normal. In the past, the diagnosis was established by culture of virus from the CSF. However, CSF viral cultures were often negative, and the diagnosis had to be inferred from isolation of virus from non-neurologic sites, such as throat washings or feces. More recently, PCR detection of enterovirus RNA in CSF has become the optimal method for confirming the diagnosis.[59]

The course of illness is generally benign, and treatment is supportive. However, neonates may develop a severe illness culminating in death, and infants younger than 1 year often have persistent neurologic sequelae. In addition, patients with antibody deficiencies may have severe infection. A syndrome of chronic enteroviral meningoencephalitis occurs in agammaglobulinemia.[60] Most of these patients present with a dermatomyositis-like syndrome and many have hepatitis. The course is prolonged, and clinical manifestations may vary and fluctuate. Neurologic manifestations include headaches, seizures, lethargy or coma, weakness, and ataxia. In this syndrome the mortality rate is high. The administration of specific neutralizing antibody has been shown to be effective.[60,61] A case of chronic enteroviral meningoencephalitis also has been reported associated with HIV.[62] Pleconaril may be used to treat patients with serious enteroviral infections. Pleconaril is given orally at a dose of 200 to 400 mg three times daily, although the appropriate dosing has not been clearly established.[62,63] A recent report on two cases of chronic enteroviral meningoencephalitis suggested that perfusion single-photon emission tomographic scans are useful for clinically monitoring treatment.[62]

Poliovirus is a neurotropic enterovirus, but owing to the widespread use of polio vaccines, the incidence of poliovirus infection has dramatically declined. Poliomyelitis still occurs in patients who have not received the vaccine and in underdeveloped countries. Rarely, paralytic polio develops in association with the use of the live vaccine. Currently, this is a very rare event, given that inactivated poliovirus vaccine has largely replaced oral poliovirus vaccine. Paralysis occurs in 0.1% of all poliovirus infections. In adults, poliomyelitis often begins with muscle pain, particularly involving the neck or lumbar region. This pain may be relieved by motion. Subsequently, there is progression to weakness and paralysis, usually over 2 to 3 days. A characteristic feature of the paralysis of poliomyelitis is its asymmetric distribution. Another key point to note in the clinical diagnosis of poliomyelitis is that sensation is usually preserved. If sensory loss is present, then an alternate diagnosis should be considered. Poliomyelitis very rarely takes the form of encephalitis.[64] When poliovirus encephalitis does occur, it is seen principally in infants. It is manifested primarily by disturbances in consciousness. In addition, seizures and spastic paralysis may be seen. The illness is not distinguishable clinically from encephalitis due to many other viruses. The diagnosis is established when virus is isolated from the CSF. Unfortunately, it is rare to isolate poliovirus from these patients. Most often, throat and stool cultures should be taken, in addition to acute and convalescent sera. PCR technology promises to aid in the confirmation of the diagnosis.[59]

Enterovirus 71 is a picornavirus that can cause an epidemic paralytic disease indistinguishable from poliomyelitis. Like other enteroviruses, it may cause hand-foot-mouth disease. Paralysis may be accompanied by encephalitis or cranial nerve involvement. The diagnosis is established when enterovirus 71 is isolated from vesicle fluid, feces, oropharyngeal sections, urine, or CSF. The treatment is supportive. The mortality rate is 29.5% in patients with paralytic disease but increases to as high as 65% in patients with bulbar disease.[65]

Lymphocytic Choriomeningitis Virus

Lymphocytic choriomeningitis virus is an arenavirus that is endemic in mice and can be transmitted to human beings.[66] Lymphocytic choriomeningitis virus infection may occur worldwide but has been demonstrated only in Europe and the Americas. Human infection is most commonly seen in young adults, although persons of all ages may be affected. Most cases occur in the autumn. The exact mode of transmission is not known but may be related to aerosols, direct contact with rodents, or rodent bites. The incubation period is usually from 5 to 10 days. The illness typically has an influenza-like prodrome followed later by a severe headache. A few patients develop a clinical picture of encephalomyelitis, with confusion, psychosis, paraplegia, or disturbances of cranial, sensory, or autonomic nerve function. Other occasional complications include orchitis, myopericarditis, arthritis, and alopecia. Laboratory findings show a leukopenia and thrombocytopenia. The CSF typically shows several hundred lymphocytes per microliter, with a normal to elevated protein level and a normal to reduced glucose content. Infection is usually diagnosed by a fourfold rise in antibodies or isolation of virus.[27] The treatment is supportive, and rarely is the illness fatal.

Rabies Virus

Rabies virus is usually transmitted to human beings by the bite of an infected mammal, although infection by the respiratory route can occur. In countries where domestic anima rabies is well controlled, most disease is associated with infection from wild animals. Human disease is rare in the United States, with only 36 cases being reported to the Centers for Disease Control and Prevention from 1980 to 1996.[67] In countries where domestic animal rabies has not been controlled, human rabies remains a significant problem. In 1996, 33,209 cases of human rabies were reported to the World Health Organization, but, because this reporting is voluntary, it underestimates the actual number of cases.[68] The incubation period is usually 20 to 90 days, although in reported cases it has varied from 4 days to 19 years. During the incubation period, the patient is well. A prodrome of 2 to 10 days, which may include paresthesia at the bite site, is followed by evidence of CNS infection, which may include agitation, hydrophobia, bizarre behavior, or delirium. About 20% of patients present with a paralytic form. The mental status gradually deteriorates, with disorientation, stupor, and coma.[68,69] The case fatality rate is virtually 100%. No tests are currently available to diagnose rabies infection before the onset of clinical disease. A diagnosis of rabies should be suspected even in the absence of a definitive history of an animal bite because this may be missing in some cases. Diagnosis can be established rapidly by using immunofluorescent procedures to detect viral antigens on biopsy of the skin of the posterior neck. Other methods for diagnosis before death include detecting antibodies to rabies virus in serum or CSF from patients with a long clinical course and virus isolation or nucleic acid detection in saliva.[70] Rabies is a disease that is much easier to prevent than cure. However, cases have occurred even in patients receiving optimal prophylaxis. Patients should be isolated because rabies virus may be present in saliva, tears, urine, CSF, and other body fluids or tissues.

Treatment is supportive, but the outcome is dismal. High-dose passive rabies immunoglobulin has been used in some cases, with no clear benefit.[71] Although no single therapeutic agent is effective, a combination of therapies such as rabies vaccine, rabies immunoglobulin, monoclonal antibodies, ribavirin, interferon α, and ketamine may be considered.[72]

Two survivors in a review of 38 human rabies cases in the United States received rabies vaccine before the onset of their illness and intensive supportive care after the onset of illness.[69]

Human Immunodeficiency Virus

HIV is a neurotropic pathogen that may cause CNS disease varying from aseptic meningitis to encephalitis resulting in dementia and death (see Chap. 48 for more details). Postmortem studies of patients dying of HIV-related complications have suggested that CNS infection is always present, even when it is not clinically apparent. The diagnosis should be suspected in patients with encephalitis who have risk

factors for or clinical evidence of HIV infection. Serology is used to confirm HIV infection, but there are no good means at present of antemortem diagnosis of CNS disease. Measurement of CSF levels of HIV RNA might prove to be a useful monitor of CNS infection.[73]

Measles

Measles is an acute infection caused by a paramyxovirus. This virus is highly contagious and causes infections with a worldwide distribution. It remains a significant problem, especially in unimmunized children and adults. Acute postinfectious measles encephalomyelitis is the most common neurologic complication of measles. Although it is rare in children younger than 2 years, it complicates approximately 1 of 1000 measles infections in older children.[74] It probably has an autoimmune pathogenesis.[75] The illness is of abrupt onset and typically begins 1 week after the onset of the rash. However, it has been reported to have occurred before the onset of the rash or weeks after. The illness is manifest by recurrence of fever, seizures, motor abnormalities, and a depressed level of consciousness. The abrupt onset of the encephalomyelitis in the setting of the typical exanthem is a characteristic feature that helps to differentiate postinfectious encephalomyelitis from other forms of viral encephalitis that have a more gradual onset. The CSF is normal in approximately 33% of patients. Neither viral RNA nor measles-specific antibody is present in the CSF. However, antibodies to myelin basic protein are present in the CSF. Up to 50% of patients with measles have detectable EEG abnormalities.[76] MRI is a sensitive modality.[77] Treatment is supportive; the mortality rate is 10% to 20%, and most survivors have neurologic sequelae.[74]

A less common complication of measles infection is SSPE, which occurs in about 1 in 300,000 cases. SSPE occurs months to years after measles, most often in children. Although the exact pathogenesis is unknown, it appears that persistent infection results from defective viral production of membrane or envelope proteins, which allow the virus to escape immunosurveillance.[78] The onset is insidious, with subtle personality changes and declining intellectual performance. The disease is progressive, with mental deterioration followed by convulsive and motor signs and invariably coma and death.[79] The most useful laboratory findings in SSPE include an abnormal EEG with the typical pattern consisting of well-defined periodic bursts of high-voltage activity with an interval of 3 to 5 seconds between bursts and increased levels of γ globulin and measles antibody in CSF or detection of viral RNA.[80–82] Biopsy is not considered necessary for the diagnosis because the clinical findings combined with the finding of measles antibody or viral RNA in the CSF are sufficient to establish the diagnosis in almost all cases. There is no well-established effective treatment for this condition; however, isoprinosine (inosiplex) has been reported to produce remission for longer than 2 years in 5 of 15 patients in one study.[83] Other reports have described mixed benefits.[84–86] Combination therapy with interferon α, ribavirin, and inosiplex has been described in one case report.[87]

Subacute measle encephalitis (SME) is a third form of measles encephalitis. SME occurs mainly in immunosuppressed children in whom it acts like an opportunistic infection. Measles virus RNA can be detected in the brain of SME patients, and it follows a rapidly progressive course. More recently, one case report documented SME in an immunocompetent adult.[88]

Mumps

Meningitis occurs in 15% of mumps cases, although CSF abnormalities may occur in up to 50%. Meningitis is a common benign condition, to be distinguished from encephalitis, which is rare and more serious. Encephalitis occurs in approximately 1 in 6000 cases of mumps.[89] There is bimodal distribution of illness: an early-onset illness that coincides with parotitis and represents damage to neurons directly due to viral invasion, and a more common late-onset illness that develops 7 to 10 days after the onset of parotitis and is a postinfectious demyelinating process.

The clinical features are diffuse encephalitis with fever, marked change in level of consciousness, seizures, paresis, aphasia, and involuntary movements. The CSF examination shows the typical picture of viral meningoencephalitis, with a lymphocytic pleocytosis and a normal or slightly elevated CSF protein level. However, there may be a PMN cell predominance and hypoglycorrhachia. No rapid procedures are available for diagnosing mumps.[24,65] Virus may be isolated from CSF on tissue culture. Serology may be used to confirm the diagnosis. Encephalitis may occur secondary to mumps in the absence of parotitis. The treatment is supportive, and sequelae of psychomotor retardation and convulsive disorders have been reported. The mortality rate is 1.4%.[66] Other neurologic syndromes rarely associated with mumps include deafness, cerebellar ataxia, facial palsy, transverse myelitis, ascending polyradiculitis, and a poliomyelitis-like syndrome.

Nipah Virus

A paramyxovirus, Nipah virus, was identified as the etiologic agent of an outbreak of severe encephalitis in Malaysia and Singapore that occurred among people who had close contact exposure to pigs.[90] Nipah virus is closely related to another zoonotic paramyxovirus, Hendra virus, which infects horses and rarely humans. Both viruses have the ability to infect a broad range of species. After an incubation period of 10 days, patients present with nonspecific symptoms such as fever, headache, myalgia, sore throat, and altered mental state.[91,92] Other clinical features may include segmental myoclonus, areflexia, hypertension, and tachycardia. The mortality rate reported from the outbreak in Malaysia was 41%.[92] An open-label trial of ribavirin for treatment has suggested some benefit.[93]

Rubella

Encephalitis is a rare postinfectious complication of rubella. It occurs with a frequency of approximately 1 in 3000 to 1 in 24,000 rubella patients.[94] It occurs more frequently in adults than in children.[95] The symptoms are similar to but milder than those seen with measles. Diagnosis maybe established on the basis of serology or on the detection of anti–rubella virus IgM in the CSF. The treatment is supportive. The case

fatality rate has been found to vary between 0% and 30%.[94] A rubella SSPE-like syndrome occurs mainly in young adults, as opposed to measles-associated SSPE, which tends to occur in children.

Mycoplasma Pneumoniae

Mycoplasma pneumoniae is a frequent cause of upper and lower respiratory tract infections in otherwise healthy people. Approximately 1 in 1000 patients with *M. pneumoniae* respiratory disease develop complicating CNS disease.[96] The pathogenesis of the CNS disease is unclear; however, it has been postulated that the disease may result from direct invasion by the organism, a neurotoxin elaborated by the organism, or an autoimmune reaction precipitated by the *Mycoplasma* infection.[96,97] Multiple patterns of CNS involvement associated with *M. pneumoniae* have been reported. These include meningitis, encephalitis, psychosis, cerebellar ataxia, hemiplegia, transverse myelitis, and polyradiculitis.[98] The encephalitis may be focal, mimicking HSVE, or nonfocal. Most patients have antecedent respiratory symptoms. In encephalitis, the CSF usually shows a lymphocytic predominance combined with a moderate elevation of the protein content and a normal glucose level. *Mycoplasma pneumoniae* genomic material has been identified in cases of encephalitis related to mycoplasmal disease by using PCR techniques after CSF was collected early in the disease process.[99] *Mycoplasma pneumoniae* has rarely been identified histologically or recovered from biopsy specimens. In the absence of PCR, the diagnosis can be established by serology. The treatment is mainly supportive, and no controlled prospective trials have evaluated the role of antibiotics. However, intravenous tetracycline would seem to be an appropriate agent. The mortality rate was 5% in one series and 23% had severe sequelae.[96]

Rocky Mountain Spotted Fever

Encephalitis may occur as a complication of Rocky Mountain spotted fever. This disease is caused by *Rickettsia rickettsii* and is transmitted by the bite of an infected tick. It is seen most frequently in the eastern United States, especially in younger people. The illness is characterized by the sudden onset of fever, malaise, headache, chills, and conjunctival injection. This is followed 2 to 3 days later by a maculopapular rash that appears first on the wrist and ankles and then rapidly spreads to the rest of the body, including the palms and soles. The rash is often petechial or may become confluent and hemorrhagic. Routine laboratory tests for rapid diagnosis early in the illness are not readily available. A fourfold rise in antibody titer between acute- and convalescent-phase sera is considered diagnostic. PCR detection has been reported, but its clinical usefulness has not been established.[100] Doxycycline or other tetracycline is considered by many to be the agent of choice, but chloramphenicol is preferred in pregnant patients.[101] Unfortunately, neurologic involvement with this disease is associated with a bad prognosis. Of 37 patients followed for 1 to 8 years after acute Rocky Mountain spotted fever, 21 had residual neurologic abnormalities.[102]

Bacillus Anthracis

Since the events of September 11, 2001 and the months following in the United States, anthrax meningoencephalitis (AME) has moved up the differential diagnostic list of meningoencephalitis because of the possibility of a bioterrorist act. Patients with AME present with fever, headache, nausea, vomiting, meningeal signs, and altered mentation associated with symptoms and signs related to the source of infection.[103] The three main sources of infection are cutaneous, inhalational, and gastrointestinal. The CSF studies typically show findings of hemorrhagic meningitis. Gram-stained smears of CSF may show large gram-positive bacilli suggestive of *Bacillus anthracis*. The organism will subsequently grow on CSF culture. PCR testing may be used to rapidly detect anthrax DNA in CSF.[104] Blood cultures are positive in approximately 70% of cases. Chest radiographs are usually abnormal in those with inhalational anthrax, with findings including pleural effusion, hilar adenopathy, widened mediastinum, infiltrates, and soft tissue edema. CT or MRI of the head in these patients may show focal intracerebral hemorrhage, subarachnoid hemorrhage, intraventricular hemorrhage, diffuse cerebral edema, or prominent leptomeningeal enhancement.

The prognosis for AME is not good, with 75% of patients dead within 24 hours of presentation. Survival rate is at most 15%, but there have been no reported cases in the world literature of survival after AME associated with inhalational anthrax. The Centers for Disease Control and Prevention have indicated that ciprofloxacin or doxycycline should be included as essential components of initial treatment for anthrax from any portal of entry. Rifampin plus vancomycin would be reasonable to add given the concern of possible antibiotic resistance in bioengineered strains.[103] Antianthrax serum and/or steroids have been recommended for consideration as adjunct agents in AME.

Brucella

Brucella, like anthrax, is a potential bioterrorism threat. Symptoms of brucella are nonspecific and include fever, sweats, malaise, anorexia, headache, and back pain. Brucellosis may involve any organ or system. Invasion of the CNS occurs in fewer than 5% of cases. Complications in the nervous system include meningitis most frequently, and encephalitis, myelitis-radiculoneuronitis, brain abscess, epidural abscess, demyelinating syndromes, and meningovascular syndromes. CSF shows a lymphocytic pleocytosis, elevated protein, and low to normal glucose levels. The diagnosis of brucellosis is generally made by recovering brucella from blood culture. CNS disease can be confirmed by culturing brucella from CSF, but cultures are positive in only about 25%. The diagnosis also can be established by detecting antibodies in the CSF. Doxycycline with trimethoprim-sulfamethoxazole and rifampin has been used to successfully treat neurobrucellosis. When the CNS is involved with brucella, therapy is often continued for 6 to 9 months.[105]

Cat Scratch Disease

Bartonella (formerly *Rochalimaea*) *henselae* has been shown to be the cause of cat scratch disease. Case reports of a variety of

CNS manifestations have been reported in cases of cat scratch disease, including encephalitis, myelitis, radiculitis, and cerebellar ataxia.[106] PCR has been used in a number of reports to identify *B. henselae* in tissue; however, such testing currently is not widely available.[107] The initial therapy of choice for these infections is doxycycline or erythromycin.[108]

Lyme Disease

Lyme disease is the most common vector-borne infection in North America and Europe. It is a multisystem disease that results from infection with the spirochete *Borrelia burgdorferi* transmitted by a tick bite.[109] Neurologic involvement occurs in 15% to 25% of patients, usually occurring weeks to months after infection. The typical pattern is fluctuating symptoms of meningitis with superimposed cranial or peripheral radiculoneuropathies. Acute or chronic encephalomyelitis may also occur. In patients with CNS involvement, the CSF may show a lymphocytic pleocytosis with elevated protein levels. Unfortunately, a test that uniformly indicates active infection in the CNS is lacking. The diagnosis has traditionally been made when patients with a clinically compatible illness are demonstrated to have positive serology. With the advent of PCR techniques, the difficult diagnosis of Lyme neuroborreliosis may be more firmly established in suspected cases.[110] In patients who have Lyme disease with neurologic abnormalities, the recommended treatment is ceftriaxone 2 g daily for 2 to 4 weeks.

Leptospirosis

Leptospirosis is a multisystem disease that may involve the CNS.[111] It is caused by spirochetes of the genus *Leptospira* and is a zoonosis of worldwide distribution. Humans become infected by direct or indirect contact with infected animals or by recreational exposure, especially in South Atlantic, Gulf, and Pacific coastal states in the United States (especially, in Hawaii). Subclinical infection occurs commonly. Clinical infection is commonly mild and anicteric; however, there is a severe icteric form. Leptospirosis is typically a biphasic illness, beginning with a septicemic phase characterized by an abrupt onset of fever, headache, myalgias, and nausea and vomiting. This persists for 4 to 7 days and is followed by a second or immune phase when fever is usually low grade or absent. The headache during this stage is characteristically intense and may be accompanied by mild delirium. Common physical findings include muscle tenderness, conjunctival suffusion, adenopathy, hepatosplenomegaly, and rashes. Examination of the CSF demonstrates a mild mononuclear pleocytosis with a normal or slightly elevated protein level. In this milder form of leptospirosis, focal neurologic signs and evidence of encephalitis are uncommon.

In icteric leptospirosis, the illness is more severe and is characterized by impaired renal and hepatic function, hemorrhage, myocarditis, and severe alterations in consciousness. The definitive diagnosis requires isolation of the organism or seroconversion. With the use of specialized media, the organisms may be isolated from the blood or CSF during the first 10 days of the illness or from the urine during the second week. PCR, where available, may be helpful in the detection of *Leptospira*.[112] Treatment consists of intravenous penicillin and general supportive therapy to manage the life-threatening complications of renal failure, hypotension, and hemorrhage. The mortality rate in the more severe cases is between 5% and 10%.[111]

Cryptococcus Neoformans

Cryptococcosis is a systemic infection caused by the ubiquitous yeast-like fungus *Cryptococcus neoformans*. Infection most frequently occurs in patients who are immunocompromised, especially those with AIDS. Infection tends to localize to the CNS. Onset may be abrupt in patients receiving corticosteroid therapy or those receiving treatment for lymphoreticular malignancies, but most frequently it is insidious, with mild and nonspecific complaints such as headache, irritability, somnolence, and clumsiness. Often there are behavioral changes. On physical examination, the patient is frequently afebrile with minimal or no nuchal rigidity. Papilledema is noted in about 33% of cases, and cranial nerve palsies are seen in about 20%.[113] CSF examination may show an elevated opening pressure with elevated protein content, decreased glucose level, and small numbers of leukocytes. It should be emphasized that in AIDS patients there are minimal or no abnormalities of the CSF, but cryptococci grow in culture. In 50% of patients with cryptococcal meningoencephalitis, the organism may be identified in India ink smears of CSF. Latex agglutination detects antigen in CSF, but positive tests must be confirmed by cultures before a definite diagnosis of cryptococcosis can be made. The recommended treatment is amphotericin B at a dose of 0.7 mg/kg body weight daily intravenously for 2 weeks followed by fluconazole 400 mg daily for at least 10 weeks.[114] Eradication of infection seldom, if ever, occurs in AIDS patients. Even after a 6-week course of amphotericin, the relapse rate was 50% to 60%.[115] It is therefore currently recommended that AIDS patients receive fluconazole, 200 to 400 mg daily, indefinitely after initial therapy with amphotericin.[113,116] The benefits of larger doses of fluconazole have yet to be determined. Even in immunocompetent hosts, the mortality rate in treated cryptococcal meningoencephalitis is approximately 25% to 30%.[113,117]

Toxoplasmosis

Toxoplasma gondii is the causative agent in toxoplasmosis. It is an obligate intracellular protozoan parasite that infects virtually all mammalian species and has a worldwide distribution. Toxoplasmic encephalitis historically was a relatively rare disease seen sporadically in immunocompromised patients, in particular those with malignancies of the reticuloendothelial system and organ transplant recipients. However, this disease has risen to prominence in association with AIDS. It is now recognized as the most common cause of intracerebral mass lesions in AIDS patients.[118] It is believed that toxoplasmic encephalitis results from reactivation of chronic latent infection. Clinically, the CNS manifestations of toxoplasmosis are nonspecific and highly variable. They may take the form of cerebral mass lesions, meningoencephalitis, or diffuse encephalitis. Focal abnormalities are common and include focal seizures, hemiparesis, hemiplegia, cerebellar tremor, cranial nerve palsies, personality changes, and severe headache. Generalized abnormalities may also occur, including weakness,

myoclonus, confusion, lethargy, and coma. Immunocompromised patients with toxoplasmosis have predominantly CNS manifestations; however, extraneural manifestations of the disease include chorioretinitis, pneumonitis, myocarditis, orchitis, and peritonitis.[108]

CSF examination of patients with toxoplasmic encephalitis generally shows an elevated protein content with a mononuclear pleocytosis of up to several hundred cells per microliter. The glucose level is normal or slightly depressed. However, results of CSF analysis may be completely normal. CT of the brain in AIDS patients with cerebral toxoplasmosis visualizes abnormalities in more than 90% of patients.[119,120] Most commonly, the lesions are in the region of the basal ganglia, midbrain, or brain stem and are rounded and hypodense with peripheral "ring" enhancement, but they may show diffuse or no contrast enhancement. Lesions may be single or multiple, with multiple lesions being more specific for toxoplasmosis. MRI is reportedly more sensitive than CT.[121]

The diagnostic serologic changes associated with toxoplasmosis infection in immunocompetent individuals are seldom seen in AIDS patients with toxoplasmic encephalitis. Moreover, although negative toxoplasmosis serology in AIDS patients reduces the likelihood of toxoplasmosis infection, there are several reports of false-negative tests.[122,123] Local antibody production to *T. gondii* in the CSF is specific but lacks sensitivity and therefore is of limited diagnostic usefulness. PCR has been used to amplify parts of the *T. gondii* genome and appears promising for diagnosis.[124] Larger studies are required to characterize the role of PCR, especially in light of the current recommendations for empirical therapy.

In AIDS patients with suspected toxoplasmic encephalitis, it is desirable to have a confirmed diagnosis because similar lesions may be due to tuberculosis, other bacteria, fungi, or lymphoma. Hence, AIDS patients who have encephalitis that is clinically and radiographically compatible with toxoplasmosis are usually given a therapeutic trial with pyrimethamine and sulfadiazine. Biopsy is reserved for patients who fail to respond to therapy or whose neurologic status is rapidly deteriorating. Clinical and radiographic responses to therapy should be seen within 10 days of starting therapy. The standard treatment regimen is pyrimethamine (a 200-mg oral loading dose followed by 50 to 75 mg/day orally), folinic acid (10 to 20 mg/day orally or intravenously), and sulfadiazine (1 to 1.5 g orally every 6 hours).[125] This therapy is continued for at least 6 weeks. In AIDS patients, discontinuation of therapy has been associated frequently with relapse of toxoplasmic encephalitis, and maintenance therapy should be continued indefinitely. Toxoplasmosis occasionally progresses to death even with appropriate therapy.

Acanthamoeba

Granulomatous amebic encephalitis (GAE) is caused *by Acanthamoeba castellani*, *Acanthamoeba culbertsoni, Acanthamoeba astronyxis*, *Acanthamoeba palestinensis*, and *Balamuthia mandrillaris*. These are free-living amebae that have been isolated from soil, water, and air from diverse geographic locations. GAE is a subacute opportunistic infection that spreads hematogenously from pulmonary or skin lesions to the CNS. It occurs predominantly in debilitated or immunosuppressed individuals. Typically these patients present with mental status abnormalities, seizures, fever, headache, and hemiparesis. They may also demonstrate meningismus, visual disturbances, or ataxia. The diagnosis is frequently made postmortem. Brain biopsy is the only way to make the diagnosis antemortem. Little is known about the treatment of GAE; however, it has been recognized that the diamidine derivatives (pentamidine) have the greatest activity against *Acanthamoeba*.[126]

Naegleria

Naegleria fowleri is another free-living ameba that causes primary amebic meningoencephalitis (PAM). This ameba has been isolated from soil, river, and lake water and is especially prominent in warmer thermally polluted freshwater lakes. PAM appears primarily in healthy children and young adults who have a history of recent swimming in warm fresh water. The illness is characterized by abrupt onset of fever, nausea and vomiting, headache, and meningismus. The encephalitis is fulminant and in most patients progresses to coma and death. CSF examination typically shows a neutrophilic pleocytosis, elevated protein level, and normal or reduced glucose value. Gram stain shows pus cells but no bacteria. However, if a wet mount is made of the CSF, motile trophozoites of *N. fowleri* may be seen. Molecular methods to rapidly and specifically diagnose *Naegleria* infections are a recent development. Only six patients are known to have survived PAM. Their treatment included large-dose systemic and intrathecal amphotericin B. Passive immunotherapy with anti-*Naegleria* immune serum or an anti-*Naegleria* monoclonal antibody may in the future prove to be useful adjunctive therapy.[126]

Supportive Therapy in the Intensive Care Unit

Intensive supportive care is indicated in patients with encephalitis because these patients may make remarkable recoveries even after prolonged periods of unconsciousness.

The usual first principles of establishing and maintaining airway patency, oxygenation, and adequate ventilation in patients with disordered CNS function should be applied. A poor gag reflex and ineffective cough are markers of the need for airway protection. Special care must be taken in the intubation of patients with suspected encephalomyelitis to prevent potentially catastrophic increases in ICP. Intubation should be performed early in an elective fashion by an experienced person. Hypotension is also dangerous for patients with increased ICP and, if present, should be treated with intravenous fluids and appropriate inotropic support.

Strict monitoring of fluid, electrolyte, and glucose balance is necessary because of the possibility of hypothalamic involvement in the encephalitic process. Moreover, depending on the specific etiologic agent of encephalitis, there may be concurrent dysfunction of other organ systems compromising the patient's normal mechanisms of autoregulation and homeostasis. Nutrition must be maintained, preferably with enteral alimentation, but parenteral nutritional support may be necessary. Routine skin and eye care should not be neglected.

Although controversial, ICP monitoring is advocated by some for adults with severe encephalitis. Treatment of increased ICP has been required in up to 75% of patients in some series.[5] Major rises in ICP may lead to further neurologic compromise or death. Elevated ICP has been associated with a poor prognosis.[127] Therapy for raised ICP includes optimizing head position, hyperventilation to maintain a partial pressure of CO_2 of 25 or 30 mm Hg, osmotic agents such as mannitol (100 g in 500 mL of 5% dextrose in water) infused intravenously over 10 to 20 minutes every 4 to 6 hours, as needed, in an effort to keep the ICP below 20 mm Hg (see Chap. 65).

Seizures are also a recognized complication of encephalitis and are best managed by phenytoin at a loading dose of 15 to 18 mg/kg. This should be infused at a rate not exceeding 50 mg/min in a glucose-free solution to prevent precipitation. Transient hypotension and heart block can occur during intravenous phenytoin administration, so blood pressure and electrocardiographic monitoring are required. A therapeutic plasma level of 10 to 20 mg/mL is usually achieved with a daily maintenance dose of phenytoin of 300 to 500 mg (4 to 8 mg/kg). This dose may be given intravenously or orally. The half-life of phenytoin is long (36 hours); therefore, a steady state is not achieved until 5 to 7 days have elapsed.

If seizures persist despite loading with phenytoin, then phenobarbital may need to be added (see Chap. 64). One should not assume that the seizures are secondary to the encephalitis until other treatable precipitating causes, such as structural or metabolic abnormalities, have been ruled out. Complications of prolonged seizures may include cerebral edema, aspiration, rhabdomyolysis, myoglobinuria, hyperthermia, and hypoxia. These should be treated as they arise. Extreme hyperthermia may develop secondary to the encephalitis itself and be an aggravating cause of seizures. It should be controlled by appropriate cooling measures. Medical and nursing staffs frequently ask questions about contagiousness. Except for a very few causes of encephalomyelitis, there is very little risk of disease transmission. Enteric precautions should be exercised when caring for patients with suspected enteroviral (including polio viral) infection. Isolation precautions against respiratory secretions should be taken in patients with suspected tuberculosis, rabies, measles, mumps, or lymphocytic choriomeningitis virus infection. Viral hemorrhagic fevers require strict isolation. Secretions from lesions of patients with VZV are potentially infectious, and appropriate precautions should be used. Standard precautions, including masks, gowns, gloves, and eye protection, should be worn by all personnel participating in acute resuscitation, especially those involved in endotracheal intubation.

Chapter 54

LIFE-THREATENING INFECTIONS OF THE HEAD, NECK, AND UPPER RESPIRATORY TRACT

ANTHONY W. CHOW

KEY POINTS

- *A thorough knowledge of the fascial relations and the potential anatomic routes of infection is a prerequisite to optimal management of deep neck infections.*
- *The microbial etiology of deep infections of the head and neck is complex and typically polymicrobial. Anaerobes generally outnumber aerobes by a factor of 10:1.*
- *The development of marked asymmetry in the course of a submandibular space infection should be viewed with great concern because it may be indicative of extension to the lateral pharyngeal space.*
- *In immunocompromised patients, the classic manifestations of infection, such as edema and fluctuance at the local site and features of systemic toxicity, may be absent.*
- *Penicillin with metronidazole is the antibiotic regimen of choice for odontogenic deep neck infections, but immunocompromised patients require a broader spectrum against organisms such as* Staphylococcus aureus *and enteric gram-negative rods.*
- *Chronic sinusitis, otitis, and mastoiditis are the most important causes of parameningeal infection and intracranial suppuration. Computed tomography is the single neuroimaging technique proved to be the most useful for the diagnosis of these conditions.*

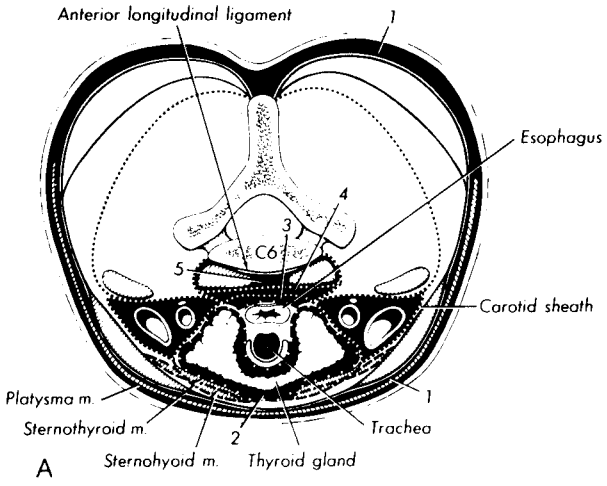
Life-threatening infections of the head, neck, and upper respiratory tract have become less common in the postantibiotic era. As a consequence, many physicians are unfamiliar with these conditions. Further, with widespread use of antibiotics and profound immunosuppression in some patients, the classic manifestations of these infections are often altered. Features of systemic toxicity, such as chills and fever, and local signs, such as edema and fluctuance, may be absent. Thus, physicians unfamiliar with these entities may underestimate their extent and severity. The situation is made more serious by the fact that these infections often have a rapid onset and may progress to fatal complications. In this chapter, the key clinical manifestations of several life-threatening infections of the head, neck, and upper respiratory tract are highlighted, and the critically important anatomic relations that underlie their diagnosis and management are emphasized.

General Anatomic Considerations

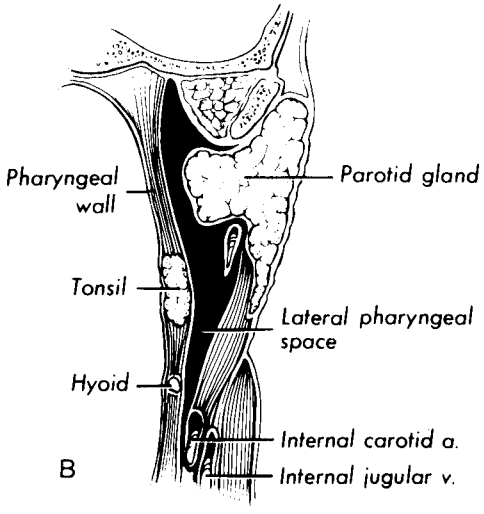
Life-threatening infections of the head, neck, and upper respiratory tract most commonly originate from suppurative complications of dental, oropharyngeal, or otorhinolaryngeal infections. From these sites, infection may extend along natural fascial planes into deep cervical spaces or vascular compartments (Fig. 54-1).[1] The deep cervical fascia ranges from loose areolar connective tissue to dense fibrous bands. It invests muscles and organs, thus forming planes and spaces. Notably, these fascial planes separate and connect distant areas, thereby limiting and directing the spread of infection. These infections may be fatal by local airway occlusion or by direct extension to vital structures such as the mediastinum or carotid sheath. Otorhinocerebral infections may cause intracranial suppuration such as cerebral or epidural abscess, subdural empyema, and cavernous or cortical venous sinus thrombosis (Fig. 54-2).[2] A thorough knowledge of the fascial relations and the potential anatomic routes of infection is a prerequisite to understanding the etiology, manifestations, and complications of deep neck infections. Such knowledge will not only provide valuable information on the nature and extent of infection but also suggest the optimum surgical approach for effective drainage.

Microbial Etiology and Pathogenesis

The microbial etiology of deep infections of the head and neck is complex and typically polymicrobial. As a rule, it reflects the autochthonous microflora of the contiguous mucosal surfaces from which the infection originated. Owing to their close anatomic relation, the resident flora of the oral cavity, the upper respiratory tract, and certain parts of the ears and eyes share many common organisms (Fig. 54-3).[3] Anaerobes generally outnumber aerobes at all sites by a factor of 10:1.[4] Although less is known about the pathogenic potential of individual species, it is clear that as a group these organisms are structural opportunists and invade deep tissues when normal mucosal barriers are broken (e.g., during pharyngitis, odontogenic infections, or direct trauma). Invasiveness is often enhanced by synergistic interactions of multiple species, aerobic and anaerobic. Moreover, certain species or combinations may be more invasive or more resistant to therapy than others.



Bacteria most commonly isolated from deep space infections include *Bacteroides*, *Peptostreptococcus*, *Veillonella*, *Actinomyces*, *Fusobacterium*, and microaerophilic streptococci. Most are sensitive in vitro to penicillin G, but more species are now resistant.[5] Although anaerobes are likely to be involved in most head and neck infections, a small but significant proportion of cases in immunocompromised patients will also involve other pathogens such as *Staphylococcus aureus* and facultative gram-negative rods, including *Pseudomonas aeruginosa*.



Clinical Syndromes

CERVICAL FASCIAL SPACE INFECTIONS

Deep fascial space infections of the head and neck are most frequently odontogenic in origin (Fig. 54-4).[1,6,7] The potential pathways of extension of these infections from one space to another are illustrated in Fig. 54-5.[8] Cervical fascial space infections considered to be life-threatening include those of the submandibular space, the lateral pharyngeal space, and

the retropharyngeal, "danger," and prevertebral spaces. Their salient clinical features are presented in Table 54-1.[9] The approach to radiographic and microbiologic diagnoses is discussed toward the end of this chapter. Recommended antimicrobial regimens for initial empirical therapy are presented in Table 54-2.[7]

SUBMANDIBULAR SPACE INFECTIONS

The prototypical infection of this space is known as Ludwig angina. In 1836, von Ludwig described five patients with "gangrenous induration of the connective tissues of the neck which advances to involve the tissues that cover the small muscles between the larynx and the floor of the mouth." The infection is characteristically an aggressive, rapidly spreading "woody" or brawny cellulitis involving the submandibular space. Although the submandibular space is divided by the mylohyoid muscle into the sublingual space above and the submylohyoid space below (Fig. 54-6), it can be considered a single unit owing to a direct communication around the posterior aspect of the mylohyoid muscle. Ludwig angina most commonly follows infection of the second or third mandibular molar teeth (70% to 85% of cases). The submylohyoid space is initially involved because the roots of these teeth are located below the attachments of the mylohyoid muscle to the mandible (see Fig. 54-4). Also, because the lingual aspects of periodontal bone around these teeth are thinner, medial spread of infection is facilitated. Infection extends contiguously (rather than by the lymphatics, which would limit the infection to one side) to involve the sublingual and thus the entire submandibular space in a symmetrical manner. Less commonly, an identical process initially involving the sublingual space arises from infection of the premolars and other teeth or from trauma to the floor of the mouth. Once established, infection can evolve rapidly. The tongue may enlarge to two or three times its normal size and distend posteriorly into the hypopharynx, superiorly against the palate, and anteriorly out of the mouth. Immediate posterior extension

Coronal section at first molar teeth: *a*, maxillary antrum; *b*, nasal cavity; *c*, palatal plate; *d*, sublingual space (above mylohyoid muscle); *e*, submylohyoid space; *f*, intraoral presentation with infection spreading through the buccal plates inside the attachment of the buccinator muscle; *g*, extraoral presentation to buccal space with infection spreading through the buccal plates outside the attachment of the buccinator muscle.** ***B*. Lingual aspect of the mandible: *a*, tooth apices above the mylohyoid muscle with spread of infection into sublingual space; *b*, tooth apices below the mylohyoid muscle with spread of infection into submylohyoid space. *(Reproduced with permission from Chow.[30])***

of the process directly involves the epiglottis (see Fig. 54-6). There exists a little-regarded dangerous connection between the submandibular and lateral pharyngeal spaces known as the *buccopharyngeal gap*. This gap is created by the styloglossus muscle as it leaves the tongue and passes between the middle and superior constrictor muscles to attach on the styloid process. Thus, cellulitis of the submandibular space may spread directly into the lateral pharyngeal space and thereby to the retropharyngeal space and mediastinum (see Fig. 54-6).

Clinically, the patient is febrile and complains of mouth pain, stiff neck, drooling, and dysphagia, leaning forward to maximize the airway diameter. A tender, symmetrical, and indurated swelling, sometimes with palpable crepitus, is present in the submandibular area. The mouth is held open by lingual swelling. Respirations are usually difficult, and stridor and cyanosis are considered ominous signs. Radiographic views of the teeth may indicate the source of infection, and lateral views of the neck will demonstrate the degree of soft tissue swelling around the airway and possibly submandibular gas. The development of significant asymmetry of the submandibular area should be viewed with great concern because it may be indicative of extension to the lateral pharyngeal space. Well-timed surgical drainage decreases the risk of spread to this space and subsequently to the superior mediastinum.[10]

The therapy of Ludwig angina has undergone a number of modifications since its initial description.[11] Although maintenance of an adequate airway is the primary concern and may necessitate urgent tracheostomy, most cases can be managed initially by close observation and intravenous antibiotics. If cellulitis and swelling continue to advance rapidly or if dyspnea occurs, artificial airway control should be gained immediately, before stridor, cyanosis, and asphyxia require that it be done under emergency conditions. There is general agreement that blind oral or nasotracheal intubation is traumatic and unsafe in advanced Ludwig angina because of the potential for induction of severe laryngospasm. A recommended approach is to use a flexible fiberoptic scope to assess the airway and to aid in inserting an endotracheal tube. Tracheostomy is still the most widely recommended means of airway control, although cricothyroidotomy is advocated by some experts because of a lower complication rate.

Penicillin G with metronidazole or a similar regimen directed at the mixed aerobic and anaerobic flora of the mouth (see Table 54-2) is the antibiotic regimen of choice, but immunocompromised patients require a broader spectrum of antibiotic coverage to include organisms such as facultative gram-negative rods and *S. aureus*. Early surgical decompression, much advocated in the era before antibiotics, is unlikely to locate pus and at best may only moderately improve the airway. Pus collections develop relatively late (they are not usually present in the first 24 to 36 hours) and are sometimes difficult to detect clinically. If the patient is not responding adequately to antibiotics alone after this initial period or if fluctuance is detectable, needle aspiration or a more formal incision and drainage procedure under general anesthetic should be performed. Preferably, this should be done with a cuffed tracheostomy in place. In addition, the infected teeth implicated in the sepsis should be extracted.

With the combined use of systemic antibiotics and aggressive surgical intervention, the mortality rate for Ludwig angina has declined dramatically from more than 50% before the antibiotic era to 0% to 4% currently.

LATERAL PHARYNGEAL SPACE INFECTIONS

Lateral pharyngeal space infections are potentially life-threatening because of involvement of vital structures within the carotid sheath and a tendency to bacteremic dissemination. Anatomically, the lateral pharyngeal space (also known as the *pharyngomaxillary space*) is shaped like an inverted cone in the lateral neck, with its base at the skull and its apex at the hyoid bone. Its medial wall is continuous with the carotid sheath, and anteriorly it lies between the superior pharyngeal constrictor muscle medially and the internal pterygoid muscle, mandibular ramus, and parotid gland laterally (Fig. 54-7). It is divided into an anterior (prestyloid or muscular) compartment and a posterior (retrostyloid or neurovascular) compartment by the styloid process and its attached muscles, the stylomandibular ligament, and the insertion of these structures into the hyoid bone. The anterior compartment contains no vital structures, but only fat, lymph nodes, connective tissue, and muscle. It is the compartment most closely related to the tonsillar fossa and the internal

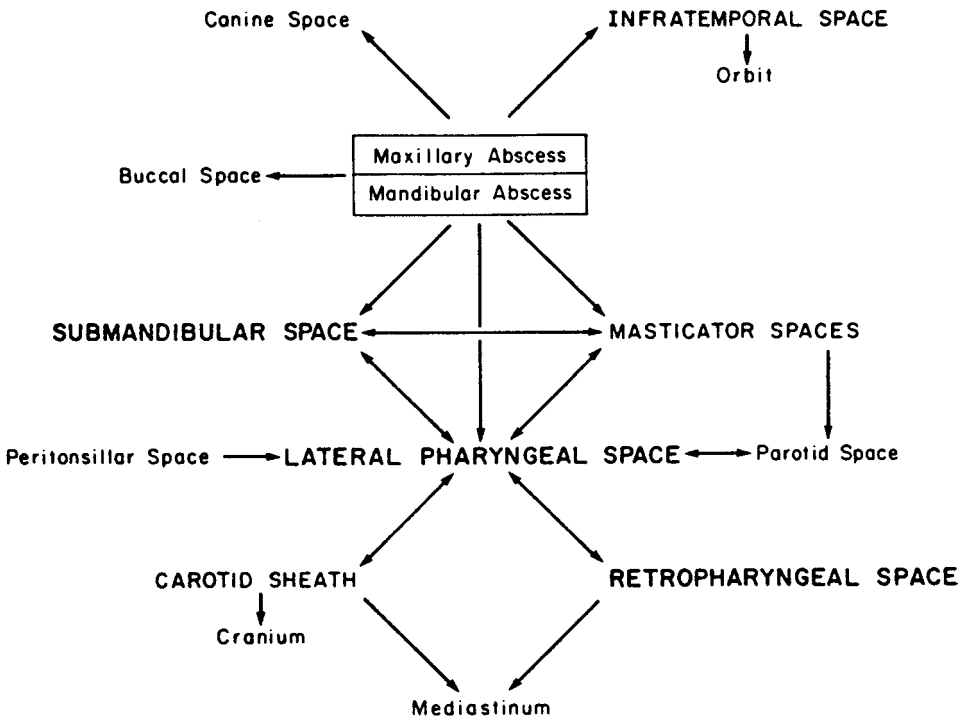

FIGURE 54-5 Potential pathways of extension in deep fascial space infections. *(Reproduced with permission from Blomquist and Bayer.[8])*

pterygoid muscle. The posterior compartment contains the ninth to twelfth cranial nerves, the carotid sheath and its contents, and the cervical sympathetic trunk. Infections of the lateral pharyngeal space may arise from sources throughout the neck. Dental infections are the most common source, followed by peritonsillar abscess (postanginal sepsis) and rarely parotitis, otitis, or mastoiditis (Bezold abscess).

Infection of the anterior compartment is often suppurative. Because most patients are already compromised by infection elsewhere, diagnosis of lateral pharyngeal involvement is often delayed. The cardinal clinical features, in order of importance, are (a) trismus, (b) induration and swelling below the angle of the mandible, (c) systemic toxicity with fever and rigors, and (d) medial bulging of the pharyngeal wall. Although not prominent, dyspnea can occur. Suppuration may advance quickly to other spaces, particularly to the retropharyngeal space and the mediastinum, or may spread to involve the posterior compartment of the lateral pharyngeal space. In these cases, timely surgical incision and drainage are of utmost importance.

Postanginal sepsis can involve the anterior or the posterior compartment, but because lymphatic drainage is the most important mechanism of spread, it most often involves the carotid sheath alone. A history of sore throat, although usually present on admission, is not invariable; it may only be mild or unilateral, and there may be a latent period of up to 3 weeks before manifestations of deep infection develop. The patient presents in a toxic condition or insidiously with a fever of undetermined origin. Trismus is absent, and signs of local suppuration may be subtle clinically because of the tight connective tissue around and within the carotid sheath. This barrier confines the infection and may limit it to only the internal jugular vein. Dyspnea may be prominent as edema and swelling may descend directly to involve the epiglottis

TABLE 54-1 Comparative Clinical Features of Deep Fascial Space Infections

Space	Pain	Trismus	Swelling	Dysphagia	Dyspnea
Submandibular	Present	Minimal	Mouth floor; submylohyoid	Present if bilateral involvement	Present if bilateral involvement
Lateral pharyngeal					
Anterior	Severe	Prominent	Anterior lateral pharynx; angle of jaw	Present	Occasional
Posterior	Minimal	Minimal	Posterior lateral pharynx (hidden)	Present	Severe
Retropharyngeal (and danger)	Present	Minimal	Posterior pharynx	Present	Present
Masticator					
Masseteric and pterygoid	Present	Prominent	May not be seen	Absent	Absent
Temporal	Present	None	Face, orbit	Absent	Absent
Buccal	Minimal	Minimal	Cheek	Absent	Absent
Parotid	Severe	None	Angle of jaw	Absent	Absent

and larynx. Swelling of the pharyngeal wall, if present, will be behind the palatopharyngeal arch and is easily missed.

Suppurative jugular thrombophlebitis (Lemierre syndrome) is the most common vascular complication of lateral pharyngeal space infection.[12] An indurated swelling a few centimeters long may be palpable behind the sternocleidomastoid muscle or may be found more deeply behind the palatopharyngeal arch. Trismus is minimal and may be absent. Vocal cord paralysis or other neurologic signs representing lower cranial nerve involvement may be present. These signs are frequently missed unless specifically sought (they were detected in only 20% of cases antemortem in one series), and they may be transient. The patient may thus present as having an obscure septicemia (50% of cases). Metastatic abscesses are common, characteristically involving the lungs, bones, and joints or other sites. There may be retrograde spread of infection with cerebral abscess or meningitis. A diagnosis of right-side bacterial endocarditis may be considered. In common with other anaerobic septicemias, hepatic enlargement, tenderness, abnormal liver function tests, and even frank jaundice may be present, which may misdirect investigations and further delay diagnosis.[13] Positive gallium or white-cell–labeled indium uptake in the neck is a useful diagnostic aid in these cases. Computed tomography (CT)

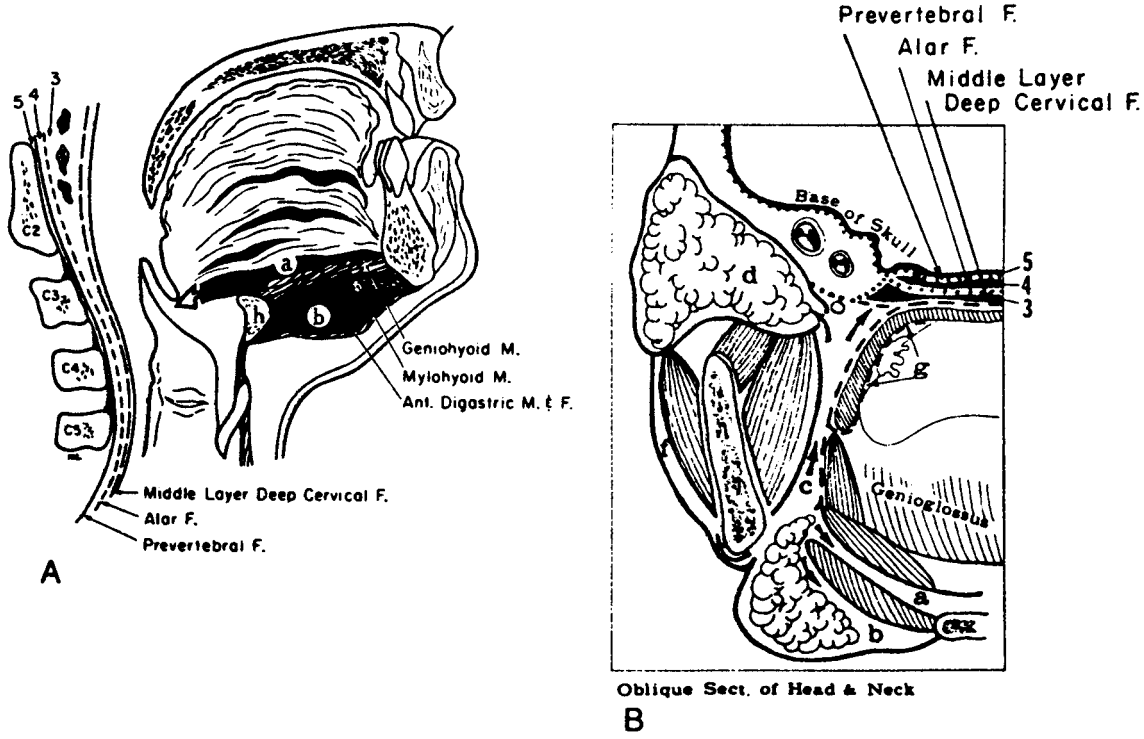

FIGURE 54-6 Anatomic relations in Ludwig angina. of the neck visualizes edema within the lateral pharyngeal space and the presence of thrombus in the internal jugular vein (Fig. 54-8). Thrombosis of the jugular vein can also be demonstrated by magnetic resonance angiography. Rarely, the carotid artery is involved, leading to an arteritis and to the formation and eventual rupture of an aneurysm. This complication is usually heralded by several minor bleeds before a major hemorrhage occurs and signals the need for urgent surgical intervention. Such bleeding may involve the oral cavity, nose, or ear or appear as ecchymosis in the neck and surrounding tissues. An ipsilateral Horner syndrome and otherwise unexplained ninth to twelfth cranial nerve palsies are additional premonitory syndromes of carotid sheath involvement.

Treatment of lateral pharyngeal space infection initially depends on whether local suppuration is present, but often this is difficult to determine. CT, careful needle aspiration, or more definitive incision and drainage may be required. Most cases of postanginal sepsis with suppurative jugular thrombophlebitis can be managed medically without the need for ligation or surgical resection of the infected vein. Prolonged courses of intravenous antibiotics (3 to 6 weeks) will be required. Because anaerobic bacteremia caused by *Bacteroides* species or *Fusobacterium necrophorum* is frequently present[14] and penicillin resistance among these organisms is increasingly recognized, therapy generally requires addition of metronidazole, clindamycin, or β-lactamase–stable cephalosporins. Fever may be slow to resolve, even in cases

successfully treated, particularly if there is metastatic involvement. Anticoagulants have sometimes been used in this setting, but their efficacy is unconfirmed. Surgical ligation of the internal jugular vein, the only available therapeutic option before antibiotics, is currently required only in the rare patient who fails to respond to antibiotic therapy alone. When there is impending or frank rupture of the carotid artery, the artery must be ligated immediately, with special attention given to the airway and to restoration of blood volume. Predictably, morbidity (e.g., stroke) and mortality rates are high (20% to 40%). In all such cases, early surgical intervention is the key to a successful outcome.

INFECTIONS OF THE RETROPHARYNGEAL, "DANGER," AND PREVERTEBRAL SPACES

The retropharyngeal, "danger," and prevertebral spaces lie between the deep cervical fascia surrounding the pharynx and esophagus anteriorly and the vertebral spine posteriorly (see Fig. 54-1). The retropharyngeal space is bound anteriorly by the constrictor muscles of the neck and their fascia and posteriorly by the alar layer of the deep cervical fascia, extending from the base of the skull to the level of the superior mediastinum, where the two fascial layers fuse. The "danger" space is interposed between the retropharyngeal space anteriorly and the prevertebral space posteriorly. It extends from the base of the skull and descends freely through the entire posterior mediastinum to the diaphragm. The prevertebral space is bound by the prevertebral fascia, which originates posteriorly on the spinous processes and encircles the splenius, erector spinae, and semispinalis muscles. Before completing its circle anterior to the vertebral bodies, it fuses to the transverse processes. At this point it is split into two layers: the more anterior alar fascia and the prevertebral fascia. The prevertebral space extends from the base of the skull to the coccyx, thus allowing infectious spread as far down as the psoas muscle sheath.

Retropharyngeal abscesses are among the most serious of deep space infections because infection can extend directly into the anterior or posterior portions of the superior mediastinum or into the entire length of the posterior mediastinum through the danger space (see Fig. 54-1).

Retropharyngeal infections may occur in children and adults. In young children, infection usually reaches this space through lymphatic channels, most commonly as complications of suppurative adenitis after infections of the upper respiratory tract. The onset may be insidious, with little more than fever, irritability, drooling, or possibly nuchal rigidity. More acute symptoms include dysphagia and dyspnea. The latter may be due to a local mass effect or to laryngeal edema. In general, there is little pain, but the neck may be held rigidly and tilted to the unaffected side. Definite bulging of the posterior pharyngeal wall is usually seen but may need careful palpation to be appreciated. The main dangers are severe laryngeal edema with airway obstruction and abscess rupture with consequent aspiration pneumonia or asphyxia. Many cases will respond to antibiotic therapy alone if treatment precedes the development of frank suppuration.

In adults, infection may reach the retropharyngeal space from local or distant sites. The former usually results from penetrating trauma (e.g., from chicken bones or after instrumentation); in such cases, the presence of a sore throat or difficulty in swallowing or breathing may be the first indications of infection. More distant sources include odontogenic sepsis and peritonsillar abscess (now a rare cause). Infection from these sources often may obscure the diagnosis because of associated trismus, which makes direct examination of the posterior pharyngeal wall difficult. In this setting, CT and radiographic views of the lateral neck are especially helpful and may demonstrate cervical lordosis with swelling and gas collections in the retropharyngeal space, which causes anterior displacement of the larynx and trachea. Radiographs may also help to differentiate this infection from prevertebral space sepsis arising from cervical osteomyelitis. Once a diagnosis is made, surgical exploration and wide drainage should be carried out without delay.

Acute necrotizing mediastinitis is the most feared complication of retropharyngeal space infections.[15] The onset is rapid and is characterized by (a) widespread necrotizing process extending the length of the posterior mediastinum and occasionally into the retroperitoneal space, (b) rupture of mediastinal abscess into the pleural cavity with empyema or development of loculations, and (c) pleural or pericardial effusions, frequently with tamponade. Aspiration pneumonia is also a significant problem (50% of cases) and may be secondary to impairment of swallowing or spontaneous rupture of the abscess into the airway. As might be expected, the mortality rate in adults is high (25%), even when appropriate antibiotics are administered. Early diagnosis and timely débridement are the mainstays of successful treatment. Mediastinal drainage may be attained by the cervical mediastinal or the transthoracic approach. Although the cervical approach may be effective in early mediastinitis, thoracotomy is generally indicated once the necrotizing process has entered the danger space. In patients who are recovering, it is important to restrict all oral intake until the swallowing impairment, which may have a prolonged course, has resolved completely.

SUPPURATIVE PAROTITIS

Acute bacterial parotitis is a specific clinical entity primarily affecting the elderly, malnourished, dehydrated, or postoperative patient.[16] Ductal (Stensen) obstruction secondary to sialolithiasis appears to be a major predisposing condition. Other predisposing factors include sialogogic drugs and trauma. Clinically, there is sudden onset of firm, erythematous swelling of the pre- and postauricular areas extending to the angle of the mandible. This is associated with exquisite local pain and tenderness but not trismus. Systemic findings of high fevers, chills, and marked toxicity are generally present. Septicemic spread may lead to osteomyelitis of the adjacent facial bones. Staphylococci have been the predominant isolates, and empirical antibiotic therapy should include an antistaphylococcal agent. Early surgical drainage and decompression of the gland are generally required because spontaneous drainage is uncommon. Because of its close relation to the posterior aspect of the lateral pharyngeal space, progression of infection into the parotid space may lead to massive swelling of the neck with respiratory obstruction and has the added potential risk of direct extension into the danger and visceral spaces and, hence, to the posterior mediastinum (see Fig. 54-1).

PERITONSILLAR ABSCESS AND PHARYNGEAL DIPHTHERIA

PERITONSILLAR ABSCESS

This condition, also known as *quinsy*, is a suppurative complication of acute tonsillitis involving the peritonsillar space. The latter consists of loose areolar tissue overlying the tonsil surrounded by the superior pharyngeal constrictor muscle and the anterior and posterior tonsillar pillars. Peritonsillar abscesses may affect patients of all ages but are most common among young adults 15 to 30 years old. The patient appears ill, with fever, sore throat, dysphagia, trismus, pooling of saliva, and a muffled voice. The abscess is usually unilateral, with associated cervical lymphadenitis. Examination of the pharynx in the majority of cases shows swelling of the anterior pillar and the soft palate and, less commonly, the middle portion or lower pole of the tonsil. Initially, needle drainage in the Trendelenburg position should be attempted, and the patient should be closely monitored and managed with intravenous antibiotics alone. Failure to obtain pus is an indication for surgical incision and more formal exploration. Delays increase the risk of spontaneous rupture. Aspiration of purulent material is the main hazard, particularly in the sleeping patient. More serious complications include (a) airway obstruction, especially with bilateral disease or when laryngeal edema develops; and (b) lateral dissection (usually from infections of the middle or lower portions of the tonsil) through the superior pharyngeal constrictor muscle to involve the lateral pharyngeal space (see Fig. 54-6B). Continued signs of sepsis after drainage of the peritonsillar space usually indicate coexisting, undrained lateral pharyngeal space infection. Fatalities associated with peritonsillar abscess (>50% before antibiotics) were due largely to this complication.

Ideally, antibiotics should be tailored according to the results of cultures of aspirated pus, but these are infrequently performed. Also, results are unlikely to be helpful unless specimens are collected without oropharyngeal contamination and are transported in appropriate media. Group A β-hemolytic streptococci (often as part of a mixed flora containing anaerobes) are most commonly isolated. Occasionally other β-hemolytic streptococci, *Haemophilus influenzae*, *S. aureus*, or anaerobes alone are cultured. Penicillin G is effective therapy in most cases. Bilateral tonsillectomy should be performed once the patient has recovered to avoid recurrences. Interim antibiotic prophylaxis should be considered in high-risk cases.

PHARYNGEAL DIPHTHERIA

Widespread immunization has substantially reduced infections caused by toxigenic strains of *Corynebacterium diphtheriae*. Nevertheless, local outbreaks of infection continue to occur sporadically, where reservoirs of infections (e.g., nasopharyngeal carriage) and suboptimal levels of immunization exist. All age groups, irrespective of immunization status, may develop diphtheria, but most cases usually occur in children and young adolescents. Those previously immunized are more likely to have milder or asymptomatic infections. Tonsillitis is the commonest manifestation, but any site in the upper airway can be infected. Nasopharyngeal involvement usually occurs by contiguous spread from the tonsils. In these patients, local symptoms of sore throat and dysphagia frequently follow a prodrome of fever, malaise, headache, nausea, and vomiting. Even though infection is limited to the mucosal epithelium (toxin absorption is responsible for systemic complications), the tonsils, uvula, and pharynx may swell considerably, sometimes sufficiently to suggest the presence of a peritonsillar or retropharyngeal collection. Further, a brawny nonpitting edema or "bull neck" may develop secondary to reactive cervical lymphadenopathy. With nasopharyngeal infection, cervical lymphadenopathy may be marked. Diphtheria is known for the formation of a tenacious membrane, but this is not an invariable finding and may be confined to the tonsillar mucosa. It may be produced by other infections, but the typical membrane of diphtheria quickly becomes discolored and necrotic (Fig. 54-9).[17] Bleeding may occur after attempts to remove it and is sometimes severe. Airway obstruction by membrane and local swelling may complicate severe tonsillar and nasopharyngeal infection but is more likely when the larynx is primarily involved. Urgent tracheostomy may then be required; if this measure fails to bypass the obstruction, bronchoscopy to remove any membrane present in the lower airways should be considered.

Circulating toxin is responsible for the neurologic and cardiac manifestations of diphtheria (peripheral neuropathy and myocarditis). These manifestations develop after a latent period of 1 to 2 weeks or longer and are influenced by the rate of toxin production (increased by more available iron) and absorption (greater in the nasopharynx). Gravis, intermedius, and mitis variants of *C. diphtheriae* are similarly toxigenic, and their distinction is of primarily epidemiologic importance. Of the neurologic complications, palatal, ocular, and ciliary paralysis are the earliest to develop and may be followed by motor or sensory changes in the limbs; but these symptoms are reversible. Myocarditis may develop acutely or insidiously, with a gradually rising serum aspartic transaminase level. Manifestations include shock, heart failure, arrhythmias, and various conduction disturbances. The prognosis

FIGURE 54-9 Tonsillar diphtheria with characteristic grayish green membrane overlying the right tonsil. (*Reproduced with permission from Whiting and Chow.*[17])

for cardiac disease is guarded, but complete recovery is the rule for those who survive.

For immediate treatment, equine diphtheria antitoxin should be given whenever clinical evidence of diphtheria exists because early administration decreases the risk of myocarditis. The dose depends on the site and severity of the infection. Testing for hypersensitivity to horse protein (and desensitization, if necessary) of all patients is mandatory. Diagnostic confirmation requires culturing *C. diphtheriae*, which must then be shown to be toxigenic. Although uncommon, toxigenic strains of *C. ulcerans* can also cause classic symptoms of laryngeal and cutaneous diphtheria.[18] These organisms are sensitive to several antibiotics, including penicillin G and erythromycin, which are equally effective and are used for treating clinical cases, carriers, and contacts.

ACUTE EPIGLOTTITIS AND LARYNGOTRACHEOBRONCHITIS

ACUTE EPIGLOTTITIS

Acute epiglottitis is an infection that produces predominantly nonsuppurative inflammatory edema involving the supraglottic structures and the epiglottis. Once caused mainly by *H. influenzae*, widespread use of vaccination against this organism in children has greatly reduced its prevalence, so that other bacteria, such as *Streptococcus pneumoniae*, *S. aureus*, *Haemophilus parainfluenzae*, and oral anaerobes, are increasingly implicated. In addition, because of vaccination, the occurrence of the disease in children has fallen dramatically; in most centers, most current cases seen are in adults.[19]

In older children and adults, the chief initial complaint is a sore throat and later odynophagia, but in younger children the physician has to rely on clinical findings alone. Typically, the triad of fever, stridor, and drooling is present. The patient tends to sit up and remain quiet, often leaning forward to facilitate breathing. The voice is muffled rather than hoarse. Inspiration tends to draw down the epiglottis and further obstruct the airway, so respirations are deliberately slow rather than rapid. Cyanosis, pallor, and bradycardia are late signs of severe airway obstruction that signal the urgent need to establish an artificial airway.

Once the diagnosis is suspected, confirmation depends on the condition of the patient, with the knowledge that this can change rapidly and unexpectedly, particularly in younger children in whom, because of the relatively small size of the supraglottic larynx, even small degrees of swelling can rapidly lead to complete airway obstruction. Particularly in adults who appear not to be in great distress, frequently only antimicrobial therapy and close observation in an intensive care unit without endotracheal intubation are required.[19] However, in a significant minority of adults (20%) and in most children (70%), respiratory distress, worsening stridor, or inability to easily clear secretions will mandate placement of an artificial airway.[20] Whether the patient is managed expectantly or by intubation, it is worth emphasizing that the personnel involved should be highly experienced with all aspects of difficult airway management because even with close monitoring there can be abrupt changes in the clinical course. If intubation is indicated, it should be done by direct visualization and in the operating room, preferably by a skilled anesthetist. Equipment and personnel necessary for emergency tracheostomy and a bronchoscope should be immediately available. Attempts to visualize the cherry-red epiglottis by direct laryngoscopy in an awake patient in the absence of these precautions for immediate intubation are discouraged because acute airway obstruction can be precipitated by dislodging a mucus plug or causing the patient to gag. Radiographic views of the lateral neck usually show an enlarged epiglottis with edematous supraglottic structures and ballooning of the hypopharynx (Fig. 54-10).[21] However, when the clinical signs point toward the diagnosis of epiglottitis with a significant compromise of the airway, radiologic investigation should not precede airway management.

Additional laboratory data may indicate a moderate leukocytosis with a left shift and positive cultures of blood and epiglottis. A concurrent pneumonia is demonstrated on chest radiographs in about 25% of cases. Antibiotic treatment may be initiated with ampicillin-sulbactam or a β-lactamase–resistant cephalosporin such as cefuroxime, cefotaxime, or

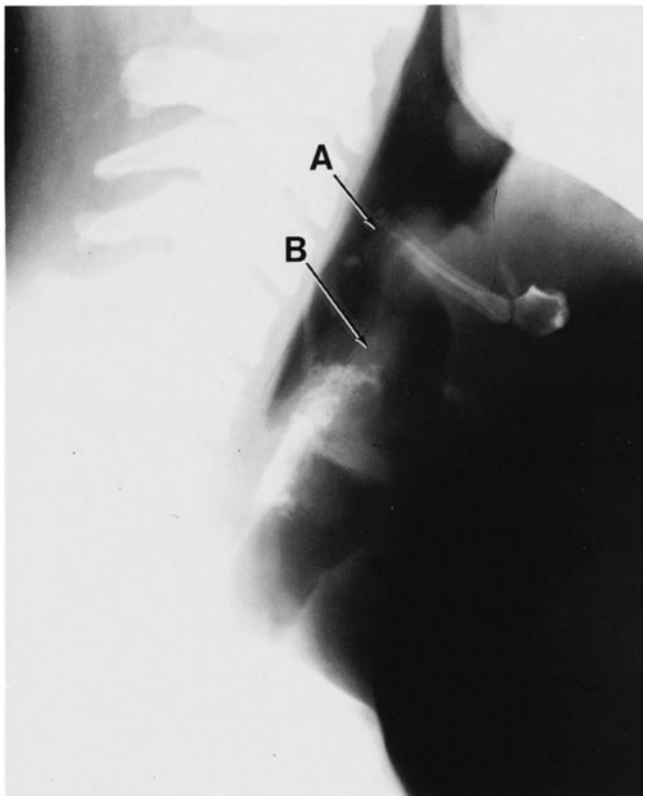

FIGURE 54-10 Lateral view of the neck in an adult with acute epiglottitis, showing soft tissue swelling of the epiglottis (*A*) and aryepiglottic folds (*B*). (*Reproduced with permission from Chow et al.*[21])

ceftriaxone. Culture and sensitivity results will dictate the ultimate choice of antibiotic, which should be continued for 7 to 10 days. When *H. influenzae* infection is demonstrated, rifampin prophylaxis should be provided for all household contacts when the household contains contacts younger than 4 years.

LARYNGOTRACHEOBRONCHITIS (CROUP)

Laryngotracheobronchitis primarily affects young children after a viral upper respiratory infection caused by influenza, parainfluenza, respiratory syncytial virus, adenovirus, and occasionally *Mycoplasma pneumoniae*.[22] Inflammation results in edematous swelling of the conus elasticus with narrowing of the infraglottic structures. Laryngotracheobronchitis follows a more gradual course than does bacterial epiglottitis and may be self-limiting or progress to respiratory obstruction. Clinical findings include a "brassy" or "barking" nonproductive cough associated with different degrees of inspiratory stridor, hoarseness, and respiratory distress. Respirations are noisy, often accompanied by chest wall retractions and inspiratory and expiratory wheezing. Nasal discharge and pharyngeal injection are common, but the epiglottis and supraglottic structures appear normal. Fever and malaise are present as part of the upper respiratory viral syndrome. A lateral radiograph of the neck can be helpful by showing the characteristic infraglottic narrowing. Management is similar to that for supraglottic laryngitis, including humidification, hydration, oxygen administration, and antibiotic therapy for secondary bacterial infection. Use of sedatives and narcotics, which suppress the cough reflex, is to be avoided. The role of steroids remains unclear.[23] Occasionally, an artificial airway is required for 2 to 5 days or longer. Extubation is sometimes difficult because of additional edema secondary to the endotracheal tube. It seems reasonable that a tracheostomy rather than reintubation should then be considered when the patient fails extubation.

PERICRANIAL INFECTIONS AND INTRACRANIAL SUPPURATION

SINUSITIS, OTITIS, AND MASTOIDITIS

Fortunately, suppurative and life-threatening complications of acute and chronic sinusitis have become relatively infrequent in the postantibiotic era. However, because of the unique pericranial location of these airspaces and the rich vascular supply in this region, contiguous spread of infection may extend intracranially through the diploic veins and result in serious complications such as meningitis, brain abscess, subdural or epidural empyema, osteomyelitis of the skull, and cavernous and other cortical venous sinus thrombosis.[24] The clinical spectrum of such complications may be quite varied (Table 54-3). Because the roof of the frontal and ethmoidal sinuses forms the anterior cranial fossa, infection in either sinus may produce a frontal epidural abscess, subdural empyema, or a frontal lobe brain abscess (see Fig. 54-2). Frontal sinusitis may also result in thrombosis of the superior sagittal sinus, which arises in the roof of the frontal air sinuses. Extension of infection anteriorly into bone can lead to "Pott's puffy tumor of the forehead," whereas an orbital extension may lead to periorbital cellulitis. The ethmoidal sinuses are separated from the orbital cavity by a paper-thin orbital plate. Perforation of the plate allows direct spread of infection into the retro-orbital space. Ethmoidal sinusitis can also spread to the superior sagittal vein or the cavernous venous sinus (see Fig. 54-2). The sphenoid sinus occupies the body of the sphenoid bone in close proximity to the pituitary gland above, the optic nerve and optic chiasma in front, and the internal carotids, the cavernous sinuses, and the temporal lobes of the brain on each side (see Fig. 54-2). Thus, sphenoid sinusitis can spread locally to cause cavernous sinus thrombosis, meningitis, temporal lobe abscess, and orbital fissure syndromes.[7,25] The superior orbital fissure syndrome, characterized by orbital pain, exophthalmos, and ophthalmoplegia, is due to involvement of the abducens, oculomotor, and trochlear nerves and the ophthalmic division of the trigeminal nerve as they pass through the orbital fissure.[24] Extension of infection from the maxillary sinus into the adjacent structures may result in osteomyelitis of the facial bones, including prolapse of the orbital antral wall with retro-orbital cellulitis, proptosis, and ophthalmoplegia. Direct intracranial extension from the maxillary sinus is rare, except in rhinocerebral mucormycosis and other types of invasive fungal sinusitis. Infections of the middle ear or mastoid within the petrous bone may extend into the middle fossa to involve the temporal lobe or into the posterior fossa to involve the cerebellum or brain stem. The skull overlying the dura of the cerebrum is covered extracranially by the galea aponeurotica. Pericranial infections due to head trauma or to a craniotomy may result in a subgaleal abscess and cranial osteomyelitis, with possible retrograde spread through the emissary veins to the epidural, subdural, and subarachnoid spaces.

TABLE 54-3 The Clinical Spectrum and Investigation of Intracranial Complications

Complication	Clinical Signs	Cerebrospinal Fluid	COMPUTED TOMOGRAPHY	
			Plain	With Contrast
Meningitis	Headache, fever (++), stiff neck, lethargy (++), rapid course	High PMN and protein levels; low glucose level	Normal	Diffusely enhanced
Osteomyelitis	Pott's puffy tumor (±)	Normal	Bony defect	Bony defect
Epidural abscess or mucocele	Headache (±), fever (±)	Normal	Lucent area	Biconvex capsule
Subdural empyema	Headache (±), convulsions (±), hemiplegia (±), rapid course (±)	High PMN and protein levels; normal glucose level	Lucent area	Crescent-shaped enhancement
Cerebral abscess	Convulsions (+), headache (+), personality change (+)	Lymphocytosis; normal glucose level	Lucency with mass effect	Capsule
Venous sinus thrombosis (cavernous)	"Picket-fence" fever (++), rapid course (++), orbital edema (++), ocular palsies (++)	Normal or high PMN count	Nonspecific	Enhancing lesion

ABBREVIATIONS: (++) characteristically seen; (+) frequently seen; (±) may or may not be seen; PMN, polymorphonuclear leukocyte.

Sinusitis occurring after prolonged endotracheal intubation is a recognized complication among critically ill patients. The incidence of this infection likely exceeds 15% in patients intubated longer than 5 days and is probably more frequent with nasal than with endotracheal and gastric tubes.[26,27] One study pointed to the difficulties in assessing sinusitis associated with intubation.[26] In this evaluation of 162 adult patients with intubation longer than 7 days, only 25% exhibited entirely normal maxillary sinuses at the time of an initial CT scan within 48 hours of admission. Some degree of mucosal thickening or an air–fluid level was present in most patients, suggesting that subsequent imaging studies must be interpreted in light of a high incidence of baseline abnormalities in patients admitted with respiratory failure. Nonetheless, when culture-positive sinusitis did develop, aggressive diagnosis and treatment appeared beneficial, and there was an association between sinusitis and bronchopneumonia. Interestingly, use of oral intubation was associated with a lower incidence of maxillary sinusitis than of nasal intubation.

Whether the use of soft feeding tubes or the Sengstaken-Blakemore tube carries a similar risk is currently unknown. This event is probably secondary to local trauma and edema within the intubated nasal cavity and is further promoted by limited head mobility, resulting in impaired drainage of the sinuses through the natural ostia. In contrast to community-acquired sinusitis, nosocomial sinusitis in the critically ill is often clinically silent, except for unexplained fever and leukocytosis. Purulent rhinorrhea and opacification or air–fluid levels on sinus roentgenograms or CT scans may suggest the diagnosis. The sequelae of unrecognized infection can be catastrophic, with intracranial extension and fulminant sepsis. A large percentage of cases of nosocomial sinusitis is polymicrobial (42% in one series), and most patients may be receiving broad-spectrum antibiotics at the time of diagnosis. The use of antral puncture for drainage and specimen collection for Gram stain and culture is strongly recommended. Antimicrobial therapy should be guided by Gram stain of the aspirate and culture results. Broad-spectrum coverage of *S. aureus* and enteric gram-negative bacilli is generally required.

RHINOCEREBRAL MUCORMYCOSIS AND MALIGNANT OTITIS EXTERNA

Rhinocerebral mucormycosis is a progressive and destructive infection of the paranasal sinuses caused by fungi of the family Mucoraceae: *Absidia*, *Mucor*, *Rhizomucor*, and *Rhizopus*.[28,29] It occurs primarily in debilitated patients with uncontrolled diabetes and ketoacidosis, in profoundly dehydrated children, and in neutropenic patients receiving cytotoxic therapy. The infection begins in the nose or nasopharynx and spreads through the sinuses into the orbit or central nervous system. It may extend through the cribriform plate to involve the meninges and the adjacent frontal lobe and cranial nerves, or it may extend through the nasolacrimal duct to involve the orbit, producing panophthalmitis. These fungi have a predilection for the walls of arteries, and infection spreads by this route, causing thrombosis and tissue infarction. The internal carotid artery or its major branches may be involved, as may the cavernous sinus. Clinically, black necrotic lesions may be found on the nasal mucous membranes or the soft palate. When orbital involvement is seen, there is proptosis, ophthalmoplegia, blindness, chemosis, and corneal anesthesia. Extension into the cranial cavity is manifested by headache, meningismus, trigeminal or facial cranial nerve palsy, seizures, and other focal neurologic signs. Progressive obtundation is seen, culminating in coma. The diagnosis is confirmed by the presence of broad, nonseptate hyphae in biopsy specimens and a positive culture. Treatment requires aggressive surgical débridement and systemic amphotericin B. With early diagnosis, control of the underlying condition, and appropriate antimicrobial therapy, long-term survival has been reported in 85% of cases.

Malignant otitis externa is a progressive and necrotizing infection of the external ear caused by *P. aeruginosa*, with spread through the cartilaginous and bony canal to the base of the skull. Affected patients are usually debilitated and often have poorly controlled diabetes mellitus. The infection is associated with severe otalgia, hearing loss, purulent discharge, edema, and granulation tissue or "polyp" in the cartilaginous portion of the external ear canal. Three stages of progression are recognized clinically: (a) locally invasive disease,

(b) disease associated with facial palsy, and (c) disease associated with multiple cranial nerve palsies. In the latter stages, infection may involve the infratemporal fossa by extension into the temporal or occipital bone. Prolonged medical therapy in conjunction with local débridement of granulation tissue and infected cartilage is effective in the majority of patients. In patients with more extensive disease involving the base of the skull and multiple cranial nerve palsies, therapy is not as successful, and up to 20 months of antimicrobial treatment may be required to achieve eradication of infection without relapse.

INTRACRANIAL SUPPURATION

These dreaded complications, which most commonly arise from chronic sinusitis, mastoiditis, or deep fascial space infections,[30] are only briefly reviewed here. Readers are referred to Chap. 52 for a more comprehensive description of these entities.

BRAIN ABSCESS

Most brain abscesses occur in association with three identifiable clinical settings (a) a contiguous focus of infection, particularly sinusitis, otitis, or mastoiditis; (b) cranial trauma or trauma after craniotomy; and (c) hematogenous spread from an extracranial focus of infection, especially the lung and heart valves. Otogenic (e.g., temporal lobe or cerebellum) and sinusitis-related (e.g., frontal lobe) brain abscesses account for approximately 50% of all pericranial sources of infection.[31] Hematogenous brain abscesses are frequently multiple and located in the distribution of the middle cerebral artery (i.e., in the posterior frontal or parietal lobes). The clinical presentations of brain abscesses are quite variable and appear to be influenced primarily by the anatomic location of the abscesses; their proximity to the ventricles, cisterns, or dural sinuses; and major alterations in the intracranial pressure dynamics secondary to the mass effect. Thus, a pontine abscess may bulge posteriorly and block the aqueduct of Sylvius acutely to cause obstructive hydrocephalus. An occipital lobe abscess could rupture or leak into the ventricular system, causing ventriculitis, or it could involve the transverse sinus and cause septic thrombophlebitis or a subdural empyema. Four distinctive clinical presentations of a brain abscess can be recognized, based on the unique pathophysiologic events implicated: (a) rapid focal mass expansion, (b) intracranial hypertension, (c) diffuse brain destruction, and (d) focal neurologic deficit. In the last category, the temporal progression of infection is so slow that it is often misdiagnosed as a neoplasm. Fever is present in only 45% to 50% of patients; therefore, absence of fever should not be used to exclude the diagnosis of brain abscess.

SUBDURAL EMPYEMA AND CRANIAL EPIDURAL ABSCESS

Intracranial subdural empyema in the adult usually results from a suppurative infection of the paranasal sinuses, mastoid, or middle ear. An acute flare-up with local pain and increase in purulent nasal or aural discharge and onset of generalized headache and high fevers are the first indications of intracranial spread. They are followed within days by focal neurologic findings such as unilateral motor seizures, hemiplegia, hemianesthesia, or aphasia, and signs of increased intracranial pressure with progressive lethargy and coma. The neck is stiff, but cerebrospinal fluid examination is more consistent with an aseptic meningitis syndrome. In infants and young children, however, an intracranial subdural empyema is almost invariably a complication of bacterial meningitis. Early signs such as irritability, poor feeding, or increased head size are nonspecific, but hemiparesis, convulsions, stupor, and coma may rapidly ensue. *Streptococcus pneumoniae*, *Streptococcus agalactiae*, and *H. influenzae* are the most common causes.

Cranial epidural abscess is usually associated with an infection after craniotomy or a cranial osteomyelitis secondary to chronic sinusitis or middle ear infection. The onset of symptoms may be insidious and overshadowed by the localized inflammatory process. Focal neurologic findings are less common than in subdural empyema. Rarely, a fifth and sixth cranial nerve palsy may develop in association with infections of the petrous portion of the temporal bone (Gradenigo syndrome).

SEPTIC INTRACRANIAL THROMBOPHLEBITIS AND MYCOTIC ANEURYSM

Septic intracranial thrombophlebitis most frequently follows infection of the paranasal sinuses, middle ear, mastoid, or oropharynx. If collateral venous drainage is adequate, septic venous thrombosis may produce only transient neurologic findings or may be silent. If the thrombus outstrips collateral flow, progressive neurologic deficits will result, with impairment of consciousness, focal or generalized seizures, and increased intracranial pressure. The clinical findings differ with the location of cortical veins or dural sinuses involved. Cavernous sinus thrombosis is characterized by abrupt onset with diplopia, photophobia, orbital edema, and progressive exophthalmos. Involvement of cranial nerves III, IV, V, and VI produces ophthalmoplegia, a midposition fixed pupil, loss of the corneal reflex, and diminished sensation over the upper face. Obstruction of venous return from the retina results in papilledema, retinal hemorrhage, and visual loss. Contrast-enhanced CT (Fig. 54-11) and magnetic resonance imaging (MRI) are the imaging modalities of choice. Treatment requires early recognition, high-dose intravenous antibiotics, and surgical decompression of the underlying predisposing infection. Anticoagulation and steroids are not indicated. Mortality remains high, approximately 15% to 30%. Thrombosis of the superior sagittal sinus produces bilateral leg weakness and may cause communicating hydrocephalus. Occlusion of the lateral sinus produces pain over the ear and mastoid and may cause edema over the mastoid (Griesinger sign). Involvement of cranial nerves V and VI produces ipsilateral facial pain and lateral rectus weakness (Gradenigo syndrome). Intracranial mycotic aneurysm usually results from septic embolization as a complication of bacterial endocarditis. This produces infection and necrosis in the arterial wall, which leads to dilation and possible rupture. Mycotic aneurysms can be multiple and are usually found on distal branches of the middle or anterior cerebral arteries. The early clinical manifestations are similar to those of cerebral emboli and infarction. The weakened vessel may be seen to progressively grow on serial angiograms. Because the clinical course

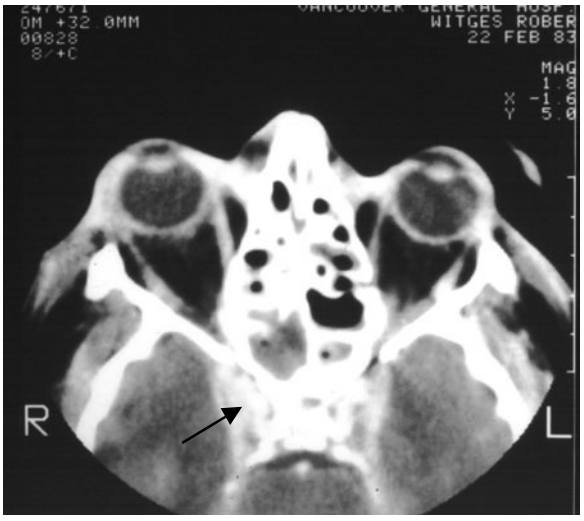

FIGURE 54-11 Computed tomographic scan of the head in a patient with cavernous sinus thrombosis secondary to sphenoid sinusitis. ***Arrow*** **indicates thrombus in the right cavernous sinus.**

of a mycotic aneurysm is quite variable and the risk of rupture with catastrophic cerebral hemorrhage cannot be predicted even after successful therapy of the underlying endocarditis, early surgical intervention is advised.

Diagnostic Considerations

MICROBIOLOGIC TECHNIQUES

It is imperative that clinical specimens for the diagnosis of deep head and neck infections be obtained without contamination by the resident oronasopharyngeal flora. This is best accomplished using a needle and syringe for aspiration of loculated pus through an extraoral approach. After the skin is cleaned, pus is aspirated into the syringe. All air is carefully expressed, and the needle tip is inserted into a rubber stopper. This allows the exclusion of air, and the specimen can then be transported directly to the laboratory. This method of specimen collection is superior to using swabs. If a swab is used, it should be saturated with purulent material and inserted into a commercially available transport tube specifically designed to transport swabs under anaerobic conditions. An additional swab should be taken for Gram staining. The Gram stain is particularly useful in the assessment of head and neck infections because a polymicrobial flora is generally present, and anaerobic bacteria may require 48 hours or longer for growth. The microscopic morphology of some of the bacteria may be characteristic enough to suggest a provisional diagnosis and, ultimately, therapy. Infected tissues obtained intraoperatively are also suitable for anaerobic and aerobic processing, provided that care is taken to prevent contamination by the normal resident flora.

IMAGING TECHNIQUES

CT and MRI are particularly useful for localization of deep fascial space infections of the head and neck.[7,32] Because CT can localize a process and define its extent, in particular invasion into the cranial vault, mediastinum, or the bone, it is an invaluable tool for guiding needle aspiration or open drainage. A lateral radiograph of the neck may demonstrate compression or deviation of the tracheal air column or the presence of gas within necrotic soft tissues. The soft tissues of the posterior wall of the hypopharynx are approximately 5 mm deep, less than one-third the diameter of the fourth cervical vertebra (C4). The retropharyngeal soft tissues should be approximately two-thirds the width of C4, and the retrotracheal space should be slightly smaller. A lateral radiograph of the cervical spine or a CT can determine whether the soft tissue swelling or abscess originated from the retropharyngeal space or the prevertebral space. The former suggests an odontogenic or oropharyngeal source, whereas the latter likely suggests involvement of the cervical spine.

CT is the single neuroimaging technique that has been most helpful for the diagnosis of intracranial infections such as brain abscess, subdural empyema, and epidural abscess. The typical CT finding in brain abscess is an area of decreased attenuation that is surrounded by a ring of enhancement after injection of contrast. CT also detects cerebral edema, hydrocephalus, an associated mass effect, and the presence of extracranial infection. In subdural empyema, CT presents inward displacement of cerebral substance due to an extracerebral mass. In epidural abscess, CT demonstrates a thick and circumscribed area of diminished density associated with extracerebral displacement and contiguous cranial osteomyelitis. Radionuclide brain scans and cerebral angiography remain useful as complementary procedures for the localization of certain central nervous system infections, in particular posterior fossa lesions and demonstration of mycotic aneurysms. MRI appears to be more sensitive than CT in the detection of suppurative intracranial infections. It is particularly useful for the detection and characterization of the early stages of cerebritis or epidural abscess. MRI is also useful for imaging vascular lesions, such as jugular thombophlebitis.[33] It remains to be seen whether newer techniques such as positron emission tomography will improve the diagnostic yield in early pericranial or intracranial infections.

Technetium bone scanning, used in combination with gallium- or indium-labeled white blood cells, is particularly useful for the diagnosis of cranial or cervical osteomyelitis. MRI is more sensitive than CT and probably more accurate than bone scan in detecting bone involvement.[34,35] T2-weighted images may identify and localize areas of pus for drainage or aspiration. Gadolinium enhancement is important to accurately define the soft tissue component.

Therapeutic Considerations

Although resuscitation and surgical measures are of primary importance in the initial management of these life-threatening infections, appropriate antibiotics are essential for a successful outcome. Empirical antimicrobial regimens for head and neck and upper respiratory tract infections are presented in Table 54-2. Recommendations for intracranial suppurative complications are discussed in Chap. 52. Maximum doses of systemic antimicrobials should be administered to optimize penetration of bone and the blood-brain barrier. Therapy should be continued for 2 to 3 weeks. Intracranial and vascular or bone infections may require at least 6 to 8 weeks

of intravenous antibiotics. Where anaerobes are implicated, penicillin G, usually in combination with metronidazole to deal with penicillin-resistant anaerobes, is the antibiotic regimen of first choice. Clindamycin is useful as an alternative in the penicillin-allergic patient and has the advantage of more effective coverage against β-lactamase–producing anaerobes. Chloramphenicol is rarely used because of its propensity for myelotoxicity. Metronidazole lacks activity against gram-positive anaerobic cocci such as *Peptostreptococcus* and facultative organisms such as streptococci and *S. aureus*, which precludes its use as monotherapy for head and neck infections. For immunocompromised and critically ill patients, broad-spectrum coverage for aerobic gram-negative rods, *S. aureus*, and anaerobes (e.g., with cefotaxime, ceftizoxime, piperacillin-tazobactam, or imipenem) is indicated (see Table 54-2). The final selection of antimicrobial therapy should be guided by culture results and susceptibility data.

Although considerable advances have been made in our understanding of these life-threatening oropharyngeal and otorhinolaryngeal infections, vigilance in terms of diagnosis and management is required to avoid the high mortality rate associated with this important group of conditions.

Chapter 55

SOFT TISSUE INFECTIONS

JOHN CONLY

KEY POINTS

- *Soft tissue infections characterized by extensive necrosis of subcutaneous tissue, fascia, or muscle are uncommon, but they require prompt recognition and urgent surgical treatment.*
- *The classic hallmarks of virulent soft tissue infections are extensive involvement of the subcutaneous tissues and a relative paucity of cutaneous involvement until late in the course of the infection.*
- *Rapidly spreading soft tissue infections present acutely with severe systemic toxicity.*
- *Successful management of these critically ill patients depends on prompt diagnosis by clinical and radiologic means.*
- *The principles of management include fluid resuscitation, hemodynamic stabilization, a broad-spectrum antimicrobial regimen, and early surgical intervention.*
- *Prompt surgery, in which a definitive diagnosis is reached and all necrotic tissue is débrided, should be considered the mainstay of treatment.*
- *The mortality rate is highest when the diagnosis is delayed or initial surgical treatment is limited.*

Classification of Soft Tissue Infections

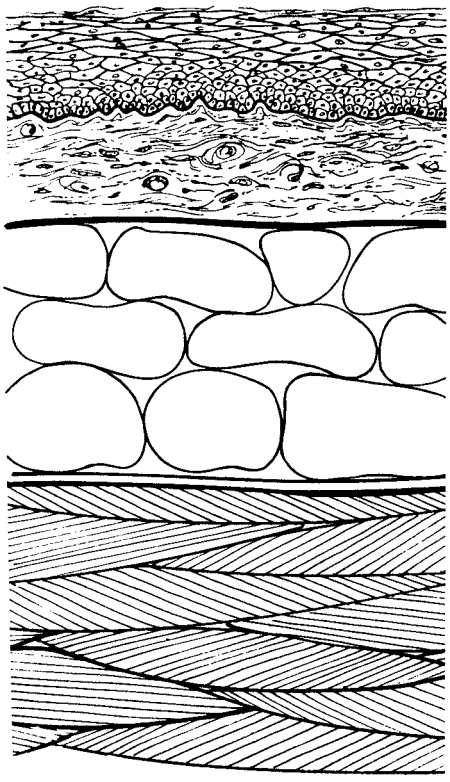
In severe soft tissue infections, the initial cutaneous presentation often belies the relentless progression of subcutaneous tissue necrosis and dissection that lies beneath a normal-appearing skin. Successful management of these soft tissue infections depends on early recognition followed by appropriate investigations to establish a specific diagnosis. A clear understanding of a classification of these entities is required, but, unfortunately, the published literature in this area is confusing because of a lack of uniformity in descriptive terminology and the use of different classification schemes. The confusion is compounded by the fact that certain clinical entities may involve one or more anatomic planes within the subcutaneous tissue, and one or more bacterial species may be responsible for the same or different clinical entities. Although classification schemes based on microbial etiology may be the most complete, they offer little to the clinical diagnostic process necessary to expedite appropriate management.[1] To place a useful clinicoanatomic classification into perspective, a review of the basic anatomy and microbial ecology of the skin and subcutaneous tissues is necessary.

BASIC ANATOMY AND MICROBIAL ECOLOGY OF THE SKIN AND SOFT TISSUES

The skin consists of an outer layer, the *epidermis,* and an inner layer, the *dermis*, which resides on a fibrous connective tissue layer, the *superficial fascia.* Beneath this layer, the avascular *deep fascia* overlies and separates muscle groups and acts as a mechanical barrier against the spread of infections from superficial layers to the muscle compartments. Between the superficial and deep fascia lies the *fascial cleft,* which is mainly composed of adipose tissue and contains the superficial nerves, arteries, veins, and lymphatics that supply the skin and adipose tissue.

Normally, the skin has a resident and a transient flora. The resident flora includes *Corynebacterium* species, coagulase-negative staphylococci, and *Micrococcus* species. *Staphylococcus aureus* is not considered part of the resident flora, but colonization rates of 10% to 30% in the anterior nares, axillae, groins, and perineum are not uncommon. Gram-negative bacilli are not considered part of the normal resident flora, although they are occasionally found in the moist intertriginous areas, such as the toe webs, groin, and perineum. The transient flora is made up of bacteria that are collected from extraneous sources and colonize the cutaneous surface for only a short period (hours to days). These organisms are highly variable but often include pathogenic gram-negative bacilli such as *Escherichia coli*, *Proteus* species, *Pseudomonas aeruginosa,* among others.[2] Critically ill patients frequently have compromised natural defense barriers, with concomitant increases in transient flora colonization.[3]

CLINICOANATOMIC CLASSIFICATION OF SOFT TISSUE INFECTIONS



Most classification schemes for soft tissue infections are based on clinical presentation or microbiologic etiology. Figure 55-1 shows a practical approach to the classification that is based on the affected anatomic plane of the soft tissues, the most commonly encountered clinical terms, and the microbial etiology.

The *common superficial pyodermas* include erysipelas, impetigo, ecthyma, furunculosis, and carbunculosis. These entities do not extend beyond the skin or its appendages and are not discussed further.

The *cellulitides* include what is commonly referred to as *cellulitis*, *anaerobic (or gangrenous) cellulitis*, and the clinically distinctive variant of gangrenous cellulitis called *progressive bacterial synergistic gangrene (Meleney gangrene).* Cellulitis is an acute spreading infection of the skin extending below the superficial fascia and involving the upper half of the subcutaneous tissues. These infections do not involve the deep fascial layer. The production of gas by anaerobic organisms and the subsequent presence of soft tissue gas, either palpable or demonstrable radiographically, and the propensity to produce necrosis in the subcutaneous tissue (and eventually in the skin) are major differentiating features of anaerobic and classic cellulitis. *Progressive bacterial synergistic gangrene (Meleney gangrene)* was the original term used to describe a distinct form of cellulitis often occurring postoperatively, with necrotic ulcer formation in the center of a cellulitic area.[4]

Necrotizing fasciitis is an acute infection involving the deep fascia, subcutaneous tissue, and superficial fascia to variable degrees.[5] The muscle tissue beneath the deep fascia is unaffected. The skin may not be involved early in the course of the infection, but as the process continues the skin becomes involved. Fournier syndrome (or gangrene) is a form of necrotizing fasciitis that affects the scrotum and genitalia.[6] In this setting, because there is virtually no subcutaneous fat

ANATOMY	SYNDROME	ETIOLOGY
Epidermis	Erysipelas	Group A Streptococcus
	Impetigo	Group A Streptococcus; Staphylococcus aureus
SKIN	Ecthyma	Group A Streptococcus; Pseudomonas aeruginosa
	Folliculitis	S. aureus; P. aeruginosa (whirlpools); rarely Candida
Dermis	Furunculosis	S. aureus; Group A Streptococcus; P. aeruginosa
Superficial Fascia	Cellulitis	Group A Streptococcus; S. aureus Occasionally enteric gram negative bacilli
SUBCUTANEOUS TISSUE	Anaerobic Cellulitis	Clostridium perfringens Bacteroides, Peptostreptococcus, Peptococcus ± gram negative bacilli (E. coli, Klebsiella, Proteus)
Adipose Tissue	Meleney's Gangrene	S. aureus or Proteus and microaerophilic streptococci
DEEP FASCIA	Necrotizing Fasciitis	Facultative gram positive and negative organisms (S. aureus, E. coli, Klebsiella, Proteus) and anaerobes (Bacteroides, Peptococcus, Peptostreptococcus); Group A Streptococcus
MUSCLE	Clostridial myonecrosis	C. perfringens (occasionally non-perfringens species)
	Nonclostridial synergistic myonecrosis	As for necrotizing fasciitis
	Pyomyositis	S. aureus; rarely Group A Streptococcus, P. aeruginosa

FIGURE 55-1 Clinicoanatomic classification of soft tissue infections.

between the epidermis and dartos fascia, cutaneous gangrene readily develops.

The *myonecroses* include clostridial myonecrosis (otherwise known as *gas gangrene*), nonclostridial myonecrosis (which has also been termed *synergistic necrotizing cellulitis*, although that is a misnomer), pyomyositis, and vascular gangrene. Rapid necrosis of the muscle and subsequent necrosis of the overlying subcutaneous tissue and skin are characteristic of the myonecrotic syndromes. Pyomyositis, an exception, is a bacterial abscess localized to the muscle, usually occurring after penetrating trauma. Vascular gangrene occurs in a limb devitalized by arterial insufficiency.

Major Soft Tissue Infections

CELLULITIS

PATHOGENESIS

Cellulitis most often occurs secondary to trauma of the skin with local inoculation of microorganisms, secondary to an underlying skin lesion or a postoperative wound infection, or by contiguous spread from a suppurative infection of other soft tissues or bone. However, cellulitis may also occur in the absence of any obvious local trauma. After inoculation of microorganisms into the subcutaneous tissues and skin, an acute inflammatory response is seen in the epidermis, dermis, adipose tissue, and superficial fascia, to different degrees.

ETIOLOGY

The most common organisms causing classic cellulitis are *Streptococcus pyogenes* and *S. aureus*, with *Streptococcus pneumoniae*, other streptococci, and gram-negative bacilli encountered less frequently. Cellulitis due to gram-negative bacilli occurs primarily in immunosuppressed or granulocytopenic patients. A severe form of cellulitis may occur in individuals exposed to *Aeromonas hydrophila* in fresh water; the organism gains access through lacerations during swimming or wading. A severe and fulminant form of cellulitis that progresses rapidly to necrosis and bacteremia may be caused by *Vibrio* species, especially *Vibrio vulnificus*, acquired by exposure of a traumatic wound to salt water or raw seafood drippings.[7]

PRESENTATION

Classic cellulitis is characterized by erythema, pain, edema, and local tenderness involving an area of the skin with ill-defined borders. The area of initial cutaneous involvement expands rapidly. Occasionally there is lymphangitis and regional lymphadenopathy. Systemic manifestations include fever, malaise, and rigors. With untreated or rapidly progressive cellulitis, the process may spread to involve an entire extremity, producing severe systemic toxicity. Dehydration, mental apathy or obtundation, disseminated intravascular coagulopathy, respiratory failure, and septic shock may follow, necessitating intensive care management.

MANAGEMENT

Appropriate laboratory diagnostic studies should be performed before antimicrobial therapy is begun. Any skin abrasions or draining sites should be swabbed for immediate Gram stain and culture. The stain is examined for the presence of organisms, their morphologic appearance, and the number and types of cells. Needle aspiration after injection of 0.5 mL of nonbacteriostatic saline into the leading edge of the cellulitis may be attempted; potential pathogens have been

isolated in 10% to 38% of cases.[8,9] A combination of needle aspiration, skin biopsy, and blood cultures results in isolation of pathogens in approximately 25% of cases.[10]

For severe infections in which streptococci and staphylococci are considered possible, parenteral administration of a large-dose penicillinase-resistant penicillin (nafcillin or cloxacillin), 8 to 12 g/day in four or six divided doses, is most appropriate. Alternate agents include a first-generation cephalosporin, such as cefazolin (6 g/day in three divided doses), vancomycin (2 g/day in two divided doses), or clindamycin (1200 to 2400 mg/day in three divided doses). If the etiologic agent proves to be streptococcal, penicillin G should be substituted (6 to 12 million U/day). In the immunocompromised host or in the presence of a rapidly progressive cellulitis developing after a freshwater or saltwater injury, an aminoglycoside (gentamicin or tobramycin), 3 to 5 mg/kg in three or four divided doses or, alternatively, 5 to 7 mg/kg as a single daily dose, should also be administered.

Local care of cellulitis includes immobilization and elevation of the affected area. These measures are most appropriate when an extremity is affected. Analgesic drugs are administered as necessary. Cool compresses may help alleviate pain. The extent of the cellulitis should be outlined on the skin with an appropriate marker at the time of admission to facilitate objective daily assessments of the extent of spread. Frequent inspection of the involved area is necessary to detect any areas of crepitus or suppuration, which may require surgical drainage. Abscesses of the subcutaneous tissue are not infrequent after extensive cellulitis; judicious use of repeated needle aspiration may be necessary. Failure to achieve defervescence and a decrease in systemic toxicity within 48 to 72 hours after institution of appropriate antimicrobial therapy should arouse suspicion of suppuration or a more virulent soft tissue infection, such as necrotizing fasciitis or myonecrosis.

ANAEROBIC CELLULITIS

PATHOGENESIS

The term used for this type of cellulitis is not properly descriptive, but it persists because it is in common use. Other terms for this process include *gas abscess*, *gangrenous cellulitis*, *localized gas gangrene,* and *epifascial gangrene.* The process usually represents infection of already devitalized subcutaneous tissue without involvement of the deep fascia or underlying muscle. Microorganisms are introduced into the subcutaneous tissues from an operative or traumatic wound or from a pre-existing local infection. The subcutaneous tissues are devitalized owing to a local injury, an inadequately débrided wound, or a metabolic disturbance that compromises vascular supply (e.g., diabetes mellitus). Usually, the infectious process is not invasive but instead remains localized in the area of devitalized tissue.[11,12] Extensive gas formation and suppuration, usually limited to the area of devitalized tissue, are present.

ETIOLOGY

Anaerobic cellulitis may be clostridial or nonclostridial. *Clostridium perfringens* is the most commonly isolated clostridial species, followed by *Clostridium septicum.* Gram-negative rods, staphylococci, or streptococci are occasionally present but are not the predominant isolates. The nonclostridial form of anaerobic cellulitis is essentially the same process as clostridial cellulitis, but has a different microbiologic etiology. Obligate anaerobes are the predominant isolates, with *Bacteroides fragilis*, *Bacteroides* species, *Peptostreptococcus,* and *Peptococcus* encountered most frequently. Other bacteria that may be present include the gram-negative enteric bacilli (*Escherichia coli* and *Klebsiella*), staphylococci, and streptococci.

PRESENTATION

The clinical pictures of clostridial and nonclostridial anaerobic cellulitis are very similar and may be discussed together. Because this infection represents the local invasion of already devitalized tissue, the process does not generally have a virulent progressive course. The onset is gradual, with mild to moderate local pain and only mild to moderate tissue swelling. Constitutional symptoms are not prominent; the relative paucity of symptoms is helpful in distinguishing this entity from myonecrotic infections. A thin, dark, malodorous discharge from the wound or inoculation site, sometimes containing fat globules, with extensive and prominent gas formation, is characteristic. A dusky erythema may be present, and there may be extensive crepitus in the involved area. Although not initially invasive beyond the area of devitalized tissue, the condition must not be considered benign. If it is inadequately managed, the infection will eventually spread and lead to a rapid and extensive undermining of the skin similar to that seen in necrotizing fasciitis, with corresponding systemic toxicity.

A distinctive variant of gangrenous cellulitis was described and named by Meleney several decades ago.[4] It has been called *progressive bacterial synergistic gangrene, postoperative progressive gangrene*, *Meleney gangrene,* and—if associated with burrowing necrotic tracts producing distant lesions—*Meleney ulcer.* The process usually begins postoperatively, particularly after abdominal or thoracic procedures, with a slowly developing shaggy ulcer with a gangrenous center surrounded by an inner zone of purple discoloration, which in turn is surrounded by an outer zone of erythema. Without treatment, the course is one of relentless indolent extension, but without significant systemic toxicity. Satellite lesions may occur; they represent tracts of burrowing subcutaneous infection that surface to produce a gangrenous ulcer on the skin. Pathologically, the process is usually limited to the upper third of the subcutaneous fat, but occasionally it extends down to fascia. The lesion was originally thought to be caused by a synergistic interaction between microaerophilic streptococci and *S. aureus,* but recently other microorganisms, including *Proteus* species and other gram-negative enteric bacilli, have been implicated.

MANAGEMENT

Drainage from the wound or site of local injury should be sent for immediate Gram stain and culture. A simple method for obtaining anaerobic specimens for culture is to use a needle and syringe to aseptically aspirate the crepitant area at a site removed from the wound. All air should be carefully expressed from the syringe. If a swab is used, contact with normal flora should be avoided, and a commercial anaerobic transport medium should be used. Blood cultures should also be obtained. Radiologic examination should be performed to assess the presence and extent of soft tissue gas.

Initial antimicrobial selection is guided by the Gram stain of the purulent drainage. If only large "boxcar-shaped"

gram-positive bacilli are present, the causative microorganism is *Clostridium,* and moderate to large doses of parenteral penicillin G (10 to 20 million U/day in six to eight divided doses) are indicated. If multiple organisms of different morphologies are present on the Gram stain, then one may assume that the process is polymicrobial, and an empirical broad-spectrum antimicrobial regimen should be instituted. An aminoglycoside (gentamicin or tobramycin, 3 to 5 mg/kg per day in three divided doses or, alternatively, 5 to 7 mg/kg as a single daily dose) and clindamycin (1200 to 2400 mg/day in three or four divided doses), with or without penicillin G (10 to 20 million U/day in six to eight divided doses), would be appropriate. In patients with impaired or changing renal function, a third-generation cephalosporin, such as cefotaxime, ceftriaxone, or ceftazidime, can be used instead of an aminoglycoside. Alternatively, a carbapenem such as imipenem or meropenem may be used as a single agent.

The major conditions to be differentiated from anaerobic cellulitis are necrotizing fasciitis and the myonecrotic syndromes.[13] Distinguishing between clostridial myonecrosis and anaerobic cellulitis is necessary to avoid unnecessary extensive débridement. This distinction is made definitively at the time of surgery, which is mandatory to establish the diagnosis. The involved soft tissue must be laid open widely; devitalized tissue must be débrided; suppurative foci should be drained; and all involved fascial planes should be opened. The deep fascia and muscle must be carefully examined; if they are healthy, no further surgery is necessary. Further débridement may be necessary, depending on the amount of devitalized tissue present. The management of Meleney gangrene includes wide excision of the lesion plus antimicrobials as dictated by the culture results.

NECROTIZING FASCIITIS

PATHOGENESIS

Necrotizing fasciitis is an uncommon but severe infection involving the subcutaneous tissue and the deep fascia. It spreads rapidly in the fascial cleft but spares the overlying skin until the later stages. Extensive undermining of the skin is the hallmark of this infection. It affects persons of all ages but is most common in middle-age and elderly adults. However, with the resurgence of group A streptococcal infections, including soft tissue infections, the incidence of necrotizing fasciitis in previously healthy young adults has increased.[14,15] The infections may occur anywhere, but infections in the perineal region and in the extremities are most commonly reported.

The most common initiating injury leading to infection is minor trauma (~80% of reported cases); operative wounds and decubitus ulcers account for most remaining cases. The presentation is usually acute or subacute, ranging from 3 to 14 days after the injury. In some cases, particularly those associated with group A streptococcus, the onset is very sudden; the condition may progress dramatically from a tiny abrasion to septic shock, with massive subcutaneous necrosis, within 24 hours.[14,16] Many patients have underlying chronic illnesses,[17,18] with diabetes present in 20% to 50% of patients, severe arteriosclerosis in 20% to 33%, and cardiovascular or renal disease in 50%. Nutritional status is also an important consideration, with marked obesity or marked wasting noted in many cases. With infection due to group A streptococcus, more than 50% of patients have no underlying illness and were previously in good health.

After the initial bacterial invasion, the infection spreads rapidly along fascial planes and subcutaneous fat, with ischemic tissue facilitating spread of the necrotizing process. At an early stage, histologic examination of full-thickness skin biopsies shows no abnormality. However, the subcutaneous fat and fascia show a contiguous nonspecific inflammatory reaction, with fibrinoid arteriolitis and thrombosis of vessels, and subsequent necrosis. If the condition is left untreated, the overlying skin becomes extensively necrotic because of thrombotic occlusion of the venules and arterioles supplying it.

It has been shown that traumatic surgical and vascular injuries generate areas of relative tissue anoxia, with the result that carbohydrate and protein metabolism proceed anaerobically, generating lactic acid. Buffer systems become depleted and acidosis develops, which causes lysosomal disruption and, hence, local autolysis and destruction. This environment provides an ideal milieu for anaerobic growth. Whether actual infection evolves is determined by several factors, including the means of inoculation and the size of the inoculum, altered host defense mechanisms, and the virulence of the bacteria. Altered host defenses play an important role in propagation of the infection. For example, high blood alcohol levels, steroids in large doses, and metabolic acidosis inhibit adherence of phagocytes, and patients with cirrhosis and metastatic carcinoma have poor phagocyte chemotaxis. The virulence of the bacteria is determined, to some extent, by their capacity to produce various enzymes (hemolysins, fibrinolysin, hyaluronidase, and collagenase). In addition, for *S. pyogenes*, the presence of M protein on the surface of the organism has an anticomplement effect and may function as a superantigen, leading to a massive release of potent vasoactive mediators such as tumor necrosis factor, interleukin 1, and myocardial depressant factor. The streptococcal pyrogenic exotoxins A, B, and C or other unknown antigens may also function as super-antigens and have been found to share DNA sequence homology with staphylococcal toxic shock syndrome toxin. Functioning as super-antigens, these toxins share the ability to mediate nonspecific binding to antigen-presenting macrophages and T-helper cells, leading to polyclonal activation of large numbers of these lymphocytes. The cytokine release associated with this activation is responsible for the severe toxic shock–like syndrome associated with *S. pyogenes* infections. Synergistic activity of different bacterial species has also been postulated on the basis of evidence from clinical experience and from experimental infections in animals.[19] It is commonly assumed that aerobic organisms assist the growth of anaerobes by using oxygen, diminishing redox potential, and supplying catalase. Local ischemia and reduced host defense mechanisms in the presence of virulent pathogens combine to produce a milieu that is responsible for the alarmingly rapid spread (Fig. 55-2).

ETIOLOGY

Necrotizing fasciitis may be due to a synergistic polymicrobial bacterial infection in which at least one anaerobic organism (usually a *Bacteroides*, *Peptostreptococcus,* or *Peptococcus* species) is isolated in combination with one or more facultative organisms (usually streptococci, *E. coli*, *Klebsiella*

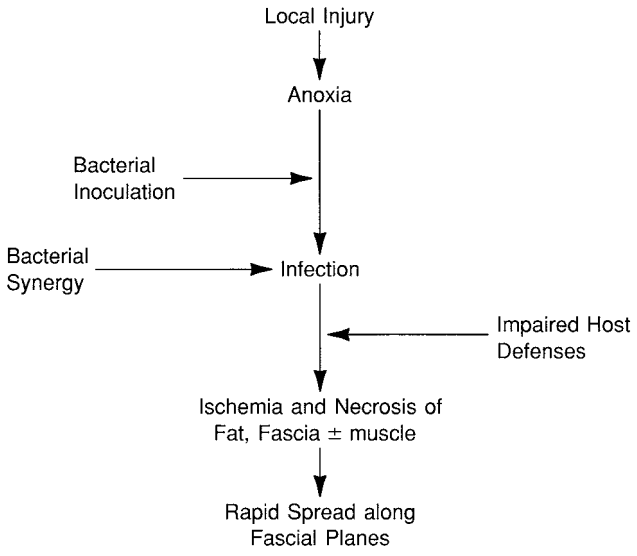

FIGURE 55-2 The pathogenic process in necrotizing fasciitis.

or *Proteus* species, or *S. aureus*),[20] or it may be due to a single organism, usually *S. pyogenes.* In most cases of polymicrobial origin, multiple organisms are present, with an average of three or four isolates per patient. Some investigators distinguish acute group A streptococcal necrotizing fasciitis as a separate entity. *Vibrio vulnificus* and *Aeromonas hydrophila* have also been reported to cause a particularly virulent form of necrotizing fasciitis.

PRESENTATION

With necrotizing fasciitis, there is often a trivial injury followed, after several hours or days, by the onset of pain and swelling accompanied by chills and fever. The pain is progressive, relentless, and severe and is often out of proportion to the severity of the physical findings. There may be considerable pale erythema in the involved area; brown-to-bluish skin discoloration is not uncommon later in the course of the illness (Fig. 55-3 and Color Plate 55-3). If the condition is left to progress, frank cutaneous gangrene may be seen. Pain is gradually replaced by numbness or analgesia as a result of compression and destruction of cutaneous nerves. Hypesthesia of the affected area may be a useful sign of the extensive undermining that occurs. Edema is present in most patients. Crepitation is not usual, but it may be found in patients seen later in the course of the illness. Fluid-filled vesicles may appear in the area of erythema, often quickly followed by frank cutaneous gangrene. If an exudate is present, it may be serosanguineous and foul smelling. Systemic toxicity with disorientation is often severe. Large extracellular fluid shifts, hypotension, shock, and jaundice may follow. When these findings are present in the setting of infection due to group A streptococci, the term *streptococcal toxic shock syndrome* is used.

FIGURE 55-3 Necrotizing fasciitis of the lower leg. Dusky erythema is present, with blistering and small patches of dermal gangrene. See Color Plate 55-3.

FIGURE 55-4 Postoperative appearance of the lower leg presented in Fig. 55-3 (see Color Plate 55-4). All necrotic subcutaneous tissue was excised.

A significant manifestation of necrotizing fasciitis is extensive undermining of the skin (Fig. 55-4 and Color Plate 55-4) associated with necrosis of subcutaneous fat and deep fascia.[21] The undermining can be demonstrated by passing a sterile instrument along the plane just superficial to the deep fascia (Fig. 55-5); the instrument cannot be passed with ordinary cellulitis.

MANAGEMENT

Before antimicrobial therapy is started, samples for immediate Gram stain and for aerobic and anaerobic cultures should be obtained by direct needle aspiration of the involved area. Probing the lesion through an existing drainage site or through a small skin incision will reveal the characteristic undermining of skin seen in necrotizing fasciitis. The use of full-thickness skin biopsy with frozen section may aid the diagnosis.[22]

The principles of management include general supportive measures, administration of antimicrobial agents, and definitive surgery. General measures include the placement of central venous and arterial monitoring catheters, administration of intravenous fluids to correct dehydration, maintenance of adequate oxygenation, treatment of any underlying diseases (e.g., correction of ketoacidosis or congestive heart failure), and attention to the patient's nutritional needs. Total parenteral or enteral nutrition is required in the postoperative state to meet the dramatically increased nitrogen requirements associated with tissue repair, hyperthermia, sepsis, and vital organ requirements. Antibiotic selection should be guided by the initial Gram stain. In the absence of specific microbiologic data, broad-spectrum coverage should be given, including coverage for anaerobes, especially *B. fragilis.*

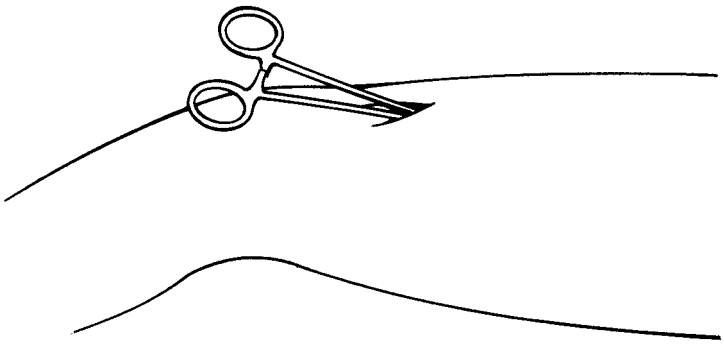

FIGURE 55-5 Necrotizing fasciitis with unopposed passage of a blunt instrument along the fascial cleft, indicating the characteristic undermining between the subcutaneous tissue and deep fascia.

An aminoglycoside (gentamicin or tobramycin), 3 to 5 mg/kg per day in three divided doses or, alternatively, 5 to 7 mg/kg as a single daily dose, plus clindamycin, 1200 to 2400 mg/day in three or four divided doses, is adequate initial therapy. If large gram-positive rods are noted, suggesting clostridia, or if group A streptococcus is suspected, penicillin G should be added (20 to 24 million U/day in divided doses). The combination of clindamycin and penicillin is considered the treatment of choice for severe soft tissue infection due to group A streptococcus. The addition of intravenous immunoglobulins, 0.4 g/kg per day for 4 to 5 days or 2 g/kg as a single dose with a repeat dose in 48 hours if the patient remains unstable, may be a useful adjunct for streptococcal toxic shock syndrome.[23–25] In penicillin-allergic patients, chloramphenicol or metronidazole is useful as an alternative anaerobic agent. In patients whose renal function is impaired or rapidly changing owing to underlying disease or acute tubular necrosis, a third-generation cephalosporin, such as cefotaxime, ceftriaxone, or ceftazidime, can be used in place of the aminoglycoside. Alternatively, a carbapenem such as imipenem or meropenem may be used as a single agent.[26]

The mainstay of management is surgical exploration, débridement, and drainage, which should be done as soon as possible. Débridement and excision of all necrotic subcutaneous adipose tissue and fascia are required. The wound should be packed open. Daily exploration under general anesthesia is indicated for truncal or perirectal infections and for all patients who remain in a toxic condition. Frequent dressing changes are performed after suitable analgesia and are continued until healthy granulation tissue appears. Careful and regular reinspection of the wound is necessary because initial débridement is seldom complete, and small foci of infection and necrotic tissue often lead to further progression. It must be emphasized that *conservative surgery leads to relapse of the process.* In the pelvic and upper thigh regions, a hip disarticulation or hemipelvectomy may be required.

Mortality rate is extremely variable, ranging from 4% to 74%. High scores on the Acute Physiology and Chronic Health Evaluation on admission, age older than 50 years, diabetes, truncal disease, and failure to achieve adequate initial débridement are associated with high mortality rates.[27]

MYONECROSIS

PATHOGENESIS

The bacterial myonecrotic syndromes involve bacterial invasion of previously undamaged healthy muscle, resulting in its rapid destruction. The process often referred to as *gas gangrene* is a fulminant, life-threatening infection for which early diagnosis and intervention are essential. Bacterial myonecrotic syndromes may be of clostridial or nonclostridial origin. Both entities have a similar pathogenesis, clinical presentation, and management.[21] Clostridial myonecrosis occurs in the setting of muscle injury and concurrent inoculation with clostridial spores from the soil or a foreign body. Although most commonly encountered in penetrating war wounds, it is seen now in the following settings: (a) trauma, especially motor vehicle or agricultural accidents involving open fractures; (b) the postoperative period, especially after bowel or biliary surgery; (c) malignancy, especially colorectal tumors; (d) arterial insufficiency in an extremity; (e) septic abortion; (f) occasionally, burn wounds; and (g) rarely, after intravascular or intramuscular injections. Although colonization of a traumatic wound by clostridia is common, the frequency of clostridial myonecrosis is only about 1%. In an animal model, the minimal dose of *C. perfringens* required to produce a fatal infection is reduced by a factor of 10^6 when the organism is injected into devitalized, as opposed to normal, muscle. Clinically, however, clostridial myonecrosis does occasionally occur even in the absence of devitalized muscle. Once the clostridia begin to proliferate, several potent exotoxins are produced that have the capacity to destroy host tissue. At least 17 toxins are produced by *C. perfringens,* including α toxin, a phospholipase that disrupts cell membranes and results in hemolysis, platelet destruction, widespread capillary damage, and myofibril destruction. The μ toxin, a hyaluronidase, facilitates tissue spread and is thought to be responsible for the massive edema associated with this condition. As the process spreads, the involved muscle undergoes rapid destruction. Early pallor, edema, and loss of elasticity give way to a discolored, noncontractile muscle, which eventually becomes friable and disintegrates. The histologic findings are of coagulation necrosis.

Myonecrosis due to organisms other than clostridia has a pathogenesis not unlike that of necrotizing fasciitis. The infection may be introduced through a break in the skin, through intravenous injection of illicit drugs,[28] a surgical wound or enterostomy, a decubitus ulcer, or a fistula. Predisposing factors include diabetes mellitus, obesity, advanced age, renal disease, and local trauma; diabetes mellitus is reported most commonly. With myonecrosis due to group A streptococci, no predisposing factors may be present. In drug addicts, infections of the extremities are more common, whereas perineal and buttock infections are more common in other populations.

When multiple microorganisms are responsible for myonecrosis, the facultative bacteria assist the growth of anaerobes by using available oxygen and destroying tissue

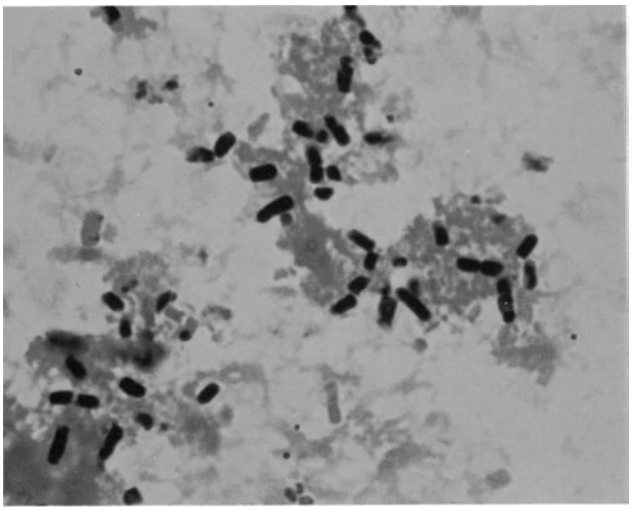

FIGURE 55-6 Gram stain of *Clostridium perfringens*. See Color Plate 55-6.

(reducing the redox potential), which promotes a favorable milieu for the proliferation of anaerobic organisms. The process often involves muscle and fascia extensively, and it may secondarily involve areas of subcutaneous tissue and skin. It should be noted that necrotizing fasciitis will ultimately involve muscle, if left to progress.

ETIOLOGY

Clostridium perfringens is the most common cause of clostridial myonecrosis, producing 80% to 95% of cases (Fig. 55-6 and Color Plate 55-6). *Clostridium novyi* and *Clostridium septicum* are responsible for 5% to 20%, with other species implicated rarely. Nonclostridial myonecrosis is usually polymicrobial, although group A streptococcus may be a single causative agent. Most commonly, a mixture of facultative bacteria (*E. coli*, *Klebsiella* species, *Enterobacter* species, *Proteus* species, and *S. aureus*) and anaerobic bacteria (*Bacteroides* species, *Peptostreptococcus* species, and *Peptococcus* species) is found, an etiology similar to that seen in necrotizing fasciitis. *Aeromonas hydrophila* has also been described as causing severe myonecrosis after penetrating muscle injury in a freshwater environment.

PRESENTATION

The incubation period of clostridial myonecrosis, from time of injury to appearance of symptoms, is usually 2 to 3 days, but it may be as brief as 6 hours. Intense pain, out of proportion to the extent of injury, is characteristic. The pain rapidly progresses in intensity and distribution. Fever is not present until later in the course. Within hours there appear signs of severe systemic toxicity: mental confusion, irritability, marked tachycardia, tachypnea, sweating, pallor, and hypotension. Delirium and stupor may supervene, although a period of intense mental alertness may occur before the onset of delirium. Renal failure, progressive hypotension and septic shock, intravascular hemolysis, and disseminated intravascular coagulopathy may ensue. Bacteremia occurs in only 10% to 15% of cases. Profound metabolic acidosis is common and can overwhelm compensatory hyperventilation, causing respiratory failure. Examination of the wound may initially show only tense edema and mild erythema. Later a spreading zone of woody edema appears, in addition to a characteristic bronzing of the skin. A thin, watery, brownish discharge with a sickly sweet odor may be present. Gas bubbles may be present in the discharge. Crepitus is usually present but is not a prominent feature. Tense blebs containing a thin serosanguineous fluid develop in the overlying skin, and areas of cutaneous necrosis appear in later stages. If an open wound is present, edematous muscle may herniate through the wound to the skin surface.

In nonclostridial myonecrosis, the process has its onset over several days. The port of entry is usually evident in the vicinity of the area of involvement. Moderate to severe pain and erythema, rather than edema, are more prominent. Progression is rapid, and systemic toxicity is severe; it may progress to shock and multisystem organ failure. Local crepitus may be present, as may a "dirty dishwater" discharge. Progression of the infection is rapid and may involve fascia and subcutaneous tissues. With infection due to group A streptococci, it is not uncommon to find myofasciitis and a toxic shock syndrome.

MANAGEMENT

Early diagnosis is critical; its importance cannot be overemphasized. Confusion about the types of gas gangrene, failure to recognize that the infection does not have the usual signs of pyogenic inflammation, and failure to recognize that clostridial infections can develop without a history of recent trauma can create diagnostic difficulties. The major considerations are other gas-forming infections of the soft tissues, including anaerobic cellulitis and necrotizing fasciitis. The severe toxemia, limited crepitus, tense edema, and characteristic bronzing of the skin are suggestive, but not definitive, evidence of clostridial myonecrosis. Similarly, areas of cutaneous necrosis in a severely toxic patient with a "dirty dishwater" discharge suggest a nonclostridial myonecrosis. Adjunctive diagnostic tools include Gram stain and radiography. A Gram stain of the discharge or of soft tissue aspirate in clostridial myonecrosis reveals large, gram-positive bacilli with blunt ends, but few or no pus cells (which are destroyed by the clostridial lecithinase). A mixed flora or gram-positive cocci (streptococci) may be seen with nonclostridial myonecrosis. Precautions should be taken to ensure that anaerobic specimens are collected appropriately and transported promptly to the laboratory. A radiograph of the involved area may visualize gas that is not palpable and will give an indication of the distribution of such gas.

The principles of management include general supportive measures, antimicrobials, and surgery. Surgical exploration is definitive and is mandatory for the mere suspicion of clostridial or nonclostridial myonecrosis. Urgent surgical intervention is the ultimate diagnostic and therapeutic maneuver, and its importance cannot be overemphasized. Bacterial myonecrosis is characterized by a darkened, "cooked" appearance of the muscle, which does not contract on stimulation and bleeds very little on incision. Excision of involved muscles—or amputation, if necessary—and decompressive fasciotomies are the mainstays of surgical treatment. Any necrotic fascia or subcutaneous tissue should be débrided. General supportive therapy includes insertion of appropriate monitoring lines, administration of isotonic crystalloid to maintain blood pressure, maintenance of adequate oxygenation, correction of severe acidosis, and maintenance of

electrolyte balance. Blood should be given sparingly during the acute stages if evidence of extensive hemolysis is present. Nutritional support is necessary in these critically ill patients, especially in the postoperative period.

For clostridial myonecrosis, the antimicrobial treatment of choice is large-dose penicillin G, 20 to 24 million U/day in six to eight divided doses. The dose must be reduced appropriately if a significant degree of renal failure is present. Chloramphenicol, 1 to 2 g/day in four divided doses, or metronidazole, 1 to 2 g/day in two to four divided doses, is a good alternative in the penicillin-allergic patient. If a mixed flora is found on Gram stain, the antimicrobial regimen should include an aminoglycoside (gentamicin or tobramycin), 3 to 5 mg/kg per day in three divided doses, or 5 to 7 mg/kg per day as a single daily dose, plus clindamycin, 1200 to 2400 mg/day in three to four divided doses. If clostridia are present on Gram stain, then penicillin should also be added to the regimen because some clostridia are resistant to clindamycin.[29] If streptococcal myonecrosis or myofasciitis is suspected, the use of clindamycin plus penicillin is recommended. In addition, the use of intravenous immunoglobulin, as discussed in the previous section, may be a useful adjunct. A third-generation cephalosporin, such as cefotaxime, ceftriaxone, or ceftazidime, may be used in place of the aminoglycoside. A carbapenem such as imipenem or meropenem is a useful alternative as a single agent in nonclostridial myonecrosis.

Hyperbaric oxygen has been advocated as an adjunctive measure in patients with clostridial myonecrosis, but its role is controversial.[30] Controlled trials have not been done and are unlikely to be done because of the limited number of cases that might be seen at a given institution and ethical considerations in the randomization of critically ill patients. Evidence supporting the use of hyperbaric oxygen comes from animal experiments, case reports, and uncontrolled small series. Its role at present appears to be in the management of selected patients with extensive involvement in whom extensive surgical débridement would be so mutilating as to threaten life or limb.

Chapter 56

URINARY TRACT INFECTIONS

GERARD J. SHEEHAN
BUSI MOOKA

KEY POINTS

- *All patients with severe urosepsis requiring admission to the intensive care unit should have immediate imaging of the urinary tract preferably by computed tomography with contrast because suppurative complications are common and require drainage as a priority.*
- *Percutaneous drainage can be used to drain definitively or stabilize temporarily a patient with suppurative complications.*
- *Empiric antimicrobial therapy for acute complicated urosepsis should include two agents with activity against gram-negative bacilli, such as a combination of ciprofloxacin or piperacillin/tazobactam with an aminoglycoside, until the pathogen is isolated and antimicrobial sensitivities are known.*
- *Urinary catheters are associated with a high incidence, 1% to 5% per day, of bacteriuria. Patients are also predisposed to candiduria, especially those receiving broad-spectrum antibacterial therapy.*
- *Asymptomatic bacteriuria should be treated in all patients before instrumentation of the urinary tract to avoid the development of gram-negative bacteremia.*
- *The continued usefulness of a urinary catheter needs to be reassessed on a regular basis, and removal in selected awake stable patients needs to be considered.*
- *Treatment of bacteriuria without local signs of infection should be considered only in patients with fever or sepsis after exclusion of other potential causes of infection.*

At the beginning of the 21st century, urinary tract infection (UTI) remains one of the commonest nosocomial infections, giving rise to prolonged hospitalization and additional cost. Eighty percent of nosocomial UTIs follow urinary catheterization, bacteremia arises in 1% to 3% of these, and the attributed mortality rate is then 13%.[1] Community-acquired pyelonephritis occasionally causes sepsis syndrome, especially when it arises in an obstructed urinary tract or when the host defense is compromised by poorly controlled diabetes. Urinary tract infection is thus an important initiating event for admission to the intensive care unit (ICU). Because of the almost universal insertion of urinary catheters in critically ill patients, UTI is a common sequel of intensive care and ranks in the top four of ICU-acquired infections. Bacteriuria, acquired through urinary catheterization in the ICU, constitutes a reservoir of resistant pathogens, which occasionally gives rise to epidemic spread of infection within the hospital.

Bacteriuria simply means the presence of bacteria in the urine. Significant bacteriuria implies the presence of at least 10^5 organisms per milliliter by a quantitative method. However, a count of at least 10^2 aerobic gram-negative organisms per milliliter from a woman with pyuria and symptoms of lower UTI represents true infection.[2] Low-level bacteriuria (or candiduria) of any quantity in a hospitalized, catheterized patient rapidly advances to significant bacteriuria, provided the patient is not receiving antimicrobial agents to which the organism is susceptible.[3,4] Thus, any level of bacteriuria in a catheterized ICU patient is worthy of consideration as a cause of sepsis.

Pyuria, the presence of white blood cells in urine, is commonly measured by counting the number of cells per microscopic high-power field in a centrifuged urine specimen. Using the criterion of five cells per microscopic high-powered field, pyuria, when present, is a reliable indicator of UTI, especially when cells greatly exceed this number. However, the sensitivity is not high, and the absence of such pyuria does not reliably exclude UTI. When measured with a counting chamber, using a criterion of more than 10 cells per microliter, a sensitivity of 96% is achieved for symptomatic UTIs.[5]

Acute Pyelonephritis

MICROBIOLOGY

Most (80% to 90%) of community-acquired UTIs in females are caused by *Escherichia coli*.[6] *Staphylococcus saprophyticus* is the second most common pathogen but rarely gives rise to sepsis and ICU admission. It remains fully susceptible to most antimicrobial agents used for UTI, including ampicillin and trimethoprim-sulfamethoxazole. Other Enterobacteriaceae (e.g., *Proteus* species, *Klebsiella* species, and *Enterobacter* species), *Enterococcus* species, and *Pseudomonas aeruginosa* account for only a small residual minority. In men *Escherichia coli* is also the commonest community-acquired urinary pathogen, but *Enterococcus* species and other Enterobacteriaceae are more commonly encountered.

For men and women, the spectrum of pathogens changes when UTI is acquired in the hospital environment. *Escherichia coli* (47%), *Enterococcus* species (13%), *Klebsiella* (11%), *Pseudomonas aeruginosa* (8%), *Proteus mirabilis* (5%), *Enterobacter* species (4%), and *Citrobacter* species (3%) together account for 91% of hospital-acquired bacterial UTIs, in a rank order that is consistent internationally.[7] In the ICU the spectrum shifts, with *Enterococcus* species (24%) and *Candida albicans* (21%) dominating and *E. coli* accounting for only 15%.[8] This predominance of more resistant species reflects the more widespread use of broad-spectrum antimicrobial agents and the nearly universal use of urinary catheters in ICUs.

Enterococcus species are an increasing concern as a cause of nosocomial UTI and bacteremia in the ICU. A Spanish prospective multicenter observational study of 21,979 ICU admissions between 1997 and 2001 found that 223 patients had 239 infections involving *Enterococcus* species, 14.3% of which were UTIs.[9] In ICUs the proportion of enterococci resistant to vancomycin is increasing but varies geographically. These isolates may also exhibit resistance to ampicillin and high-level aminoglycoside.[10] A retrospective study in one tertiary care center found a rate of vancomycin-resistant enterococci (VRE) bacteriuria of 23 per 10,000 admissions. Of 107 positive cultures, there were 13 symptomatic UTIs, two associated with bacteremia and one associated with death.[11] Most are *Enterococcus faecium* and are sensitive to linezolid, nitrofurantoin, and chloramphenicol.[12] Infection with VRE usually occurs in patients with significantly compromised host

defenses and serious comorbidities, and this magnifies the importance of early effective antimicrobial treatment.[13]

VRE may serve as a reservoir of resistant genes for *Staphylococcus aureus*. Transfer of the VanA gene has occurred clinically, giving rise to vancomycin-resistant *S. aureus* invasive infection.[14] Isolation of *S. aureus* in a urine culture is uncommon and should always raise the possibility of seeding of the urinary tract through the bloodstream. Such patients should be reviewed for evidence of vascular cannula infections ("line sepsis"), endocarditis, osteomyelitis, and pneumonia. Multiple or single cortical renal abscesses (renal carbuncle) may be present.

Persistent or relapsing bacteriuria caused by *Proteus mirabilis* should prompt a search for a staghorn calculus. Chronic bacteriuria due to *Corynebacterium urealyticum* may be also associated with alkaline urine and renal stones. This organism is fastidious and commonly resistant to most antimicrobial agents other than vancomycin.[15]

Infection with less common nosocomial urinary pathogens may arise, sometimes in outbreaks, depending on local antimicrobial usage patterns. These include *K. pneumoniae* and *E. coli* with extended-spectrum β-lactamase resistant to cephalosporins and most other antimicrobial classes other than carbapenems[16] and *Stenotrophomonas (Xanthomonas) maltophilia,* resistant to carbapenems, cephalosporins, and aminoglycosides.[17] UTI secondary to Shiga toxin-producing *E. coli* has rarely presented with hemolytic-uremic syndrome in children and adults, sometimes accompanied by bacteremia.[18]

PATHOGENESIS

Women with recurrent UTIs often have vaginal and periurethral cells to which *E. coli* adhere more readily as compared to controls. Most *E. coli* implicated in UTIs have several virulence factors, which include diverse adhesins, siderophores, toxins, polysaccharide coatings, and other properties that assist the bacteria in avoiding or subverting host defenses, injuring or invading host cells and tissues, and stimulating a noxious inflammatory response. Thus, certain strains are "selected out" of the fecal floral that are capable of causing UTI (uropathogenic *E. coli*).[19] These various factors allow adhesion to periurethral cells, multiplication in the bladder, ascent of the ureters, and invasion of renal tissue in patients with anatomically normal urinary tracts. In contrast, those *E. coli* causing UTIs in patients with reflux nephropathy or obstruction are not specifically uropathogenic.[19]

Tamm-Horsfall protein, secreted by the loop of Henle, contains mannose residues that bind to type 1 fimbriae on *E. coli* and aggregate the organism preventing uroepithelial attachment and ascent against the urinary flow.[20] Voiding of the bladder is another important host defense mechanism. Vesicoureteric reflux frustrates this defense and allows establishment of upper UTI. The medulla and papillae of the kidney are prone to infection because of hyperosmolality and low blood flow. During pyelonephritis, an acute inflammatory exudate develops that limits infection but contributes to scarring.[19]

DIAGNOSIS

Acute pyelonephritis is a syndrome of fever with evidence of renal inflammation, such as costovertebral angle tenderness or flank pain. There are often signs of systemic toxicity and sometimes bacteremia. However, silent pyelonephritis is present in up to 33% of patients with clinical cystitis in primary care settings and may be latent for long periods. Patients with spinal cord injury are especially prone to silent, complicated, life-threatening pyelonephritis associated with urinary obstruction due to calculi and often will have fever with nonspecific abdominal discomfort, increased spasms, and autonomic dysreflexia.

Patients requiring ICU admission sometimes will have been admitted to the ward with a classic history of acute pyelonephritis. Subsequent deterioration should prompt a search for a urinary tract obstruction, such as calculus or renal papillary necrosis, or for a suppurative focus in or around the kidney (intrarenal or perinephric abscess, see below). Alternatively, such deterioration may arise if the urinary pathogen is resistant to the chosen empiric antimicrobial regimen. Features that suggest obstruction include classic renal colic, severe costovertebral angle tenderness, or a palpable kidney due to hydronephrosis.

At presentation, Gram stain of a drop of unspun urine can provide rapid, specific information. It may show gram-negative bacilli, gram-positive cocci in clumps, gram-positive cocci in chains, large gram-positive yeasts, or, much less often, a polymicrobial pattern. The stain can be valuable for distinguishing the less common etiologies (*S. aureus*, *Enterococcus* species, *Candida* species, and polymicrobial anaerobic) from the aerobic gram-negative bacilli that comprise the vast majority of pathogens.

A urine culture should always be obtained before therapy, if necessary, urinary catheterization. The culture identifies the infecting organism unless the patient has received prior antimicrobial agents or has complete obstruction or a perinephric abscess. Blood cultures also should be obtained because patients may have concomitant bacteremia. Renal function should be assessed, although acute renal failure caused directly by pyelonephritis is rare.[21] If present, it is usually due to acute tubular necrosis due to sepsis or to drug toxicity.

ANTIMICROBIAL THERAPY

A wide variety of regimens has been shown to be effective as empiric therapy of acute pyelonephritis. These include an aminoglycoside combined with ampicillin, trimethoprim-sulfamethoxazole alone, third-generation cephalosporins, extended-spectrum penicillins combined with β-lactam inhibitors, carbapenems, monobactams, and quinolones. All of these are excreted through the kidneys, with the exception of moxifloxacin and gemifloxacin. The choice of the initial antimicrobial regimen for a patient with severe urosepsis hinges primarily on the absolute necessity of covering the pathogen while awaiting definitive culture and sensitivity data at 24 to 48 hours. This has become increasingly difficult with the evolution of resistance to most antimicrobial classes. An initial combination of two agents effective against aerobic gram-negative bacilli is therefore appropriate in a septic patient with UTI, with consideration given to anti-enterococcal activity and to the risk of toxicity. The prevalence of resistance to a given agent will vary geographically and evolve with time. Such rates are invariably higher for nosocomial isolates and in patients with a prior history of antimicrobial exposure. In patients with a higher risk of aminoglycoside toxicity, such as those with prior renal impairment, liver dysfunction, advanced age, shock, or oliguria, consideration should be given

to a non-aminoglycoside regimen or to a limitation to a single dose to cover the first 24 hours.

Historically, a combination of an aminoglycoside and ampicillin provided cost-effective, empiric coverage against most aerobic gram-negative bacilli and enterococci. However, in many geographic locations, greater than 50% of *E. coli* and most other Enterobacteriaceae are now ampicillin resistant. The addition of a β-lactamase inhibitor, such as clavulanic acid or sulbactam, eliminates the resistance in many cases. Similarly, resistance rates in uropathogens to trimethoprim-sulfamethoxazole are growing, with an excess of 20% of isolates resistant in many areas in North America and even higher rates in Latin America and Europe.[7] A combination of a quinolone with an aminoglycoside offers initial double coverage against aerobic gram-negative bacilli but will not reliably cover enterococci because an increasing proportion has become quinolone resistant. Alternatively, piperacillin-tazobactam or ticarcillin-clavulanic acid will cover most aerobic-gram negative bacilli and enterococcal species. An aminoglycoside also can be added for double coverage until sensitivity data emerge. A third-generation cephalosporin will be active against most gram-negative bacilli but will have no activity against enterococci.

Once the organism is isolated and identified, then the antimicrobial regimen should be promptly adjusted to a single agent with the least toxicity and cost. Once fever has resolved and the patient can tolerate oral agents, an oral regimen can be started. Acute pyelonephritis requires 10 to 14 days of antimicrobial therapy. Cell wall synthesis inhibitors, such as the β-lactams, may have a higher relapse rate after completion of therapy. The hypertonic renal medulla may allow residual bacteria to survive as L forms (cell wall–deficient protoplasts).[22,23] Trimethoprim alone, trimethoprim-sulfamethoxazole, or a quinolone is preferred as oral therapy.

The optimal treatment for VRE is not known and should be chosen in consultation with an infectious diseases physician. Case reports of success and failure of treatment of difficult infections due to VRE have been published, in addition to noncomparative series with large numbers of patients. Treatment options include chloramphenicol (which may not be suitable for UTI because it is not excreted in the urine), tetracycline, high-dose ampicillin or ampicillin-sulbactam, and nitrofurantoin (for lower UTI). Newer agents (linezolid and quinupristin-dalfopristin) have been approved, and additional agents are likely to emerge in the next few years.[10]

IMAGING

Contrast-enhanced computed tomography (CT) is currently the initial study of choice for most patients with urosepsis. For patients in whom renal calculi may be present, the study should also include noncontrast images through the kidneys. CT scanning more accurately defines the anatomy of the renal parenchyma than ultrasound and gives a clear cross-sectional view of the surrounding anatomy. Helical scanning technology has greatly increased the quality and usefulness of the information CT provides. CT scan can more readily distinguish complications of upper UTI such as cortical abscess, acute focal bacterial nephritis (AFBN), and perinephric abscess. Accurate placement of percutaneous drains into suppurative collections may require CT scanning to delineate all structures precisely.[24,25]

Ultrasound can be technically inadequate because of obesity, overlying bowel gas, subcutaneous emphysema, wounds, or dressings. Although it has the advantage of being portable, the results depend on the skill and persistence of the operator. It will reliably diagnose most causes of obstruction and perinephric collections. Ultrasound may be chosen as the initial investigation for patients with severe urosepsis, when transport out of the ICU is hazardous or there are significant concerns about the risk of contrast induced nephrotoxicity. Intravenous urography currently has little or no role because helical CT scan is superior at demonstrating the collecting system and early papillary necrosis at a reversible phase and other lesions, such as tuberculosis and renal scarring due to childhood reflux nephropathy.[26]

Retrograde urography in conjunction with cystoscopy may be useful at demonstrating the anatomy of the collecting system in a nonexcreting kidney. Different adverse effects rarely result from the passage of the ureteral catheters or stents, including hemorrhage, perforation, or septicemia. However, this procedure may permit relief of obstruction by passage of a stent or manipulation of a calculus.

Acute Focal Bacterial Nephritis

Human kidneys consist of five to 11 lobes (usually eight), each of which contains a conical medullary pyramid whose apex converges into a renal papilla projecting into a calyx. Each pyramid is capped by cortical tissue to form a renal lobe and is separated from other lobes by a renal column containing the interlobar arteries and veins.[27] With the advent of CT scanning, there has been increasing recognition of AFBN.[28] This is analogous to lobar pneumonia because the abnormalities are limited to one or more renal lobes. Patients manifest the usual features of acute pyelonephritis but do not respond with defervescence within 48 hours, thereby prompting investigation for obstruction or suppurative focus. Ultrasound may be normal or may visualize a solid, hypoechoic, poorly defined mass without evidence of liquefaction. Noncontrast CT scanning is frequently normal, but with intravenous contrast enhancement, the nephrogram invariably shows one or more wedge-shaped areas of decreased density. Such lesions may be demonstrated in a significant proportion of patients with acute pyelonephritis. The differential diagnosis of AFBN includes neoplasm, evolving renal infarct, and abscess. Demonstration of enhancing tissue within the mass on delayed CT images excludes cancer and abscess. AFBN usually resolves with antimicrobial therapy, but scarring and atrophy may result. Histopathology shows intense polymorphonuclear leukocyte infiltration without liquefaction, so needle aspiration or percutaneous drainage is not indicated. *Escherichia coli* is the most common organism isolated from patients with AFBN.[28,29]

RENAL ABSCESS

AFBN may progress to suppuration, especially when associated with obstruction. The abscess may drain spontaneously into the calyxes or may rupture through the renal capsule to form a perinephric abscess. The usual pathogens are Enterobacteriaceae (*E. coli*, *K. pneumoniae*, and *Proteus* species). These organisms, which arise by the ascending route, are now commoner than cortical abscess arising from hematogenous spread. The latter was the commonest form of renal

suppurative infection before the antibiotic era and usually resulted from *S. aureus*. Patients at high risk for staphylococcal septicemia, such as intravenous drug users, may present with renal cortical abscess, with or without other features of invasive staphylococcal infection, such as right-side endocarditis or multiple lung abscesses.

The clinical features of either form of renal abscess can be initially subtle. The patient often has chills, fever, and back or abdominal pain. Costovertebral angle tenderness, a flank mass, or involuntary guarding of the upper lumbar and paraspinal muscles may suggest the diagnosis. Prominent abdominal features such as nausea, vomiting, and abdominal guarding may suggest another intra-abdominal cause.

Ultrasound usually demonstrates an ovoid mass of decreased attenuation within the parenchyma. This may initially mimic AFBN, a cyst, or a tumor. Dependent echoes changing with position represent shifting debris within the abscess cavity. Gas within the abscess can be present. Definitive characterization of fluid within the mass is done by demonstration of enhanced transmission of the beam through the mass and refraction of the beam at the fluid–solid interface. The presence of debris within a cyst or an abscess is a strong indication of infection. CT shows a distinctly marginated low-attenuation (0 to 20 Hounsfield units) mass that fails to enhance. Sharp demarcation is demonstrated between the mass and the surrounding normally enhancing renal tissue. There may be a surrounding rim of increased enhancement (the ring sign). CT is more sensitive than ultrasound for small lesions (<2 cm in diameter) and for gas. Because hemorrhage within a cyst or necrotic debris within a tumor occasionally can mimic an abscess, confirmation by aspiration or nuclear medicine scanning is desirable. Alternatively, serial scanning until resolution while the patient is receiving antimicrobial therapy may suffice.

The classic therapy of intrarenal abscess is incision and drainage with a nephrectomy, if necessary, for larger abscesses. It is now clear that a trial of intravenous antimicrobial therapy will succeed in most patients once microbial etiology is established by urine, blood, or aspirate culture. Close monitoring of the response, including disappearance of fever and leukocytosis and diminution of size as assessed by ultrasound or CT, is necessary. Percutaneous drainage using ultrasound or CT guidance is another alternative to surgery and should be tried as initial therapy when the abscess cavity is large.[30]

EMPHYSEMATOUS PYELONEPHRITIS

Emphysematous pyelonephritis is a fulminant disorder, historically associated with a mortality rate of 80%. The patient typically presents acutely with features of pyelonephritis and severe sepsis with or without multiorgan failure. Gas formation occurs in the renal parenchyma and surrounding tissues due to mixed acid fermentation of glucose by Enterobacteriaceae, which forms hydrogen and carbon dioxide. Most patients have uncontrolled diabetes mellitus and some have obstruction of the urinary tract. *Escherichia coli* accounts for the majority of pathogens, with most of the rest being due to *Klebsiella* species.[31] Strict anaerobes have not been reported, but optimal anaerobic isolation techniques may not have been applied in all studies. Pathology demonstrates extensive necrotizing pyelonephritis with abscess formation and papillary necrosis. Poor perfusion is present in most cases due to infarction, vascular thrombosis, arteriosclerosis, and/or glomerulosclerosis.[31]

Plain radiographs may show diffuse mottling of the parenchyma as an early sign. More advanced cases show extensive bubbles in the parenchyma and a gas crescent surrounding the kidney within the perinephric space. Ultrasound and CT are much more sensitive than plain films at detecting gas. CT identifies the gas clearly and unambiguously. Ultrasound identifies gas by the artifacts produced. Artifacts include an intense band of echoes distant to the gas and "dirty shadowing" distally with poorly defined margins and many echoes. This must be distinguished from the shadows associated with calculi, which produce "clean shadows" with sharply defined margins.[24]

Case reports published before 1982 associated surgical intervention within 48 hours and antimicrobial therapy with improved outcome. Although relief of obstruction was sometimes sufficient, nephrectomy was frequently necessary. The possible involvement of the contralateral kidney was a concern. More recent reports have suggested that a combination of antimicrobial agents, ICU support, including tight control of hyperglycemia, and percutaneous drainage guided by modern imaging techniques is successful in most cases, with nephrectomy reserved for a minority (18% mortality rate in a series of 46 cases).[31]

PERINEPHRIC ABSCESS, PYONEPHROSIS, AND PYOCYSTIS

The perinephric space, containing the kidney, renal fat pad, and adrenal gland, is conical and opens inferiorly to the pelvis. In most cases, it communicates to the contralateral perinephric space anterior to the aorta and inferior vena cava. Bridging septae exist within it, which act as lamellar barriers against the spread of infection or hematoma. Multiple loculations may arise, causing difficulty with percutaneous drainage.[32]

Most cases of perinephric abscess occur secondary to pyelonephritis caused by Enterobacteriaceae (*E. coli*, *K. pneumoniae,* and *Proteus* species). However, a minority is bacteremic in origin due to *S. aureus* or pyogenic streptococci. Polymicrobial infection involving anaerobic bacteria also occurs. There have been rare reports of perinephric abscess due to *Candida* and *Aspergillus* species. Many patients have associated renal obstruction or diabetes mellitus. Perinephric abscess is usually confined by the renal fascia, but additional spread to adjacent structures and spaces can occur.

Initial descriptions of perinephric abscess emphasized its insidious nature, delay in diagnosis, and 50% mortality rate.[33] Most patients have fever and chills. Other features may include weight loss, nausea, vomiting, dysuria, flank pain, abdominal pain, pleuritic chest pain, and pain in the thigh or groin. Symptoms usually last at least 2 weeks and sometimes persist for months.[34] The patient may present for investigation of fever of unknown origin. Other patients are given an initial diagnosis of acute pyelonephritis. Flank mass or renal tenderness will be present in most patients.

With the ready availability of ultrasound and CT, the diagnosis is now made sooner. Ultrasound demonstrates fluid that may contain debris or gas. CT shows loculated collections

with decreased attenuation (0 to 20 Hounsfield units). The abscess wall may show increased attenuation after intravenous injection of contrast material. Thickening of the renal fascia (Gerota fascia) and unilateral enlargement of the kidney or psoas muscle may also be seen. The diagnosis can be confirmed by ultrasound-guided aspiration of pus. Most patients can be treated by a combination of antimicrobial agents and percutaneous drainage. Empiric antimicrobial therapy should be directed at mixed anaerobes and *S. aureus*, in addition to the usual aerobic gram-negative bacilli.[24,30,34]

Pyonephrosis arises when infection develops proximal to an obstructed hydronephrotic kidney. Unilateral loss of renal function is present, as is infection of the renal parenchyma. Occasionally gas may form; if so, the prognosis is much better than with emphysematous pyelonephritis. The clinical presentation is similar to perinephric abscess and may be insidious. Initial investigations should include a plain abdominal radiograph to look for calculi. Ultrasound will show a distended upper urinary tract. Specific features of pyonephrosis that allow distinction from simple hydronephrosis include sedimented echoes and dispersed internal echoes within the dilated collecting system. These findings are present in a minority of patients with pyonephrosis.[35] In a septic patient with hydronephrosis, direct aspiration is indicated. CT is more sensitive for detecting radiolucent calculi and will establish whether there is accompanying infection in the tissues around the kidney. Once the diagnosis is made, a nephrostomy tube should be inserted, which usually suffices to drain the infection.

Pyocystis (pus in the urinary bladder) with or without gas-forming organisms can present with sepsis, lower urinary tract signs, and pneumaturia. Patients with chronic oliguria on dialysis or those who have had diversion of urine away from the bladder (e.g., ileal conduit) are especially predisposed. Antimicrobial therapy and bladder irrigations may be sufficient therapy, but necrosis of the bladder wall as demonstrated by gas in the muscular layers on CT will require surgical resection.[36,37]

INFECTED CYSTS

Dependent debris can be demonstrated in a renal cyst by ultrasound or CT and suggests infection. However, absence of such a finding does not exclude a pyocyst. Aspiration of cyst fluid for Gram stain and culture establishes the diagnosis. Assessment is much more problematic in polycystic renal disease. Pyocysts may arise from ascending infection or by hematogenous seeding. In the presence of uremia, systemic responses to infection, such as fever and leukocytosis, are often blunted. Infected cysts may manifest as persistent sepsis unresponsive to intravenous antimicrobial agents. Ultrasound or CT frequently fails to distinguish an infected cyst from the rest of the polycystic kidney. Delineation of the infected cyst as the cause may require white blood cell scanning, magnetic resonance imaging, or positron emission tomography,[38,39] followed by percutaneous drainage of the particular cyst. Alternatively, unilateral nephrectomy can be carried out with preservation of the uninfected kidney. A trial of antimicrobial therapy should be carried out first if the patient is stable. Lipophilic agents, such as trimethoprim-sulfamethoxazole, ciprofloxacin or ofloxacin, are more likely to succeed. Lipophobic agents such as β-lactams and aminoglycosides penetrate cysts poorly, if at all.[40]

URINARY TRACT INFECTION DUE TO *CANDIDA*

By microscopic examination, *Candida* species are readily recognized as gram-positive, ovoid, unicellular forms and grow readily on routine culture systems. Quantitative methods are commonly applied in urine; 10^4 colony-forming units per milliliter, especially when associated with pyuria, should be regarded as indicating at least infection of the bladder and possibly the upper tract.

Disseminated invasive candidiasis may originate in the urinary tract or secondarily seed it. Widespread microabscesses often form in the kidney and in other parenchymal organs. The skin, bones, spleen, eyes, liver, endocardium, myocardium, and central nervous system are typical sites of seeding, but the kidneys are almost universally involved. Renal failure may develop from bilateral renal infection. Neutropenia, loss of mucous membrane integrity due to chemotherapy, burns, steroid use, diabetes mellitus, total parenteral nutrition, and upper gastrointestinal tract surgery predispose to invasive candidiasis. Overgrowth on superficial tissues such as skin, mucous membranes, and the gastrointestinal tract frequently precedes invasion and is often associated with prolonged broad-spectrum antibacterial therapy. Although there may be extensive tissue involvement, direct proof of such deep candida infection is frequently lacking. Blood cultures are positive in only 50% of cases.[41]

Primary infection of the kidneys by *Candida* is generally associated with an indwelling urinary catheter, broad-spectrum antibacterial agents, and an obstructed urinary tract. Candiduria confined to the bladder is usually present for a variable period before renal infection. Persistent candiduria should be assumed to reflect renal infection if the patient has any of the predispositions listed above, is receiving broad-spectrum antibacterial therapy, and continues to have features of sepsis such as fever or leukocytosis. A search should be made for specific features of disseminated candidiasis such as white "cotton wool" exudates in the retina and nodular skin lesions. Unilateral or bilateral hydronephrosis should raise suspicion of a fungus ball. Microscopic examination of the urinary sediment may show *Candida* casts.[42] A careful evaluation of these clinical and laboratory data should allow selection of those patients who require early empiric antifungal therapy.

Renal or disseminated infection requires systemic amphotericin B therapy with its attendant toxicities or fluconazole.[43] Outcome is superior if intravenous catheters are removed on or before the first day of therapy.[41] Amphotericin B carries a significant risk of nephrotoxicity; fluconazole is not active against many non-*Albicans* species. However fluconazole may overcome such resistance in the urine by its high urinary levels.[44] To date, there are no clinical trials validating the efficacy of other agents, such as the less nephrotoxic lipid formulations of amphotericin B, 5-flucytosine, voriconazole, and caspofungin in the treatment of ascending *Candida* pyelonephritis or renal candidiasis. Concern has been raised that the structure of lipid formulations of amphotericin B could impair their urinary excretion. Caspofungin and voriconazole are metabolized through the liver with little urinary excretion. 5-Flucytosine is excreted in high concentration

in urine, but resistance can develop rapidly when used alone.

Hydronephrosis due to a fungus ball should be relieved by a percutaneous nephrostomy tube. Irrigation of the ureter with an amphotericin B solution is effective in some cases. Lack of response radiologically should prompt surgical excision.

A more commonly encountered situation is that of the stable ICU patient who has persistent candiduria. For many individuals, this is a benign condition, which resolves spontaneously or after withdrawal of the urinary catheter. Asymptomatic patients with candiduria should receive treatment if they have undergone transplantation, are neutropenic, or are about to undergo invasive urologic procedures. Amphotericin B washouts, although effective, have been largely abandoned because they are labor intensive and require the continuation of a catheter.[44,45]

PROSTATIC INFECTIONS

Acute bacterial prostatitis rarely causes sepsis requiring ICU admission. It presents with high fever and urgency, frequency, dysuria, difficulty voiding or acute retention of urine, with suprapubic or perineal pain.[46] Rectal examination demonstrates a tender and swollen prostate. Gram-negative bacilli are the most frequent pathogens, and *E. faecalis* may also be responsible.

Because of the intense inflammatory response in acute bacterial prostatitis, most antimicrobial agents cross the prostatic epithelium effectively. Rarely, a patient with acute prostatitis may develop chronic infection, so we recommend continuing with an oral antimicrobial agent that penetrates the prostatic acini well, such as trimethoprim alone, trimethoprim-sulfamethoxazole, ciprofloxacin, or ofloxacin, for a total of 6 weeks in an attempt to eradicate the organisms from the prostate. Prostatic abscess, if present, can be confirmed by transrectal ultrasonography or CT. Transurethral resection of the prostate and unroofing or perineal aspiration of pus guided by transrectal ultrasonography usually provide adequate drainage.[46]

CATHETER-ASSOCIATED BACTERIURIA

Before the 1960s, urinary catheters had "open" drainage systems, with a significant bacteriuria prevalence of 95% within 4 days of continuous use. The principal route of acquisition was intraluminal. The widespread introduction of closed urinary drainage systems has significantly reduced these high rates to 10% to 27% in various studies. The prevalence of catheter-associated bacteriuria is time-dependent. One percent of patients will acquire bacteriuria from single "in-out" catheterizations.[47] The per-day risk of developing bacteriuria has varied from 1% to 5%, with lower figures reported in the ICU setting, but with a higher prevalence of resistant pathogens.[8,48,49] Other factors associated with a higher prevalence of catheter-associated bacteriuria include advancing age and female sex.[8] Systemic antimicrobial agents initially protect against catheter-associated bacteriuria. Subsequently, organisms manifesting extensive antimicrobial resistance become prevalent, such as enterococci, coagulase-negative staphylococci, *Candida* species, and *Pseudomonas* species. Disconnections of the collecting tube–catheter junction are associated with a two- to threefold increase in bacteriuria. Samples should always be taken by aspiration of urine through the distal catheter or collection port, after local disinfection.

Ascent of bacteria to the bladder occurs predominantly outside the lumen when a closed drainage system is used. The space between the catheter and the urethral mucous membrane is filled by a variable amount of fluid, mucus, and inflammatory exudate. This is static and lacks inhibitory factors against bacterial proliferation. A progressive multiplication of organisms originating from the meatus occurs, which accounts for the time-dependent acquisition and for the higher rates associated with the female urethra.[50]

In a small minority of patients, the organism originates from the collecting bag and ascends intraluminally. Contamination of the collecting bag can occur in association with disconnections of the distal catheter or during emptying of the bag near the drainage port. Organisms have been carried on the hands of personnel or in the collecting urinal from one source patient to the collecting bags of others. Thus, intraluminal spread is the mechanism associated with most epidemics of catheter-associated bacteriuria.[51]

Catheterization of the bladder is unavoidable in most patients in the ICU. Indications include the monitoring of urine output in patients with shock, hemodynamic instability, or polyuric renal failure and the relief of lower urinary tract obstruction. Catheterization should not be used routinely, to avoid incontinence and contamination of the perineal skin. The almost universal use of urinary catheters in most ICUs can be reduced by early withdrawal of catheters in selected patients. These include alert and stable patients who can maintain continence, patients with anuric renal failure for whom once-a-day catheterization will suffice, and male patients with an intact voiding mechanism who can be managed with condom drainage.[1] Intermittent catheterization can be used in stable patients with neurogenic bladders and in some patients with disturbed consciousness. The necessity for the catheter should be frequently questioned and a trial of removal attempted when feasible. Once in place, there is no need for regular scheduled replacements of the catheter, which can be left indefinitely provided it is functioning well and there are no encrustations.[52] Bacteremia can arise with instrumentation, including passage of a new urinary catheter. Bacteriuria should be treated in a catheterized patient before instrumentation of the urinary tract. Catheter-associated bacteriuria is generally asymptomatic. Treatment is sometimes justified to relieve symptoms of cystitis, especially in the patient in whom removal of the catheter is imminent. Short-course treatments will work well once the catheter has been removed.[53]

Studies of recent technical innovations to reduce catheter-associated bacteriuria have shown equivocal results. These include urinary catheters impregnated with nitrofurazone or minocycline and rifampin or coated with a silver alloy-hydrogel. Conflicting opinions exist concerning their efficacy and cost effectiveness. We do not recommend them at this time.[49,54]

Chapter 57
GASTROINTESTINAL INFECTIONS

STEPHEN G. WEBER

KEY POINTS

- *In addition to immunologic mechanisms, physical (motility), chemical (gastric acidity), and microbiologic (normal colonizing flora) factors normally protect the gastrointestinal tract against infection.*
- *Esophagitis, most commonly caused by* Candida albicans *or herpes simplex virus, may be underrecognized among patients in the intensive care unit.*
- *Infection with* Helicobacter pylori *may play a role in the pathogenesis of gastric stress ulceration among critically ill patients.*
- *The epidemiology and microbiology of diarrheal illness is significantly different among patients in the critical care unit than is observed in the community setting. Most infectious diarrhea is hospital-acquired and is usually attributable to* Clostridium difficile.
- *A systematic approach to the critically ill patient with diarrhea includes consideration of pathogens that cause noninflammatory, inflammatory, and hemorrhagic diarrhea. Thorough history taking supplements laboratory data in the diagnosis of these patients.*
- C. difficile *infection is the single most common cause of gastrointestinal infection among patients in the intensive care unit. The spectrum of disease induced by* C. difficile *infection is broad. Timely diagnosis and treatment is critical both for the management of the infected patient and to prevent the spread of infection through the unit.*

While rarely severe enough to warrant admission to the ICU, gastrointestinal infections account for substantial morbidity and mortality among critically ill patients. Because of severe comorbid disease, impaired immune defenses, and the invasive interventions to which they are subjected, patients in the ICU are especially susceptible to hospital-acquired GI infection. Nevertheless, despite the frequency with which these infections occur, the morbidity and mortality that they cause, and the costs they incur, GI infections can go undetected and untreated in the ICU. While trying to manage patients with deteriorating cardiac function, marginal ventilatory performance, and life-threatening metabolic abnormalities, clinicians in the ICU may fail to recognize the important early signs of GI infection.

Any discussion of GI infections among critically ill patients must begin with a consideration of the host defenses that normally protect the alimentary tract. As such, the first section of this chapter is devoted to a description of the unique nonimmunologic mechanisms normally active in the GI tract. Particular consideration is given to the means by which these defenses may be compromised in patients in the ICU. Following this introduction, the clinical manifestations of infection affecting each segment of the GI tract are discussed (Table 57-1). In addition to describing the microbiology associated with each syndrome, a rational diagnostic and therapeutic approach is offered, based on the most up-to-date experience reported in the medical literature. The chapter concludes with an expanded discussion of the unique clinical challenges presented by the patient in the ICU with *Clostridium difficile* infection.

Host Defenses

MOTILITY

GI motility, in addition to its central role in normal digestion, is one of the principal host defenses against infection. By continuously flushing the lumen of the GI tract, normal motility prevents the accumulation of infectious organisms and the virulent toxins associated with disease. When bacteria are permitted to collect and reproduce unchecked, such as in blind bowel loops rendered devoid of normal motility by surgical interventions, infection can ensue. Patients in the ICU are routinely exposed to interventions that can have the effect of impairing gut motility, rendering the patient vulnerable to infection. For example, while narcotics can provide appropriate and necessary analgesia for the critically ill patient, these agents have the side effect of inhibiting gut motility.

GASTRIC ACIDITY

Gastric acidity provides a unique chemical barrier to the establishment of upper GI colonization and infection. In the highly acidic environment of the stomach, few pathogens are able to survive, much less thrive. However, the gastric pH of patients in the ICU is often much higher, providing an environment that is more hospitable to bacteria. More importantly, ingested microbes can pass into the lower GI tract. Once again, pharmacologic interventions are primarily responsible for this disruption of normal protective physiology. The attenuation of gastric acidity is deliberate—an effort to lessen the likelihood of stress-induced gastritis and resultant GI hemorrhage. Medications such as histamine (H_2)-receptor blockers and proton pump inhibitors are

TABLE 57-1 Clinical Manifestations of Infection of Different Segments of the Gastrointestinal Tract

Site	Normal Host Defense	Clinical Syndrome	Typical Pathogens
Esophagus	Motility, acidity	Esophagitis	*Candida* species, herpes simplex virus, cytomegalovirus
Stomach	Acidity, motility	Gastritis	*Helicobacter pylori*
Small and large intestine	Normal flora, motility	Infectious diarrhea	*Clostridium difficile, Escherichia coli, Salmonella*, and *Shigella* species

commonly employed for this practice in both medical and surgical ICUs.

NORMAL COLONIZING FLORA

While not intuitively obvious as a component of host defense against infection, the normal colonizing flora of the GI tract provides as much protection as any physical or chemical barrier. Together, the host and normal GI flora comprise a delicate and varied ecology into which the introduction of new and potentially virulent flora is not favored. The bacteria that populate the GI tract are varied, depending on the anatomic segment under consideration. The mouth normally contains a mixed population of gram-positive, gram-negative, and anaerobic bacteria. In the esophagus, the population is less diverse. As already noted, the acidic environment of the stomach is distinctly inhospitable to the establishment of bacterial colonization. However, one organism, discussed in detail later, has been found to be of profound clinical relevance. Because of its ability to survive in the stomach, *Helicobacter pylori* plays a critical role in the pathogenesis of peptic ulcer disease. In contrast to the case of the stomach, the lower GI tract plays host to substantial microbiologic diversity. An enormous range of gram-negative, gram-positive, and anaerobic flora populates the intestines, especially the colon. Specific constituents include enterococci and *Bacteroides* species, as well as members of the family Enterobacteriaceae.

Disturbance of the dynamic between host and bacterial colonizers, such as occurs after exposure to broad-spectrum antimicrobials, predisposes patients to GI infection, most notably colitis caused by *Clostridium difficile*. While this association is well recognized, the factors that govern this phenomenon are still not well understood. It is not known if the normal flora compete with infecting pathogens for nutrients or substrates, occupy limited mucosal binding sites, or somehow otherwise alter the microenvironment in a way that reduces the likelihood of colonization. Regardless of the actual mechanism, an interesting therapeutic corollary can be inferred from the relationship between the normal host and GI colonizers. Deliberate intestinal colonization with so-called probiotics such as *Saccharomyces cerevisiae* may offer a means by which to preclude the onset of nosocomial infection or to attenuate the effects of these infections once established.[1]

Esophagitis

The esophagus may be easily overlooked as a site of infection in patients hospitalized in the ICU. These patients may be unable to verbalize or otherwise express to caregivers the subjective complaints that indicate the presence of infection. To make matters worse, mechanical instrumentation commonly employed in the ICU, including endotracheal, nasogastric, and orogastric tubes, may limit the clinician's ability to thoroughly examine the patient for signs of upper GI infection. Moreover, even when characteristic physical findings of infection are visualized, they may be incorrectly ascribed to mechanical irritation or inflammation associated with such tools. When the opportunity to diagnose upper GI infection is missed, directed therapy may be withheld and infection allowed to proceed unchecked.

CLINICAL PRESENTATION

Nearly 20% of ICU patients who underwent upper endoscopy in one study were incidentally noted to have esophagitis.[2] These patients typically experience dysphagia with or without odynophagia. The pain of esophagitis is described as retrosternal and is typically exacerbated by the recumbent position. In the alert, awake, and communicative patient, these hallmark complaints are easily called to the attention of caregivers. However, as was already noted, the intubated and sedated patient in the ICU may not be able to express these complaints. Fever is an unreliable clinical finding in the patient with esophagitis. Regardless of the causative organism, fewer than one third of all patients with esophagitis will experience an elevation in temperature.[3]

MICROBIOLOGY

Among hospitalized patients, esophagitis is most often caused by *Candida albicans*. While *C. albicans* remains the yeast species most frequently associated with esophagitis, an increasing proportion of cases have been linked to non-*albicans Candida* species, including *C. tropicalis*, *C. parapsilosis*, *C. krusei* and *C. glabrata*.[4] This changing epidemiology has been attributed to the increasingly common use of empiric and prophylactic therapy with triazole antifungal agents such as fluconazole, to which many non-*albicans Candida* species are resistant. This epidemiologic phenomenon needs to be incorporated into the approach to therapy for such patients.

Herpes simplex virus (HSV) is another frequent cause of esophagitis and is the most common serious viral infection of the upper GI tract among patients in the ICU. For the most part, HSV type 1 is more likely to cause esophagitis than is HSV 2, which is more typically associated with genital infections. Less frequently, other viruses, including cytomegalovirus (CMV) can cause esophageal ulceration. For patients with CMV disease, lesions may extend throughout the length of the GI tract.

DIAGNOSIS

Thorough physical examination is not only essential to the diagnosis of esophagitis, but may offer preliminary clues as to the causative pathogen. Both yeast and viral pathogens infecting the esophagus can produce telltale lesions in the oral cavity, where they will be easily detected on routine physical examination. Although present in fewer than one third of all patients with HSV esophagitis, oral or labial herpetic ulcers should not be missed in the physical examination of the critically ill patient with unexplained fever.[5] Similarly, an adherent white coating to the lateral aspects of the tongue, which when scraped away reveals patches of inflammation, should point to *Candida albicans* as the cause of a suspected case of esophagitis. Despite the utility of such findings, it is equally important to recognize that esophagitis most often occurs in the absence of such clues. Nevertheless, to miss these clinical findings, when present, is to miss a critical opportunity for early diagnosis and intervention.

Upper GI endoscopy can be a useful tool to confirm the pathologic and microbiologic diagnosis of esophagitis. Unfortunately, even when visualized through the endoscope, the lesions of *Candida* and HSV esophagitis may appear quite similar. Even the large shallow ulcers typical of CMV esophagitis

may be mimicked by *Candida* or HSV. Because of this lack of discriminatory power, it is advisable to proceed to confirmatory biopsy. Brush specimens alone can be inadequate, especially as *Candida* species can be isolated as colonizers of the upper GI tract in up to 20% of normal individuals.[6] Once obtained, tissue should be sent for viral and fungal culture as well as for histopathologic examination to confirm tissue invasion.

THERAPY

Under most circumstances, directed therapy for esophagitis should be withheld until the causative organism has been identified. However, for critically ill patients with suspected esophagitis in whom endoscopy is not practical and microbiologic diagnosis is impossible, it is reasonable to treat empirically for *C. albicans*, based on the prevalence of this entity in this population. For esophagitis when *C. albicans* is known or suspected to be the cause, the most effective treatment is fluconazole given intravenously at a dose of 100 to 200 mg per day for 14 to 21 days. For those infected with *Candida* species resistant to fluconazole, or for patients with persistent infection despite first-line therapy, amphotericin B can be used as salvage therapy. The role of newer antifungal agents, including voriconazole and the echinocandins has not yet been fully clarified.

For HSV esophagitis, the antiviral agent with which there is the most clinical and published experience is acyclovir. Most patients in the ICU will require parenteral therapy—5 mg/kg intravenously every 8 hours for 7 to 14 days. If the virus is resistant to acyclovir, intravenous foscarnet can be substituted.

Gastritis

While the stomach is not typically considered an important site of infection among hospitalized patients, the potential association between *Helicobacter pylori* infection and gastric stress ulceration suggests another means by which GI pathogens may take a toll among critically ill patients. The etiologic relationship between the presence of *Helicobacter pylori* and ulcerative disease of the upper GI tract, and particularly the duodenum and stomach, has been established. Importantly, treatment of *H. pylori* infection with combinations of antimicrobial agents and inhibitors of gastric acidity will eradicate *H. pylori* infection, and in so doing promote the resolution of peptic ulcer disease.[7] Antibiotics employed for this purpose are active against *H. pylori* and include macrolides and β-lactam agents. Acid suppressive agents given concurrently include sucralfate, H_2-receptor blockers, and proton pump inhibitors.

Given these findings and a growing clinical experience with this strategy, it is not surprising that a link between *H. pylori* infection and the stress-induced gastritis that affects patients in the ICU has been proposed. Thus far, the results have been generally inconclusive. In a prospective, single-institution study of patients admitted to a medical/surgical ICU, half of all patients admitted were positive for *H. pylori* by urea breath test. After adjusting for other risk factors, *H. pylori* infection was the only clinical factor significantly associated with major mucosal injury. The organism was detected in 80% of such patients.[8] However, the same investigators observed that the prevalence of *H. pylori* infection among ICU patients declined to 8% by the third day of admission, and to 0% by 1 week, owing to intercurrent antibiotic exposure.[9]

Diarrhea

Diarrhea, the principal manifestation of intestinal infection among the critically ill, affects approximately one third of all patients admitted to the ICU.[10] Patients in the ICU with diarrhea are especially vulnerable to the clinical sequelae of infection. For the critically ill patient, the dehydration that frequently accompanies severe diarrhea strains a circulatory capacity already limited by impaired cardiac contractility and septic hemodynamics. Such individuals are at high risk for further systemic deterioration, often culminating in multisystem organ failure. In addition to life-threatening volume loss, diarrhea in the critically ill patient can precipitate metabolic derangements including electrolyte imbalances and acidosis, further exacerbating the potential for cardiac rhythm irritability. Finally, uncontrolled diarrhea in a severely ill immobile patient can predispose to compromise of the protective barrier of the skin. As such, the patient is rendered vulnerable to further infectious complications. Considering these dire clinical consequences, the prompt detection, microbiologic diagnosis, and therapy of diarrhea must be a high priority for clinicians in the ICU.

The epidemiology of diarrheal illness among patients in the ICU is substantially different from that seen among less severely ill patients in the community. Such differences render most of the schemes used to classify diarrhea in other settings less applicable to the evaluation of the critically ill patient. Infectious diarrhea acquired in the outpatient setting is rarely sufficiently severe to warrant admission to the ICU. Therefore, infectious diarrhea among patients in the ICU is most often acquired in the hospital. As a result, the spectrum of clinical disease and associated pathogens for the patient in the ICU tends to be less diverse than that encountered in the community. In fact, the majority of all cases of infectious diarrhea diagnosed in the ICU can be attributed to a single pathogen, *Clostridium difficile*. For many of these patients, the differential diagnosis consists largely of noninfectious entities, such as diarrhea induced by hyperosmolar enteral feeding solutions.[11] Norwalk-like viruses, one of the most common causes of endemic and epidemic diarrhea in the outpatient setting, are rarely identified as the cause of diarrhea in critically ill patients. Similarly, while outbreaks of food-borne gastroenteritis have been reported among hospitalized patients,[12] in the absence of an identified cluster, the work-up of the ICU patient with diarrhea usually need not include consideration of these pathogens.

It is in recognition of the rarity with which the clinician in the ICU will encounter diarrhea that is not hospital-acquired that a review of these less familiar presentations is warranted. While the distinctions between these syndromes are somewhat arbitrary, and there is considerable overlap between them, it is imperative that the clinician caring for critically ill patients at least be able to recognize these syndromes. In the sections that follow, inflammatory, noninflammatory, and hemorrhagic diarrheas are considered separately. Each is discussed with respect to the most common

TABLE 57-2 Features of Noninflammatory, Inflammatory, and Hemorrhagic Diarrhea

	Noninflammatory	Inflammatory	Hemorrhagic
Clinical presentation	Large volumes of watery stool; signs and symptoms of dehydration	Dysentery; small quantities of blood and mucus, often accompanied by fever	Grossly bloody bowel movements
Laboratory findings	Fecal leukocyte studies negative; acidosis; azotemia	Fecal leukocyte studies positive	Anemia; azotemia in the setting of hemolytic uremic syndrome (HUS)
Typical pathogens	*Vibrio cholerae*, enterotoxigenic *Escherichia coli*	*Shigella* species, *Salmonella* species, *Campylobacter jejuni*	*E. coli* type O157:H7
Pathophysiology	Toxin-mediated secretory diarrhea	Compromise of the intestinal epithelium with varying degrees of bacterial invasion	Poorly understood
Approach to therapy	Rehydration and antimicrobial therapy	Antimicrobial therapy if severely ill or immunocompromised	Supportive therapy; antimicrobials may increase the risk of HUS

clinical presentations and pathogens that could be expected in the ICU (Table 57-2). A general approach to the diagnosis and treatment of diarrhea among patients in the ICU follows. The chapter concludes with an in-depth discussion of diarrhea caused by *C. difficile*—an organism whose central role as a cause of diarrhea among patients in the ICU has already been discussed.

NONINFLAMMATORY DIARRHEA

In general, the noninflammatory diarrheal syndromes are characterized by the production of large volumes of watery stool devoid of gross blood or inflammatory cells. By definition, stool examination for fecal leukocytes in such patients will be negative. The typical presentation and pathophysiology of noninflammatory diarrhea is best exemplified by infection with *Vibrio cholerae*. While this gram-negative bacillus is the most prevalent cause of dehydrating diarrhea throughout the world, it is rarely encountered as a pathogen causing serious disease in the developed world. That said, the metabolic sequelae of cholera are capable of generating systemic illness sufficiently severe as to require ICU admission in a returning traveler.

While the diarrhea experienced by the patient infected with *V. cholerae* is characteristic of the other noninflammatory diarrheal infections, the severity of disease is unique to cholera. Diarrhea is voluminous, and patients can lose more than 1 liter of fluid *every hour.* Affected patients are at high risk for life-threatening dehydration. Vital signs will reveal tachycardia and hypotension. The metabolic abnormalities can precipitate severe acidosis. To compensate, the patient may become tachypneic. Skin evaluation in these individuals reveals decreased turgor. The mucous membranes, including conjunctivae, appear dry. In extreme cases, the patient's eyes will appear sunken, producing a characteristic facies. If fluids are not replaced promptly and in sufficient quantity, the infection will be fatal.

The diarrhea of cholera is secretory in nature. Having established itself in the lumen of the bowel, *V. cholerae* releases an extracellular protein that binds to the membrane of intestinal epithelial cells. The enterotoxin induces an increase in intracellular cyclic adenosine monophosphate (cAMP). The high concentration of cAMP induces an increase in chloride secretion and a decrease in sodium absorption, producing the massive fluid and electrolyte loss characteristic of cholera.[13]

While *V. cholerae* is the prototypical pathogen associated with noninflammatory diarrhea, an array of other organisms can produce the same syndrome. While the diarrhea induced by these other pathogens tends to be less severe than that of cholera, the greater frequency with which these organisms cause infection in the developed world makes them more likely to be encountered as a cause of diarrhea in this setting. Most important among these are the so-called enterotoxigenic strains of *Escherichia coli*. These isolates produce an extracellular toxin, a component of which is similar to that produced by *V. cholerae*. The end result is comparable—profuse watery diarrhea that challenges patient and clinician to maintain adequate hydration.

INFLAMMATORY DIARRHEA

Spanning a broad spectrum of clinical severity, inflammatory diarrhea is strictly defined by the presence of fecal leukocytes when the stool from affected patients is examined microscopically. In terms of pathophysiology, these infections are characterized by compromise of the integrity of the intestinal epithelium. Depending on the causative organism, there may be varying degrees of bacterial invasion. As a result of this process, inflammatory cells, including both neutrophils and lymphocytes, are recruited to the affected area, where some are shed into the intestinal lumen.

In the most extreme cases, inflammatory diarrhea causes the clinical syndrome commonly referred to as dysentery. The patient with dysentery presents with semisolid or liquid bowel movements that are not as voluminous as those seen with noninflammatory diarrhea. In fact, some patients report very scant production of fecal matter. For them, bowel movements are characterized by small quantities of gross blood and mucus. Fever is often present, but is usually not exceedingly high. Patients with dysentery may experience severe cramping abdominal pain or tenesmus—pain with the passage of bowel movements. Because of the limited ability of critically ill patients to report such complaints, clinicians should be alert for the presence of the unique stool characteristics that identify the patient with dysentery and inflammatory diarrhea.

A number of pathogens have been described in association with the clinical manifestations of inflammatory diarrhea, but the classical description of the syndrome is associated with infection with *Shigella* species, particularly *S. dysenteriae*. As was true for cholera and other noninflammatory diarrheas, this association once again points to a shared pathophysiology. Pathogenic *Shigella* species elaborate an exotoxin (Shiga toxin) that acts by inhibiting protein synthesis, damaging the

intestinal mucosa. Analogous shiga-like toxins have been detected in association with other bacterial species linked to inflammatory diarrhea, including both enteroinvasive and enterohemorrhagic strains of *E. coli*.

Like *Shigella*, the other bacterial species commonly identified in cases of inflammatory diarrhea are generally acquired through fecal oral transmission, often in the setting of food-borne outbreaks. In the United States, the most common such pathogens are members of the *Salmonella* species. Outbreaks of food-borne salmonellosis, while most commonly linked to undercooked poultry and dairy products, have even been reported in the context of a deliberate release associated with an episode of domestic bioterrorism.[14] Other important pathogens identified in association with inflammatory diarrhea include *E. coli* and *Campylobacter jejuni*.

HEMORRHAGIC DIARRHEA

Patients with hemorrhagic diarrhea, characterized by the presence of frank blood, are increasingly being seen in the setting of the ICU. In addition to the hemodynamic and metabolic complications that characterize other inflammatory diarrheas, patients with hemorrhagic diarrhea have been found to be predisposed to systemic illness that can warrant admission to critical care. Strains of *E. coli* belonging to serogroup O157:H7 have been epidemiologically linked to the development of the hemolytic uremic syndrome.[15] While the mechanism linking infection and this syndrome is not yet well understood, the resultant deposition of fibrin thrombi in the renal glomeruli can induce sufficient anemia, thrombocytopenia, and azotemia as to be life threatening. The hemolytic uremic syndrome typically follows the onset of diarrhea by about 1 week. While many of these patients will require intensive supportive therapy, including blood transfusion and hemodialysis, for most the condition is reversible. Of particular concern to clinicians caring for these patients is the observation that antimicrobial treatment may contribute to the emergence of this syndrome.[16]

EVALUATION OF THE CRITICALLY ILL PATIENT WITH DIARRHEA

The foremost consideration in the evaluation of the critically ill patient with diarrhea is the prompt recognition of infection with *C. difficile*. In the setting of prior exposure to antimicrobials or antineoplastic therapy, diarrhea can be presumptively attributed to *C. difficile* infection until proven otherwise. Identification of these patients is critical not only for the initiation of directed therapy, but to ensure that adequate infection control procedures are followed to limit the spread of infection to other vulnerable patients in the ICU. A comprehensive approach to the diagnosis of *C. difficile* is provided at the end of this chapter.

Whether or not *C. difficile* infection can be excluded, the evaluation of diarrhea in the ICU must progress in a systematic fashion with respect to the microbiology of the most likely infecting organism (Table 57-3). The initial assessment of these patients should include an accurate history of both the course of diarrhea and the presence of any precipitating factors that might suggest a causative organism. The patient, or for the uncommunicative patient a family member or friend, should be queried about the timing of onset of diarrhea, the progression of symptoms, associated systemic complaints such as fever or chills, and the nature and quantity of bowel movements (with particular emphasis on the presence or absence of bloody stools). Additional essential data includes information about recent travel, unusual dietary intake, and the presence of similar symptoms among companions with whom the patient has shared a meal. Of course, a history of prior antibiotic therapy or cancer chemotherapy will be needed to distinguish individuals at risk for *C. difficile* colitis. By the end of this process, the clinician should be able to characterize the diarrhea as acute or chronic, community- or hospital-acquired, and severe or mild. The last finding is of particular importance in that supportive therapy to alleviate severe dehydration should not be withheld pending further laboratory and microbiologic evaluation.

TABLE 57-3 Diagnostic Approach to the Patient with Infectious Diarrhea

History
Timing and rapidity of onset
Associated signs and symptoms (fever)
Nature and quantity of bowel movements
Prior antibiotics or chemotherapy
Physical examination
Hemodynamic compromise (tachycardia or hypotension)
Signs of dehydration (orthostasis, skin tenting)
Rectal examination for gross or occult bleeding
Laboratory
Stool for fecal leukocytes
Immunoassay for *C. difficile* toxins A and B
Stool culture (especially in the setting of outbreak or community acquisition)
Stool for ova and parasites (if travel-related)
Endoscopy (reserve for persistent cases in which other tests are not revealing)

Given the emphasis placed on distinguishing inflammatory from noninflammatory diarrhea, it will come as no surprise that the initial laboratory work-up of the critically ill patient with diarrhea should include an objective measure of inflammation. Testing for fecal leukocytes offers a reliable means by which to do so. The test is performed by mixing a drop of stool with methylene blue on a slide, followed by examination under a microscope. Testing for stool occult blood has been suggested as another useful tool to identify patients in the ICU with inflammatory diarrhea. Unfortunately, testing for occult blood, even in the presence of a new fever in a critically ill patient, may be of little use in discriminating inflammatory infectious diarrhea from other common, noninfectious causes of bloody bowel movements among such patients, including stress-induced gastric ulceration and ischemic colitis.

In the setting of noninflammatory diarrhea, epidemiologic data must be interpreted to assess the likelihood of infection with *V. cholerae*. For a traveler returning from an endemic area presenting with signs and symptoms consistent with cholera, direct stool examination under darkfield or phase contrast microscopy can reveal the linear motility characteristic of *V. cholerae*. The organism will also grow on nonselective bacteriologic media, but the preferred method is culture on thiosulfate-citrate-bile salts-sucrose agar. If infection with enterotoxigenic *E. coli* is suspected, an assay to detect toxin is available from reference laboratories.

Especially in a patient with community-acquired diarrhea, the identification of fecal leukocytes on direct observation

TABLE 57-4 Recommended Antimicrobial Regimens for Patients Hospitalized with Bacterial Diarrhea

Pathogen	Recommended Treatment Regimen	Notes
Campylobacter jejuni	Azithromycin or ciprofloxacin	Fluoroquinolone resistance increasing in some regions
Clostridium difficile	Metronidazole	Vancomycin is not preferred because of risk of precipitating resistance; avoid antimotility agents
Escherichia coli O157:H7	No antimicrobial therapy advised	Antimicobials may increase the risk of hemolytic uremic syndrome
Salmonella species	Ciprofloxacin	Treat only if symptoms are severe or patient is immunocompromised
Shigella species	Ciprofloxacin	
Traveler's diarrhea	Fluoroquinolone	Use of antimotility agents is appropriate
Vibrio cholerae	Ciprofloxacin	Rehydration is cornerstone of therapy
Yersinia enterocolitica	Ciprofloxacin	

should warrant a search for bacterial pathogens that cause inflammatory diarrhea, including *E. coli*, *C. jejuni*, *Salmonella*, and *Shigella* species.[17] Stool culture can be particularly useful in distinguishing the bacterial pathogens that are commonly associated with these food-borne gastroenteritides. Selective media, such as MacConkey, desoxycholate, and salmonella-shigella agars, are employed in the microbiology lab to enhance the ability to detect these pathogens. It is useful to identify particular epidemiologic concerns to the microbiology lab so that the appropriate media can be employed.

The examination of stool for the presence of ova and parasites is of limited utility among patients in the ICU. First and foremost, the clinical syndromes caused by infection with these organisms tend not to be so serious as to require admission to the ICU. Moreover, the incidence of parasitic infections in ICU patients is so low as to make the positive predictive value of the stool ova and parasite examination vanishingly small. In this context, even a positive finding on stool ova and parasite exam is more likely to represent a false-positive than it is to represent actual infection. Many clinical laboratories have gone so far as to not accept stool ova and parasite specimens from patients who have been hospitalized for 48 to 72 hours.

The role of endoscopy in the evaluation of infectious diarrhea is limited. While biopsy may detect the presence of specific pathogens such as *Entamoeba histolytica*, the relatively low incidence of these infections in this population makes this the diagnostic procedure of last resort. Lower GI endoscopy will not help to discriminate or diagnose infection with common bacterial pathogens such as *E. coli* or *C. jejuni*. As discussed later, sigmoidoscopy and colonoscopy can be helpful in the detection and diagnosis of colitis caused by *C. difficile* infection.

TREATMENT

The foremost objective in the care of the patient with infectious diarrhea is to restore the patient to a normal fluid and electrolyte balance as rapidly as possible. While oral rehydration solutions, such as that recommended by the World Health Organization, have proven safe and effective in settings in which intravenous therapy is either impractical or unavailable, most patients with diarrhea in the ICU will require parenteral replenishment. Effective regimens include lactated Ringer solution and normal saline with electrolyte supplementation. The use of large volumes of 5% dextrose and water for these patients may precipitate dangerous hyponatremia. No matter the regimen selected, serum chemistry analyses should be performed frequently to ensure adequacy of electrolyte replacement.

In general, empirical antimicrobial therapy for infectious diarrhea not associated with *C. difficile* should be avoided. Indiscriminant antibiotic use for this indication exposes the patient to needless toxicity, may precipitate the emergence of resistant organisms as a cause of systemic infection, can worsen the course of some infection (as in the case of *E. coli* serotype O157:H7), and might predispose the patient to prolonged carriage with the offending pathogen.[18] However, once a specific pathogen has been identified, therapy can be directed by documented susceptibility information—or at least trends among known or suspected pathogens. Pathogen-specific recommendations are listed in Table 57-4.

Clostridium Difficile Infection

As was already noted, *Clostridium difficile* is the single most common cause of infectious diarrhea among all hospitalized patients, including those in the ICU. When patients receiving antibiotics during hospitalization are considered, the incidence of *C. difficile* colitis approaches 10%.[19] It is estimated that fully one quarter of diarrheal episodes among hospitalized patients may be attributable to *C. difficile* infection.[20] Hospital costs for patients who acquire *C. difficile* diarrhea are more than 50% higher than for those without infection, and an episode of *C. difficile* colitis prolongs the average length of stay for infected patients by nearly 4 days.[21] Of greater concern, the incidence of *C. difficile* colitis appears to be increasing.[22]

CLINICAL PRESENTATION

The clinical presentation of patients with *C. difficile* can be quite diverse. In addition to asymptomatic carriage, some patients may report only a minimal increase in the frequency or liquidity of bowel movements. Such individuals, while at low risk of complication from infection, if not identified and appropriately isolated from other patients, represent an

important reservoir for the spread of *C. difficile* within the ICU. At the other extreme, patients may experience severe clinical deterioration as a result infection with *C. difficile.* The bowel movements of the patient with *C. difficile* infection may be watery and voluminous, such as is seen in noninflammatory diarrheas. Other patients with *C. difficile* infection experience a clinical syndrome more consistent with that of the inflammatory gastroenteritides, occasionally even reporting gross blood in the stool. Fever is present in about half of patients. Leukocytosis, sometimes profound, is often a reliable indicator of the onset of *C. difficile* colitis.

In extreme cases, patients infected with *C. difficile* present with the complication of toxic megacolon. Such patients may or may not experience diarrhea. Abdominal radiography in these cases reveals grossly dilated colonic loops without evidence of mechanical obstruction. The patients frequently demonstrate end-organ dysfunction as is typical for the sepsis syndrome. The diagnosis of toxic megacolon carries with it a high degree of mortality. Colonic perforation can result if the infection is not treated promptly.

MICROBIOLOGY

C. difficile is an obligate anaerobic gram-positive bacillus whose virulence is attributed to the production of extracellular toxins. *C. difficile* can be identified as part of the normal flora in patients without overt diarrheal disease. In these individuals, toxin-negative strains of *C. difficile* are likely no more than harmless commensal organisms. In fact, there are data suggesting that progression to diarrhea occurs early after acquisition of *C. difficile* or not at all.[23] To produce diarrhea and other manifestations of clinical disease, infecting strains of *C. difficile* must produce extracellular toxins. Together, toxin A (enterotoxin) and toxin B (cytotoxin) cause epithelial cell necrosis through the disruption of the actin cytoskeleton.[24] Recently, strains of toxin A–negative, toxin B–positive *C. difficile* have been described in association with outbreaks of hospital-acquired disease.[25]

DIAGNOSIS

The spectrum of clinical disease associated with *C. difficile* infection makes diagnosis solely on the basis of clinical observations impractical. That said, experienced clinicians often point to what they consider to be a typical picture of *C. difficile* diarrhea, including foul-smelling stool that is greasy and green in color. Unfortunately, such observations are of limited value. On the other hand, readily available historical data, when accurately obtained, can be far more informative in leading the clinician to an accurate diagnosis.

While once closely linked to exposure to clindamycin or other agents from the lincosamide class, *C. difficile* colitis has since been observed to occur after therapy with nearly every antimicrobial agent available to clinicians, including metronidazole.[26] Because of their widespread use and broad spectrum of activity, there appears to be an especially close association between *C. difficile* diarrhea and prior therapy with the cephalosporin class of β-lactam agents.[26] While there may be an association between the anaerobic activity of an antibiotic and its likelihood of precipitating *C. difficile* diarrhea, the specific mechanisms and implications of this relationship remain to be explored. The observed association between some antineoplastic chemotherapy agents and *C. difficile* infection similarly challenges our understanding of the pathophysiology of these infections.

The onset of diarrhea due to *C. difficile* infection most commonly occurs in close relation to antibiotic administration. Twenty-five percent of cases present while dosing is ongoing.[27] However, both the published literature and clinical experience reveal episodes of *C. difficile* colitis that occur within 48 hours of the initiation of antibiotic therapy, and others that develop months after exposure. In addition to the pharmacologic agents already mentioned, a number of factors are thought to predispose patients to *C. difficile* colitis, including advanced age, increased severity of illness, and impaired GI motility.[28] In one study, the odds ratio for *C. difficile* infection among patients with the most severe underlying disease was 17.6.[19] Each of these factors is commonly encountered among patients in the ICU, rendering them especially susceptible to infection.

While a patient's clinical history might suggest *C. difficile* infection, accurate diagnosis depends on the prudent use of objective laboratory assays. Attempts to culture *C. difficile* from the stool have proven clinically unreliable and have little utility in the evaluation of the hospitalized patient with diarrhea. The results of fecal leukocyte testing in the setting of *C. difficile* infection are similarly unreliable as an aid to diagnosis. The accurate identification of *C. difficile* colitis depends on the detection of the characteristic toxins produced by the organism. Previously, the gold standard for diagnosis was the cytotoxic assay. With this study, diluted stool is added to monolayers of cultured cells. Observation of a cytopathic effect that is neutralized by antibody against the toxins is more than 95% sensitive and specific for the identification of toxigenic *C. difficile*.[29] Because of the labor and expertise required to perform this assay, most labs now rely on immunoassays for the direct detection of *C. difficile* toxins. Newer immunoassays capable of detecting both toxin A and B are more sensitive than earlier versions that detected only the enterotoxin.

Endoscopy can be helpful in the diagnosis of *C. difficile* colitis, but its widespread application for this purpose is limited. The characteristic finding of pseudomembranes comprised of necrotic epithelial tissue and inflammatory cells all but confirms the diagnosis of *C. difficile* colitis in the appropriate clinical setting. However, this finding is not always encountered, even in severe episodes of *C. difficile* colitis. Moreover, to perform colonoscopy or even flexible sigmoidoscopy in the setting of *C. difficile* infection is to expose the patient to the risk of unnecessary trauma that could result in the accidental perforation of an already inflamed and friable GI tract.

TREATMENT

Whenever feasible, the first and most important step in the treatment of the patient with *C. difficile* colitis is the discontinuation of the pharmacologic agent that precipitated the infection. In most cases, this means that ongoing antimicrobial therapy for other indications should be withdrawn as soon as it is safe to do so. This is a particular challenge when dealing with the critically ill patient. Broad-spectrum antimicrobial therapy, even when given empirically, is essential to the survival of the septic patients commonly encountered in this setting. For them, the discontinuation of therapy is not advisable, and an agent with activity against *C. difficile* (discussed below) must instead be added to the antimicrobial regimen.

The most appropriate antimicrobial strategy to treat *C. difficile* colitis can be the source of some controversy and confusion for even experienced caregivers in the ICU. Both metronidazole and vancomycin, when administered orally, have been shown to be effective in the treatment of *C. difficile* colitis. While many clinicians persist in the belief that vancomycin is superior to metronidazole for the treatment of *C. difficile*, the available literature does not yet support this position. Several clinical trials have pointed to the equivalence of vancomycin and metronidazole therapy.[30] However, it is worth noting that the percentage of isolates of *C. difficile* that are resistant in vitro to metronidazole may be increasing, but remains less than 10%.[31] The clinical implications of this observation have yet to be sorted out.

Reduction in the overall use of vancomycin, and specifically in the setting of initial treatment of *C. difficile* colitis, has been recommended by the Centers for Disease Control and Prevention as a means by which to stem the emergence of resistant bacteria.[32] Vancomycin-resistant enterococci are familiar to ICU physicians as a frequent cause of serious hospital-acquired infections. Strains of *Staphylococcus aureus* resistant to vancomycin have also been reported recently.[33]

For patients with *C. difficile* colitis who can tolerate oral therapy, treatment should be initiated with metronidazole, 500 mg every 8 hours. While many clinicians elect to treat for longer periods, the duration of metronidazole therapy necessary to treat *C. difficile* need not extend beyond 10 to 14 days. For patients who cannot tolerate metronidazole, vancomycin is an effective alternative, but should not be used as first-line therapy for the reasons previously outlined.

When oral therapy is not feasible, when given intravenously, metronidazole achieves adequate intraluminal concentrations to eradicate *C. difficile* colitis.[34] The recommended dosage is 500 mg every 8 hours. Intravenous vancomycin should never be used to treat *C. difficile* infection. After parenteral vancomycin administration, drug levels within the intestinal lumen are not sufficient to guarantee eradication. The role of vancomycin in treating *C. difficile* infection in the critically ill patient instead focuses on intraluminal therapy. When administered via a rectal tube or in the form of an enema, vancomycin can serve as a useful adjunct to intravenous metronidazole for the severely ill patient. Such methods are particularly useful in the setting of toxic megacolon caused by *C. difficile,* when GI motility has all but halted, and reliable delivery of drug administered orally or by a feeding tube cannot be assumed. However, caution is advised when employing these techniques. The GI mucosa is exceedingly friable in the setting of *C. difficile* infection, particularly when toxic megacolon has evolved. Such patients are at high risk for GI perforation. When the patient is critically ill as a consequence of *C. difficile* colitis (rather than critically ill and also having *C. difficile* colitis), combined therapy (500–750) mg IV every 6–8 h plus vancomycin 500 mg enterally every 6 h) has been advised.[35]

Retreatment of patients with either recurrent *C. difficile* colitis or those who fail to respond to initial metronidazole therapy is controversial and bears special attention. Clinicians should avoid the practice of routine laboratory testing to detect *C. difficile* toxin at the end of a course of therapy in an effort to confirm clearance. Infected patients may continue to shed detectable toxin after therapy is complete. Some individuals may do so intermittently for years. In these cases, additional therapy is not warranted. However, when diarrhea continues despite initial therapy or recurs soon thereafter, additional treatment is advised. In these circumstances, a switch to vancomycin or a more prolonged course of metronidazole has been advocated. However, in most cases, simple retreatment with metronidazole appears to be just as efficacious.

Chapter 58
SEVERE MALARIA

DAVID A. WARRELL

KEY POINTS

- *Consider the diagnosis of malaria in any acutely febrile patient with a history of recent travel to a malarious area or who might have been infected through blood transfusion, needlestick, or other nosocomial parenteral exposure.*
- *Transfer severely ill patients to an ICU and make a rapid clinical assessment, including spot measurement of blood glucose.*
- *If the diagnosis of severe falciparum malaria is proved or suspected, initiate antimalarial chemotherapy using optimal doses of an appropriate agent (licensed quinine or quinidine or an artemisinin derivative such as artesunate on a named-patient basis) administered intravenously, using a loading dose. Monitor the clinical and parasitologic responses.*
- *Prevent, or detect early and treat, the numerous complications (especially generalized convulsions, hypoglycemia, hyperpyrexia, and secondary bacterial infections).*
- *Ensure correct fluid, electrolyte, and acid-base balance. Control fluid replacement to prevent circulatory overload and pulmonary edema. Anticipate renal and respiratory failure.*
- *Expert nursing care of the unconscious patient is essential.*
- *Avoid the use of potentially harmful ancillary treatments of unproven benefit, such as corticosteroids, heparin, and epinephrine.*

Malarial Parasites and Life Cycles

Malaria is a mosquito-borne protozoal infection caused in humans by four species of *Plasmodium: P. falciparum, P. vivax, P. malariae,* or *P. ovale.*[1] Only *P. falciparum* causes life-threatening malaria, but other species can cause severe illness in debilitated individuals. *Plasmodium* sporozoites, inoculated by female *Anopheles* mosquitoes during their blood meal, invade hepatocytes where they mature into schizonts, and after 6 to 16 days rupture to release merozoites into the bloodstream. In the cases of *P. vivax* and *P. ovale,* some sporozoites remain dormant in the liver for months or years in the form of hypnozoites, and can give rise to relapsing infections months or even years later. *Plasmodium falciparum* and *P. malariae* may persist as inapparent low-grade parasitemias to cause symptomatic recrudescences. However, these species do not persist in the liver. The erythrocytic cycle consists of invasion, development from rings to mature pigmented multinucleated schizonts, and rupture with release of 4 to 32 merozoites, depending on the species. These invade erythrocytes to produce repeated cycles of infection, or develop into male and female gametocytes. Merozoites cannot reinvade the liver from the blood. Erythrocytes containing mature trophozoites and schizonts of *P. falciparum* are sequestered in the tissues. Gametocytes taken up by mosquitoes complete a sexual cycle producing sporozoites which are injected with the mosquito's saliva during a blood meal. The usual intervals between the mosquito bite and the appearance of parasitemia are 10 days for *P. falciparum,* 8 to 13 days for *P. vivax,* 9 to 14 days for *P. ovale*, and 15 to 16 days for *P. malariae.* Minimal intervals between the bite and first symptom (incubation period) are a few days longer.

EPIDEMIOLOGY

Malaria is endemic throughout tropical countries except in Pacific Islands east of Vanuatu (Fig. 58-1). *P. falciparum* is the most common cause of malaria in Africa, Haiti, some parts of South America, Southeast Asia, and New Guinea, but is now absent from Europe. *Plasmodium vivax* has been the dominant species in most parts of the Indian subcontinent where there is now a resurgence of *P. falciparum;* it is replaced by *P. ovale* in West Africa, but occurs with varying frequency throughout other parts of the malaria endemic area. *P. malariae* infections are widespread but usually infrequent.

Children who grow up in endemic areas eventually acquire, through frequent infections, immunity to symptoms and severe malaria.[1] In these regions, severe disease is confined to infants and young children. This immunity lapses in those who move outside the endemic area for several years. Thus Asian or African immigrants living in Europe or North America may become susceptible to symptomatic malaria by the time they return home on vacation. Outside the endemic areas, autochthonous malaria may occur in those living around international airports or in immigrant communities. Malaria can be transmitted by transfusion of blood products and bone marrow, by transplanted organs and contaminated needles (for example, among intravenous and subcutaneous drug abusers), and transplacentally (congenital malaria). Nosocomial outbreaks have followed contamination of intravenous lines and contrast medium, and administration of drugs.

GENETICS

So far, eighteen human genetic polymorphisms have been associated with resistance to malaria.[2] These include thalassemias, hemoglobins S, E, and C, South East Asian ovalocytosis, glucose-6-phosphate dehydrogenase (G6PD) deficiency, interferon-α and -γ receptors, toll-like receptor 4, and for vivax malaria, the Duffy blood group. The highest frequencies of these resistance genes occur in intensely malarious areas.

GENERAL PATHOPHYSIOLOGY

Symptoms and pathologic changes are attributable to the asexual erythrocytic cycle and to secondary activation of macrophages and the immune system. A malarial toxin, released at schizont rupture, stimulates macrophages to release interleukin-1, tumor necrosis factor-α (TNF-α), and other cytokines. Cytoadherence to the wall of venules by erythrocytes containing mature trophozoites and schizonts plays an important role in producing organ and tissue dysfunction. The molecular basis of cytoadherence is the binding of malarial antigens expressed on the erythrocyte surface (notably the diverse and variable adhesive antigens, $PfEMP_1$) to endothelial receptors such as intracellular adhesion molecule-1 (ICAM-1), vascular cell adhesion molecule (VCAM), E-selectin, chondroitin-4-sulfate and hyaluronic acid (on placental villi),

membrane glycoprotein CD36, or the multifunctional adhesive glycoprotein thrombospondin.[1] Sequestration of parasitized erythrocytes is most marked in brain, kidney, gut, placenta, skeletal muscle, liver, bone marrow, and retina.[2–4] The resulting stagnation of blood flow causes hypoxia and anaerobic glycolysis with increased lactic acid production.[5]

PATHOPHYSIOLOGY OF SPECIFIC ORGAN AND TISSUE DYSFUNCTIONS

Anemia results principally from hemolysis of parasitized erythrocytes and perhaps some immune hemolysis. Enhanced splenic removal of nonparasitized erythrocytes and dyserythropoiesis may contribute. *Intravascular hemolysis* and *hemoglobinuria* in patients with inherited erythrocytic enzyme defects such as G6PD deficiency is commonly associated with the use of oxidant antimalarial drugs such as primaquine and chloroquine. Classic *blackwater fever* has been attributed to quinine-related immune hemolysis, but the evidence is inconclusive. *Thrombocytopenia* results from splenic sequestration or immune destruction; there is no evidence of reduced marrow production. There is evidence of *disseminated intravascular coagulation* (DIC) in about 15% of severe cases. Neurologic symptoms (*cerebral malaria*) are attributable to sequestration of parasitized erythrocytes in venules with some inflammatory change, especially in children. Plasma concentrations of TNF-α correlate directly with severity and incidence of neurologic sequelae.[6] In human cerebral malaria, permeability of the blood-cerebrospinal fluid barrier is only mildly deranged. Cerebral edema does not explain coma. *Acute pulmonary edema* may be precipitated by fluid overload, but is more commonly associated with normal or low pulmonary artery wedge pressures and resembles acute respiratory distress syndrome. Leukocyte sequestration in the pulmonary capillaries resembles experimental "endotoxin lung." *Hypoglycemia* may result from quinine- or quinidine-induced hyperinsulinemia or from inhibition of hepatic gluconeogenesis by TNF-α, in association with appropriately low plasma insulin levels. *Renal* and *hepatic dysfunction* result from vasoconstriction and vascular obstruction by sequestered parasitized erythrocytes.[1,7] *Shock* (*algid malaria*) is frequently associated with secondary gram-negative rod septicemia, but may also arise in patients with acute pulmonary edema, dehydration, lactic acidosis, hypoglycemia, and hemorrhagic shock following gastrointestinal hemorrhage or splenic rupture.

CLINICAL FEATURES

FALCIPARUM MALARIA

The shortest interval between the infecting mosquito bite and the first symptom is 7 days. This fact may be useful in excluding the diagnosis of malaria in patients who fall ill too soon after entering a malarial endemic region. More than 80% of patients with imported falciparum malaria become ill within 1 month of leaving the endemic area, whereas only a few percent present between 3 and 12 months or longer after leaving. None of the symptoms of malaria is specific. The illness may start with headache, a fever, a chill, tiredness, or lethargy. Backache, myalgias, postural syncope, prostration, vomiting, and diarrhea are common. Physical signs include anemia, jaundice, and tender hepatosplenomegaly. An absence of focal symptoms, lymphadenopathy, and rash (other than herpes labialis) help distinguish malaria from some other fevers. The classical tertian or subtertian fever (a fever spike every 36 or 48 hours) is rarely seen, and even the classic "paroxysm" (chill, hot phase, and diaphoresis) is uncommon.[1,8]

Life-threatening falciparum malaria is defined by the presence of any of the features listed in Table 58-1.[9] There are age and geographic variations in the frequency of these different features. In most parts of the world, cerebral malaria is the most familiar manifestation of severe malaria in adults, but jaundice is more common in Vietnam and Papua New Guinea, and in African children acidotic breathing is more common.[1,9]

Cerebral malaria[10,11] should be considered in any acutely febrile patient, possibly exposed to *P. falciparum* infection, whose level of consciousness is impaired. A typical history would be that after a few days of febrile symptoms, coma developed insidiously or suddenly with a generalized convulsion. An immediate trial of antimalarial chemotherapy is warranted in such patients even if parasitemia is not evident in the peripheral blood smear. A strict definition of cerebral malaria (essential for comparative clinical trials) demands unrousable coma (Glasgow Coma Scale score $\leq$11), the demonstration of asexual *P. falciparum* parasitemia, and the exclusion of other causes of coma, especially of bacterial meningitis and locally prevalent viral encephalitides.[9,12]

Other clinical features of cerebral malaria include seizures (which may be subclinical in children),[13] dysconjugate gaze, forcible jaw closure and tooth grinding (bruxism), signs of a symmetrical upper motor neuron lesion (with extensor

plantar responses and absent superficial reflexes), and abnormal extensor or flexor posturing (decerebrate/decorticate rigidity). Retinal hemorrhages, and the less frequent exudates and papilledema, carry a severe prognosis. Survivors recover consciousness within a few days and are usually free of neurologic sequelae (but see discussion of children below). Psychiatric manifestations (brief reactive psychosis), involuntary (extrapyramidal) movements, and focal convulsions without loss of consciousness are seen but are uncommon. Delayed and reversible postmalaria ataxia has been described, especially in South Asia, but is not usually associated with cerebral malaria or severe disease.[1,10]

Renal functional impairment of some degree occurs in about a third of adult patients with severe falciparum malaria.[14] Acute tubular necrosis develops in a minority. Acute renal failure is a feature of classic blackwater fever.

Acute pulmonary edema is often fatal. It is associated with hyperparasitemia, renal failure, lactic acidosis, use of excessive parenteral fluid replacement, and parturition. It has been rarely reported in vivax and ovale malarias (see below).[15]

Hypoglycemia is increasingly recognized. Symptoms of hypoglycemia may be confused with those of malaria itself, and so hypoglycemia must be specifically excluded in all patients with impaired consciousness, abnormal posturing, convulsions, shock, tachypnea, and in pregnant women in whom there is evidence of fetal distress. Hypoglycemia commonly develops as a complication of treatment with cinchona alkaloids (quinine and quinidine), which induce hyperinsulinemia, even in convalescence, particularly in pregnant women who may be asymptomatic, and in adults and children with hyperparasitemia and other features of severe disease.

Shock (algid malaria) may complicate severe malaria itself or be a result of simple dehydration or acute hemorrhage, but in many patients there is superimposed gram-negative septicemia. Cardiac arrhythmias and myocardial failure are extremely rare.

Bleeding, coagulopathy, and DIC are found in about 15% of nonimmune travelers with severe falciparum malaria. Thrombocytopenia is common in both falciparum and vivax malarias; its degree is not related to prognosis.

Acidosis, usually resulting from lactic acid accumulation, presents with rapid deep respirations in severely ill patients.

Massive intravascular hemolysis and hemoglobinuria in patients with normal erythrocyte enzymes has been termed "blackwater fever." This puzzling syndrome is associated with intermittent use of quinine, mild or absent parasitemia, fever, loin pain, vomiting, diarrhea, polyuria followed by oliguria and passage of black urine, tender hepatosplenomegaly, profound anemia, and deep jaundice.

Hepatic dysfunction is manifested by deep jaundice with a major component of conjugated bilirubin, prolonged prothrombin time, increased concentrations of serum aminotransferases (rarely more than 3 to 5 times greater than normal), and a low or falling serum albumin.

Severe falciparum malaria in children[1,16,17] is found in endemic regions of the tropics, where children under the age of 5 years are the most vulnerable. The history may be very short with less than 24 hours between the first feverish symptom and loss of consciousness. Generalized and subclinical convulsions are common.[13] There is evidence of raised intracranial pressure (cerebrospinal fluid [CSF] opening pressure at lumbar puncture is elevated), brain swelling (confirmed by computed tomography [CT] or magnetic resonance imaging [MRI]), and in some cases neurologic signs suggesting cerebral and brain stem herniation.[17] A syndrome of metabolic acidosis, respiratory distress, and profound anemia carries a particularly bad prognosis.[16] Jaundice, renal failure, hemostatic abnormalities, and pulmonary edema are much less common than in adults, but hypoglycemia is very common. The incidence of persistent neurologic sequelae after childhood cerebral malaria may exceed 10%.

The mortality of severe falciparum malaria ranges from 10% to 50%. In a recent report of imported cases of malaria managed in a European ICU, the mortality was 11%.[18] However, in adults, impaired consciousness alone, without evidence of other organ or tissue dysfunctions, carries a good prognosis.[12,18]

OTHER MALARIAS

Initial febrile and influenza-like symptoms associated with other *Plasmodium* species are as unpleasant as in falciparum malaria. The fever in untreated vivax and ovale malarias has a tertian periodicity (fever spike every 48 hours), and in *P. malariae* infection has quartan periodicity (every 72 hours). Vivax and ovale malarias may relapse 8 years or longer after the initial infection, and malarial infection may recrudesce for 50 years or more.

If, in a patient whose blood film shows only parasites of *P. vivax*, *P. ovale,* or *P. malariae*, there are clinical features of severe disease, inapparent mixed infection with *P. falciparum* should be suspected and the patient treated accordingly. Rapid antigen detection tests specific for *P. falciparum* can be useful in this situation (see below). However, *Plasmodium vivax* and *P. ovale* malarias can cause increased pulmonary capillary permeability, and on rare occasions, even clinically apparent pulmonary edema.[15] Fatal splenic rupture has been described in vivax, and some debilitated children or adults have died of severe anemia. *P. malariae* malaria may prove severe or even fatal in immunocompromised patients who acquire the infection by transfusion. *P. malariae* infection is an important cause of nephrotic syndrome, especially in Africa.

IMPACT OF OTHER CONDITIONS ON DISEASE SEVERITY

Malaria is more severe in pregnant women, especially in the third trimester, and even women with acquired malarial immunity become newly vulnerable to severe disease during their first pregnancy. Splenic dysfunction predisposes to severe disease with high parasitemia with schizonts, and other mature forms may be present in the peripheral blood smear. An interaction between human immunodeficiency virus (HIV) immunosuppression and malaria has so far been demonstrated only in pregnant women, who show higher parasitemias, and in their babies, who suffer higher perinatal mortality. Although sickle cell trait partially protects against falciparum (but not ovale) malaria, malaria may be disastrous in children with sickle cell disease.

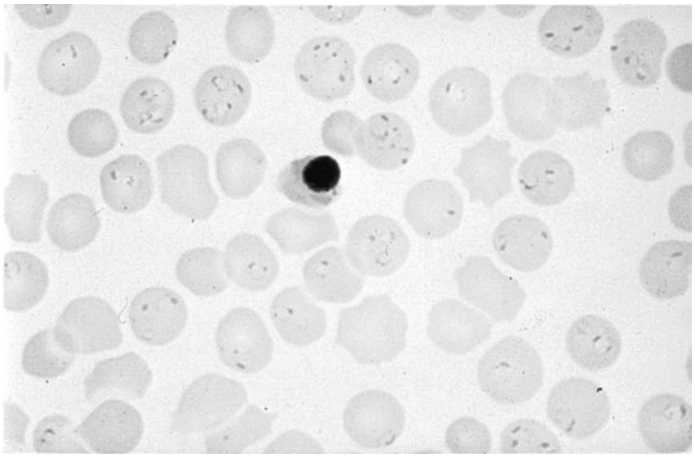

FIGURE 58-2 ***Plasmodium falciparum*** **hyperparasitemia in a thin blood film from a patient with cerebral malaria. (*Copyright D.A. Warrell*.) (See Color Plate 58-2.)**

INVESTIGATIONS

In a case of suspected malaria, the most urgent investigation is confirmation of diagnosis by microscopy or rapid antigen detection (see below). Other useful laboratory tests include a full blood count to detect anemia, thrombocytopenia (also common in vivax malaria), and neutrophil leukocytosis (of prognostic significance); examination of a thin blood film to detect malarial pigment in leukocytes (see below); measurement of plasma electrolytes (hyponatremia, hypophosphatemia, and hypocalcemia are reported); blood urea, creatinine, creatine kinase (for evidence of rhabdomyolysis), bilirubin, albumin, aminotransferases, lactate dehydrogenase and other serum enzymes (evidence of hepatic dysfunction); blood glucose; arterial blood gases, pH, bicarbonate and lactate (of prognostic significance); rapid urine testing for blood, hemoglobin, and myoglobin, and microscopy (sediment typical of acute glomerulonephritis); and, in cases of cerebral malaria, lumbar puncture and examination of CSF to exclude a bacterial, viral, fungal, or protozoal meningoencephalitis.[1]

The chest radiograph may show pulmonary edema or an incidental pneumonia or, if clear, supports the diagnosis of "acidotic breathing" in a hyperventilating patient. Electrocardiography (ECG) may confirm an arrhythmia or conduction defect attributable to quinine or quinidine. Abdominal ultrasound may show hepatosplenomegaly or evidence of splenic rupture. Electroencephalography may reveal subclinical seizure activity.[13]

BRAIN IMAGING

CT and MRI scans have been reported in patients with cerebral[19,20] and noncerebral malaria.[21] Abnormalities include diffuse cerebral edema, focal hemorrhagic and nonhemorrhagic infarcts in various parts of the brain, subarachnoid hemorrhage, areas of hypoattenuation, and symmetrical infarction of the thalamus and cerebellum in adults who died of cerebral malaria.[21] Not all those with cerebral malaria showed evidence of cerebral edema, and the prognosis was better in patients with normal scans.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

Malaria must be included in the differential diagnosis of any acutely ill, febrile patient with an appropriate travel history. Exposure can occur during a brief stopover in a malarious area, even if the ultimate destination was malaria-free. Routes of infection other than mosquito bites must be considered, such as blood transfusions and needlestick injuries and other nosocomial parenteral exposures to blood products. A diagnosis of malaria is more likely if the patient took no precautions against mosquito bites and no antimalarial chemoprophylaxis (or took the drugs irregularly or stopped them prematurely). The differential diagnosis of malaria includes other acute infections that cause chills and rigors, especially those that do not cause focal signs or symptoms (e.g., influenza, enteric fevers, or brucellosis); jaundice (e.g., viral hepatitis, leptospirosis, and relapsing fevers); hemorrhage (e.g., viral hemorrhagic fevers or hepatic failure); hyperpyrexia (e.g., heatstroke, neuroleptic malignant syndrome, malignant hyperthermia, or thyroid storm), gastrointestinal symptoms (e.g., gastroenteritis, traveler's diarrhea, or salmonellosis); and encephalopathy (e.g., viral, bacterial, fungal, or protozoal encephalitides, heat stroke, or metabolic coma).

LABORATORY DIAGNOSIS

Rapid antigen detection tests employing monoclonal antibodies to *P. falciparum* histidine-rich protein 2 and lactate dehydrogenase have proved to be sensitive and specific screening tests.

Microscopic diagnosis, which remains the gold standard, is achieved by examining conventional hematologic thin blood smears and thick films (a simple concentration method), preferably made at the bedside using blood straight from the patient that has not been stored with anticoagulant. Wright, Field, Leishman, and Giemsa stains are suitable (Fig. 58-2 and Color Plate 58-2). Parasites should be counted in relation to erythrocytes or leukocytes in the same field, and the parasite concentration (per microliter) calculated from total erythrocyte or leukocyte counts. Blood examinations should be repeated at least every 12 hours, as parasitemia may fluctuate. Blood sampling need not be timed to coincide with a fever spike or paroxysm. There is no advantage in using venous or arterial blood instead of blood obtained by finger prick. Blood smears should be examined at 12-hour intervals (minimum) after starting treatment until parasitemia has disappeared for at least 24 hours. Malaria parasites may not be seen or recognized in travelers who

are taking antimalarial drugs prophylactically. For this reason, such drugs should be stopped immediately, in the interest of making a diagnosis. Peripheral parasitemia may sometimes be undetectable in patients subsequently found (at autopsy) to have parasitized erythrocytes sequestered in their brains, and so a therapeutic trial of antimalarial drugs should be considered if there is clinical suspicion of severe malaria. The presence of gametocytes indicates recovery from infection; their morphology distinguishes falciparum from other malarias. Malarial pigment may be found in circulating leukocytes; its density is of prognostic value.

MANAGEMENT OF SEVERE MALARIA

Severe malaria is nearly always the result of *P. falciparum* infection. Because the disease can evolve rapidly, with sudden clinical deterioration and successive involvement of many vital organs and tissues, severe falciparum malaria is a medical emergency that should ideally be managed in an ICU.

INITIAL CLINICAL ASSESSMENT AND MANAGEMENT

The clinical history, taken from the patient or accompanying friends and relatives, should include precise details (times and places) of travel to the tropics, preventive methods, recent antimalarial therapy or prophylaxis, and previous attacks of malaria. A history of ominous events such as convulsions, drowsiness, diminishing urine output, black urine, and psychosis should be elicited. It is important to know whether a female patient is pregnant. In severely ill patients, a rapid initial examination should be carried out to exclude other diagnoses (e.g., meningitis) and to detect life-threatening complications such as pulmonary edema, renal failure, shock, and hypoglycemia. In patients with malarial parasitemia, the physician must keep an open mind about other disease processes, especially in residents of the malarious zone in whom parasitemia may be irrelevant to their current illness. Initial investigations must include a parasite count (which is of prognostic importance), hematocrit, full blood count, and measurement of electrolytes, blood urea, and creatinine (Table 58-2). Frequent measurement of the blood glucose concentration is most important. It can be checked rapidly and repeatedly at the bedside using one of the many commercially available methods. The blood should be cultured. In patients with respiratory distress, arterial pH, blood gas tensions, bicarbonate, and lactic acid concentrations should be measured. In patients with impaired consciousness and other neurologic signs, lumbar puncture is important to exclude treatable meningoencephalitides. The usual precautions should be observed before carrying out a lumbar puncture: search for clinical evidence of raised intracranial pressure, lateralizing neurologic signs, and signs of imminent coning, local skin sepsis, etc. If there is any doubt, a CT or nuclear magnetic resonance (NMR) scan should be performed first. Lumbar puncture is safe in *adult* patients with cerebral malaria. However, African children may show progressive signs of cerebral compression and raised intracranial pressure, and some authorities recommend delaying lumbar puncture for 24 hours and giving presumptive antimicrobial treatment against bacterial meningitis.[17] In cerebral malaria the CSF is usually normal. However, a mild lymphocyte pleocytosis (up to about 15 cells/μL) and mildly raised total protein concentration are found occasionally. Low or undetectable CSF glucose concentration indicates hypoglycemia. CSF opening pressure was normal in 80% of Thai adults with cerebral malaria, but was elevated in Kenyan children.[17]

TABLE 58-2 Initial Management of Patients with Severe Malaria

1. Clear and maintain airway.
2. Position semiprone or on side.
3. Weigh the patient, calculate drug dosage.
4. Start antimalarial chemotherapy.
5. Make rapid clinical assessment.
6. Take blood for diagnostic smear, monitoring of blood sugar (rapid "stix" method), hematocrit, and other laboratory tests.
7. Exclude or treat hypoglycemia.
8. Assess state of hydration.
9. Consider need for additional drugs (antimicrobials, vitamin K, etc).
10. Measure and monitor urine output. If necessary, insert urethral catheter. Measure urine specific gravity and sodium concentration.
11. Plan first 8 hours of intravenous fluids, including diluent for antimalarial drug, glucose therapy, and blood transfusion.
12. Consider inserting central venous pressure or pulmonary artery catheter to monitor fluid replacement.
13. If rectal temperature exceeds 39°C, remove patient's clothes, tepid sponge, fan, use hypothermia mattress, and consider antipyretic (acetaminophen).
14. Do lumbar puncture to exclude meningitis. Consider other infections.

ANTIMALARIAL CHEMOTHERAPY

In patients with proven or suspected severe falciparum malaria, appropriate parenteral chemotherapy (usually with licensed quinine or quinidine) must be started immediately. Artemisinin derivatives such as artesunate, artemether (which has proved as effective as quinine in the treatment of cerebral and severe falciparum malaria),[22] or arteether, may be available for treatment on a named-patient basis. Delay in diagnosis and treatment and the use of inappropriate antimalarial drugs account for most cases of fatal imported malaria.

In severely ill patients, chloroquine-resistant *P. falciparum* infection should be assumed. Recommended parenteral regimens for treatment of severe malaria are summarized in Table 58-3.

Cinchona Alkaloids (Quinine and Quinidine)

Quinine remains effective in the treatment of severe falciparum malaria. In the United States quinidine[23] is supplied by the Centers for Disease Control and Prevention in Atlanta, Georgia, whose 24-hour malaria hotline telephone number is (404) 332-4555. Quinine and quinidine should never be given by intravenous push or bolus injection, but should be administered by slow, controlled-rate intravenous infusion using an intravenous drip with a metered chamber or an infusion pump. Unless the patient has been given quinine, quinidine, or mefloquine within the previous 12 hours, an initial loading dose should be used so that therapeutic blood concentrations can be achieved rapidly.[23–25]

TABLE 58-3 Severe Falciparum Malaria: Antimalarial Chemotherapy

1. *Quinine*: 7 mg dihydrochloride *salt*/kg (loading dose) IV by infusion pump over 30 minutes followed immediately by 10 mg *salt*/kg (maintenance dose) diluted in 10 mL/kg isotonic fluid by IV infusion over 4 hours, repeated every 8–12 hours until the patient can swallow,[c] then quinine tablets,[b] approx. 10 mg salt/kg every 8 hours to complete 7 days of treatment.[25]

or

2. *Quinine*: 20 mg dihydrochloride *salt*/kg (loading dose)[a] by IV infusion over 4 hours, then 10 mg *salt*/kg over 4 hours, every 8–12 hours until patient can swallow,[c] then quinine tablets,[b] to complete 7 days of treatment.[24]

or

3. *Quinidine*: 15 mg *base*/kg (equivalent to 20 mg/kg of quinidine gluconate) (loading dose)[a] by IV infusion over 4 hours, then 7.5 mg *base*/kg over 4 hours, every 8–12 hours until patient can swallow,[c] then quinine tablets[b] to complete 7 days of treatment.[23]

or

4. *Artesunate:* (reconstitute with 5% bicarbonate immediately before injection) 2.4 mg/kg (loading dose) by IV (bolus) or IM injection, followed by 1.2 mg/kg daily as a single dose for a minimum of 3 days or until patient can take oral therapy or another effective antimalarial.[1]

or

5. *Artemether*: 3.2 mg/kg (loading dose) by IM injection, followed by 1.6 mg/kg daily for a minimum of 3 days or until patient can take oral treatment or another effective antimalarial.[1]

[a] Quinine/quinidine loading dose should not be used if patient received either drug or mefloquine within the preceding 12 hours.
[b] For infections acquired in areas of quinine resistance (e.g., Thailand) add an oral course of tetracycline 250 mg, 4 times a day *or* doxycycline 200 mg a day every day for 7 days except in children under 8 years of age and pregnant women, or clindamycin 10 mg/kg twice daily for 3–7 days.
[c] In patients requiring more than 48 hours of parenteral therapy reduce the maintenance dose to one half to two thirds (i.e., quinine *salt* 5–7 mg/kg or quinidine *base* 3.75–5 mg every 8–12 hours).

The initial dose should not be reduced in pregnant women[26] or in patients with renal and hepatic dysfunction, but the maintenance dose should be reduced after 48 hours of parenteral treatment, unless the patient can continue treatment by the oral route. The dose should also be reduced if at any stage the plasma concentration exceeds 15 mg/L (45 mmol/L). In patients treated with quinidine, the ECG should be monitored for QTc prolongation, and blood pressure measured every 30 minutes during the initial loading dose infusion.[23]

TOXICITY OF CINCHONA ALKALOIDS Plasma concentrations of cinchona alkaloids above about 5 mg/L are associated with cinchonism: giddiness, tinnitus, high-tone deafness, tremors, blurred vision, nausea, and vomiting. Concentrations above 20 mg/L may cause blindness, deafness, hypotension, ECG abnormalities, and central nervous system depression. However, most patients with malaria are more tolerant of high plasma concentrations than uninfected patients who take overdoses of these drugs, due to binding of quinine by acute phase reactive proteins, especially α_1-acid glycoprotein. Quinidine more than quinine causes prolongation of the QTc interval and QRS complex, but this is rarely associated with dysrhythmia or hypotension unless the drugs are given too rapidly. The most frequent important side effect of quinine and quinidine is hypoglycemia, which may occur at any stage of treatment and may cause recurrent neurologic symptoms in patients who appear to have recovered from cerebral malaria. Normal therapeutic doses can be used safely even in the third trimester of pregnancy.[26] In these patients it is important to assess uterine activity and fetal heart rate before starting quinine, to avoid confusing the effects of malaria and high fever per se from those of the drug.[26] In severe quinine toxicity (following oral or parenteral administration), quinine elimination can be increased by oral or nasogastric administration of activated charcoal.[27]

Artemisinin Derivatives (Artesunate, Artemether, and Arteether)

These compounds are convenient to administer, rapidly clear parasitemia, and have proved safe in clinical use. Large comparative studies have demonstrated that they reduce case fatality of cerebral and severe falciparum malaria at least as effectively as quinine.[22] They are particularly valuable where quinine resistance is emerging and in patients with recurrent quinine-induced hypoglycemia.

Artesunate, a water soluble preparation for intravenous injection, is inherently unstable in aqueous solution, but can be made up with 5% bicarbonate immediately before use. Artemether is an oily suspension for intramuscular injection which is licensed for use in a number of countries (but not the United States, Canada, or the United Kingdom). Arteether, a virtually identical compound, is being prepared for registration in the United States. Artemether and arteether have proved to be neurotoxic and fetotoxic in animals, but these effects have never been observed in tens of thousands of human patients monitored during and after treatment with these drugs.

SUPPORTIVE CARE OF PATIENTS WITH SEVERE FALCIPARUM MALARIA

HYPERPYREXIA

Hyperpyrexia can cause febrile convulsions in children, fetal distress in pregnant women, and when sustained at core temperatures above 40°C, irreversible neurologic damage. Core temperature should be monitored, and when necessary the patient should be tepid-sponged and fanned, placed

on a hypothermia mattress, or given an antipyretic (e.g., acetaminophen).

CEREBRAL MALARIA

Generalized or covert seizures are common, especially in children. These must be controlled rapidly with appropriate anticonvulsants such as diazepam. Single-dose phenobarbital prophylaxis effectively reduces the incidence of generalized convulsions in adult and childhood cerebral malaria, but in a large randomized, placebo-controlled trial in African children, excess mortality was associated with this treatment, and thus it is not recommended.[28] Cerebral edema does not require treatment in adult patients with cerebral malaria. However, in African children with cerebral malaria, intracranial pressure is commonly raised, and in those who are deteriorating, intravenous infusion of mannitol 1 g/kg over 20 minutes should be considered.[17] Most of the ancillary treatments for cerebral malaria advocated in the past, including dexamethasone, have proved ineffective and potentially dangerous.[12,29,30]

ANEMIA

Anemia is an inevitable consequence of severe malaria. If transfusion becomes necessary, packed red blood cells should be used while the patient is carefully monitored for evidence of incipient pulmonary edema. Diuretics, such as intravenous furosemide, may be required to reduce the risk of fluid overload. Children with profound malarial anemia may present in shock with tachycardia and tachypnea. Hypovolemia and metabolic (lactic) acidosis are usually the main problems requiring urgent correction. Blood transfusion may have little permanent effect in raising the hematocrit of patients with severe malaria because of the greatly reduced survival of even nonparasitized erythrocytes.[31]

HYPOGLYCEMIA

The possibility of hypoglycemia in patients with severe or deteriorating symptoms must constantly be borne in mind. Frequent monitoring of the blood glucose is essential. Intravenous 50% dextrose (25 to 50 mL) should be tried if hypoglycemia is suspected or proved.

METABOLIC (LACTIC) ACIDOSIS

Metabolic (lactic) acidosis results from impaired tissue perfusion caused by hypovolemia and microvascular obstruction, reduced hepatic clearance of lactate, and in patients with a large parasite burden, from the parasites' lactic acid production. Tissue perfusion and oxygenation should be improved by correcting hypovolemia, clearing the airway, increasing the inspired oxygen concentration, and providing mechanical ventilatory support if necessary. The treatment of gram-negative bacteremia, a frequently associated complication, should be considered as well. Use of epinephrine as a pressor agent may increase lactic acidosis, an effect not seen with dopamine.[32]

DISSEMINATED INTRAVASCULAR COAGULATION

Severe DIC with spontaneous bleeding and fibrin deposition in the lungs and other tissues is occasionally seen (for treatment of DIC see Chap. 69).

DISTURBANCES OF FLUID AND ELECTROLYTE BALANCE

Patients with severe falciparum malaria are commonly dehydrated and hypovolemic on admission to the hospital as a result of decreased fluid intake, increased insensible losses through sweating and hyperventilation during febrile episodes, gastrointestinal fluid losses (vomiting and diarrhea), and sometimes during the diuretic phase of recovery from acute renal failure. These patients require parenteral fluid replacement, but this must be carefully controlled or else the increases in pulmonary capillary permeability may lead to acute and catastrophic pulmonary edema. A central venous or pulmonary artery catheter should be inserted. For correction of hyponatremia, hypocalcemia, hypophosphatemia, and hyper- or hypokalemia, see Chap. 76.

PULMONARY EDEMA

This may be associated with high central venous and pulmonary wedge pressures (caused by volume overload and/or anemia), or with low pressures as in acute respiratory distress syndrome from other causes. Mechanical ventilation may be required.[18] See Chaps. 36 and 38 for a discussion of the management of these complications.

RENAL FAILURE

Oliguria may be prerenal—caused by volume depletion—or attributable to direct renal injury.[14] If dialysis is indicated (see Chap. 75), hemofiltration has proved more effective than peritoneal dialysis.[18,33]

HEMOGLOBINURIA AND BLACKWATER FEVER

Intravascular hemolysis may be associated with acute renal failure. To protect the kidney from "pigment nephropathy," hypovolemia and acidosis must be corrected. Mannitol diuresis is recommended by some nephrologists. Packed red blood cells should be transfused to maintain the hematocrit above 20%. Despite the unproven suspicion that quinine may be responsible for the massive intravascular hemolysis of blackwater fever, treatment with cinchona alkaloids should not be stopped unless an alternative drug such as an artemisinin derivative is available.

HYPERPARASITEMIA

Mortality generally increases with parasitemia, exceeding 50% at parasitemias above 500,000/μL. It has been suggested that exchange transfusion, by reducing the burden of parasitemia more rapidly than chemotherapy alone, might reduce mortality, although the introduction of artemisinin derivatives that clear parasitemia very rapidly may weaken the argument for this intervention. Other theoretical advantages of exchange transfusion include the removal of harmful metabolites, toxins, and mediators, and the replenishment of normal red blood cells, platelets, clotting factors, and other depleted blood constituents. However, these potential advantages must be weighed against potential dangers, such as electrolyte disturbances (hypocalcemia and hyperkalemia), cardiovascular complications, line infections, and contamination of transfused blood with blood-borne pathogens, notably HIV, human T-lymphocyte virus-1, hepatitis viruses, and protozoa. In more than 200 reported cases, red blood cell exchange achieved rapid reduction in parasitemia, which in some cases was accompanied by evidence of clinical

improvement.[34] Exchange transfusion should be considered for nonimmune travelers who are severely ill, who have deteriorated on optimal chemotherapy, or who have parasite densities above 10% of circulating erythrocytes.[1]

RUPTURED SPLEEN

This life-threatening complication may occur in vivax or falciparum malaria. It must be suspected and excluded in patients who develop abdominal pain and shock. Ultrasound is useful for detecting free blood in the peritoneum and a tear in the splenic capsule. Invasive techniques such as needle aspiration of the peritoneal cavity, laparoscopy, or laparotomy may be required.

Chapter 59
TETANUS

PERRY GRAY

KEY POINTS

- *Tetanus is a toxin-mediated disease caused by* Clostridium tetani *and characterized by trismus, dysphagia, and localized muscle rigidity near a site of injury, often progressing to severe generalized muscular spasms complicated by respiratory failure and cardiovascular instability.*
- *The diagnosis of tetanus is made on clinical grounds alone. A clinical diagnosis of presumed tetanus is sufficient to initiate treatment.*
- *Patients with tetanus should be managed in an ICU. In severe cases, the first priority is control of the airway to ensure adequate ventilation and correction of hypotension related to hypovolemia and/or autonomic instability.*
- *Antitoxin therapy with human tetanus immune globulin is given intramuscularly (3000 to 6000 IU) as early as possible. In cases that have not yet progressed to generalized spasms, 250 IU given intrathecally by lumbar puncture may be of benefit.*
- *Treatment to limit continued production and absorption of toxin includes surgical débridement of the site of injury and antimicrobial therapy with intravenous metronidazole.*
- *Traditionally muscle rigidity and spasms have been treated with high-dose benzodiazepines and narcotics. However, intravenous magnesium therapy should also be considered.*
- *Cardiovascular instability due to autonomic dysfunction is managed by ensuring normovolemia and using benzodiazepine, narcotic, and/or magnesium sulfate infusions when needed.*
- *Supportive measures include early provision of nutrition, correction of electrolyte disturbances, subcutaneous heparin administration for prophylaxis of deep venous thrombosis, and prompt antimicrobial therapy for nosocomial infection.*
- *With meticulous management of the manifestations of this disease and careful attention to prevention of its major complications, complete recovery is possible in most cases.*

Tetanus is one of the best examples of a disease for which modern intensive care can offer a truly major improvement in long-term useful survival. Often a disease of otherwise healthy active people, the fully developed form is frequently rapidly fatal unless the patient is supported through a lengthy period of painful muscle spasms complicated by respiratory failure, cardiovascular instability, and increased risk of pulmonary embolism and nosocomial infection. However, if all these problems are meticulously managed, complete recovery can be expected. In developed countries, this disease is likely to remain an uncommon but challenging problem that demands an alert and aggressive approach to initial diagnosis and management, coupled with careful attention to supportive care and avoidance of complications over a period of weeks to months to achieve the eventual excellent outcome possible in most cases.

Pathogenesis

Although tetanus is primarily a disease of underdeveloped countries, there are approximately 36 to 48 cases per year reported in the United States.[1] The male:female ratio is approximately 3:2, representing a greater incidence of tetanus-prone wounds in males. Because preformed circulating antibody to tetanospasmin can completely prevent development of the disease, tetanus occurs primarily in nonimmunized or inadequately immunized patients, particularly the poor and elderly.[1,2] However, in rare instances tetanus has developed in patients who had received their primary series, as well as proper booster doses of toxoid,[3,4] so a history of proper immunization does not exclude the diagnosis of tetanus.

The disease is caused by *Clostridium tetani*, an anaerobic bacterium that exists in both vegetative and sporulated forms and has been isolated from soil, feces of humans and animals, dust, wounds, intact skin, catgut, and talcum powder. During unfavorable conditions the organism exists in the sporulated form, which can remain viable for several months. It is resistant to boiling and antiseptics but is killed by autoclaving at 121°C for 15 minutes. *Clostridium tetani* is not locally invasive and does not provoke an inflammatory response, and inoculation of spores into viable tissue does not produce tetanus. However, tissue necrosis, foreign bodies, or concurrent anaerobic or facultative anaerobic infections lower the normal oxidation-reduction potential of the tissue, which allows conversion to the vegetative form with subsequent toxin formation. The toxins produced include tetanolysin, which is capable of causing local damage to viable tissue, thereby optimizing conditions for bacterial multiplication, and production of tetanospasmin, which is a potent neurotoxin responsible for the clinical disease state.[5] Toxin formed in a skin wound enters the underlying muscle and may spread to adjacent muscles. It then accumulates in the nerve endings of motor fibers. Retrograde transport of the toxin then occurs via intra-axonal and periaxonal pathways from nerve endings to the ventral horns of the spinal cord or motor nuclei of the cranial nerves. If toxin is produced in larger amounts, it also accumulates in the lymphatic system of the invaded muscle, enters the bloodstream via the thoracic duct, and is disseminated throughout the body. Toxin passing from blood to skeletal muscle then accumulates in the nerve endings of the motor fibers and proceeds to the ventral horns (or cranial nuclei), or is taken up by the lymphatic system and recirculated in the blood. The rate of accumulation of toxin in the ventral horns of the spinal cord depends on the length of the neural pathway and the activity of the muscles involved.[6] Since jaw muscles and spinal postural muscles have short neural pathways to the ventral horns and are continually active in the awake human, this is the likely explanation for trismus and neck stiffness early in the course of the illness.

In the anterior horn or cranial nerve nuclei the toxin accumulates in the presynaptic apparatus, impairing spontaneous secretion and evoked release of the inhibitory neurotransmitter γ-aminobutyric acid (GABA) and glycine.[1,5] Because inhibitory synapses are more sensitive to the effects of tetanus toxin than excitatory synapses, impaired inhibition of motoneurons and interneurons results in enhanced excitation and muscular rigidity. Disruption of the inhibitory interneurons within the propriospinal connections results in

enhanced excitation such that stimulation from the periphery, such as light touch or visual or auditory stimuli from the reticular formation, can result in the generalized spasms seen in tetanus.

The effect of tetanus toxin on the neuromuscular junction is presynaptic inhibition of acetylcholine release, which can result in paralysis of muscles. Paralysis is less frequent and usually localized to areas of high toxin concentration because the neuromuscular junction is not as sensitive to tetanus toxin as the inhibitory neurons.

Autonomic dysfunction occurs later in the course of the disease because of the longer neuronal path. Sympathetic and parasympathetic overactivity has been attributed to impaired inhibition.[5]

Classification

There are three clinical forms of tetanus: generalized, local, and cephalic. Generalized tetanus is the most common form and is characterized by diffuse muscle rigidity. Localized tetanus is characterized by rigidity of a group of muscles in close proximity to the site of injury. Cephalic tetanus, which is a variant of local tetanus, is defined as trismus plus paralysis of one or more cranial nerves.[7] *Both local and cephalic tetanus may progress to generalized tetanus,* the latter occurring in approximately 65% of cases.

Clinical and Laboratory Manifestations

The most common means by which *C. tetani* enters the human host is through lacerations, especially if associated with tissue necrosis or foreign body. Tetanus can also follow burns or animal bites, septic abortion complicated by gangrene of the uterus, and rarely after otherwise uncomplicated abdominal surgery.[8] Untreated middle ear infections account for up to 30% of the cases of tetanus in India.[9] Intravenous drug users can develop tetanus associated with skin infections caused by use of inadequately sterilized needles.[10] However, in 15% to 25% of cases a portal of entry cannot be determined (cryptogenic tetanus).[3,9,10]

The interval between injury and onset of clinical symptoms is usually from 3 days to 3 weeks, but occasionally is as long as several months. Cephalic tetanus after scalp or facial injury tends to occur earlier with an incubation period of 1 day to 2 weeks.[7] In general, the shorter the incubation period, the more severe the disease. However, a long incubation does not guarantee a mild attack.

Muscular rigidity is the most prominent early symptom of tetanus. Rigidity of the masseter muscle (trismus) results in difficulty with opening the mouth and chewing. Rigidity of the facial muscles gives the characteristic smile of tetanus (risus sardonicus). Opisthotonos is caused by rigidity of the vertebral muscles and antigravity muscles. Abdominal muscle rigidity may simulate peritonitis. Nuchal rigidity may simulate meningitis. In the Edmondson and Flowers series of 100 patients,[3] trismus and dysphagia (described as sore throat) were the presenting symptoms in 75 cases and neck and back stiffness in 14 cases. However, in 88 cases, it was possible to demonstrate trismus on initial physical examination. In cephalic tetanus cranial nerve palsies may precede trismus.[3,11]

The *period of onset* of the disease is defined as the interval between the first symptom and the first generalized muscular spasm. A shorter period of onset is usually predictive of a severe attack.

Spasms are initially tonic, followed first by high-frequency and then low-frequency clonic activity. In very severe tetanus, spasms may occur so frequently that status epilepticus may be suspected, and may be forceful enough to cause fractures of long bones and of the spine. Spasm-induced damage to muscles can also result in rhabdomyolysis complicated by acute renal failure.[12] Spasms may be initiated by touch, noise, lights, and swallowing, even in the sleeping patient. Spasms severe enough to require treatment may persist for up to 6 weeks.

In addition to being extremely painful, spasms can produce a variety of significant secondary effects. Apnea occurs when spasms involve the respiratory muscles or larynx. Paralysis of skeletal muscles may occur following periods of sustained spasms due to presynaptic inhibition of acetylcholine release at the neuromuscular junction. Similarly, paralysis of urinary bladder musculature together with spasm of perineal muscles have been implicated in causing acute urinary retention. In pregnancy, spasms can cause abortion or miscarriage, although the fetus is not directly affected, since the toxin does not cross the placenta. Inadequately treated spasms can also produce fever, although secondary infection and direct and indirect actions of toxin on hypothalamic temperature regulation are often implicated.

The autonomic nervous system dysfunction of severe tetanus usually occurs 1 to 2 weeks after the onset of the disease but may occur earlier.[13] Manifestations of impaired sympathetic inhibition include tachycardia, labile hypertension alternating with hypotension, peripheral vasoconstriction, fever, and profuse sweating. Overactivity of the parasympathetic nervous system causes increased bronchial and salivary gland secretions, bradycardia, and sinus arrest.[14]

A complete blood count will usually show a leukocytosis with a left shift, and less frequently, a lymphocytosis. Examination of urine may reveal proteinuria and leukocytes thought to result from accumulation of tetanus toxin in the kidneys.[9] Other nonspecific laboratory abnormalities include elevation of serum transaminases, increased catecholamine levels in serum and urine, and decreased serum cholinesterase level. Creatine phosphokinase (CPK) is usually normal initially but generally rises with the onset of muscular spasms. Idoko and colleagues reported elevated cerebrospinal fluid (CSF) protein levels in 26 of 34 (76.5%) patients with tetanus.[15] The elevation of CSF protein appeared to correlate with disease severity. Nineteen patients with severe disease (10 ultimately fatal) had significantly higher CSF protein values (mean = 1582 mg/L) than mild cases (mean = 400 mg/L).

Complications of tetanus are numerous and frequent. The need for long-term endotracheal intubation and ventilatory support coupled with increased risk of aspiration may result in bacterial pneumonia. Other nosocomial infections also occur, as many patients require a long-term stay in an ICU. These may include infections of vascular access catheters, catheter-related urosepsis, and infected decubitus ulcers. Protracted immobilization places the patient at risk for deep venous thrombosis and pulmonary thromboembolism, which is commonly reported as a cause of death.

TABLE 59-1 Differential Diagnosis of Tetanus: Clinical Features

	Tetanus	Strychnine	Neuroleptics	SMS[a]	Rabies	Meningitis
Trismus	+	+	+	+	−	−

Risus sardonicus	+	+	−	−	−	−
Opisthotonus	+	+	+	−	+	−
Muscle rigidity (continuous)	+	+	+	−	−	−
Muscle rigidity (intermittent)	−	−	−	+	+	−
Encephalopathy	−	−	−	−	+	+
Rapid course	−	+	+	−	−	−

[a] Stiff-man syndrome.

Diagnosis

The diagnosis of tetanus is based on clinical manifestations rather than laboratory tests. Tissue cultures are positive in less than 50% of patients.[16] Since the organism is noninvasive, blood cultures are of little value except in diagnosing secondary infection. The major clinical features on which the diagnosis of tetanus is based are listed in Table 59-1 along with the features of other conditions with which it can be confused. Symptoms of strychnine poisoning usually begin 5 to 60 minutes after ingestion and resolve after 6 hours, although the hyperreflexia, stiffness, and muscle pains may last 3 to 7 days. The rapid course distinguishes strychnine poisoning and acute dystonic reactions from tetanus. Stiff-man syndrome is characterized by initially intermittent followed by continuous spasms of limb and trunk muscles that disappear during sleep. Trismus, facial palsy, nuchal rigidity, and continuous muscle rigidity are not seen in rabies. Cutaneous hyperesthesia is quite marked in rabies, as are disturbances in mentation, and both are absent in tetanus. Isolated paralysis of the facial nerve may be due to Bell palsy or an early manifestation of cephalic tetanus.[9] Patients with meningitis have nuchal rigidity but not trismus. However, examination of CSF is mandatory if the diagnosis is uncertain. Determination of serum calcium will rule out hypocalcemic tetany. Unlike trismus owing to these processes, tetanic trismus becomes more pronounced as the jaw is forced open.[9] Isolated trismus may be due to subluxation or arthritis of the temporomandibular joint or any inflammatory process involving teeth, mouth, tonsils, or pharynx.

Treatment

Patients with a presumptive diagnosis of tetanus should be admitted to an ICU.[3,16] Since the period of onset of the disease ranges from less than 1 to 12 days, even patients with mild tetanus (trismus, dysphagia, and localized rigidity) should be observed in an ICU for at least 1 week (2 weeks if no resolution of symptoms is noted). Patients with incubation periods of greater than 20 days who have only localized rigidity can be safely discharged to the ward after a few days of observation provided no progression of the disease has occurred.

The principles of initial treatment of tetanus consist of airway management, sedation, treatment of the portal of entry, antitoxin therapy, administration of appropriate antibiotics, and general supportive measures.[3,5,9,16] Drugs commonly used in the management of tetanus are listed in Table 59-2 together with their indications and usual doses.

Appropriate management of the airway is the first priority. Patients with trismus and localized rigidity with no evidence of respiratory compromise do not require prophylactic endotracheal intubation. Patients with diffuse rigidity, especially if unresponsive to benzodiazepine therapy, should be intubated, even in the absence of respiratory compromise. Intubation should be performed in all patients who have already had a generalized spasm or in any patient with evidence of respiratory compromise, including patients with severe dysphagia who are in danger of aspiration. The preferred route (nasotracheal vs. orotracheal) and method (awake vs. anesthetized) of intubation depends on the clinical situation. Ideally an anesthesiologist should perform intubation. An

TABLE 59-2 Drugs Used in Medical Management of Tetanus

Medication	Indication	Dose (Usual)
HTIG[a]	Local or cephalic tetanus	250 IU intrathecal
HTIG[a]	Generalized tetanus	3000–6000 IU intramuscular
Metronidazole	Toxin production (given in all cases)	500 mg IV/PO q6h
Midazolam	Spasms, sedation, and cardiovascular instability	0.3–30.0 mg/h IV (mean = 9.0 mg/h)
Magnesium sulfate	Spasms and cardiovascular instability	70–80 mg/kg IV load then 1–3 g IV q1h
Vecuronium	Neuromuscular blockade for severe muscle spasms	3–4 mg/h IV
Dantrolene	Rigidity and spasms	0.5–1.0 mg/kg IV q4–6h
Clonidine	Cardiovascular instability	300 μg q8h via nasogastric tube

[a] Human tetanus immune globulin.

emergency cricothyrotomy tray should be at the bedside prior to attempted intubation. If paralysis is required to facilitate intubation, a nondepolarizing agent should be used, since depolarizing neuromuscular blocking agents (e.g., succinylcholine) may cause hyperkalemia and cardiac arrest in patients withbreak tetanus.[17]

The classical approach for patients with muscular rigidity is sedation with intravenous benzodiazepines and narcotics. The doses should be titrated to reduce rigidity and provide adequate analgesia, respectively. Intubation, ventilation, sedation, and neuromuscular blockers[3,9,16,18] are the conventional therapies for tetanic spasms. However, in the early 1990s case reports suggested that neuromuscular blockade and ventilation could be avoided by using dantrolene and sedation.[19,20] More recently Attygalle and Rodrigo published their experience with 40 patients using intravenous magnesium as a first-line therapy for rigidity, spasms, and control of autonomic dysfunction.[21] In 95% of patients, control of spasms and muscle rigidity was achieved with serum magnesium levels of 2.0 to 4.0 mmol/L. The authors published their specific treatment protocol and stressed the importance of early tracheostomy for tracheal toilet. If neuromuscular blockade is required, pancuronium,[9] atracurium,[22] and vecuronium[18] have been reported as being safe and effective. Vecuronium has no cardiovascular side effects, which may be advantageous in treating patients with autonomic dysfunction.[18]

Aggressive surgical treatment of tetanus-producing wounds results in improved survival. The wound should be excised with a 2-cm margin.[23] If gangrene is present, the extremity should be amputated at least one uninvolved joint proximal to the wound.[23] The decision to perform a hysterectomy on a patient who develops tetanus following induced abortion or in the postpartum period should be based on the presence of associated invasive bacterial sepsis, gangrene of the uterus, or uterine injury. Tetanus is not itself an indication for hysterectomy.[9]

Several studies comparing mortality rates of patients with tetanus treated with and without antitoxin have produced conflicting results. However, the importance of answering this question has been markedly reduced by the availability of human tetanus immune globulin (HTIG), which has no serious adverse effects. It is now generally agreed that patients with tetanus should be treated with antitoxin as soon as possible.[1,5,16] However, controversy persists regarding the preferred route and dosage of antitoxin. There is evidence that in patients who have not yet progressed to generalized rigidity and spasms or those with very mild disease, intrathecal HTIG may reduce length of stay, prevent generalization, and in one study reduced mortality.[24,25] Conversely, once generalization has occurred, the administration of intrathecal HTIG has failed to improve survival. Intramuscular doses of HTIG ranging from 3000 to 6000 IU have been suggested.[5,16] It is important to administer antitoxin prior to débridement because the toxin may be introduced into the bloodstream during manipulation.[16]

Antibiotics are generally given both to treat infection at the injury site and to eliminate continued toxin production. Metronidazole 500 mg intravenously every 6 hours for 10 days is the antibiotic of first choice for *C. tetani*.[26] Penicillin G, tetracycline, erythromycin, clindamycin, and chloramphenicol are also effective.[5,26] Penicillin is a GABA antagonist. Given the pathophysiology of tetanus, the use of GABA antagonists is concerning.

General supportive measures include establishing intravenous access to maintain adequate fluid and electrolyte balance. A Foley catheter should be inserted in all but the mildest cases to prevent urinary retention. Appropriate prophylaxis for stress ulcers is indicated. Ideally, intubated patients should be fed using the nasojejunal route to minimize the possibility of aspiration. Energy expenditure in patients with severe tetanus receiving appropriate sedation are within 10.5% of predicted basal metabolic rates using the Harris-Benedict equation.[27] Subcutaneous heparin is given to prevent deep venous thrombosis. Physiotherapy prevents contractures in patients treated with neuromuscular blockers.

Arterial and pulmonary artery catheterization may be useful to manage the autonomic dysfunction of severe tetanus. In the absence of cardiac disease the cardiac index tends to be elevated. Rapid changes in systemic vascular resistance are responsible for fluctuations in blood pressure.[5] The pulmonary capillary wedge pressure and central venous pressure are usually normal, but may be low in patients with severe spasms and diaphoresis, which have led to hypovolemia. It is important to ensure that hypovolemia is promptly corrected, since this will substantially increase the potential for immediately life-threatening hypotension in the presence of the autonomic instability. Core body temperature should be monitored and hyperpyrexia (core temperature greater than 41°C) avoided owing to the increased risk of sudden death.[28] Treatment of cardiovascular instability consists of deep sedation, which if unsuccessful is followed by high-dose magnesium sulfate infusions.[29–31] Continuous benzodiazepine intravenous infusion should be tried initially, followed by continuous narcotic infusion if required. Successful control of autonomic dysfunction has been achieved using a bolus (5.0 μg/kg IV) plus a continuous infusion (4.0 to 6.0 μg/kg per hour IV) of fentanyl when a benzodiazepine alone was insufficient.[30] Patients unresponsive to deep sedation have been successfully treated with intravenous magnesium sulfate. A loading dose of 70 mg/kg IV over 5 minutes is followed by a continuous infusion titrated to maintain serum magnesium levels between 2.5 and 4.0 mmol/L.[29] This usually requires infusion rates of 1 to 3 g/h. Serum calcium and magnesium levels should be measured every 4 hours.[31] Calcium supplements may be required to maintain serum calcium levels above 6.8 mg/dL (1.7 mmol/L).[29] Any magnesium-induced cardiac arrhythmias should also be treated with IV calcium and the infusion rate of magnesium should be reduced. There is conflicting opinion regarding the ability to reduce sedation and/or analgesic medications in patients who respond to intravenous magnesium therapy.[29,31] Autonomic dysfunction unresponsive or incompletely responsive to magnesium may respond to clonidine.[32,33] Continuous epidural infusion of bupivacaine and sufentanil was retrospectively evaluated in 11 patients with severe tetanus and autonomic dysfunction.[34] In two patients the epidural alone was ineffective, therefore morphine, muscle relaxation, and phenobarbitone or chlorpromazine were added. One patient developed an epidural abscess requiring a laminectomy with surgical drainage. The authors discuss in detail the risks of placing epidural catheters in patients with tetanus and suggest a caution for advocates of intrathecal therapy. In the past, β-blockers have been used. However, there is now

evidence that their use is associated with a significant risk of death due to cardiac arrest,[14,35–37] and they are no longer recommended.

Prognosis

With modern intensive care management, mortality ranges from 10% to 15% overall and is no longer influenced by age.[5,38] In areas where such care is not available, mortality rates of between 25% and 50% are usual.[1,3,5,39] The general quality of critical care support is likely a key determinant of prognosis. In a recent study tracking mortality from severe tetanus in Brazil over two decades, mortality fell from 36.5% in the early time frame to 18.0% in the later period, likely related to general advances in ICU management.[40]

Finally, it is important to remember that recovery from tetanus does not guarantee natural immunity.[1] Patients should begin their primary immunization series prior to leaving the hospital; indeed, since passive immunization with HTIG does not interfere with successful active immunization, the series can begin even before the patient leaves the ICU.

Chapter 60

VIRAL HEMORRHAGIC FEVERS

SUSAN P. FISHER-HOCH

KEY POINTS

- *Viral hemorrhagic fevers (VHFs) are seen worldwide as either locally endemic disease or as imported cases in travelers.*
- *Travelers may be the source of epidemics in countries far from the source.*
- *Clinical presentation may be a flu-like syndrome, but may also be abrupt, with fever associated with generalized myalgia and headache. Severe cases progress to respiratory and gastrointestinal symptoms followed by systemic "capillary leak'' causing pulmonary edema, shock, and bleeding from mucosal surfaces.*
- *Clinical diagnosis hinges on a history of potential exposure within the preceding few days up to a maximum of 4 weeks. The exposure may be to rodents, ticks, or fresh animal or human blood, or patients, usually in remote rural areas where these diseases are endemic.*
- *Management is mainly supportive, but effective antiviral therapy is available for some fevers. The critical issues are respiratory support, replacement of blood components as needed, and support of the circulation (using vasopressor drugs if necessary) while avoiding large infusions of intravenous fluids, which worsen pulmonary edema.*
- *Ribavirin is effective for several VHF infections, and when indicated should be given intravenously and as soon as possible.*
- *Prevention of transmission of infection is effected by providing routine isolation of suspect cases in a single room, preferably one with negative pressure, and use of standard universal precautions for exposure to contact with blood or body fluids, including gloves, gowns, and other barrier nursing procedures, and careful disinfection of exposed surfaces. With appropriate barrier precautions the risk of nosocomial transmission is minimal.*
- *With prompt and appropriate supportive therapy, many patients with these infections can make a rapid and complete recovery without significant sequelae.*

Overview of the Viral Hemorrhagic Fevers

Viral hemorrhagic fevers (VHFs) are endemic on every continent with the possible exception of Australia. The diseases are characterized by acute onset with high fever, and in some cases, high mortality. The bleeding by which they are known is a complication only of severe disease, but the underlying pathology is of widespread leakage from the capillaries, with prominent pulmonary edema. The clinical syndrome is mainly caused by endothelial cell dysfunction, not by tissue necrosis. Death usually results from hypovolemic shock with or without acute respiratory distress syndrome (ARDS). In survivors, recovery is rapid and usually complete.

The diseases are caused by many different enveloped RNA viruses. Almost all are zoonoses, and infection of humans is accidental, usually the consequence of intrusion of a human into the ecologic niche of the virus. The viruses belong to four major families: bunyaviridae, arenaviridae, filoviridae, and flaviviridae. The bunyaviruses include hantaviruses and Crimean Congo hemorrhagic fever (CCHF), a member of the genus *Nairovirus*. CCHF is spread by ticks, and occurs widely across Africa, Southeastern Europe, the Middle East, and Asia. Hantaviruses are found throughout the world as natural silent infections of a number of rodents. A New World hantavirus in North and South America is a pathogen of deer mice and related species, and causes the hantavirus pulmonary syndrome (HPS). Arenaviruses are also natural infections of rodents, the most important being Lassa virus, which is confined to West Africa, and the South American hemorrhagic fever viruses belonging to a complex of New World rodent viruses, four of which at present are known to cause VHF. The filoviruses are a unique family of filamentous viruses that includes Ebola and Marburg. African filoviruses have high mortality, but Asian filoviruses seen in monkeys from the Philippines do not appear to be pathogenic for humans. The flaviviridae include yellow fever virus and dengue virus, both spread by mosquitoes. Other viruses may cause hemorrhagic fever, such as Kyasanur Forest disease and Omsk hemorrhagic fever, but these are confined to very local areas and will not be discussed in detail.

EPIDEMIOLOGY

The zoonotic character of these infections means that they are primarily rural diseases in developing communities in areas with poor medical facilities, and they often go undiagnosed. Clinical reports and trials are scant, and data are limited. Essentially, VHFs are diseases of the poor. However, with increasing mobility of populations, and the migration and enrichment of individuals from poor communities who may revisit their villages for family events, infected patients can and do appear almost anywhere in the world. Missionaries and medical staff working in remote areas are also at risk and more likely than locals to reach tertiary care facilities, and thus to be diagnosed. Peace keepers and other aid workers are particularly at risk and several have been infected with Lassa fever in Sierra Leone and a few have died. Epidemics of VHFs such as yellow fever may be devastating, and there can be thousands of cases of this mosquito-borne disease. Some viruses, particularly filoviruses, have only emerged in small epidemics; however their very high mortality has given them prominence disproportionate to the number of patients. Recently Ebola outbreaks in equatorial Africa, specifically Gabon and the Republic of Congo, are associated with a massive epizootic in great apes whose populations are threatened now with extinction due to a combination of Ebola virus, logging, and hunting for bush meat. This epizootic is fueling epidemics in rural communities in the adjoining areas.

HISTORY AND CLINICAL DIAGNOSIS

The most critical element in the clinical diagnosis is a thorough history covering the incubation period, a maximum of 4 weeks prior to onset of fever. The element that alerts the

Copyright © 2005, 1998, 1992 by The McGraw-Hill Companies, Inc. Click here for terms of use.

physician to a viral hemorrhagic fever (and usually indicates which one it is likely to be) is the contact the patient might have had with known ecologic niches or patients who may have one of these infections (Table 60-1). Questions must include a thorough travel history; information on any possible contact with ticks, fresh animal blood, rodent urine or blood, wild animals, and mosquitoes and other insects; recent camping in exotic areas; possibly entry into bat caves; and attendance at ceremonial funerals. All of these factors can be significant, especially in remote areas. A medical care provider or other worker who might have had contact with blood from a primary case is also cause for alert.

An essential element is a short history of fever, often high and of abrupt onset. However, some patients present with a flu-like syndrome, which is of course difficult to differentiate. Severe body pains and headache are prominent and may be excruciating. Other features may be severe sore throat, nausea and vomiting, petechiae, oozing from the gums, and bradycardia. Proteinuria is frequent. Total peripheral white counts are usually unhelpful, but differential counts usually show lymphopenia and neutrophilia, which may be marked, and may actually mislead one into thinking it is caused by a bacterial infection. Thrombocytopenia is common, and platelet function is impaired. Partial thromboplastin times may be prolonged, but prothrombin times are relatively spared. Disseminated intravascular coagulation (DIC) is not a feature of VHF except as a complication of the terminal phase. As disease progresses, hypovolemic shock, pulmonary edema, and frank bleeding ensue. Serum glutamate oxaloacetate transaminase (SGOT; aspartate aminotransferase) is usually raised, and VHFs distinguish themselves from viral hepatitis because the SGOT is disproportionately high compared with the serum glutamate pyruvate transaminase (SGPT; alanine aminotransferase). Ratios of SGOT:SGPT may be as high as 11:1, and the level of the SGOT also reflects prognosis. Patients are rarely jaundiced, and the bilirubin is usually normal, the exception being yellow fever as its name suggests. The central nervous system (CNS) is relatively spared, but encephalopathy and neurologic sequelae such as ataxia and deafness occur. Isolated ocular sequelae in Ebola including blindness have been reported, as has a syndrome of polyserositis following Lassa fever.[1,2]

LABORATORY DIAGNOSIS

Care must be taken in collection, handling, and transport of specimens, and consultation with the laboratory is essential. Gloves must be worn at all times and the specimens clearly labeled as hazardous. Blood samples should be drawn, preferably into a vacuum tube system. Specimens for transport should be transferred to a leakproof plastic container and double wrapped in further leakproof containers for shipping to a suitable reference laboratory. Sera may be safely handled for immunologic tests by inactivation by heating to 60°C for 30 minutes.

The most rapid and accurate method of diagnosis is by reverse transcriptase polymerase chain reaction (RT-PCR). This technique is reliable and safe to perform directly on serum or tissues. However, availability of the assay specific for a particular virus may not be locally available and specimens need to be directed rapidly to a competent laboratory. The chemical reagents used in RT-PCR will reliably inactivate virus, so the technique also has advantages in safety, provided the initial steps are performed with care. In some circumstances antigen detection techniques in blood and tissues are available using enzyme-linked immunosorbent assay (ELISA) methodology, but once again these are usually only available in reference laboratories. Laboratory diagnosis is also by isolation of virus from serum, but this usually requires a high level of laboratory biocontainment, and takes time, often a week or more. Demonstration of a fourfold rise in antibody titer, or high-titer IgG antibody with virus-specific IgM antibody in association with compatible clinical disease is also diagnostic, but the more rapid VHFs, particularly Ebola and CCHF, evolve so quickly that patients may never develop antibody before death. Antibody detection techniques include immunofluorescence assay (IFA) and ELISA, and are increasingly being produced using recombinant antigens, thus avoiding the use of infectious agents in their preparation.

MANAGEMENT

VHFs in survivors are self-limiting diseases, so providing the acute crisis can be managed, recovery is rapid and usually complete, though convalescence may be prolonged.[3,4] Some viruses are highly treatable using the antiviral agent ribavirin, provided therapy is instituted as early as possible in the disease course (Table 60-2). Therapy with immune plasma has also been advocated, but with the exception of Argentine hemorrhagic fever, it has not been shown to have efficacy.

The main challenge is careful management of fluid balance. Patients will often present with high hematocrit due to capillary leakage aggravated by dehydration. Despite this, pulmonary edema is a real risk, and patients should be infused with caution. Blood and platelet replacement may be necessary. Full intensive care support may be required including mechanical ventilation, monitoring of central venous pressure, and dialysis. Seizures and arrhythmias will need to be controlled. DIC is not generally a major feature, and heparin is contraindicated. Exchange transfusion and use of steroids are controversial and cannot be recommended at this time. Early accurate diagnosis and good intensive care support are the most important underlying principles for the physician.

Patients with VHF do not travel well, since their cardiovascular system is often unstable, and even the moderate trauma of travel can induce bleeding or hypotension. For this reason moving a patient should be avoided whenever possible.[5] Moving the patient also increases the risk and the number of people exposed and thus the risk of secondary infections.

PREVENTION OF SPREAD

The fearsome reputation of some of these viruses, such as Ebola, Lassa, and CCHF, comes from their ability to spread to medical staff and patients in facilities where inadequate barrier nursing and other practices lead to blood-to-blood contact with the virus, such as needlestick injuries, blood spills on unprotected damaged skin, or mouth-to-mouth resuscitation. In some countries, reuse of needles and syringes has produced nosocomial and community outbreaks.[6] There are also reports of outbreaks in surgical teams who unwisely performed laparotomy on infected patients.[7] In these circumstances mortality has been high.

TABLE 60-1 Guide to Viral Hemorrhagic Fevers by Continent and Potential Exposures

RECENT TRAVEL IN CENTRAL OR SOUTH AMERICA				
Exposure	Clinical Syndrome	Virus	Therapy in Addition to Routine Support of Organ Function	Prevention
Rodents	Fever with insidious onset; sore throat, myalgia; dyspnea with ARDS; bleeding, thrombocytopenia; elevated SGOT and bilirubin; seizures, obtundation, and coma	South American hemorrhagic fever viruses (Argentinian, Junin, Machupot, Sabia, Guanarito)	Immune plasma (AHF only) Ribavirin; likely that most viruses respond, but no clinical trial data are available	Oral ribavirin for high risk exposures; Vaccinate for AHF; Avoid rodent contact
Mosquitoes	Fever, bleeding, and thrombocytopenia; jaundice with raised SGOT, SGPT, and bilirubin; ARDS; wasting	Yellow fever	None	Vaccinate; Prevent mosquito bites
Mosquitoes	Fever and myalgia; thrombocytopenia, with petechiae; ARDS; shock	Dengue	None	Prevent mosquito bites
Rodents	Sudden onset of fever and myalgias; shock; prominent ARDS	Hantavirus pulmonary syndrome	Consider ribavirin	Avoid rodent contact
RECENT TRAVEL IN RURAL AFRICA				
Exposure	Clinical Syndrome	Virus	Therapy	Prevention
Rodents; infected patients	Insidious onset of fever, sore throat, and myalgia; bleeding with moderate thrombocytopenia; ARDS; elevated SGOT, SGPT, and bilirubin; proteinuria; seizures and coma	Lassa fever	Ribavirin	Oral ribavirin for high-risk exposure Strict barrier nursing Avoid rodent contact
Infected patients; sick or dead monkeys Bush meat ?Unknown	Sudden onset with fever, sore throat, myalgia; severe bleeding with thrombocytopenia and elevated APTT; elevated SGOT, SGPT and bilirubin; proteinuria; effusions; ARDS	Ebola/Marburg	None	Strict barrier nursing
Mosquitoes	Bleeding and thrombocytopenia; jaundice with raised SGOT, SGPT, and bilirubin; ARDS; wasting	Yellow fever	None	Vaccinate; prevent mosquito bites
Ticks; blood from infected patients	Sudden onset of fever and myalgias; severe bleeding and ecchymoses with thrombocytopenia and elevated APTT; elevated SGOT; proteinuria	Crimean-Congo hemorrhagic fever	Ribavirin	Oral ribavirin for high-risk exposure Avoid tick contact Strict barrier nursing
RECENT TRAVEL IN RURAL EUROPE AND RURAL AND URBAN ASIA				
Exposure	Clinical Syndrome	Virus	Therapy	Prevention
Rodents	Insidious onset; thrombocytopenia; proteinuria and oliguria to anuria; shock; ARDS	Hemorrhagic fever with renal syndrome; nephropathia epidemica	Ribavirin	Avoid rodent contact

TABLE 60-1 Guide to Viral Hemorrhagic Fevers by Continent and Potential Exposures (Continued)

RECENT TRAVEL IN RURAL EUROPE AND RURAL AND URBAN ASIA				
Exposure	Clinical Syndrome	Virus	Therapy	Prevention
Ticks; infected patients	Sudden onset with fever and myalgia; severe bleeding and ecchymoses with thrombocytopenia and elevated APTT; elevated SGOT; proteinuria	Crimean-Congo hemorrhagic fever	Ribavirin	Oral ribavirin for high-risk exposures Avoid tick contact Strict barrier nursing
Mosquitoes	Fever and myalgia; petechiae and thrombocytopenia; shock; ARDS	Dengue	None	Prevent mosquito bites

Clinical syndromes overlap considerably, particularly early in disease, so the detailed travel history is critical. This table is intended as a general guide for the clinician and advice from experts should be sought immediately if any of these diagnoses are under consideration. Note that medical personnel and possibly family members may have not traveled themselves, but may have been in contact with sick travelers.
ABBREVIATIONS: AHF, Argentine hemorrhagic fever; APTT, activated partial thromboplastin time; ARDS, acute respiratory distress syndrome; SGOT, aspartate aminotransferase; SGPT, alanine aminotransferase.

The key to prevention of transmission both in endemic and nonendemic areas has consistently been good hospital and laboratory practice, with strict isolation of febrile patients at risk of VHF and rigorous use of gloves and disinfection.[8] A small number of designated personnel should undertake direct care and be kept fully informed about the nature of the virus and the precautions to be taken.

Intensive care and full life support should not be denied. Essential surgery should be performed with meticulous attention to avoiding accidental inoculation of blood or fluids. Pregnant patients are a major challenge. They often present with absent fetal movements, and maternal survival in Lassa fever and probably other hemorrhagic fevers has been shown to depend on aggressive obstetric intervention to evacuate the uterus.[9]

Aerosol spread in hospitals has not been documented; indeed there is much published evidence that this is not a major hazard. Past recommendations for isolation of patients in a plastic isolator have long given way to simple strict barrier nursing. Indeed, the risk to personnel is about equal to that of human immunodeficiency virus (HIV) transmission, and the practices now universally adopted for HIV nursing and medical care are quite adequate to prevent transmission of VHFs, provided they are fully implemented and observed. This practice presents no excess risk to hospital personnel and allows substantially better care to be given to the patient.

The major factor in nosocomial transmission is unawareness of the possibility of VHF by a health care provider who is also inattentive to the requirements of effective barrier nursing. Many outbreaks in developing countries have been due to lack of hygiene and to unwise surgery on febrile patients. Once the diagnosis has been entertained and appropriate precautions instituted, the risk of nosocomial transmission is very small.

High risk of infection is associated with direct percutaneous or mucosal contact with blood or body fluids. Postexposure prophylaxis with ribavirin for CCHF and for arenaviruses should be offered to contacts with high-risk exposures. People with medium- or low-risk contact histories (includes most unprotected contact with blood or body fluids, and casual or social contact) may safely be observed for development of persistent high fever for 3 weeks from the last date of contact. The practice of following up airline passengers and other low-risk

TABLE 60-2 Ribavirin Therapy for Viral Hemorrhagic Fevers

Intravenous regimen:	Ribavirin 2 g IV loading dose, then 1 g IV every 6 h for 4 days, infused over at least 20 min; then 0.5 g every 8 h for 6 more days
Oral regimen:	Ribavirin 2 g loading dose, then 4 g/d in four divided doses every 6 hours; then 2 g/d in four divided doses for 6 days
Potential side effects:	Hemolysis

RESPONCE TO RIBAVIRIN THERAPY		
Highly Effective	May Have Some Efficacy	No Efficacy
Lassa fever South American hemorrhagic fevers Crimean Congo hemorrhagic fever	Hantavirus pulmonary syndrome Hemorrhagic fever with renal syndrome	Ebola and Marburg viruses Yellow fever Rift Valley fever Dengue hemorrhagic fever

exposures has been discontinued. Low-risk contacts (entered the room) do not need to be placed under surveillance.

The 1988 Centers for Disease Control and Prevention (CDC) Guidelines for the Management of Patients with VHFs recommends routine patient isolation in a single room, preferably but not necessarily with negative air pressure gradient from the hallway through an anteroom to the patient room.[3] Staff education; use of gloves, gowns, and masks; and rigorous disinfection are mandatory. The recommendations issued for patient management and handling of clinical specimens from acquired immunodeficiency virus (AIDS) patients are adequate for containment of VHFs.

Lassa and Ebola viruses in particular are robust and withstand drying. However, all the viruses can be inactivated by heat (60°C), detergents, chlorine, formalin, and ultraviolet (UV) radiation (sunlight). All the hemorrhagic fever viruses have envelopes that are disrupted by detergents and soaps, rendering them inactive. Though detergents cannot be recommended for disinfection, it is useful to remember that their liberal use will greatly reduce the number of infectious particles. Disinfection can be accomplished by washing with 0.5% phenol in detergent (e.g., Lysol), 0.5% hypochlorite solution, formaldehyde, glutaraldehyde, or paracetic acid. Care should be taken to ensure solutions are freshly and correctly made up and time allowed for disinfectant to work on spills.

Finally a problem of VHFs, particularly viruses such as Ebola, is the fear and press attention they receive. A single case can be quite traumatic for an institution unless the situation is carefully handled. A measured and informed approach from a collaborative team of doctors, nurses, administrators, and others is needed. Careful education of all medical staff, emphasizing the real risks and the way to avoid them, allaying unnecessary fears, and avoiding panic will result in appropriate management of the patient and avoid secondary infections. Press attention can be quite disruptive and is best managed by the sharing of accurate and regular information.

Bunyaviruses

Bunyaviruses are a large family of spherical (85 to 100 nm) negative-sense RNA viruses found in animals and insects. Crimean Congo hemorrhagic fever (CCHF) virus is a member of the tick-borne *Nairovirus* genus of this family, and the hantaviruses, which are rodent-borne, form their own genus.

CRIMEAN CONGO HEMORRHAGIC FEVER

CCHF is a tick-borne viral disease initially described in the USSR in the 1930s, and the virus was isolated in the Belgian Congo in the 1950s. The virus is now known to occur from Eastern Europe through Asia, the Middle East, and in all of Africa and the People's Republic of China (PRC), where the disease is known as *Xinjiang fever.*[4,10–13] Humans are infected from ticks or by handling blood or secretions from infected people or domestic animals. Because of the high mortality of infection with CCHF virus, the virus is classified as Biosafety Level 4 (BSL4).

CCHF virus infects at least 24 species of ixodid (hard) ticks, particularly *Hyalomma* species, which serve as both reservoir and vector of this agent. CCHF infection of humans has emerged as a sporadic but important disease, particularly in arid livestock farming areas. Seasonality depends on local climatic conditions, with peaks corresponding to maximum periods of tick infestation.[14,15] A wide range of wild and domestic animals and birds may be infected.

The illness:infection ratio of CCHF virus ranges from 1 : 5 in the southern USSR to more than 50% of infected persons in South Africa, and mortality varies from 5% to 10% in the southern USSR to 35% in South Africa; rates of 35% to 50% or higher are possible in nosocomial outbreaks. Mild or inapparent infection appears to be the rule for most mammalian species, with the exception of humans.

The high risk of nosocomial outbreaks was first recognized in 1976, when a laparotomy was performed on a patient in Pakistan with abdominal pain, hematemesis, and melena. Eleven secondary cases in hospital staff resulted in three deaths, including a surgeon and an operating theater attendant.[7] Since then, similar nosocomial outbreaks have been reported in many countries from South Africa through countries of the former Yugoslavia, Iran, Dubai, Afghanistan, China, and Russia.[10–13,16–20] In hospital outbreaks heavy blood contamination or needlestick injury is frequently recorded.[16]

CLINICAL AND LABORATORY FEATURES

The incubation period of CCHF is only about 2 to 9 days.[21] There is a rapid, dramatic onset with severe headache, high fever, chills, and excruciating myalgia strongly localized to the lower back and joints. There is often epigastric pain. Conjunctivitis and a mild flushing of the face and chest, pharyngeal hyperemia, and petechiae on the palate are frequent. Bradycardia is typical, and diarrhea occasional.

Within 3 to 5 days after onset, signs of hemorrhagic diathesis may develop with bleeding from the gums, epistaxis, hematuria, and bloody diarrhea. Petechiae and purpura are frequent. Massive hematemesis, melena, extensive bloody effusions, bleeding from virtually every orifice and from venipuncture sites, and hypovolemic shock precede death with development of sometimes spectacular ecchymoses. Despite the high fever, bradycardia is typical, with tachypnea due to pulmonary edema.

Liver function tests may show mild to marked hepatocellular dysfunction, sometimes accompanied by renal failure. SGOT may be markedly raised, but SGPT elevation is usually minimal. There is no evidence of myocardial involvement. There is no objective evidence of direct CNS infection. Intracranial bleeding is a possibility. Changes in affect and mood, including aggressive behavior, are a feature of the convalescent phase.

Severe thrombocytopenia is invariable, frequently with counts below 20,000/μL. Prothrombin times (PTTs) and activated partial thromboplastin times (APTT) may be prolonged but usually not severely so. Platelet counts of less than 20,000/μL, PTT >60 seconds, SGOT >200 IU/L, and SGPT >150 IU/L are associated with a risk of death of more than 90% in untreated patients. Leukopenia may be profound with an early predominance of polymorphonuclear cells, giving way to a marked relative and absolute lymphopenia after 7 to 10 days. Some patients have a relative neutrophilia. During convalescence there may be lymphocytosis with atypical forms.

DIAGNOSIS

Diagnosis is most rapidly made by RT-PCR. Though there is some genetic diversity, sufficient conserved sequences may be targeted for broad specificity. Virus may also be isolated from blood of acutely ill patients, but viremia is early and of short duration, and the virus is labile, so that specimens have to be carefully taken and preserved for transportation. Antigen detection systems are also available using recombinant antigens.[11,12] Virus-specific antibodies appear 7 to 10 days after infection and neutralizing antibodies after day 14 to 16, but since the incubation period is very short, often only 3 to 4 days, acute diagnosis by antibody detection is not reliable.[22]

SPECIFIC TREATMENT

CCHF virus is sensitive to the antiviral ribavirin in vitro and in vivo in concentrations as low as 5 μg/mL, and the CDC recommends the empirical use of the intravenous preparation for treatment of CCHF infections.[3] Ribavirin has shown to be effective in vivo.[16]

Oral ribavirin has been used for postexposure prophylaxis for CCHF infection, but its efficacy has not been formally examined. Though intravenous ribavirin is the treatment of choice, oral therapy may be used if it is the only form available, since ribavirin is well absorbed from the gastrointestinal tract and would be expected to attain adequate levels in the blood. There is presently no role for immune plasma in the treatment of CCHF infection.

PREVENTION

Avoidance of tick bite using repellents applied to skin or soaked into clothing are methods of choice. Slaughter of potentially viremic animals is hazardous. Care of infected patients should avoid blood contact and high-risk procedures such as mouth-to-mouth resuscitation. The combination of epigastric pain and hematemesis has sometimes led an unwary surgeon to perform laparotomy.[16] Generalized oozing results in large blood losses and inevitably difficulty in achieving hemostasis. The patient does not survive, and the surgeon and operating attendants themselves have a high risk of fatal infection.

HANTAVIRUSES

Hemorrhagic fever with renal syndrome (HFRS) loosely describes a complex of diseases in which fever and acute renal failure are associated with bleeding, first reported from Manchuria and from Scandinavia during the 1930s. Until the early 1990s the diseases and the viruses that cause them were thought to belong exclusively to the Old World. In 1993 hantavirus pulmonary syndrome (HPS) was identified in an outbreak in the United States,[23] and since then patients and infected rodents have been found from Canada to Argentina. Both disease syndromes are now known to be caused by related viruses collectively called hantaviruses, which are members of the bunyaviridae.[24,25]

EPIDEMIOLOGY

Hantaviruses are all natural parasites of a wide variety of rodents, in which they persist for life without apparent disease. The rodents are infected at or around birth, and excrete large amounts of virus in urine, probably for life. The virus groups are determined primarily by the rodent host species, which govern geographic distribution of diseases they cause. Thus among the Old World hantaviruses, particularly in Siberia, mainland China, and Korea, the most common rodent host is the Manchurian striped field mouse, *Apodemus agrarius.* This mouse carries the Hantaan virus strain, which is the cause of the most severe clinical manifestation, HFRS. Throughout Europe, a less pathogenic group of hantaviruses, Puumala virus and related strains, cause nephropathia epidemica (NE). These viruses are endemic in the red bank vole, *Clethrionomys glareolus.* In the Balkans, Belgrade virus isolated from the yellow-neck mouse, *Apodemus flavicollis,* causes severe HFRS and is more closely related to Hantaan virus. In urban centers in the Far East and in rural areas in China, yet another strain, Seoul virus, with intermediate pathology, is endemic in house rats. Transmission appears to be from direct contact with rodent urine, but aerosol dispersal in heavily rodent urine–contaminated dust is also reported. Human disease occurs in agricultural areas with high human and rodent population densities, during military campaigns or exercises, in crowded urban housing, or in laboratories housing infected rodents. Person-to-person contact has not been reported, and these viruses do not cause nosocomial outbreaks.[26] All ages and both sexes may be affected.

Until the early 1990s, HFRS was thought to be exclusively an Old World disease. In 1993, however, a pulmonary disease emerged in the United States that was found to be associated with hantavirus infection (hantavirus pulmonary syndrome; HPS), without a significant renal component.[23] This virus, named the Sin Nombre virus, infects deer mice mainly in the southwestern United States. Risk of infection is related to exposure to infected rodent populations. By 1999, 277 cases had been reported from 31 states.[27] Canada had also reported 32 cases, but it was South America that rapidly emerged as bearing the greatest burden, with over 500 reported cases in Argentina, Uruguay, Chile, Paraguay, and Bolivia. Two more related South American viruses were identified, Andes and Laguna Negra viruses, and a number of rodents of the sigmodontine and oligoryzomys species appear to be the natural hosts. The ecology of these viruses and rodents appears to be as complex as in the Old World. On both continents the viruses persist in its chosen rodent species despite robust immune responses, probably because they are able to continuously produce quasispecies, thereby escaping immune surveillance. Such viruses probably coevolved with their rodent hosts over as long as 9 million years.

CLINICAL AND LABORATORY FEATURES

Hantaviruses are distinguished from most other hemorrhagic fever viruses by their longer incubation period of 2 to 3 weeks; for the Sin Nombre virus it is 9 to 33 days.[28] The underlying pathology of both HPS and HFRS appears to be induction of cytokines in lung or renal tissue, and there is in fact overlap between the two syndromes,[27] the difference being the predominant target tissue. The Old World hantaviruses induce a brief period of acute renal impairment, which may be as severe as anuria, requiring dialysis. However, this is usually self-limiting and of short duration. In HRFS vascular impairment and thrombocytopenia may result in bleeding that is usually minor, and the "leaky capillary syndrome," which manifests variably as shock, renal failure, and in severe cases, ARDS. Renal involvement is seen in some HPS patients, but HPS pathology is centered on the lungs, and the ensuing severe respiratory distress carries a higher mortality than HFRS,

earlier thought to be about 50%, but now recorded as being on the order of 27%. Though HPS mortality in South America appears to be higher than in North America, it appears that the illness:infection ratio is lower in South America. Mortality from HRFS is about 5% to 15%, with survival often depending on experience in fluid management, and death in NE patients is rarely recorded. In all these syndromes, raised hematocrit on admission to hospital probably reflects hemoconcentration due to leaking capillaries as in other hemorrhagic fevers, and thrombocytopenia, left shift in white cell counts, and hypoxia are characteristic, with the difference in HPS being that bleeding does not appear to be a problem. Pulmonary edema, which may be aggravated by injudicious IV fluids, can coexist with profound hypovolemic shock. Pathologic lesions are compatible with endothelial dysfunction and leakage, since no evidence of endothelial damage is seen. Viral antigen is seen in lung tissue of patients with HPS, and local production of cytokines is involved in the pathology.[24,29] Recovery in survivors is rapid, and sequelae are not reported. Antibody has been found in up to 40% of some populations in South America, demonstrating that a large number of infected people have asymptomatic infection or mild disease, but in the north it is difficult to find antibody-positive people with no history of the disease.[27] There is no nonhuman primate model for hantavirus infection in which to study these processes in more detail, but recently infection of cynomolgus macaques with the most virulent strain, Andes virus, has been established.[30]

In Asia and Europe, HFRS and NE are distinct clinical entities, very familiar to physicians working in endemic areas, who normally have little difficulty in making an accurate clinical diagnosis. HFRS was first described in the literature in Eastern Siberia in 1912, and NE in Scandinavia in the 1930s. During the Second World War Japanese investigators conducted some ethically highly controversial studies in prisoners in China. Throughout the twentieth century the disease was a well recognized hazard of war, particularly with soldiers bivouacking in the open or in trenches, and NE may have been one of the causes of "trench fever" in the First World War. There were probably about 30,000 cases in American troops during the Korean War.

HRFS is classically described to exhibit five stages. First is the febrile stage, during which the patient will have headache, malaise, and muscle pains. Petechiae are found not only on the soft palate and under the axillae, but also on the face, neck, upper hips, and thighs. Flushing and edema are marked around the eyes. The liver may occasionally be palpable, and abdominal and renal tenderness are most common. Platelet counts are reduced and may be very low. White cell counts are variable, but in some severe cases, marked transient neutrophilia can lead to confusion with bacterial infection. Proteinuria is invariable. After 2 to 4 days the patient either recovers spontaneously or progresses to the shock phase. This period of low blood pressure is followed within 24 hours by the oliguric or anuric phase. Within a further 24 hours or so most patients enter the diuretic phase. Finally the convalescent phase leads to full recovery with no well-documented sequelae. Although bleeding is uncommon, when it occurs it is usually in the convalescent phase and hemorrhage may be difficult to control, and death may result from intracranial bleeding. There are no clinical and laboratory data to suggest bleeding is due to hepatic failure and consumption coagulopathy is only recorded in terminal disease.

LABORATORY DIAGNOSIS

RT-PCR on blood is the most reliable method of diagnosis for all the hantaviruses. Quantitative RT-PCR is available (qPCR), with the ability to measure as few as 10^3 copies per reaction.[27] The viruses are difficult to culture, and it appears that many virions and viral antigens are bound in immune complexes in the blood, increasing the difficulty of isolation. In any event, viremia is an early event, so for success specimens must be taken early. The disease may be immunologically mediated, occurring mostly after disappearance of the virus. Laboratory diagnosis of hantavirus infections can also be made by demonstration of a rise in specific antibodies or demonstration of virus-specific IgM. Over 90% of patients have hantavirus-specific IgM and IgG antibody when first seen. Antibodies persist for up to 3 decades and generally react to highest titer with homologous antigens. Neutralizing antibody can be detected.

SPECIFIC TREATMENT

Intravenous ribavirin may be useful in HFRS if given on or before the fourth day of disease, in doses similar to those used for Lassa fever.[31] Early treatment is essential. Ribavirin has similarly been recommended for patients with HPS,[32] but some adverse effects were noted (principally anemia) and efficacy was not demonstrated (see Table 60-2). Further studies are needed. For both of these syndromes the focus in supportive management of the patient is on careful fluid balance. Intravenous fluids given during the febrile and shock phases may leak into the extravascular space, aggravating edema, particularly during the period of shock and oliguria. Judicious use of vasopressor drugs for severe hypotension is preferred. When pulmonary edema leads to severe dyspnea and impending acute respiratory failure, intubation and mechanical ventilatory support are mandatory. Diuretics are relatively ineffective in HFRS, but peritoneal dialysis or hemodialysis may be life-saving. With these supportive measures and careful fluid management, most patients have the potential to make a spontaneous and complete recovery.

PREVENTION

The variety and ubiquity of rodent carriers and their success in many ecologic settings make the reduction of hantaviral infections by rodent control virtually impossible. Improvement of housing, particularly food storage, will help prevent those cases caused by rodent invasion of houses. However, a large number of infections occur in rural settings associated with agriculture and forestry. Education of populations to avoid direct contact with rodents in these circumstances may only have marginal effect because the virus may be made airborne by agricultural practices. Some vaccines have undergone preliminary trials in China and North and South Korea with encouraging results, but none has undergone the safety and clinical trials necessary for licensing in any country.

Arenaviruses

Rodents experience silent, lifelong infection with arenaviruses, with persistent viruria, and are the primary source of contamination of the environment. Five arenaviruses cause hemorrhagic fevers: Lassa in West Africa, and Junin, Machupo, Guanarito, and Sabia in South America, causing

Argentine, Bolivian, Venezuelan, and Brazilian hemorrhagic fevers, respectively. These viruses occupy circumscribed, sometimes remote ecologic niches, intrusion into which determines human infection. The viruses infect primarily through skin cuts and scratches and possibly the mucosae, contaminated with rodent urine, although there is evidence with Argentine hemorrhagic fever that dust generated by agricultural implements and laden with infected rodent urine may infect by aerosol. In endemic foci, the number of infected people may be very high. Human-to-human spread through blood contact is reported for Lassa fever both in community and hospital settings but is apparently rare with the other pathogenic arenaviruses.

Arenaviruses are enveloped, pleomorphic, membrane viruses containing two segments of single-stranded RNA, tightly associated with a nucleocapsid protein. The small RNA strand encodes the glycoprotein precursor and the nucleoprotein. Lassa and the South American hemorrhagic fever viruses are categorized as BSL4 laboratory agents. Disease may be severe and hemorrhagic, but with Lassa fever at least, mild or asymptomatic infection is also common.

LASSA FEVER

EPIDEMIOLOGY

Lassa fever is confined to West Africa, where it is responsible for up to 16% of all adult medical admissions and about 30% of adult deaths on medical wards.[33] It has been estimated that more than 100,000 infections with Lassa virus may occur each year, with several thousand deaths. All age groups and both sexes are affected. In endemic areas, illness:infection ratios range from 9% to 26%, and the proportion of febrile illness associated with seroconversion is between 5% and 14%. Five to eight percent of infected people may be hospitalized, of whom 17% will die if untreated. However, the fatality among all infections (hospitalized and nonhospitalized) is of the order of 2%.[34]

Person-to-person spread of Lassa virus occurs within homes as well as in hospitals. Hospital outbreaks are associated with inadequate disinfection and direct contact with infected blood and contaminated needles. Increasing and indiscriminate use of needles for intravenous therapy, or intramuscular injections in West African hospitals along with inadequate needle and syringe sterilization has led to large-scale epidemics. These epidemics can be devastating, resulting in the deaths not only of patients but also medical staff, surgeons, nurses, and other scarce personnel.[6,35]

Lassa fever is an increasing threat. It now affects communities in West Africa outside of its already broad area of rural endemicity. Indeed, urban Lassa fever in West Africa has been occurring with increasing frequency. In early 2000 hospital epidemics in large towns were again being seen in Nigeria, the most populous country in Africa. Since 1990, severe social disruption from conflicts and terror campaigns in Sierra Leone and Liberia have resulted in displacement of up to two million people—25% of the population of the area—with a substantial increase in the already large number of Lassa fever cases and deaths.[36]

Lassa fever is the exotic hemorrhagic fever most likely to occur in developed countries due to infection in returning travelers. This is because of the prevalence of disease in the endemic areas, and the relatively long incubation period (up to 3 weeks). In the year 2000 at least four cases were imported into Europe.[37] All died, due in great part to delay in diagnosis, and therefore delay in instituting antiviral therapy. Increased cases in non-West Africans in 2000 has been seen as a result of United Nations peacekeeping efforts in Sierra Leone, where the rebels' stronghold is the center of the Lassa fever endemic area. One of the fatal cases in expatriates was an Englishman who had been working to disarm the rebel soldiers in the diamond mining area of Eastern Sierra Leone.[38]

The only known reservoir is *Mastomys natalensis*, one of the most commonly occurring rodents in Africa. Direct contact between virus-contaminated articles and surfaces and cuts and scratches on bare hands and feet may be the most important and consistent mode of transmission. The sporadic pattern of human infection in the household does not suggest aerosol transmission. Nosocomial spread in hospitals was and continues to be associated with inadequate disinfection and direct contact with infected blood and contaminated needles. Ill advised surgery performed on infected patients has resulted in infection and death among medical staff. Increasing and indiscriminant use of routine intravenous therapy in West African hospitals along with inadequate needle and syringe care has led to large-scale epidemics. Nevertheless, where simple but rigorous barrier nursing techniques have been applied, Lassa virus infection does not spread.[8] In a study in London, none of 173 unprotected hospital contacts of a severely ill Lassa fever patient were infected.[39]

CLINICAL AND LABORATORY FEATURES

Following an incubation period of 7 to 18 days, Lassa fever begins insidiously, with fever, weakness, malaise, severe headache—usually frontal—and a very painful sore throat.[15] More than 50% of patients then develop joint and lumbar pain, and 60% or more develop a nonproductive cough. Many also develop severe retrosternal chest pain, and about half will have nausea with vomiting or diarrhea and abdominal pain. On physical examination respiratory rate, temperature, and pulse rate are elevated, and blood pressure may be low. There is no characteristic skin rash in Lassa fever, and petechiae and ecchymoses are not seen. About one third of patients will have conjunctivitis. More than two thirds have pharyngitis, half with exudates, diffusely inflamed and swollen posterior pharynx and tonsils, but few if any ulcers or petechiae. The abdomen is tender in 50% of patients. Neurologic signs in the early stages are limited to a fine tremor, most marked in the lips and tongue.[40]

Up to one-third of hospitalized Lassa fever patients progress to a prostrating illness 6 to 8 days after onset, usually with persistent vomiting and diarrhea. Patients are often dehydrated with elevated hematocrit. Proteinuria occurs in two thirds of patients. About half of Lassa fever patients will have diffuse abdominal tenderness but no localizing signs or loss of bowel sounds. The severe retrosternal or epigastric pain seen in many patients may result from pleural or pericardial involvement. Bleeding is seen in only 15% to 20% of patients, limited primarily to the mucosal surfaces or occasionally conjunctival hemorrhages or gastrointestinal or vaginal bleeding. Severe pulmonary edema and acute respiratory distress syndrome is common in fatal cases, with gross head and neck edema, pharyngeal stridor, and hypovolemic shock.

Over 70% of patients may have abnormal electrocardiograms including nonspecific ST-segment and T-wave abnormalities, ST-segment elevation, generalized low-voltage complexes, and changes reflecting electrolyte disturbance, but none of these correlate with clinical or other measures of disease severity or outcome, and they are unassociated with clinical manifestations of myocarditis.[41] Neurologic signs are infrequent but carry a poor prognosis, progressing from confusion to severe encephalopathy with or without general seizures, but without focal signs. Cerebrospinal fluid is usually normal, but with a few lymphocytes, and low titers of virus relative to serum. Pneumonitis and pleural and pericardial rubs develop in early convalescence in about 20% of hospitalized patients, occasionally in association with congestive cardiac failure.

Although the mean white blood cell count in Lassa fever on admission to hospital is often normal, there may be early lymphopenia and later relative or absolute neutrophilia, as high as 30,000/μL. Thrombocytopenia is only moderate, and petechiae are uncommon. Endothelial and platelet dysfunction (despite adequate numbers of circulating platelets) are characteristic of severe disease,[42] and the capillary leak syndrome results in ARDS, as with most hemorrhagic fever viruses.

A serum aspartate aminotransferase (SGOT) level of >150 U/L is associated with a case fatality rate of 50%, and there is a correlation between an increasing level and a higher risk of fatal outcome.[34] Alanine aminotransferase (SGPT) is only marginally raised, and the ratio of SGOT to SGPT in natural infections and in experimentally infected primates is as high as 11:1. Prothrombin times and glucose and bilirubin levels are near normal, excluding biochemical hepatic failure, suggesting that some of the SGOT may be nonhepatic in origin.

Nearly 30% of patients with Lassa fever infection suffer an acute loss of hearing in one or both ears, not associated with severity of the disease.[43] About half show a near or complete recovery by 3 to 4 months after onset, but the remainder have persistent significant sensorineural deafness, which after about a year will be permanent. Many patients also exhibit cerebellar signs during convalescence, particularly tremors and ataxia, but these usually resolve with time. Infrequent complications are uveitis, pericarditis, orchitis, pleural effusion, ascites, and acute adrenal insufficiency.[44] Renal and hepatic failure are not seen.

Lassa fever may be a common cause of maternal mortality in many areas of West Africa, with case fatality about 20%.[9] Fetal loss is as much as 87%, and does not seem to vary by trimester. Lassa virus is known to be present in the breast milk of infected mothers, and neonates are therefore at risk of congenital, intrapartum, and puerperal infection with Lassa virus. Lassa fever is common in children, but may be difficult to diagnose because manifestations are so general. In very young babies marked edema has been reported. In older children the disease may manifest as diarrhea or as pneumonia or simply as an unexplained prolonged fever.

DIAGNOSIS

RT-PCR is the most rapid and accurate method for acute diagnosis and has been shown to be more sensitive even than virus isolation.[45] Virus may persist in serum into the convalescence phase and coexist with antibody, and virus has been detected in urine as many as 60 days after onset.[40] By the sixth day of Lassa illness antibodies are found in about 50% of patients. Virus is easily isolated from serum or tissues in cell culture, but this should be performed in BSL4 laboratory facilities. Virus has also been isolated from breast milk, spinal fluid, pleural and pericardial transudate, placenta, and from autopsy material, and may be recovered intermittently for 1 to 2 months in urine. Neutralizing antibodies to Lassa virus are absent in the serum of patients at the beginning of convalescence, and in most people they are never detectable.

Viral protein may be detected by monoclonal antibodies in tissue imprints (usually liver) on a microscope slide or using ELISA techniques. Efforts to detect antigen in conjunctival scrapings, buffy coat preparations, cells from pharyngeal aspirates, and urinary sediment have not been successful.

SPECIFIC TREATMENT

Ribavirin is effective in treating acute Lassa fever and should be given as early as possible.[40,46] A five- to tenfold decrease in the case fatality ratio was demonstrated in patients treated with ribavirin compared with untreated patients when therapy was given within the first 6 days of illness. Treatment later in disease is effective, but less so.

PREVENTION

Avoidance of contact with rodent urine and with blood and tissues from infected rodents is an obvious precaution in the field. In the hospital, spread of Lassa virus is by blood-to-blood contact and can be prevented by simple barrier precautions.[8] The importance of awareness by medical teams of the possibility of Lassa fever in patients in or from endemic areas cannot be overemphasized.[47] Complete support should not be denied because of the suspected diagnosis. Carefully conducted intensive care or surgery by informed and trained personnel using maximum precautions (double gloves, educated staff, limited theater personnel) does not carry major risks.

SOUTH AMERICAN HEMORRHAGIC FEVER VIRUSES

The New World arenaviruses causing human disease are Junin (Argentine hemorrhagic fever; AHF), Machupo (Bolivian hemorrhagic fever, BHF), Guanarito (Venezuelan hemorrhagic fever; VHF), and Sabia (Brazilian hemorrhagic fever). All are endemic in geographically limited areas, but new, related viruses may emerge in other yet unstudied areas. The major rodent hosts are *Calomys* species, and the viruses are related to numerous other nonpathogenic arenaviruses from South American rodents ("Tacaribe complex").

Argentine hemorrhagic fever was first recognized in the 1950s in the fertile farmland of northwestern Buenos Aires Province in Argentina, and Junin virus was first isolated in 1958. By 1990 about 21,000 cases had been reported over 30 years, but with the recent introduction of a live attenuated vaccine, this disease has diminished. Before the introduction of the vaccine, the disease was seasonal with peaks each May. The major routes of virus transmission to humans is probably through virus-infected dust and grain products, possibly from mechanical harvesters. There is no recorded person-to-person spread.

CLINICAL AND LABORATORY FEATURES

The South American hemorrhagic fevers are similar in presentation, although Guanarito may more closely resemble

Lassa fever.[48] After an incubation period of about 12 days there is insidious onset of malaise, high fever, severe myalgia, anorexia, lumbar pain, epigastric pain and abdominal tenderness, conjunctivitis, and retro-orbital pain, often with photophobia and constipation. Nausea and vomiting frequently occur after 2 or 3 days of illness. There is no lymphadenopathy or splenomegaly, sore throat or cough, but there is marked erythema of the face, neck, and thorax and conjunctivitis. Petechiae may be observed in the axillae by the fourth or fifth days of the illness. There may be a pharyngeal enanthem, but pharyngitis is uncommon. Relative bradycardia is often observed.

The second stage of illness begins with epistaxis, hematemesis, or acute neurologic disease. In contrast to the relative infrequency of bleeding in Lassa fever, the South American diseases are associated with hemorrhagic manifestations in nearly half of the patients, manifest as gingival hemorrhages, epistaxis, metrorrhagia, petechiae, ecchymoses, purpura, melena, or hematuria. Hypotensive shock, hypothermia, and pulmonary edema precede death. Renal failure has been reported. There is some electrocardiographic evidence of myocarditis. Fifty percent of AHF and BHF patients also have neurologic symptoms during the second stage of illness, such as tremors of the hands and tongue, progressing in some patients to delirium, oculogyrus, and strabismus. Meningeal signs and cerebrospinal fluid abnormalities are rare.

A low white blood cell count, under 1000/μL, and a platelet count under 10,000/μL are invariable. Bleeding and clot retraction times are concomitantly prolonged, although DIC is apparently not a significant feature. Proteinuria is common, and microscopic hematuria also occurs. Liver and renal function tests are only mildly abnormal. Mortality is about 16% in laboratory-confirmed hospitalized patients with untreated AHF. There are no estimates of overall mortality from population-based surveys.

A late neurologic syndrome has been described in AHF, consisting mainly of cerebellar signs, and associated with high-titer antiserum used in treatment in about 10% of cases.[49] The syndrome begins between 4 and 6 weeks after onset of acute illness and lasts less than a week. It is characterized by fever, headache, ataxia, and intention tremors, and a mild cerebrospinal fluid pleocytosis with anti-Junin virus antibody in the CSF. Most patients recover within 3 months. Mild permanent damage to acoustic centers has been detected. AHF is also reported to be severe in pregnancy, but no formal studies are available, and women are less frequently affected.

Despite the different degrees of bleeding, there are sufficient similarities between the course of disease in AHF, BHF, and Lassa fever to speculate that they share similar pathophysiologic pathways. Organ function, other than the endothelial system, appears to remain intact, and the critical period of shock is brief, lasting only 24 to 48 hours. Hepatitis is mild, and renal function is also well maintained. Bleeding is more pronounced with AHF and BHF than Lassa fever, but it is not the cause of shock and death. Capillary leakage is significant, with loss of protein and intravascular volume being much more pronounced than loss of red cells.

In marked contrast to Lassa fever, the antibody response to Junin virus is effective in clearing virus during acute disease and may also be sufficient to protect against infection. Neutralizing antibody may be detectable at the time the patient begins to recover from the acute illness, and the therapeutic efficacy of immune plasma in patients with Junin infection is directly associated with the titer of neutralizing antibody in the plasma given.

DIAGNOSIS

RT-PCR is the most rapid and accurate method of acute diagnosis. The IFA may be positive by the end of the second week of illness. Neutralizing and complement-fixing antibody to Junin are usually detectable 3 to 4 weeks after onset. IgM is more difficult to read by IFA, and an ELISA system may be preferred. Virus may also be cultured from serum, but this should be performed in Biosafety Level 4 conditions.

SPECIFIC TREATMENT

In contrast to Lassa fever, convalescent-phase plasma has been shown to be highly successful in Argentine hemorrhagic fever, reducing the mortality from 16% to 1% in patients treated in the first 8 days of illness.[49] Efficacy is directly related to the concentration of neutralizing antibodies. Late initiation of therapy is less successful. Availability of appropriately screened plasma may be a problem. Ribavirin may also be effective in treating South American hemorrhagic fever.

PREVENTION

The human-rodent encounter resulting in AHF occurs during the crop harvests, and there are no means of controlling feral rodents. A successful live attenuated vaccine, Candid 1, for AHF has now undergone phase III studies, and is in use in the endemic area of Argentina, where it has almost eliminated the disease. The vaccine has proved safe in large-scale trials, and has a protective efficacy of 84%.[50]

Filoviruses

Human infections with filoviruses are exceedingly rare, but their occurrence has invariably been dramatic and mysterious.[51] The first appearance was in Marburg in 1967. There were 7 deaths among 32 infected laboratory technicians, medical personnel, animal care personnel, and relatives. Primary cases had been exposed to tissues and blood from African green monkeys imported into Germany and Yugoslavia from Uganda. A unique virus was isolated from these with a strange looped and branched filamentous form, hence named *filovirus.* In 1976 and 1979, epidemics of a hemorrhagic disease with very high mortality in northern Zaire and in southern Sudan were found to result from two strains of a related yet distinct filovirus, named Ebola virus after a river in Zaire.

At first thought related to rhabdoviruses, it has become clear that these viruses form a family of their own, now designated *filoviridae.* Nucleotide sequence analyses now place the family in the order mononegavirales, which also includes the paramyxoviridae (e.g., respiratory syncytial virus) and rhabdoviridae (such as rabies). Filoviruses are among the largest known viruses, with highly variable length (up to 14,000 nm), but uniform 80-nm diameter, with a helical nucleocapsid, consisting of a central axis 20 to 30 nm in diameter. The virions contain a single negative-strand RNA genome.

EPIDEMIOLOGY

Since the 1967 Marburg outbreak, there have been three further, isolated, primary human Marburg infections (and only two secondary cases), all in adventurous expatriates in remote parts of Africa. In the late 1990s, epidemics in eastern Congo (formerly Zaire) were traced to miners entering disused, partially flooded gold mines. These outbreaks may be ongoing, but the civil disturbances in the area have made it impossible to get accurate information. Between 1976 and 1979 three separate major outbreaks of Ebola occurred in northern Zaire and the southern Sudan.[52,53] In each instance, early index cases were rapidly followed by dissemination, mainly in hospitals and clinics, where reuse of needles for injection and exposure of staff to blood were strongly implicated in transmission. Case mortality ranged from 53% to 88%.

Ebola disappeared after 1979, only to re-emerge in 1994 in Kikwit, Zaire, again amplified in a hospital. The outbreak involved some 315 confirmed cases, among whom 244 died (77% fatality).[54,55] The virus from the Kikwit outbreak is apparently identical to the 1976 Zaire strain of Ebola. In 1994 a Swiss animal researcher reported 30 deaths in monkeys due to Ebola in the Ivorial rainforest bordering Liberia, and in 1996, 27 cases were reported from Gabon with 18 deaths (67% fatality) in humans. In this last outbreak, 12 of the fatalities had had direct contact with the blood of a dead chimpanzee.[56]

Person-to-person spread has been the major mode of transmission in epidemics. Contact with patients ill with Ebola is the most important factor in determining risk of illness. Other risk factors associated with human-to-human transmission are infection from contaminated materials such as needles, contact with blood or secretions, preparation of a body for burial, or occasionally, sexual contact. Close contact with blood or tissues of infected monkeys is also important.[56] The virus enters through mucous membranes or skin lesions, and outbreaks have been abruptly terminated when blood transmission was interrupted.[57] Relatively frequent epidemics of Ebola Zaire in Gabon and the Congo, Ebola Sudan in Uganda, and Marburg in eastern Congo have been reported, and several outbreaks of Ebola Zaire are ongoing, and apparently closely linked to a major epizootic in great apes. This Ebola epizootic, combined with hunting and loss of habitat, is now thought to threaten chimpanzees and gorillas in the area with extinction.[58]

CLINICAL AND LABORATORY FEATURES

The incubation period is 3 to 12 days, 3 to 7 days for needle transmission, and 6 to 12 days for person-to-person spread. The illness:infection ratio for Marburg and Ebola viruses approaches unity, since few if any asymptomatic infections have ever been observed.

The disease caused by the African filoviruses is dramatic.[52,53,59,60] Onset is abrupt with fever, severe headache (usually periorbital and frontal), myalgia, arthralgia, conjunctivitis, and extreme malaise. Sore throat is a common symptom, often associated with severe swelling and dysphagia, but no exudative pharyngitis. A papular, eventually desquamating rash may occur in some patients, especially on the trunk and back; a morbilliform rash has been observed on white skin. Gastrointestinal symptoms develop in most patients on the second or third day of illness with abdominal pain, cramping, diarrhea, and vomiting. Jaundice is not a feature of Marburg or Ebola disease. Persistence of vomiting and the onset of any signs of mucosal bleeding carry a high risk of fatal outcome. Bleeding begins about the fifth day of illness and is most commonly from the mucous membranes, gastrointestinal tract, gingiva, nasopharynx, and vagina. The most profound physiologic alteration is shock (manifested by hypotension, effusions, and facial edema), which is invariably fatal. Severe, acute fluid loss often with frank bleeding into the tissue and into the gut results in dehydration, and electrolyte and acid-base imbalance. Infection in pregnancy results in high maternal fatality and virtually 100% fetal death. CNS involvement has led to hemiplegia and disorientation and sometimes frank psychosis. Even in convalescence patients show prolonged weakness and severe weight loss, and in a few survivors serious but reversible personality changes are recorded, namely confusion, anxiety, and aggressive behavior.

Thrombocytopenia is invariable, but bleeding is not usually of sufficient volume to account for the shock, nor is it associated with solid evidence of DIC in the small number of animals or humans studied so far. Platelet dysfunction has also been described in experimentally infected nonhuman primates. Profound lymphopenia early in disease is accompanied by marked neutrophilia. Laboratory evidence of moderate DIC appears only in the terminal stages. Liver enzymes (SGOT and SGPT) are raised, but the rise in SGOT is disproportionately higher than SGPT, as in Marburg disease.

At autopsy there is widespread hemorrhagic diathesis into body cavities, membranes, and soft tissue, with focal necrosis in liver, lymph nodes, ovaries, and testis. Most prominent are eosinophilic inclusion bodies in hepatocytes (Councilman-like), without significant inflammatory response.

Very little is understood about the immunology of Ebola virus infections except for the observation, made many years ago, that neutralizing antibodies are difficult to demonstrate in both humans and primates, and that like many zoonotic viruses, notably Lassa virus and now the severe acute respiratory syndrome (SARS) human coronavirus, Ebola virus appears to be able to circulate in humans in the presence of detectable antibody and to show varying ability to persist at least for short periods following acute infection. Nevertheless protection must be achieved, since reactivation disease should have been observed by now, were it occurring. Studies using specimens from patients in Gabon have shown that the innate immune system plays a very important role in disease.[61] Evidence from these studies and from animal studies suggest that the proinflammatory response is a central figure both in pathogenesis of severe disease and in protection from disease, in that an early, orderly innate immune response was observed in infected individuals who never developed disease.[62] Conversely primate studies have shown that infection of monocular phagocytes is critical, and that these trigger a cascade of cytokines/chemokines and oxygen free radicals, and that it is this process, not direct viral replication destroying critical cells, which lead to the manifestations of disease. These manifestations are associated with massive intravascular apoptosis.[61,63]

DIAGNOSIS

RT-PCR is the method of choice for acute diagnosis of Ebola hemorrhagic fever.[64] Extreme care should be taken in both

drawing and handling blood specimens, since virus titer may be extremely high, and the virus is stable for long periods even at room temperature. High- or rising-titer filovirus-specific IgG is diagnostic, as is the presence of IgM by ELISA or IFA. Patients may die, however, before developing detectable antibodies. Virus may be isolated and identified within 2 to 3 days if suitable facilities are available. An antigen detection ELISA system is also used, but is less sensitive than RT-PCR.[64] Antigen may also be detected in biopsies, including skin.[65] Unexplained, nonspecific reactions in antibody assays (sometimes up to 15% of sera), particularly with IFA, have plagued serologic studies.

SPECIFIC TREATMENT

Patients will require full intensive care support, including mechanical ventilation, along with blood, plasma, or platelet replacement. Provided strict barrier precautions are observed, intensive care should not be denied and may be life saving. Every effort is justified, since the crisis is short-lived, and complete recovery can be expected in most survivors.

No antiviral therapy (including convalescent plasma, ribavirin, or related compounds) has been shown to be effective against either Marburg or Ebola virus infection in patients or in experimentally infected nonhuman primates. Suitably screened and stored human plasma is in any event unavailable. Human interferon is ineffective in vitro.

Flaviviruses

Flaviviruses are positive-strand RNA viruses, spread by mosquitoes. Yellow fever and dengue virus cause hemorrhagic disease. Dengue is the only exclusively human VHF.[66]

YELLOW FEVER

EPIDEMIOLOGY

Since it was first described in 1498, yellow fever has been a recognized scourge of West Africa, and subsequent to colonization and the slave trade, the West Indies, and Central and South America. Outbreaks in the Americas in the nineteenth century were reported as far north as Hartford, Connecticut, and frequent devastating epidemics were familiar to the southern United States. Mosquito eradication programs successfully controlled epidemics from the beginning of the twentieth century, and with the introduction of an effective vaccine in the 1930s, yellow fever became a preventable disease. Nevertheless it continues to circulate in West and Central Africa, and in the interior of South America. Large epidemics are regularly seen in Africa, particularly Nigeria and the Cameroon, in areas where for political or economic reasons vaccine coverage is low.[67]

Yellow fever virus is transmitted to humans by mosquito bite; the principal vector is *Aedes aegypti,* but other *Aedes* species are also capable of transmission. Two epidemiologic forms are recognized, sylvatic and urban. In the sylvatic cycle the virus circulates from monkey to monkey via mosquitoes, with humans occasionally being infected peripherally. Several species of monkey are involved, but in general, South American nonhuman primates are much more susceptible to disease than Old World primates, and they mostly die from the infection. In the urban form of the disease, the virus is maintained by transmission from humans to humans by mosquito. Direct person-to-person spread has not been reported. Distribution in Africa and South America generally follows that of the equatorial rain forests. For reasons that are unclear, Asia has been spared this virus. Nevertheless, globally the disease affects more than 200,000 persons a year in endemic areas and is a significant risk to unvaccinated travelers.[68]

CLINICAL AND LABORATORY FEATURES

Though the disease has been well described in the past, there are no recent data concerning either clinical disease or pathogenesis,[66,68] relegating this fulminating disease to the neglected diseases of the poor of the developing world. The incubation period is usually 3 to 6 days. Clinical presentation varies from a nonspecific low-grade febrile disease to a fulminant hepatitis with renal failure and hemorrhage, which is usually fatal. Onset is abrupt with fever and chills, intense headache, generalized myalgia, nausea, and vomiting. High fever continues for about 3 days, with conjunctival injection, edema and hyperemia of the face and neck, and occasionally a macular or scarlatiniform rash. Then epistaxis and gum bleeding may develop, and there will be proteinuria. Some patients then deteriorate to the "yellow" phase, with jaundice, hemorrhages, violent epigastric pains, and vomiting that may become black from altered blood, the "vomito negro" from which they rarely recover. The renal syndrome progresses from oliguria to anuria. Hypotension and shock appear late. Electrocardiographic changes consist of increase in PR and QT intervals, with bradycardia accompanying high fever. Terminal phases are characterized by agitation, delirium, and convulsions, leading to coma and death. Mortality as high as 50% has been recorded in urban outbreaks in Nigeria.[67] When recovery occurs, it is complete, without sequelae.

There is generalized leukopenia and thrombocytopenia. Liver function tests show high SGOT and SGPT, but as in other VHFs, SGOT is disproportionately high. Unlike other VHFs, however, bilirubin rises rapidly and continues to be high in convalescence. Elevated bilirubin and serum aminotransferase levels reflect the severity of illness, and as in Lassa fever, are of prognostic value. In fatal cases hepatic failure contributes to the hypoglycemia and metabolic encephalopathy. Virus may be recovered from the liver, and it is likely that direct viral injury accounts for most of the observations. There is marked albuminuria and oliguria, and in severe cases renal failure may be observed. Metabolic acidosis is an important component of the terminal stages of this disease.

Bleeding is common, often with upper gastrointestinal hemorrhage. Thrombocytopenia is prominent, and prolongation of the prothrombin time, APTT, and clotting time are reported along with reduced levels of clotting factors, particularly those derived from the liver. Disseminated intravascular coagulation may be an important component of the terminal stages and may be associated with the severe hepatic injury. Unlike some other flaviviruses (e.g., West Nile virus) direct involvement of the central nervous system by this virus probably does not occur; however, metabolic encephalopathy results in agitation, mania, delirium, convulsions, and coma. There are no focal neurologic signs.

Yellow fever is by far the most hepatotropic of the VHF viruses. Histology shows the characteristic Councilman bodies, consisting of eosinophilic degeneration in mesolobular

or midzonal regions. Generally the liver shows coagulative necrosis with some sparing about the centrilobular veins and portal vessels.

DIAGNOSIS

RT-PCR is the method of choice. Diagnosis is made by isolation of the virus from blood, but the virus is labile and culture may be difficult, requiring suckling mouse inoculation. Though person-to-person spread is not a feature of this disease, care should nevertheless be taken that specimens are handled by persons vaccinated against yellow fever. Serologic data are more difficult to interpret than in other VHFs because of the notorious cross-reactivity of flaviviruses, particularly in persons from endemic areas who may have encountered many of the myriad of related viruses that abound. "Original antigenic sin" is a major feature of all flavivirus infections, since infected people tend to have highest antibody titers to whichever virus was their first exposure, regardless of the virus causing their current or most recent infection. Specific IgM assays using modern ELISA techniques may be helpful, but again in patients from endemic areas pre-existing flavivirus antibody may yield confusing results. For all these reasons diagnosis of yellow fever outside the setting of a known epidemic may be difficult, and RT-PCR performed on specimens (blood or tissue) early in infection is the surest means to identify the virus. Antigen detection techniques using ELISA have also been developed, but await full evaluation.

SPECIFIC TREATMENT

Management is supportive. Yellow fever virus is not susceptible to ribavirin or to any other known antiviral agent.

PREVENTION

Prevention is by vaccination with the 17D strain of yellow fever virus, one of the oldest and most successful vaccines. This is a live attenuated vaccine. A single shot apparently provides lifelong protection, although WHO recommends validity for 10 years. The current preparation has been one of the safest vaccines in existence, with millions of doses having been given over more than 50 years. Recently there have been isolated reports of actual yellow fever–like disease following vaccination. Nevertheless, the long history of safety of the 17D strain now makes it an important candidate for insertion of other genes, particularly other flavivirus genes such as dengue and hepatitis C. Mosquito control is the ultimate control method, resulting in near complete eradication of disease, as was demonstrated in Brazil and the southern United States. However, the recent resurgence of yellow fever in Brazil that accompanied the reintroduction of *Aedes aegypti* to many areas of that country is a warning that eradication is a mirage given a zoonotic focus of the virus, and that constant surveillance is essential.

Yellow fever is one of four notifiable diseases in the international health regulations of WHO. Notification of suspected as well as confirmed cases is mandatory.

DENGUE HEMORRHAGIC FEVER

Dengue virus infection is frequently asymptomatic or a mild febrile illness. However, dengue hemorrhagic fever (DHF) usually occurs in children less than 15 years of age and in some circumstances in adults. There are four dengue virus serotypes, and DHF is apparently due to infection with a second serotype, though in outbreaks due to newly introduced virus in nonimmune populations, fulminant hemorrhagic disease may be seen in young adults. It is hypothesized that the replication of the second infecting serotype is enhanced by pre-existing antibody at suboptimal levels, but this remains controversial.[66]

The epidemiology of dengue is recent, dating back to the Second World War. Whether it was the disruption of this war which allowed the virus to spread, or more likely the rapid and explosive population increases and development of large urban areas and megacities is unclear. However, the end result is clear: dengue is endemic in the cities and the countryside of Southeast Asia and has spread widely east and south to Africa and even threatens Australia.[69] Deterioration of urban environments with crowding and mosquito infestation also favors the virus. Reintroduction of dengue has now been documented in Central and South America including Brazil, Ecuador, Bolivia, Peru, Venezuela, and many Caribbean islands. It has also been reintroduced into the Pacific. Epidemics are reported each year from Central and South America, and cases are now seen in south Texas. The potential for further spread is great, particularly in the southern United States and more widely in South America. The disease must be considered in febrile travelers from all the affected areas, which now includes most of the tropical regions of the world and many subtropical regions. Unlike yellow fever, the natural history is a cycle involving only mosquito and human, the main vector for its spread is humans, but still it has proved difficult to control given the ubiquity of both mosquito and human hosts.

Large epidemics occur, often annually in all endemic areas. In areas where the virus has been recently reintroduced the most severe disease may be in adults, but in Southeast Asia, DHF is a disease of young children, thousands of whom are affected annually. Epidemics tend to occur in the hot rainy season. The vector is *Aedes aegypti,* but *Aedes albopictus* has also been implicated. *Aedes* prefer to breed in clean cool water, and in Southeast Asia are abundant in drinking water pots kept in the shade. Intercontinental trade in used tires containing moisture was thought to be responsible for the recent introduction of *Aedes albopictus* in the United States, but no disease or indeed presence of virus has been demonstrated in association with these tires.

CLINICAL AND LABORATORY FEATURES

The incubation period is 2 to 10 days. Onset is abrupt, with fever, severe headache, and a combination of myalgia, backache, photophobia, and retro-orbital pain, accompanied by anorexia and vomiting. Most patients then recover uneventfully, but some may progress to dengue hemorrhagic fever or dengue shock syndrome (DSS). These conditions are characterized by low platelet counts, petechiae, and hypovolemic shock. This is normally of short duration and self-limiting, but a few patients may deteriorate and die with pulmonary edema or intracranial bleeding. Patients may also have marginally raised liver function tests, with SGOT levels higher than SGPT levels.

The cardinal signs of dengue hemorrhagic fever are shock, with narrow pulse pressure and petechiae. Hepatic involvement is variable. There is often severe thrombocytopenia and marked intravascular volume depletion with edema as in HFRS. During the acute phase there is lymphopenia. Serous effusions are common. These are transudates with

high albumin content. Endothelial cell biopsies show swelling of endothelial cells, with enlarged endothelial gaps in some sections, but no necrosis of cells themselves. Indeed since most patients recover promptly, responding to careful fluid management, it must be assumed that the increased permeability is the result of some acute metabolic or biochemical dysfunction.

The pathogenesis of DHF has been the subject of much debate. Various studies have reported complement consumption, activation of the plasma kinin system, circulating immune complexes, leukopenia, depression of T-cell function, increased natural killer cell activity, or interferon-γ production by dengue-stimulated T lymphoctyes. It has been suggested that an initial infection with one type of dengue virus, followed by a second infection with another serotype, induces an immune response resulting in enhancement of virus entry into monocytic cells where it replicates. This observation, which has been under consideration for decades, still remains controversial.

DIAGNOSIS

Serologic diagnosis is difficult to interpret, again because of cross-reactions with pre-existing flavivirus antibodies, particularly in endemic areas. The RT-PCR detecting dengue virus RNA in serum or white cells is likely to be the most practical approach where it is available and affordable. IgM assays may be useful in identifying acute infection. Identification of the specific virus type is difficult by antibody or antigen detection methods, and may require virus isolation. However, this information is principally of importance for epidemiologic evaluation of epidemic and endemic behavior of the viruses.

SPECIFIC TREATMENT

Management of DHF and DSS is supportive. Dengue virus is not susceptible to ribavirin or to any other antiviral agent.

Chapter 61
BIOWARFARE AGENTS

MANOJ KARWA
RAGHU S. LOGANATHAN
VLADIMIR KVETAN

KEY POINTS

- *Unlike other mass casualty events, mass exposure to a biological agent is unlikely to be realized until cases start presenting and a high degree of suspicion is needed to realize this.*
- *Specific knowledge of the various types of agents is required to help in the diagnosis and management.*
- *Victims of class A agents such as plague, anthrax, botulinum toxin, smallpox, and viral hemorrhagic fever are likely to be critically ill and in need of the expertise of intensivists.*
- *Preparedness for a mass casualty event is key in dealing with effective care of patients in the hospital setting, containment of spread of particularly virulent organisms, and controlling public hysteria.*

Since the terrorist attacks of September 11, 2001, and the distribution of mail containing anthrax spores that led to seven deaths in the U.S., the threat of a large-scale bioterrorist attack has become very real.[1] A recent report by the Monterey Institute for International Studies found a total of 121 biocrimes were committed since 1960, with a reported sharp rise since 1995.[2] Reports of biological agent stockpiles and their weaponization by Iraq and the former Soviet Union, as well as the use of various biological agents by cult organizations such as the Rajneesh cult, Aum Shinrikyo, and Minnesota Patriots make the possibility of their use by a rogue nation or nonmilitary organization a very real one.

Attack of a civilian target would cause a large number of casualties, panic, and civil disruption. There would be a rapid overwhelming of public health facilities and capabilities.[3–5] It is highly likely that many if not the majority of patients would need some degree of critical care such as a ventilator or hemodynamic support. Thus the critical care physician's role could be a central one that depends on specific knowledge of the various agents, and preattack preparedness, the two cornerstones in dealing with such a catastrophe. The main objectives of this chapter are to provide a concise review of individual agents likely to be used in a bioterrorist attack, and focus on key issues related to the intensivist in preparing to deal with such an event.

The Centers for Disease Control and Prevention's strategic planning workgroup categorizes biological warfare agents into groups A, B, and C, based on capability to cause illness or death, stability of the agent, ease of delivery, ease of mass production, person-to-person transmissibility, potential for creating public fear and civil disruption, and the ability of the public health systems to deal with such an attack.[6] Category A agents would have the greatest impact on public health and its infrastructure. Category B agents would have less impact on the public health and its infrastructure. Category C agents are least likely to impact on the public health and include various emerging infectious agents.[6,7] This list is not definitive and serves only as a guideline for preparation for a bioterrorist attack (Table 61-1).

Recognition of a bioterrorist attack would require prompt identification based on typical clinical syndromes, since awaiting laboratory confirmation of these otherwise rare illnesses might be delayed. Certain epidemiologic features peculiar to a bioterrorist attack help distinguish it from a natural outbreak of disease as outlined in Table 61-2.[8,9]

Because of the greater absorption surface area of the alveolar bed, a biological weapon is more likely to be delivered via an aerosol spray or a cloud. This would require an agent to be aerosolized into droplets or particle sizes of 1 to 5 μm in diameter in order to reach and be absorbed via the alveolar bed. Particles >5 to 10 μm would be filtered out by or deposited into the upper respiratory tract. However, many viruses like influenza, viral hemorrhagic fevers, and smallpox can be infective at these sites.[10–12] Aerosol delivery of an agent would also give rise to unusual presentations of diseases such as inhalational anthrax and pneumonic plague.

A bioterrorist attack through the contamination of food and water is less likely for several reasons. Most category A agents are not transmitted via food and water, while category B agents that can be transmitted by these routes usually cause short-term vomiting and diarrhea with a relatively quick recovery. Current water treatment methods effectively kill many biological agents and contaminating a water or food supply effectively would require large amounts of toxin and bacteria in order to overcome any dilution factor. Furthermore, boiling water and cooking food destroys most agents. A recent study warns of the United States' vulnerability to such an attack based on very centralized food processing methods and distribution of the foods over large areas. Likely agents are botulinum toxin, *Salmonella*, *Shigella*, *Escherichia coli*, and *Vibrio cholerae*.[13]

Contact with intact skin with any of these agents is unlikely to result in disease. However, if the skin integrity is compromised, the potential for disease exists. Current studies suggest that thorough washing with soap and water is sufficient to overcome even this threat.

Anthrax

Bacillus anthracis is a gram-positive spore-forming bacterium. It is an encapsulated, nonmotile, and nonhemolytic organism, and usually grows within 6 to 24 hours on conventional culture media. The vegetative form is incapable of surviving outside of a warm-blooded host, and colony counts are undetectable in water after 24 hours. As a biological weapon it is likely to be delivered as an aerosol. Clinically this would produce inhalational anthrax, the deadliest and rarest form of the disease.[14] The cutaneous form is not considered lethal with current antibiotic regimens, and the gastrointestinal form is exceedingly rare with essentially no cases having been reported in the U.S.[15,16]

Inhalational anthrax occurs after spores are ingested by alveolar macrophages and transported via regional lymphatics to mediastinal lymph nodes. Germination takes place in 2 to 5 days, but can be delayed as much as 60 days, after which disease rapidly occurs.[1,16,17] The major virulence factors are the antiphagocytic capsule and three toxin components (lethal factor, edema factor, and protective antigen).[18] The

TABLE 61-1 Categorization of Potential Biological Agents

Biological Agent	Disease
Category A	
Variola major	Smallpox
Bacillus anthracis	Anthrax
Yersinia pestis	Plague
Clostridium botulinum (botulinum toxin)	Botulism
Francisella tularensis	Tularemia
Filoviruses and arenaviruses (e.g., Ebola virus, Lassa virus)	Viral hemorrhagic fevers
Category B	
Coxiella burnetii	Q fever
Brucella spp.	Brucellosis
Burkholderia mallei	Glanders
Burkholderia pseudomallei	Melioidosis
Alphaviruses (VEE, EEE, WEE)	Encephalitis
Rickettsia prowazekii	Typhus fever
Toxins (e.g., ricin, staphylococcal enterotoxin B)	Toxic syndromes
Chlamydia psittaci	Psittacosis
Food safety threats (e.g., *Salmonella* spp., *Escherichia coli* O157:H7)	
Water safety threats (e.g., *Vibrio cholerae*, *Cryptosporidium parvum*)	
Category C	
Emerging threat agents (e.g., Nipah virus, hantavirus)	

ABBREVIATIONS: EEE, eastern equine encephalomyelitis; VEE, Venezuelan equine encephalomyelitis; WEE, western equine encephalomyelitis.
SOURCE: Reproduced with permission from Rotz et al.[6]

three toxins cause edema, hemorrhage, and necrosis, producing a thoracic lymphadenitis and hemorrhagic mediastinitis. Death can occur despite antibiotic administration if toxin levels have reached a critical threshold.

Clinically anthrax presents as a biphasic illness. The first stage is characterized by nonspecific symptoms of fever, chills, weakness, headache, vomiting, abdominal pain, dyspnea, cough, and chest pain, lasting for hours up to a few days.[1,16,19] This may be followed by a short period of apparent recovery. The second stage is characterized by sudden resurgence of fever, shortness of breath, profound sweating that drenches the patient, and shock. Hypocalcemia, hypoglycemia, hyperkalemia, depression of the respiratory centers, and terminal acidosis are some of the biochemical and physiologic signs that develop in severe infections.[20,21] Delirium, meningismus, obtundation, seizures, and coma secondary to hemorrhagic meningitis occur in up to 50% of cases.[14,22,23] Involvement of the gut is also a common feature of advanced disease and thought to be secondary to hematogenous spread (different from primary gastrointestinal anthrax) presenting as abdominal pain (33%), and can lead to necrotizing enteritis of the bowel.[1,22,100] In a series of 11 cases in the U.S., there was a 33% incidence of supraventricular arrhythmias and one case that had fatal pericardial effusion.[1] Severe infection leads to hypotension and cyanosis progressing rapidly to death.[1,19,24,25] The lag period between initial exposure and the onset of symptoms seems to be inversely proportional to mortality.[16]

TABLE 61-2 Distinguishing Features of a Biological Attack

A rapid rise and fall of the epidemic curve over a short period of time (a few hours to days)
Instead of the peaks and troughs seen in natural outbreaks, there may be a steady rise in cases
A disproportionate number of people seeking care for similar symptoms
Large numbers of patients arriving from the same geographical area
Large numbers of rapidly fatal cases
A lower attack rate in people who were indoors compared to those who were outdoors
Appearance of an uncommon disease that has bioterrorism potential (e.g., anthrax, plague, tularemia, botulism)
Increased numbers of sick or dead animals
A large number of cases within 48–72 hours of an attack suggests a bacterial agent, while those presenting within a few hours suggests a toxic agent

Diagnosis of inhalational anthrax clinically requires a high degree of suspicion given that the symptoms on initial presentation can easily be confused with a seasonal viral syndrome. Presenting symptoms and routine laboratory tests are nonspecific, and the only clue prior to development of fulminant disease may be a widened mediastinum on chest x-ray[25,27,100] (Fig. 61-1). Autopsies of victims from the Sverdlovsk incident failed to reveal any diffuse bronchopneumonic process; however, 11 of the 42 autopsies did show a necrotizing lung lesion similar to a Ghon complex.[22] The recent series of cases in the U.S. suggest a parenchymal process is likely to be more common than previously thought.[1] Small pleural effusions that rapidly progress to a large size appears to be a consistent finding and may correlate with the progression of the disease. Thoracentesis yields a hemorrhagic fluid with relatively few WBC, and is positive for the bacteria by Gram stain and culture.[1] Noncontrast computed tomography (CT) scan of the chest is extremely helpful in determining the extent of mediastinal adenopathy and edema[25] (Fig. 61-2). Given the rapidity at which death can occur, a delay in administration of antibiotics greatly decreases chances of survival.[1,25,27,28]

Meningeal signs develop in 50% of cases, with contrast CT scan of the brain revealing diffuse leptomeningeal enhancement, with intracerebral and subarachnoid hemorrhages.[23]

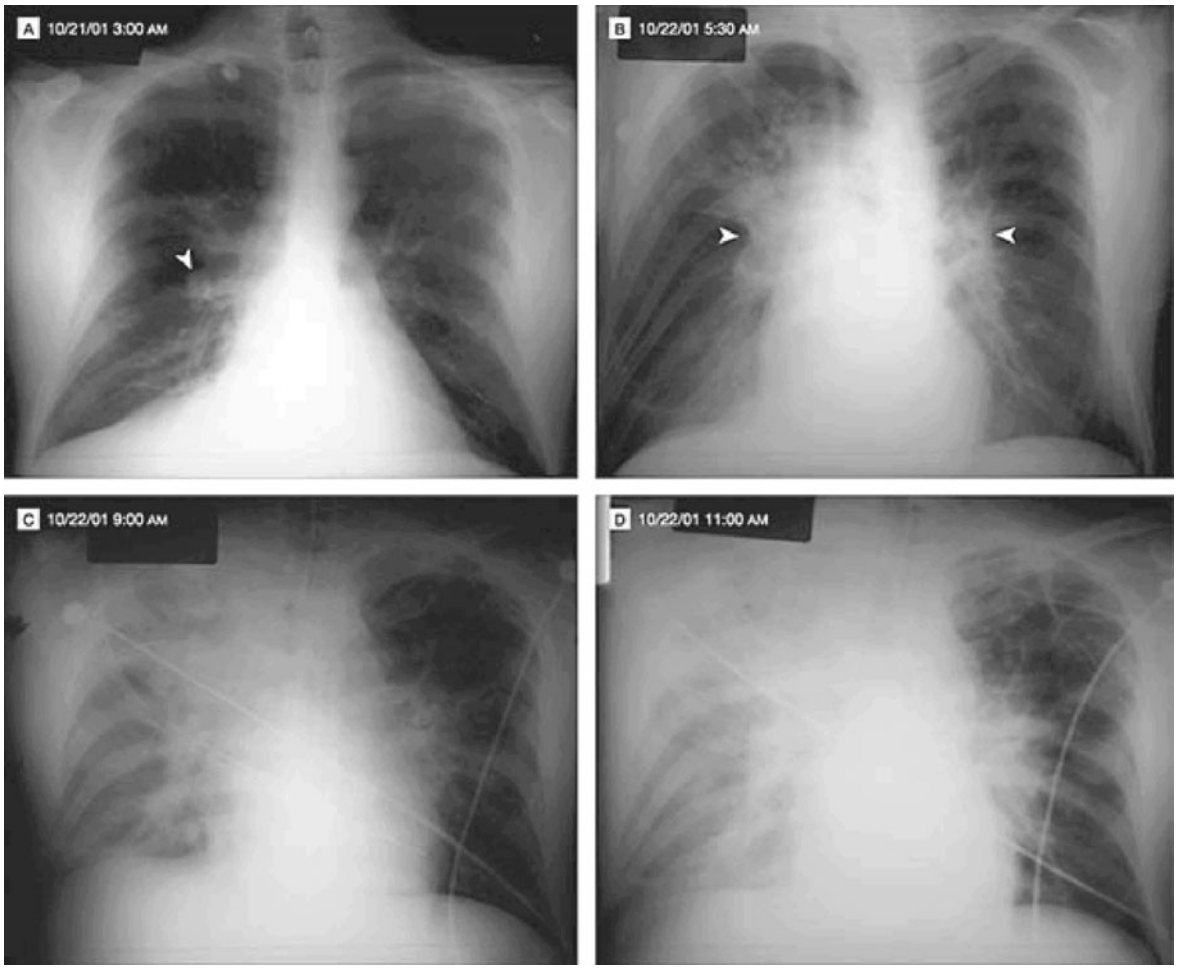

FIGURE 61-1 ***A*****. In this case of inhalation anthrax, initially only a subtle bilateral hilar prominence (*arrowhead*) and right perihilar infiltrate was noted, but subsequent images (*B*, *C*, and *D*) revealed a progressively widened mediastinum (*B*, *arrowheads*) and marked perihilar infiltrates, peribronchial cuffing, and air bronchograms.** ***(Reprinted with permission from Borio et al.[100])***

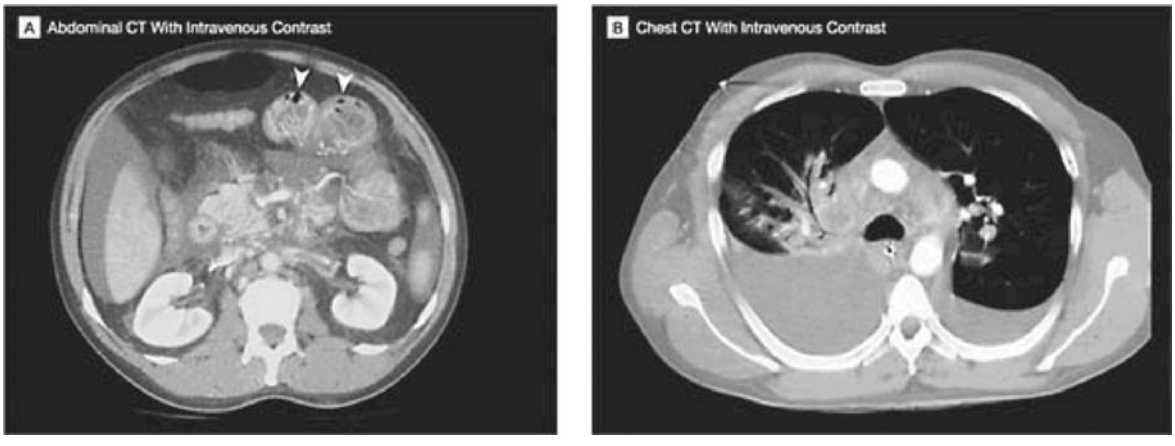

FIGURE 61-2 Abdominal and chest CT images of a patient with inhalation anthrax. ***A*****. Abdominal CT scan with intravenous contrast showing moderate amount of ascites, small-bowel wall edema, and intramural pneumatosis (*arrowheads*) consistent with a necrotizing enteritis. Other CT windows showed air within the hepatic branches of the portal venous system.** ***B*****. Chest CT scan with intravenous contrast showing large bilateral perihilar infiltrates, perihilar lymphadenopathy, and widened mediastinum. Other CT windows showed high-attenuation mediastinal lymphadenopathy and blood in the mediastinum, consistent with hemorrhagic lymphadenopathy and hemorrhagic mediastinitis.** ***(Reprinted with permission from Borio et al.[100])***

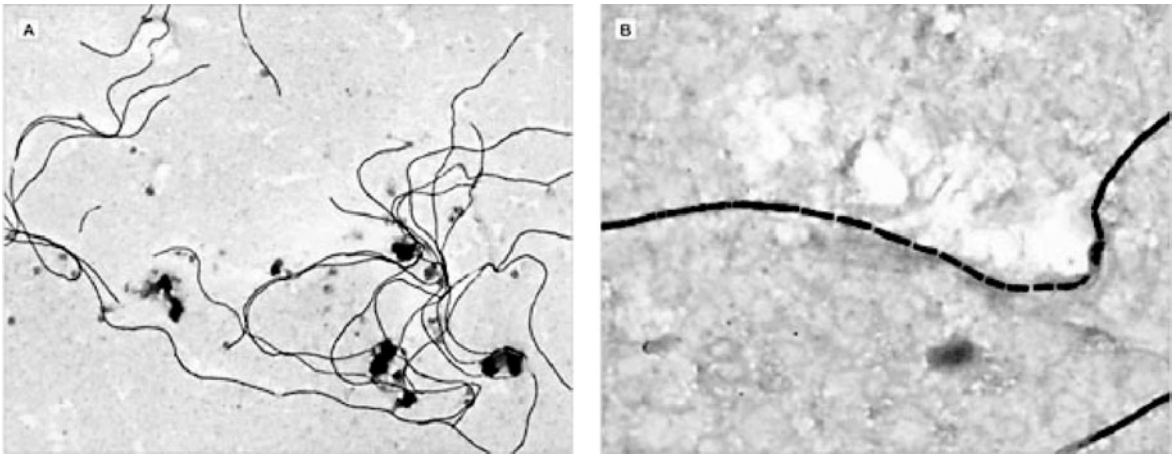

FIGURE 61-3 Gram stain of anthrax in blood in culture media. ***(Reprinted with permission from Borio et al.[100])***

Cerebrospinal fluid (CSF) is usually bloody and gram-positive. Gram stains of sputum are typically negative, while those of blood and pleural fluid are more likely to be positive (Fig. 61-3). Blood cultures are almost always positive within 24 hours; however, laboratories may presumptively assume a contamination of specimens with *Bacillus cereus*.[29] Thus microbiology labs need to be notified of the suspicion, so they may use selective media to isolate anthrax.[30] Confirmatory testing such as growth on special nutrient agars, susceptibility to lysis by gamma phage, direct fluorescence antibody staining, nucleic acid signatures, and enzyme-linked immunosorbent assay (ELISA) for protective and capsule antigens are performed at level B and C laboratories of the Laboratory Response Network (LRN) for Bioterrorism, CDC, or the United States Army Medical Research Institute of Infectious Diseases (USAMRIID).[14,32] Serological testing of acute and convalescent serum is useful only retrospectively.

Postexposure prophylaxis for adults (including pregnant women and the immunosuppressed) is initially with ciprofloxacin 500 mg orally every 12 hours or doxycycline 100 mg every 12 hours. If the strain is susceptible, then amoxicillin 500 mg orally every 8 hours or the above dose of doxycycline can be taken. These regimens should be taken for 60 days owing to the unpredictable latency of inhalational anthrax.[14,33] An aluminum hydroxide adsorbed, licensed vaccine made of noninfectious sterile culture filtrate from attenuated B. anthracis is available, and evidence shows it to protect against aerosol challenge. However, currently it is not recommended for postexposure prophylaxis in either health care workers or the public. However should it become available, it would be used at 0, 2, and 4 weeks postexposure.[32]

Treatment of patients with inhalational anthrax that has progressed to its fulminant stage warrants close observation in a monitored setting. Surveillance of serum chemistries, oxygen saturation, and EKG are all warranted. Chest tube placement for moderately large pleural effusions is necessary as they can increase rapidly and worsen respiratory distress.[1] Patients with meningeal involvement may require steroids, phenytoin, and benzodiazepines to control edema and seizures. They may also need mechanical ventilation for airway protection. The additional support of mechanical ventilation and vasopressors are ominous signs.

Current CDC recommendations for empiric treatment of inhalational anthrax in adults (including pregnant women and immunosuppressed) are ciprofloxacin 400 mg intravenously every 12 hours or doxycycline 100 mg intravenously every 12 hours. These should be given with another one or two additional antibiotics that have in vitro activity against anthrax (rifampin, penicillin, ampicillin, vancomycin, imipenem, clindamycin, chloramphenicol, or clarithromycin).[33,34] If the strain of the organism is susceptible, then 4 million units of penicillin G intravenously every 4 hours can be used.[14,33] High-dose intravenous penicillin may provide better CNS penetration in cases associated with meningitis. Recent survivors of inhalational anthrax were treated with a combination of ciprofloxacin (based on official recommendations), rifampin (for increased gram-positive coverage and for its intracellular mechanism of action), and clindamycin (for its ability to prevent expression of toxin).[25] It is important to note that *B. anthracis* isolates produce cephalosporinase, making treatment with cephalosporins such as ceftriaxone useless.

As person-to-person transmission does not occur, patients can be cared for under standard precautions. However, it should be remembered that in an act of suspected bioterrorism one would not immediately know whether patients are affected with anthrax or a more transmissible agent such as plague, which warrants respiratory isolation precautions as well (Table 61-3). Patients with cutaneous anthrax should be cared for under contact isolation. Specimens should be handled under Biosafety Level (BSL) 2 precautions.[31] Decontamination of individuals exposed to the initial aerosol attack is not necessary, and washing with soap and water is sufficient to eliminate any secondary aerosolization. For contaminated hospital areas, bleach solutions and 0.5% hypochlorite solution are adequate for decontamination.[14,31]

Of the 77 cases of anthrax in the Sverdlovsk incident, only 11 patients survived. There was a reported hospital stay of 1 to 2 days for those who died and 3 weeks for those who survived. There are no details of the medical therapy that they had received but some of the survivors did need mechanical ventilation.[16] Prior to 1978, inhalational anthrax in the U.S. had a mortality of 80% to 90%.[19] However, the more recent experience in the U.S. showed a 40% mortality, and this may

TABLE 61-3 Differential for a Large Number of Persons Presenting with Febrile Illness and Respiratory Symptoms

Agent	Time to Onset	Chest X-Ray	Fatality	Onset to Respiratory Failure	Person-to-Person Infection	Complications	Diagnosis	Treatment
Anthrax[14,25,26] (inhalational)	1–6 days	Mediastinal widening; pleural effusions	90%	1–3 days	None; use standard precautions	Meningitis	Blood culture, Gram stain, ELISA for serology and antigen	Ciprofloxacin or doxycycline; addition of rifampin likely useful
Plague[35,42–44] (pneumonic)	2–3 days	Bilateral infiltrates; may have pleural effusions	90%	Within 1 day	High; use respiratory isolation	Early hemoptysis	Gram/Wayson stain, cultures, Fl Ag assay by ELISA, fluorescent Ab for F1 AG	Streptomycin or gentamicin or ciprofloxacin or doxycycline
Tularemia[53,55,58,61]	2–10 days	Bilateral infiltrates > hilar adenopathy > pleural effusions	30% w/o therapy; <5% with therapy	Low incidence	None; use standard precautions	Regional adenopathy in ulcer glandular type; sepsis/shock in typhoidal type	Cultures usually not revealing; fluorescent Ab, ELISA, and PCR	Streptomycin gentamicin, ciprofloxacin, or doxycycline
Legionella	2–10 days	Variable, bilateral subsegmental infiltrates, or consolidation	15%	Variable incidence	None; use standard precautions	Sepsis, ARDS	Urine Ag assay	Azithromycin or a fluoroquinolone; for severe cases add rifampin
Influenza	1–2 days	Variable bilateral interstitial or alveolar infiltrates	10–25% in those with underlying diseases	Variable incidence	High; use standard precautions	ARDS; secondary bacterial pneumonia	Immunofluorescence Ab staining, ELISA, tissue culture	Amantidine or oseltamivir or rimantidine; supportive care
Staphylococcal Enterotoxin B[24,94] (SEB)	3–12 hours	No abnormalities	<1%	None reported	None; use standard precautions	Gastrointestinal anorexia	Ag ELISA, Ab ELISA	Supportive, antiemetics, oxygen support
Ricin[96] (inhalation)	18–24 hours	Likely bilateral infiltrates/ARDS	High	Likely within 30 hours	None; use standard precautions	Hemoptysis likely; gastrointestinal bleeding and hepatic necrosis if ingested	ELISA for Ag, ELISA for Ab	Supportive; activated charcoal if ingested

ABBREVIATIONS: ARDS, acute respiratory distress syndrome; ELISA, enzyme-linked immunosorbent assay; PCR, polymerase chain reaction.

be due to early recognition, better antibiotics, and modern intensive care units.[1]

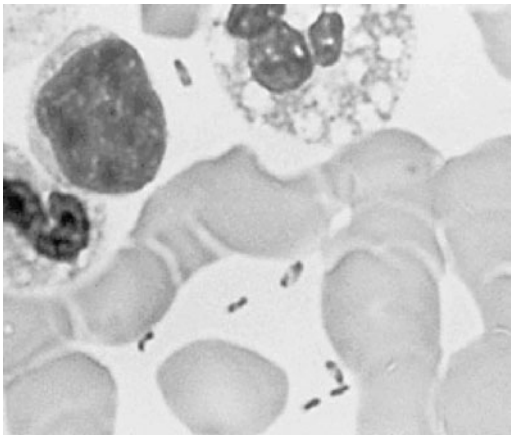
Plague

Yesinia pestis is a nonmotile, gram-negative bipolar coccobacillus that is the causative agent of plague. Recently, the organism has been used as the hypothetical biological weapon in the TOPOFF scenario,[4] theoretically causing thousands of casualties and widespread disruption of the public health system.[14,35] The most likely route of delivery during an attack would be via aerosol.

Human plague occurs worldwide and is endemic to the southwestern U.S., with an average of 10 cases reported each year.[36] Its natural reservoirs are urban and rural rodents. The transmission vector is the oriental rat flea (*Xenopsylla cheopis*). Humans become accidental hosts after being infected by an infected flea's bite. Humans very rarely are responsible for its propagation, except when they have the pneumonic form of the disease.[37]

Humans contract plague from the bite of an infected flea, inhalation of respiratory secretions of animals or humans with pneumonic forms of plague, or direct handling of infected animal tissues.[37] The former is the most common route, while the latter two are very rare in nature and usually give rise to the pneumonic form of disease. In the U.S. there were 390 cases of plague reported between 1947 and 1996. Of these 84% was bubonic, 13% septicemic, and 2% pneumonic. Fatality rates were 14%, 22%, and 57% respectively.[38]

Y. pestis has a number of virulence factors including V and W antigens, lipopolysaccharide endotoxin, capsular envelope (antiphagocytic fraction I antigen), coagulase, and fibrinolysin. Bacteria inoculated into the skin by an infected flea become phagocytosed by mononuclear cells. They multiply intracellularly, eventually lysing the cells, after which they become resistant to further phagocytosis. Bacteria are transported via lymphatics to the regional lymph nodes causing inflammation and hemorrhagic necrosis, and subsequently give rise to the typical bubo.[37,39]



The incubation period for bubonic plague is 2 to 8 days. It presents with sudden onset of fever, chills, weakness, and headache. Within a few hours to a day patients notice the bubo, which is characterized by its sudden onset, absence of overlying skin lesions, marked surrounding edema, and extreme pain that limits the motion of the region. Buboes can occur in the inguinal, axillary, or cervical nodes, and can present as an 1 to 10 cm firm, extremely tender, nonfluctuant mass.[35,37,40,41] Subsequently patients deteriorate rapidly over 2 to 4 days, having high fever, tachycardia, malaise, headache, vomiting, chills, alterations in mental status, prostration, and chest pain, eventually progressing to vasodilation and septic shock. During this time patients may have signs of disseminated intravascular coagulation (DIC), with acral purpura that may progress to gangrene. Hematogenous spread can give rise to complications such as plague pneumonia (5% to 15%), meningitis, hepatic and splenic abscesses, and endophthalmitis. Patients ultimately manifest signs of multiorgan failure and acute respiratory distress syndrome (ARDS).[37,39,41–45] A minority present with the septicemic phase of disease (primary septicemic plague without bubo formation). A distinguishing clinical feature is severe abdominal pain. Patients in this group present earlier, are more likely to be elderly, are more toxic in appearance, and are hospitalized sooner than patients with bubonic plague. Despite this they have a higher mortality, likely related to the delay in the diagnosis.[45]

Primary pneumonic plague occurs by inhalation of aerosolized bacteria from patients who have lung involvement secondary to fulminant bubonic plague, or animals (cats) with secondary plague pneumonia.[46] This is the most fatal form of the disease and its incubation time is 1 to 3 days. It manifests suddenly with fever, chills, headache, body pains, weakness, and chest discomfort.[38,47] As the disease progresses there is an increase in cough and sputum production, as well as increasing chest pain, hemoptysis, and hypoxia, progressing rapidly to frank respiratory failure. The presence of hemoptysis should alert the clinician to the possibility of primary pneumonic plague, since it is less likely to present in inhalational anthrax (see Table 61-3). Death usually occurs within 18 to 24 hours after the onset of symptoms. Pulmonary complications include localized necrosis, cavitation, pleural effusion, and ARDS.[16,18,32,41] In addition the course is complicated by endotoxemia and septic shock.

Patients with primary pneumonic plague have an infectious pneumonitis at the onset of the disease. These patients are capable of a vigorous and highly infectious cough, and are not usually debilitated like patients with bubonic disease. Secondary plague pneumonia on the other hand, is usually a result of hematogenous spread of the disease to the lungs. Usually the patient is ill for several days, debilitated, and unable to cough vigorously, making them less infectious. However, pneumonic plague (primary or secondary) should always be considered extremely infectious.[40,43]

Routine blood tests are nonspecific. Bacteremia initially is transient, and single blood cultures at presentation are only 27% positive. Blood, sputum, bubo aspirates, and CSF Gram stains can reveal gram-negative bipolar coccobacilli, while the Wayson stain shows light blue bacilli with dark blue polar bodies on a pink background (Fig. 61-4). Automated culture detection systems may present a delay or even misidentify the organism. Thus a high level clinical suspicion of the disease should prompt immediate notification of the lab. State level B or national level C (CDC or USAMRIID) laboratories should be notified through the LRN. Direct fluorescence staining for fraction 1 (F1) envelope antigen, phage lyses of cultures, or

FIGURE 61-4 Peripheral blood smear from a patient with septicemic plague. ***(Reprinted with permission from Inglesby et al.[35])***

polymerase chain reaction (PCR) assay should confirm identification. Acute and convalescent serum titers for antibody to F1 antigen are retrospectively diagnostic.[31,35,37,39] Chest radiographs in cases of bubonic plague may show small transient unilateral infiltrates. However, nodular or bilateral alveolar infiltrates in these patients is strongly associated with a more fulminant and fatal course. Primary pneumonic forms of plague are associated with bilateral alveolar and nodular infiltrates, with over half of them having pleural effusions. Cavitary lesions have also been noted to occur.[42,43,44,46]

Treatment requires the prompt administration of antibiotics, especially in the septicemic and pneumonic forms. As the bacteria is capable of inducing an endotoxemia leading to DIC, septic shock, ARDS, and multiorgan failure, close observation of the patient and early resuscitative measures are warranted at the earliest sign of progression toward a more fulminant course. These patients require aggressive volume resuscitation, and may need mechanical ventilation as well as vasopressor support.[47,48]

Based on the Working Group on Civilian Biodefense's recommendations for pneumonic plague, first-line therapy is with streptomycin 1 g IV or IM twice a day, or gentamicin 0.5 mg/kg IM or IV twice daily. Alternate therapies are doxycycline 100 mg IV twice daily, ciprofloxacin 400 mg IV twice daily, or chloramphenicol 25 mg/kg IV four times daily. Therapy should be implemented in anyone exposed with a temperature >38.5°C or a new cough.[35]

In the setting of mass casualties where public health facilities may be overwhelmed, first-line therapy recommendations for postexposure prophylaxis in adults include doxycycline 100 mg orally twice daily, or ciprofloxacin 400 mg orally twice daily. Alternatively, chloramphenicol 25 mg/kg can be used. The reader is referred to the CDC article for dosing in children and pregnant women.[35] Currently no recommendations exist for vaccination of public or health care providers in the postexposure setting.[35,40,49]

Patients with pneumonic forms of plague should be kept under respiratory droplet isolation protocols (Table 61-4) until they have received at least 48 hours of appropriate antibiotic therapy or shown improvement. Persons who have been exposed who refuse to take antibiotic prophylaxis but are not symptomatic do not require isolation, but need to be watched and treated at the first sign of cough or fever. The use of standard disposable surgical masks is recommended. Microbiology lab personnel should be aware of the potential of getting infected from handling samples during high-risk lab procedures, and BSL 3 precautions should be observed during such times.[31,35,39]

Tularemia

Tularemia is caused by a gram-negative, facultative intracellular bacterium, *Francisella tularensis*. It is a zoonotic disease of small mammals and is transmitted by arthropod vectors (primarily ticks). There are two biovars of *F. tularensis*. Biovar tularensis or type A is more common in the south-central and western U.S., and is highly virulent to rabbits and humans. Biovar palearctica or type B is more common in Eurasia and less virulent to humans. The bacteria can survive for long periods in soil, water, and animal carcasses. Organisms infect humans by direct contact with mucous membranes, broken skin, ingestion, or inhalation.[50] Hunters, animal handlers, and laboratory personnel working with the bacteria are at greater risk for developing disease. Only 10 to 50 organisms are needed to cause infection in humans, via contact, inoculation, or inhalation.[51] Theoretically, a biological attack with tularemia would be with an aerosolized form. From the site of entry, bacteria are ingested by macrophages and transported to regional lymph nodes where they multiply and disseminate. At the site of the entry, a predominantly cell-mediated inflammatory reaction causes necrosis and granuloma formation. Granulomas are also formed at other target organs after dissemination.[50,52]

The incubation period is 3 to 5 days. Patients present with abrupt onset of fever, chills, headache, coryza, malaise, and weakness. A temperature-pulse deficit is noted in 42% of patients. Patients may complain of cough and chest discomfort without having signs of pneumonia. Patients may have varying degrees of sore throat, abdominal pain, arthralgias, and myalgias. If untreated, anorexia, continued weight loss, and debility occur over a period of weeks to months.[50,51,53] Clinically the disease may present as either ulceroglandular (which includes glandular, oculoglandular, and pharyngeal), or pneumonic (typhoidal) forms.

Ulceroglandular tularemia accounts for about 85% of natural cases, presenting as a cutaneous ulcer at the inoculation site within a few days of the onset of symptoms. The tender ulcer usually measures 0.4 to 3 cm in diameter, has raised edges, and is associated with regional lymphadenopathy. Affected lymph nodes are also tender, and can become fluctuant and suppurate. A minority present with the glandular form and no signs of skin involvement.[50,52,54] The oculoglandular and pharyngeal forms refer to the primary sites of inoculation, and are associated with intense inflammation, edema, hemorrhage, and granulomatous disease of the inoculation site, as well as regional lymphadenopathy. Of interest is that the pharyngeal form of the disease is frequently associated with pneumonia.[53]

Typhoidal tularemia refers to illness without lymphadenopathy or signs of a portal of entry. It occurs in 15% of natural cases. It is likely that this is actually a primary pneumonic form of the disease, acquired by inhalation of the organism. Onset is more abrupt, and patients are more toxic, with pronounced gastrointestinal symptoms such as abdominal pain, prostration, and watery diarrhea. Respiratory complaints and pneumonia are associated with 80% of cases. Pharyngitis, pleuritic chest pain, cough with minimal sputum production, and bronchiolitis are common, while hemoptysis is uncommon.[50,53–55] However, unlike both primary pneumonic plague and inhalational anthrax, the disease does not usually rapidly deteriorate to respiratory failure and death (see Table 61-3).

Both forms of tularemia are capable of causing pneumonia, ARDS, and septic shock, with the need for mechanical ventilation and vasopressor support, although only a handful of such cases exist in the postantibiotic literature.[56] Interestingly, those that did had ulceroglandular forms of the disease. Mortality is 35% in pneumonic forms of the disease without therapy. With appropriate antibiotics fatalities would be <5%. However, potential for widespread disability would be great.[24,57]

Initial laboratory tests are nonspecific. Moderate leukocytosis, elevations in lactate dehydrogenase, serum transaminases, and alkaline phosphatase are common. CSF may show a small elevation in protein, low glucose, and minimal

STANDARD PRECAUTIONS – Standard Precautions prevent direct contact with all body fluids (including blood), secretions, excretions, non-intact skin (including rashes), and mucous membranes. Standard Precautions routinely practiced by health care providers include: splash/spray, and gowns to protect skin and clothing during procedures.

[a] Contact precautions needed only if the patient has skin involvement (bubonic plague: draining bubo) or until decontamination of skin is complete (T-2 Mycotoxins).

[b] A surgical mask and eye protection should be worn if you come within 3 feet of patient. Airborne precautions are needed if patient has cough, vomiting, diarrhea, or hemorrhage.

[c] Contact precautions needed only if the patient is diapered or incontinent.

increases in white blood cells (WBCs).[50,53] Typically blood cultures are negative, owing to poor growth on standard media and a low index of suspicion, and historically there is usually a delay of several days before identification. However, organisms have been recovered from blood, ulcers, conjunctival exudates, sputum, gastric washings, and pharyngeal exudates.[53,58,61] Direct microscopic examination using fluorescent labeled antibodies provides a means of rapid diagnosis.[50] Antigen detection, PCR, and ELISA are also used, and these methods are available at state and national reference labs through the LRN. Manipulation of cultures is a well-known hazard to laboratory personnel, and should only be done under BSL 3 containment. A fourfold increase in serum antibody is also diagnostic, but of retrospective importance.[31,61]

In a large series of inhalation-acquired tularemia 50% of the patients had chest x-ray abnormalities; 40% had infiltrates described as 2- to 8-cm oval-shaped lesions with indistinct borders, mostly in the juxtahilar position; 21% had unilateral hilar adenopathy always associated with other x-ray abnormalities; and 11% had pleural effusions.[58] Pneumonia can occur in ulceroglandular disease, especially with the pharyngeal form. Interstitial patterns, cavitary lesions, bronchopleural fistulae, and frank ARDS have been reported on chest radiographs.[59] Pleural fluid analysis shows a serosanguineous exudate with a lymphocytic predominance. Increased adenosine deaminase, lysozyme, and β_2-microglobulin occur similarly to tuberculous effusions.[53,55,60]

Isolation of proven cases is not required since human-to-human transmission does not occur (see Table 61-4). Standard precautions should be applied to care of patients with draining lesions or pneumonia. Decontamination of soiled linen and equipment can be done with heat and standard disinfectants.

The Working Group on Civilian Biodefense's first-line therapy recommendations for treatment of adults in a contained casualty setting is streptomycin 1 g IM twice daily or gentamicin 5 mg/kg IM or IV once daily, for 10 days. Alternative therapies are doxycycline 100 mg IV twice daily for 14 to 21 days, chloramphenicol 15 mg/kg IV four times daily for 14 to 21 days, or ciprofloxacin 400 mg IV twice daily for 10 days. Of note, in the 1950s a fully virulent streptomycin-resistant strain was developed that could potentially be used in a bioterrorist attack. Fortunately the strain was sensitive to gentamicin. Since gentamicin has broader gram-negative coverage and is more readily available, it may be a more attractive first-line agent, especially if the diagnosis of tularemia is considered but in doubt.[61]

In a mass casualty setting where hospital resources are overwhelmed, adults can be treated with doxycycline 100 mg orally or ciprofloxacin 500 mg orally, twice daily for 14 days. Recovery from the illness is usually within 5 to 7 days. Currently vaccination is only recommended for microbiology laboratory workers handling cultures.[53,57,61]

Botulinum

Clostridium botulinum is a ubiquitous spore-forming anaerobic bacillus that produces a group of seven potent neurotoxins (types A through G). Botulism is the clinical syndrome produced by these toxins, and naturally occurs in three forms: food-borne, intestinal, and wound. Sporadic outbreaks of botulism occur throughout the U.S. due to contamination of food sources.[62] No water-borne cases have ever been reported.[63,64]

All cases of botulism occur secondary to absorption of toxin from gut, lung, or wounds into the bloodstream. Toxin is not absorbed through intact skin. Once absorbed it is carried to the peripheral neuromuscular junctions, where it binds irreversibly. The toxin is made of two polypeptide subunits (light and heavy chains). Toxin is endocytosed into the nerve terminus by virtue of its heavy chain. Subsequently, the light chain cleaves various components of the synaptic fusion complex, preventing release of acetylcholine into the synaptic cleft. This causes presynaptic inhibition of neuromuscular transmission, affecting cholinergic, muscarinic, and nicotinic receptors. Recovery may take weeks or months and is dependent on regeneration of new motor axons to reinnervate muscle.[65,66]

Botulinum toxin is likely to be used as an aerosol agent in a bioterrorist attack. Aside from the general epidemiologic clues to a bioterrorist attack, identification of toxin types C, D, F, and G should arouse suspicion, since types A, B, and E are the most common forms found in the U.S.[63] Botulinum toxin is the most potent toxic agent (per weight) known. Toxin A given in doses of 0.09 to 0.15 μg IV or IM, 0.7 to 0.9 μg inhaled, or 70 μg orally is enough to kill a 70-kg human. The toxin itself is colorless, odorless, and a relatively large protein (150,000-da). It quickly denatures under environmental conditions: 12 hours in air, 3 hours in sunlight, several minutes with heat >100° C, and 20 minutes at 0.4% mg/mL free available chlorine in water.[67]

The incubation period for food-borne botulism can vary from hours to days, but typically is between 12 and 72 hours, similar to that of the inhalational form.[59,63] The rapidity of the onset of symptoms varies with the dose of the toxin, but most often is acute. Patients present initially with cranial nerve palsies and prominent bulbar signs of blurred vision, mydriasis, ptosis, diplopia, dysphonia, dysarthria, and dysphagia. A progressive symmetric descending flaccid muscle paralysis follows, the rapidity of which is also variable. It is important to note that the patient remains conscious throughout this time and is not febrile. Patients may also manifest with anticholinergic signs and postural hypotension. Nausea and vomiting may occur as nonspecific sequelae of an ileus.[62,65,68] The upper airway may collapse due to weakness of oropharyngeal musculature, and handling of secretions may be problematic if the gag reflex is absent. Later the diaphragm is involved and respiratory failure ensues. Progression to hypercapnic and secondary hypoxic respiratory failure has been noted to occur within 24 hours in severe food-borne botulism.[63,65,68,69]

The diagnosis of botulism in the scenario of a bioterrorist attack should be made on the basis of its clinical and epidemiologic features mentioned above. This is because the definitive diagnosis can be delayed for days. The differential diagnosis for isolated cases includes stroke syndromes, intoxication, Guillain-Barré (Miller-Fischer variant), myasthenia gravis, and tick paralysis. However, for multiple cases presenting within a short period of time, the differential would be organophosphate and nerve agent poisoning (Table 61-5).

Routine laboratory tests, CSF examination, and brain imaging are unremarkable. Electromyography (EMG) studies show normal nerve conduction velocity, normal sensory function, and decreased amplitude of action potentials in affected

TABLE 61-5 Differential Diagnosis of a Large Number of Afebrile People Presenting with Paralysis

	Nerve Agent/ Organophosphate Toxicity	Botulinum Toxin[2]
Mechanism of action	Inhibits acetylcholinesterase	Inhibits presynaptic acetylcholine neurotransmission
Routes of acquiring	Inhalation and dermal	Inhalation, ingestion, and contamination of wounds; not dermally active
Onset to action	Minutes to hours	12 hours to several days
Central nervous system effects	Agitation, confusion, delirium, seizures, coma	Patients remain conscious but anxious
Motor system (nicotinic receptors)	Muscle fasciculations, pain, progressive weakness to rigid paralysis	Bulbar palsy (dysarthria, dysphonia, dysphagia, diplopia), progressive descending flaccid muscle paralysis
Autonomic system (muscarinic receptors)	Salivation, lacrimation, urinary incontinence, diarrhea, vomiting	Dry mouth, variable degree of gastrointestinal symptoms
Respiratory signs	Variable bronchoconstriction, rapid progression to respiratory failure within minutes	Comparatively slower progression to respiratory failure
Ocular signs	Progressive miosis	Mydriasis, early ptosis, 4th and 6th cranial nerve palsy
Cardiovascular	Bradyarrythmias > tachycardia	None
Electromyography	Normal nerve conduction, decreased amplitude at low rates of repetitive nerve stimulation	Normal nerve conduction, increased amplitude at high rates of repetitive stimulation
Diagnosis	Blood butyrocholinesterase and erythrocyte-cholinesterase levels	Mouse neutralization bioassay, specific toxin typing
Decontamination	Only for dermal agents, charcoal and sorptive resins, do not wipe (blot only)	None needed if inhalational. If ingested give activated charcoal
Therapy	Atropine, pralidoxime. anticonvulsants, antiarrhythmics, ventilator support	Trivalent or heptavalent antitoxin, anxiolytics, ventilatory support
Recovery	Hours to a few days	Weeks to months in severe cases

muscle groups. An incremental increase in amplitude after repetitive 30- to 50-Hz stimulation helps distinguish botulism from Guillain-Barré syndrome and myasthenia gravis, but not Eaton-Lambert syndrome. The edrophonium test can be transiently positive.[70]

Ventilatory failure should be watched for by following vital capacity and carbon dioxide tension on arterial blood gases. Patients without gag reflex are at high risk for aspiration and may need endotracheal intubation. In one large series of patients many had significant hypoxia without significant hypercapnia.[69] The time to mechanical ventilation was up to 5 days after the onset of symptoms, and was required for an average of 97 days. Aspiration pneumonia was presumed to occur in 29% of patients, all of whom received mechanical ventilation. Patients generally regained respiratory muscle strength later than in other muscle groups. Death from sepsis and shock were related to aspiration or ventilator-associated pneumonia.[69]

Definitive diagnosis of botulism is by mouse neutralization (bioassay), where type-specific antitoxin is used to protect mice against toxin in a patient's serum. Serum should be obtained prior to administration of antitoxin, as it may interfere with the assay. Results may take up to 2 days. Gastric, stool, and vomitus samples can also be used.[63] Samples should be handled under BLS 2 conditions at a level B lab.[31]

The mainstays of therapy are administration of antitoxin, ventilatory assistance, and supportive care. Patients presenting with food-borne botulism should be given activated charcoal and then antitoxin when available. Currently an equine botulinum antitoxin that provides passive immunity against types A, B, and E toxins is available from the CDC through state and local health departments. Prompt administration limits the severity of disease, but does not reverse existing paralysis. An investigational heptavalent antitoxin against types A through G is available in the U.S. Army for other toxin types. Unlike organophosphate poisoning, atropine is not indicated and would possibly exacerbate symptoms.[67]

Patients unable to handle oropharyngeal secretions should be placed in reverse Trendelenburg position with frequent pulmonary and oropharyngeal toilet to avoid aspiration. Patients with clinical signs of respiratory failure require mechanical ventilation. It is important to recognize that patients remain conscious throughout and may require sedation to relieve anxiety. Aminoglycosides, clindamycin, and steroids should be avoided, as they may worsen muscle atrophy and exacerbate neuromuscular blockade and myopathy.[72,73]

Postexposure prophylaxis with antitoxin is currently neither recommended nor practical. Exposed persons who are not symptomatic should be watched closely and given antitoxin if symptoms develop. Vaccination against botulinum toxin using a multivalent toxoid is advocated only for military personnel and laboratory workers who may be at great risk.[74] Decontamination is not required, as the agent is not dermally active. However, the possible use of a nerve agent should be considered in a scenario with many patients presenting with muscular weakness, and dealt with appropriately with decontamination (see Table 61-5).

Smallpox

Smallpox vaccination ceased in 1980, after the disease was declared eradicated by the WHO.[75] This has left a civilian population under the age of 30 totally susceptible. If the virus were ever intentionally released, its properties like high person-to-person transmission, viability outside its human host, and high fatality rate would cause colossal damage.[76]

Smallpox is caused by the variola virus of the orthopoxvirus family. Smallpox is highly infectious and person-to-person spread occurs by inhalation of expectorated respiratory droplet nuclei and by direct contact of the mucous membranes. Fomites such as contaminated linen of infected patients have also been responsible for spread. The incubation period is 12 to 14 days. Following deposition on the upper airway mucosa, the virus is transported to regional lymph nodes and then other lymphoid tissues. The virus then spreads systemically and localizes in small vessels of the dermis and oropharyngeal mucosa. This prodromal phase lasts for 3 days, and is marked by high fever, rigors, malaise, vomiting, headache, and backache.[77]

The clinical manifestations of smallpox are of five types. The classic or ordinary type accounted for 90% of cases with a fatality rate of 30%. Modified type occurred in 25% of unvaccinated and 2% of vaccinated cases with rare fatalities. Flat type occurred in 7% of cases and was characterized by slow evolution of flat, soft focal skin lesions and severe systemic toxicity. It had a fatality rate of 95% and 33% in the unvaccinated and vaccinated, respectively. Hemorrhagic type was almost uniformly fatal, occurring in 3%, and was characterized by diffuse hemorrhagic manifestations and rapid progression to death even before any skin lesions could be discerned. Variola sine eruptione was seen in vaccinated persons and was characterized by a 48-hour period of febrile illness. Unfortunately the various types cannot be distinguished until they start to manifest.[77]

The classical type of disease begins acutely with prodromal symptoms, followed by an enanthema of the tongue, mouth, and oropharynx. The next day a discrete centrifugal rash, characterized by 2- to 3-mm reddish macules begins on the face, hands, and forearms. These lesions progress to become papules and then vesicles of 3 to 5 mm in size, and spread centrally to cover the whole body by the fourth to seventh day. By the eighth day pustules of 4 to 6 mm are formed. Over the next 5 to 8 days, the pustules become larger and have a central depression (umbilicated). Later they become flattened and more confluent. During this phase of rash another fever spike occurs. By the thirteenth day the lesions start to crust and over the ensuing week start to scab and separate, leaving depressed depigmented lesions. The rash is typically more peripherally distributed and homogeneous in stage when compared to the rash of chickenpox.[77,78] Secondary infections of the rashes were reportedly not common. Complications of the disease included panophthalmitis and secondary infection causing blindness in 1%, arthritis in 2% of children, and encephalitis in 1%. Bronchitis was occasionally reported; however, pneumonia was rare.[76,77]

Death from the classic type of disease was reported to be most common during the second week. The fatality rate in the classic type seems directly related to the degree of confluence among the lesions. This may have direct bearing on the degree of fluid sequestration and protein loss during the vesicular and pustular stage. Renal failure, electrolyte imbalance, protein loss, and metabolic derangements were reportedly similar to those of burn victims and likely accounted for the majority of the morbidity of shock, infection, and death.[77,79]

The two most dreaded forms of the disease are the hemorrhagic and flat types. Hemorrhagic type has a predilection for pregnant women. There was no difference in incidence between vaccinated and unvaccinated individuals. It was characterized by a shorter more severe prodromal phase and marked prostration. Diffuse hemorrhagic lesions (likely due to DIC) occurred in all mucous membranes and skin, leading to sloughing of these surfaces. Pulmonary edema and hemoptysis were common. Patients were reportedly conscious until the very end and death often occurred within a week.[77] Flat type disease was rare in vaccinated individuals. The prodromal fever was present throughout the eruptive phase of the disease, and patients were extremely toxic in appearance. Mucous membrane sloughing was also characteristic.

It is likely that the vast majority of practicing clinicians would not be able to recognize smallpox in its early stages, by which time it would already be too late to prevent its spread. The differential diagnosis of the disease is quite vast, but the most common misdiagnosis would be that of chickenpox. Chickenpox has a less pronounced prodromal illness, a more centripetal rash, asynchronous evolution of the rash, quicker scab formation (1 week), and a fatality rate of <1%. Other illnesses that can be confused with smallpox are monkeypox, various cutaneous drug reactions, atypical measles, and molluscum contagiosum. Cases of hemorrhagic and flat type smallpox would be difficult to diagnose clinically, and would likely be misdiagnosed as severe meningococcemia, DIC from other diseases, Stevens-Johnson syndrome, or a filovirus hemorrhagic fever.[80]

Notification of local, state, and national public health authorities is of the utmost importance, as the diagnosis of smallpox is an international public health emergency. Specimens should be sent to state and national health authorities using the LRN, under BSL 4 precautions. Information regarding handling of specimens is detailed on the CDC website: http://www.bt.cdc.gov/agent/smallpox/response-plan/#guided.

Demonstration of the characteristic brick-shaped virus under electron microscopy is confirmatory for an orthopoxvirus, and aggregations of variola virus particles called Guarnieri bodies can be found under light microscopy. However, none of these tests are capable of discriminating variola from other orthopoxviruses. Definitive diagnosis is by isolation of the virus on chorioallantoic membrane culture and further testing with PCR.[80,81]

In a recent report, it was estimated that if as few as 10 persons were initially infected by a covert biological attack with smallpox, within 1 year as many as 224,000 persons would be infected if the disease went unchecked. Furthermore, a combination of quarantine (25% removal of cases from society daily) and a mass vaccination program (reducing the number of transmissions by 33%), would lead to halting of an epidemic within 1 year, and the cumulative number of cases would be 4200. In order for this scenario to be feasible it was estimated that over 9 million doses of vaccine would be necessary.[82]

Strict airborne and contact isolation in a negative pressure room is of primary importance in dealing with a case of smallpox. However, this is only feasible in a small, contained outbreak. In a massive outbreak separate hospitals would need to be designated for those with complications or more severe forms of the disease. More likely, people would have to be quarantined within their homes for routine supportive care. Patients requiring admission to the hospital in a scenario like this would likely be critically ill. Keeping pace with fluid losses, electrolyte imbalances, and nutritional needs would

be a major goal of therapy in these patients. This is especially true for patients with more confluent rashes, as well as flat type and hemorrhagic type variants of the disease. Meticulous skin care should be performed. Early placement of central venous access and invasive hemodynamic monitoring catheters may be warranted in severe cases as progressive distortion of the superficial anatomy occurs.[77,79] Patients with the flat and hemorrhagic types would be most likely to need some degree of mechanical ventilatory support, as the incidence of pulmonary edema is higher. In addition they would likely need transfusion therapy for complications related to DIC.

Currently there is no definitive treatment of the disease. Cidofovir (currently FDA approved for treatment of cytomegalovirus retinitis) is reportedly useful in preventing monkeypox and vaccinia in animals. It may have roles in postexposure prophylaxis and treatment of vaccinia vaccination complications. This drug would possibly be made available in a smallpox epidemic.[81]

Vaccination is done with reconstituted lyophilized vaccinia. It is applied with a bifurcated needle via 15 punctures at right angles into the skin overlying the deltoid without drawing blood. Successful vaccination is confirmed by the appearance of a characteristic Jennerian pustule after a week, and this provides immunity for up to 10 years, and 20 years with revaccination. The vaccinee must understand that there is viable vaccinia virus in the lesion from the moment the papule forms (2 to 5 days after vaccination) until the scab dislodges (on days 14 to 21). The lesions should be covered as there is a risk of transmission to an unvaccinated individual ("contact vaccinia").[101]

A three phase smallpox vaccination program was recently put forth by the U.S. government, under which medical and health care personnel are offered smallpox vaccination on a voluntary basis. The plan also calls for the creation of smallpox vaccination teams comprised of health care workers and public health officials in each state. These teams will assist in epidemiologic investigation and vaccination efforts during the first 7 to 10 days of an outbreak. Vaccination within 4 days of exposure will provide some protection from getting disease and will decrease mortality.[102] Vaccination of patients with suspected smallpox should also be considered for fear of misdiagnosis.[81] Recently it has been established that an increase in the dilution of the vaccine from 1:5 to 1:10 establishes immunity, and this practice could substantially boost the availability of the vaccine to the public.[83]

Contraindications for vaccination include immunosuppression, human immunodeficiency virus (HIV) infection, history of exfoliative dermatologic conditions, and pregnancy. Complications of vaccination in order of frequency are infection, generalized vaccinia (usually self-limited), eczema vacciniatum, postvaccinial encephalitis (with 10% significant neurologic morbidity), and vaccinia gangrenosa (occurs in immunosuppressed individuals and has a high fatality rate). Vaccinia immune globulin (VIG) is indicated for eczema vacciniatum, and vaccinia gangrenosa.[76,77,84]

Viral Hemorrhagic Fever

Viral hemorrhagic fever (VHF) is caused by a diverse group of RNA viruses that are transmitted to humans from their natural animal and arthropod reservoirs. They produce clinical syndromes characterized by fever, myalgias, prostration, increased vascular permeability, disturbances in regional circulation, and bleeding. Several of the hemorrhagic fevers (Marburg, Ebola, Lassa, Junin, and Machupo viruses) have been weaponized and experimented with for aerosol infectivity by the former Soviet Union, Russia, and the U.S. Experimental infection of animals via aerosol is highly effective. However, aerosol infection of humans has never been documented, except in the case of hantavirus. However, these agents are highly infective by direct contact with needles, fluids, and tissues of infected persons.[85] Important human pathogens are:

- Arenaviruses: Lassa, Junin, and Machupo viruses that cause Lassa fever, Argentinean, and Bolivian hemorrhagic fevers, respectively.
- Bunyaviruses: Rift Valley fever (RVF) virus and Crimean-Congo hemorrhagic fever (CCHF) viruses cause RVF and CCHF. Hantaviruses cause hemorrhagic fever renal syndrome (HFRS) and hantavirus pulmonary syndrome (HPS).
- Filoviruses: Marburg and Ebola viruses.
- Flaviviruses: Dengue fever, Kyasanur forest disease, and Omsk hemorrhagic fever.

VHF viruses target vascular endothelium, causing microvascular damage and derangement in vascular permeability. Common presenting complaints are fever, myalgias, and prostration. On examination patients may have conjunctival injection, mild hypotension, flushing, and petechial hemorrhages. Bleeding is variable and generally not life threatening, but it is an index of severity. Progression to shock and generalized bleeding from the mucous membranes is often accompanied by neurological, hematopoietic, or pulmonary involvement. Hepatic involvement is common; however, jaundice and frank hepatic failure is seen in a small percentage patients with RVF, CCHF, Marburg, and Ebola hemorrhagic fevers, and yellow fever. Death is secondary to increased vascular permeability, intravascular volume loss, and multiorgan failure.[86] The Working Group on Civilian Biodefense has concluded that CCHF and HFRS are unlikely to be employed as biowarfare agents, because they are technically difficult to produce in large quantities. Dengue is also an unlikely agent as it is not transmissible by aerosol, and only rarely causes VHF.

Each virus has unique features that set it apart clinically. Lassa fever is endemic in West Africa, and has a high mortality in children and pregnant women. Hemorrhagic and neurologic complications are not pronounced and occur only in the severely ill. Case-fatality rates in hospitalized patients average 15% to 25%.[87] In survivors deafness is a frequent sequela. In contrast, the South American arenaviruses (Argentine and Bolivian hemorrhagic fevers) have prominent neurologic and hemorrhagic manifestations.

RVF is endemic in sub-Saharan Africa. Frank hemorrhagic disease is seen in a minority of patients. Retro-orbital pain and blindness from retinitis occurs in 10%. In 1% of patients, fulminant disease with hemorrhage, jaundice, and hepatitis develops, with a 50% fatality rate. Fatal encephalitis occurs in <1%.[88] Marburg and Ebola viruses produce prominent maculopapular rashes and DIC is a major component in their pathogenesis. Both are characterized by pronounced bleeding. Forty-one percent of patients manifest bleeding from

puncture sites and mucous membranes; however, this form of bleeding does not distinguish nonsurvivors from survivors. Pulmonary involvement is uncommon and death usually results from multiorgan system failure and cardiovascular collapse.[89,90] Fatality rates for Ebola and Marburg hemorrhagic fevers are 80% and 25%, respectively.[86]

Routine laboratory tests in patients with VHFs are nonspecific, but the presence of early thrombocytopenia and coagulation abnormalities should arouse suspicion. Definitive diagnosis of VHF is done by isolation in cell culture or immunohistochemical staining of formalin-fixed tissues. These techniques should only be attempted under BSL 4 conditions at the CDC or USAMRIID. In the field, viral identification can safely be done following chemical inactivation with ELISA to detect viral antigen as well as IgM and IgG antibodies. Reverse transcriptase PCR has also been successfully applied to field diagnosis.[86]

Medical management for VHF is largely supportive. Patients should be handled as gently as possible as they are especially prone to bleeding. Aspirin and other antiplatelet drugs should be avoided. Immunosuppression with steroids or other agents is contraindicated. Uncontrolled clinical observations support the transfusion of red cells for severe hemorrhage and platelet and clotting factors for DIC. Hemodialysis is of particular help in treatment of HFRS. Mechanical ventilation may be necessary. Treatment of hypotension and shock is often difficult and the use of invasive hemodynamic monitoring techniques may help to guide therapy. Limited experience has shown that rapid infusion of fluids may quickly worsen pulmonary edema because of increased vascular permeability. Fluids are best administered carefully using crystalloids first, and later with the addition of colloids.[86,91] In cases of HPS the use of inotropes may be warranted.[92]

The only specific antiviral therapy available for VHF is ribavirin, a nonimmunosuppressive nucleoside analogue with broad antiviral properties. It has been shown to reduce mortality in Lassa fever and shows promise with the treatment of other arena- and bunyaviruses. Passive immunotherapy has been used successfully in Argentine hemorrhagic fever and shows promise in Bolivian hemorrhagic fever. However, passive immunization is contraindicated in HFRS since an active immune response is already evolving in most patients who are diagnosed. Currently the only licensed vaccine is for yellow fever and is mandatory for all travelers to endemic areas.[86]

Isolation of suspected VHF cases is essential as secondary infections of close contacts and medical personnel are well documented. Until the definitive diagnosis has been made, patients with suspected VHF should be isolated in a single room with an adjoining anteroom serving as an entrance. Negative pressure rooms and strict respiratory precautions may be more appropriate in confirmed severe end-stage disease where the viral load is maximal (see Table 61-4). These precautions may not be possible in the case of large outbreaks. However, it is essential to enforce stringent barrier nursing, with the use of mask, glove, gown, and needle precautions, along with hazard labeling of all laboratory specimens. Patient access should be restricted and the incineration or autoclaving of all contaminated materials including linens is mandatory. Decontamination of areas can likely be carried out by detergents, bleach, and hypochlorite solutions, as these viruses have lipid envelopes making them susceptible.[85]

Category B Agents

Discussion of all the possible biological weapons is beyond the scope of this chapter. However, *Coxiella burnetii* (Q fever), staphylococcal enterotoxin B (SEB toxin), viral equine encephalitides, and ricin toxin deserve attention, as they have been weaponized. Furthermore they can all present as an upper respiratory viral illness, making differentiation of biological attack from a natural viral epidemic difficult (see Table 61-3).

Q fever is a zoonotic disease of herded animals. Humans acquire it via inhalation. It is extremely infectious, requiring as few as 10 organisms to produce disease. The incubation time is 2 to 14 days. Patients present with signs and symptoms of a seasonal viral syndrome that can be prolonged in two thirds for up to 2 weeks. The most frequent physical finding is rales on chest exam. Chest x-rays are abnormal in 50% to 60% of cases, most often showing consolidation, but effusions also occur. Routine blood tests commonly show elevations of liver transaminases and alkaline phosphatase up to three times normal. Fatalities are extremely rare; however, the disease is incapacitating. Treatment and prophylaxis is with doxycycline or tetracycline.[93]

SEB is a heat-stable pyrogenic toxin produced by *Staphylococcus aureus*. This toxin can be mass produced and is stable as an aerosol. When inhaled it binds to the MHC class II molecules that stimulate T cells with a massive release of cytokines including interferon-γ, interleukin-6, and tumor necrosis factor (TNF)-α. Within 3 to 12 hours of exposure high fever (up to 106°F), myalgias, nonproductive cough, chest tightness, dyspnea, headache, and vomiting develop. Conjunctival signs are notably absent. On chest examination, rales are the prominent finding. Chest x-ray typically is normal, but can show interstitial pulmonary edema. Postural hypotension as well as profound vasodilatory shock can occur. Patients usually progress rapidly to a relatively stable level of disease, but can be incapacitated for weeks. Lethality is low. Diagnosis is clinical, but serum detection of the toxin is possible with ELISA. Therapy is currently limited to supportive care.[24,94]

The viral equine encephalitides include Venezuelan, eastern, and western viruses (VEE, EEE, and WEE) of the alphavirus family. Humans are accidental hosts, acquiring the virus via a mosquito vector. However, they are highly infectious by aerosol and readily grow in cell cultures. All three of the viruses are capable of killing with varying degrees of neurologic involvement. EEE is most virulent with 50% to 70% mortality, WEE follows with <10% mortality, and VEE has <1% mortality. A febrile prodrome of 1 to 5 days marks replication in bone marrow and lymphoid tissue resulting in lymphopenia. Subsequently high viremia seeds the brain and spinal cord. Central nervous system symptoms and signs include menigismus, hyper- or hypoactive reflexes, and spastic paralysis that can progress to death. Loss of airway protection and status epilepticus may require mechanical ventilation and ICU management. CSF shows elevated protein and 50 to 2000 WBCs/mL with lymphocyte predominance. Definitive diagnosis relies on viral culture of serum or CSF, or antibody detection from serum by ELISA. Therapy is limited to supportive treatment. A live-attenuated vaccine for VEE is available, along with inactivated vaccines for VEE, WEE, and EEE. These vaccines are available under investigational new drug

(IND) release status from the US government but are only 50–85% effective for <1 year.[95]

Ricin toxin is an extract of castor beans. It is highly lethal via ingestion, injection, and inhalation. At the cellular level it kills through the inhibition of protein synthesis. Its clinical features are route-specific. Studies in primates show that within several hours of inhalation a severe diffuse acute tracheobronchitis manifests, followed by fibrin purulent pneumonia with diffuse severe alveolar flooding, peribronchovascular edema, and mediastinal lymphadenitis. Respiratory failure and ARDS are likely to occur within 30 hours. Distinguishing an attack with ricin from either anthrax or pneumonic plague would be extremely difficult. Diagnosis would be largely clinical, but antigen ELISA of nasal swabs should be done within 24 hours. Treatment would be largely supportive, though vaccination with a toxoid in animals is very effective and in development by the U.S. Army.[96]

Role of Critical Care in Bioterrorism

The scenario of a biological weapons attack poses several unique challenges for the intensivist. Although most external disasters will occur with some degree of warning, biological agent exposure is an exception. Here the diagnosis is more likely to be made within a hospital, perhaps a few days after the environmental release.[97] Patients are more likely to seek medical care at the most convenient medical facility instead of responders going to the patients.[98,99] Unlike natural disasters or conventional wars, victims in a biological attack are likely be a more homogenous population. Potentially enormous numbers of ill and exposed patients presenting with the same level of severity will rapidly overwhelm the health care system, its infrastructure, and supplies. Issues of supplies and distribution of medical resources would be a major problem, as already predicted in the TOPOFF exercise.[4] Applying conventional mass disaster triaging schemes may therefore not be possible to a such homogeneously affected population. It is thus important to consider these unique features related to biological agent attacks in both preparation and acute disaster management.

The need for the critical care personnel to be involved in the planning process cannot be overstated. The intensivist will become a key figure in governing the flow of patient traffic, making triage decisions, and allocating ICU resources for patients in the ER, OR, recovery room, and the rest of the hospital. Intensivists should understand capabilities, resources, and limitations of various governmental and nongovernmental disaster-related agencies, as well as consider their hospital's location and community resources in anticipating a likely disaster scenario.[97]

Although the full details of a hospital's preparedness plan are beyond the scope of this chapter, certain key issues deserve attention in coping with such a disaster. Readers are referred to the CDC web site for preparation and planning for a bioterrorist attack at http://www.bt.cdc.gov/planning/index. asp, as well as individual state health department guidelines for preparedness, and their own hospital's disaster management plans.

1. Define the area to be covered during a disaster scenario. Intensivists should familiarize themselves with their hospital disaster plan, and know their responsibilities relative to other departments in the plan.
2. Identification and assignment of key personnel in the hospital, emergency response personnel, state and local authorities, and key members of the community.
3. Assessment of hospital infrastructure, supplies at hand, and manpower for a given situation. This would also include knowing the vendor lists to meet sudden demand for supplies and knowledge of the absolute limits of the hospital resources (inventory of ventilators, oxygen tanks, intravenous catheters, isolation capabilities of the hospital, etc).
4. Establishing secure lines of communication internally via a central command post or incident center, as well as externally with the LRN, National Pharmaceutical Stockpile (NPS), and local, state, and federal authorities. Successful interaction with these agencies will likely define the successful management of a disaster response (Table 61-6).
5. Defining portals of entry to the hospital and creating safe arrival and triage areas, in addition to decontamination areas.
6. Establishing algorithms for triage from the ED and clinics, as well as criteria for ICU admission. As surge capacity nears, the risks and benefits of treating existing patients in the hospital and carrying out elective surgeries needs to be weighed. Knowledge of alternative beds and transfer agreements with nearby ICUs would be crucial in this regard.
7. Early efforts must be made to contain the agent. This can be achieved by education of staff and public, early efforts to identify the agent through the LRN, reporting of the agent to the local, state, and federal health authorities, early intervention and treatment of the disease, and early implementation of appropriate infection control measures (Tables 61-6 and 61-7).
8. Ensuring the safety of workers. This includes issues of isolation precautions, evaluation of the potential for spread among other patients and staff once the agent has been confirmed, postexposure prophylaxis, and vaccination. Staff exhaustion and posttraumatic stress disorder should be anticipated, and dealt with by scheduling adequate rest periods, appropriate use of volunteer staff, and a program of critical incident stress management.
9. Carrying out drills and mock events for continual assessment of flaws in organization and execution of the plan.

Summary

A bioterrorist attack of any kind has the potential to overwhelm a community and indeed an entire nation. A high degree of suspicion and prompt recognition of an event will be required in order to contain it. The likelihood of exposed patients to require hospitalization and specifically critical care is high, and specific knowledge of the possible agents and estimating the needs of a health care facility and community will be the cornerstones in disaster preparedness for a biological attack. Aside from the delivery of critical care to the patient in the ICU, the intensivist will be involved in making triage decisions (which automatically dictates how other non-ICU beds are used and managed), managing resources related to the ICU, and coordinating a multidisciplinary effort in caring for the exposed.

TABLE 61-6 Biosafety Precautions

Biosafety Level	Agents	Practices	Safety Equipment (Primary Barriers)	Facilities (Secondary Barriers)
1	Not known to cause disease in healthy adults	Standard microbiological practices	None required	Open bench-top sink required
2	Associated with human disease; hazard from autoinoculation, ingestion, mucous membrane exposure	BSL-1 practice plus: a) Limited access; b) Biohazard warning signs; c) Sharps precautions; d) Biosafety manual defining any needed waste decontamination or medical surveillance policies	Primary barriers; Class I or II BSCs or other physical containment devices used for all manipulations of agents that cause splashes or aerosols of infectious materials; PPEs: laboratory coats, gloves, face protection as needed.	BSL-1 plus: autoclave available
3	Indigenous or exotic agents with potential for aerosol transmission; disease may have serious or lethal consequences	BSL-2 practice plus: a) Controlled access; b) Decontamination of all waste; c) Decontamination of lab clothing before laundering; d) Baseline serum	Primary barriers; Class I or II BCSs or other physical containment devices used for all manipulations of agents; PPEs: protective lab clothing, gloves, respiratory protection as needed	BSL-2 plus: a) Physical separation from access corridors; b) Self-closing, double-door access; c) Exhausted air not recirculated; d) Negative airflow into laboratory
4	Dangerous/exotic agents that pose high risk of life-threatening disease, aerosol-transmitted lab infections, or related agents with unknown risk of transmission	BSL-3 practices plus: a) Clothing change before entering; b) Shower on exit; c) All material decontaminated on exit from facility	Primary barriers: All procedures conducted in Class III BSCs or Class I or II BSCs in combination with full-body, air-supplied, positive-pressure personnel suit.	BSL-3 plus: a) Separate building or isolated zone; b) Dedicated supply/exhaust, vacuum, and decon systems

ABBREVIATIONS: BSC, biosafety cabinets; PPE, personal protective equipment.

Chapter 62

DELIRIUM IN THE INTENSIVE CARE UNIT

E. WESLEY ELY

KEY POINTS

- *Delirium may be considered to be present when there is an acute or fluctuating change in mental status and inattention coupled to disordered thinking or an altered level of consciousness.*
- *Delirium is extraordinarily common among patient populations in the intensive care unit (ICU) and is under-recognized by care providers, in part related to a previous lack of tools to assess this phenomenon.*
- *Hypoactive or mixed forms of delirium are more common than pure hyperactive delirium.*
- *The Confusion Assessment Method for the ICU is a well-validated tool to provide simple and reproducible assessment of delirium at the bedside.*
- *The risk factors for delirium may be divided into host factors, the acute illness, and environmental or iatrogenic factors.*
- *Because age and pre-existing mental impairment are powerful risk factors for delirium, it is likely to be encountered with increasing frequency in the ICU in the future.*
- *Because administration of psychoactive drugs, including sedatives and analgesics, is an important risk factor for delirium, this represents a fruitful area for modification of practice to reduce the incidence of delirium in ICU patients.*
- *Delirium is independently associated with increased morbidity, cost of care, and mortality rate, even after adjusting for severity of illness, age, coma, and other relevant covariates.*

Patients in the intensive care unit (ICU) who experience delirium are exhibiting an under-recognized form of *organ dysfunction*. Delirium is extremely common in ICU patients due to factors such as comorbidity, critical illness, and iatrogenesis. This neurologic complication can be extremely hazardous in hospitalized older persons and is associated with death, prolonged hospital stays, and institutionalization. Neurologic dysfunction compromises patients' ability to be removed from mechanical ventilation or achieve full recovery and independence. Unfortunately, health care providers in the ICU are unaware of delirium in many circumstances, especially those in which the patient's delirium is manifesting predominantly as the hypoactive (quiet) subtype as opposed to the hyperactive (agitated) subtype. In the past few years, research on ICU delirium has demonstrated the importance of this problem in critically ill patients in addition to methods for routinely monitoring delirium at the bedside. This chapter reviews the definition and salient features of delirium, its primary risk factors, validated methods for bedside delirium assessment, pharmacologic agents associated with the development of delirium, and pharmacologic and nonpharmacologic strategies for delirium management.

Historically, two words were used to describe confused patients. One was the Roman word *delirium*, which referred to an agitated and confused person (think of hyperactive delirium). The other was from the Greek word *lethargus*, which was used to describe a quietly confused person (think of hypoactive delirium). ICU patients commonly demonstrate both subtypes as they progress through different stages of their illness and therapy. In either case, the patient's brain is not functioning normally. It therefore makes sense that the original derivation of delirium comes from the Latin word *deliria*, which literally means to "be out of your furrow." For greater clarity and to avoid misuse of terms such as *dementia* and *delirium*, Table 62-1 lists basic definitions of some common cognitive syndromes.

Health care professionals in the ICU have traditionally used inadequate monitoring devices to detect dysfunction in arguably the most important organ of all, the brain. Delirium, an acute central nervous system (CNS) dysfunction resulting from any number of common insults that ICU patients experience, has largely been overlooked in critical care research until the past few years. Recent discussions of encephalopathy and organ dysfunction secondary to sepsis have not mentioned delirium as one of the clinical manifestations of CNS dysfunction.[1,2]

The ICU literature often refers to delirium as *ICU psychosis*,[3–8] which represents a potentially dangerous misnomer. The development of delirium often goes unnoticed in the ICU because we think of it as "part of the scenery" or an expected and inconsequential outcome of mechanical ventilation and other therapies. A series of investigations has recently been conducted that provide validated means of detecting delirium by nonpsychiatrists (e.g., internists, nurses, or respiratory therapists). The CNS monitoring instruments and observations from these investigations are leading to a change in the culture and practice in the ICU in which health care providers more closely follow patients for the development of delirium and modify their care to help prevent this potentially disastrous complication. The most recent clinical practice guidelines from the Society of Critical Care Medicine (SCCM)[9] have recommended routine (daily) monitoring of delirium in all mechanically ventilated patients, which is discussed later in this chapter.

Pathophysiology and Etiology of Delirium

Delirium is thought to be related to imbalances in the synthesis, release, and inactivation of neurotransmitters that modulate the control of cognitive function, behavior, and mood.[8,10] Three of the neurotransmitter systems involved in the pathophysiology of delirium are dopamine, γ-aminobutyric acid, and acetylcholine.[11,12] Whereas dopamine increases excitability of neurons, γ-aminobutyric acid and acetylcholine decrease neuronal excitability.[11] An imbalance of one or more of these neurotransmitters results in neuronal instability and unpredictable neurotransmission. In general, an excess of dopamine and depletion of acetylcholine are two major physiologic problems felt to be central to delirium. In addition to these neurotransmitter systems, others are thought to be involved in the development of delirium, such as serotonin imbalance, endorphin hyperfunction, and increased central noradrenergic activity.[10,12]

TABLE 62-1 Highlights Regarding Cognitive Syndromes

Confusion	A characteristic occurring in delirium, resulting in an altered state of consciousness, and characterized by deficits in attention, memory, visual-constructional ability, and executive functions (also defined as reduced mental clarity, coherence, comprehension, and reasoning). *Think:* Disturbed orientation with respect to person, place, and time.
Delirium	A disturbance of consciousness characterized by an *acute* onset and fluctuating course of impaired cognitive functioning, so that a patient's ability to receive, process, store, and recall information is strikingly impaired. Delirium develops over a short period (hours to days), is usually reversible, and is a direct consequence of a medical condition, substance intoxication or withdrawal, use of a medication, toxin exposure, or a combination of these factors. *Think:* Rapid onset, clouded consciousness (bewildered/confused), often worse at night, fluctuating.
Dementia	Development of a state of generalized cognitive deficits in which there is a deterioration of previously acquired intellectual abilities usually developing over weeks and months. The deficits include memory impairment and at least one of the following: aphasia, apraxia, agnosia, or a disturbance in executive functioning. The cognitive deficits must be sufficiently severe to cause impairment in occupational or social functioning, and they may be progressive, static, or reversible depending on the pathology and the availability of effective treatment. *Think:* Gradual onset, intellectual impairment, memory disturbance, personality/mood change, no clouding of consciousness.
Psychosis	A major mental disorder characterized by hallucinations, delusions, or the inability to distinguish reality from fantasy, which lead to an inability to maintain interpersonal relations and to compromised daily functioning. *Think:* Hallucinations/delusions, impaired reality testing, inappropriate mood and impulse control, no clouding of consciousness.

SOURCE: Reprinted with permission from Ely EW, et al: Delirium in the intensive care unit: An unrecognized syndrome of organ dysfunction. *Semin Respir Crit Care Med* 22:115, 2001.

Several causal factors lead to neurotransmitter imbalance, including reduction in cerebral metabolism, primary intracranial disease, systemic illness, secondary infection of the brain, exogenous toxic agents, withdrawal from substances of abuse such as alcohol or sedative-hypnotic agents, hypoxemia, metabolic disturbances, and the administration of psychoactive medications such as benzodiazepines and narcotics.[12,13] Cognitive neuroscience and psychopharmacology are active areas of research that may advance our understanding and treatment of delirium.

"Confusion" Regarding Delirium Terminology

There are more than 25 terms in the literature used to refer to delirium, such as "subacute befuddlement" and "toxic confusional state." Others simply refer to delirium as confusion or neurological impairment. The neurologic literature tends to use the terms *delirium* to refer exclusively to the hyperactive subtype[14] and *encephalopathy* to refer to hypoactive delirium. These subtypes are discussed in the next section of this chapter. *ICU psychosis* is a potentially dangerous misnomer that refers to delirious patients who demonstrate increased psychomotor activity and hallucinations (i.e., hyperactive delirium).[3–8]

Occurrence of Delirium in the ICU and Its Subtypes

The prevalence of delirium in ICU cohort studies has been reported as 20%,[15] 70%,[16] and 80%,[17] depending on the characteristics of the patient population and the instrument used. Its incidence is likely to increase in future years as older persons more frequently receive ICU care. Two events that are frequently linked during older patients' ICU course are the need for mechanical ventilation and the development of profound and possibly persistent cognitive impairment.[18] Almost every patient in the ICU receives narcotics or benzodiazepines at some point during their stay, yet physicians rarely modify the quantity or dosing intervals of these drugs based on patients' age. Patients on mechanical ventilation are frequently sedated to the point of stupor or coma to improve oxygenation, alleviate agitation, and prevent them from removing support devices. However, age is only rarely factored into complex decisions concerning how to dose these potent medications or when to remove sedatives and liberate patients from mechanical ventilation. The result is that it is now commonplace in the ICU to find that most elderly patients receiving mechanical ventilation are in a drug-induced state of "suspended animation."[19]

The subtypes of delirium based upon motor activity are hypoactive, hyperactive, and mixed. Peterson et al recently reported on delirium subtypes from a cohort of 613 ventilated and nonventilated ICU patients in whom delirium was monitored for more than 20,000 observations.[20] These investigators found that, among patients who developed delirium, pure hyperactive delirium was rare (<5%), whereas hypoactive and mixed types of delirium were the predominant subtypes (~45% each). Interestingly, the hypoactive subtype was significantly more common in older than in young patients. The risk factors for and clinical implications of these subtypes are the subject of ongoing investigations.

The period surrounding cessation of sedation represents a typical scenario in the ICU setting in which delirium may be easily recognized or completely missed by clinicians. Patients emerging from the effects of sedation may do so peacefully or in a combative manner. At one extreme are the "peaceful" patients who are often erroneously assumed to be thinking clearly. Delirium in this context is referred to as *hypoactive delirium* and is characterized by decreased mental and physical activities and inattention.[6] Such mental status changes could lead to adverse outcomes such as reintubation, which itself has been shown to increase 10-fold the risk of nosocomial pneumonia and death. In addition, hypoactive delirium is associated with aspiration, pulmonary embolism, decubitus ulcers, and other complications related to immobility.

At the other extreme are agitated or combative patients (i.e., hyperactive delirium) who are at risk not only for self-extubation and subsequent reintubation but also for pulling out central venous access and even falling out of bed. These patients are most often given larger doses of sedatives that commit them to at least another day of mechanical ventilation. This places patients at risk for being left in a cognitively impaired state and on mechanical ventilation unnecessarily.[21] Because of this difficult cycle, it is important for health care professionals to avoid overuse of psychoactive medications and to develop better methods of assessing cognitive function, especially during the transition from drug-induced or metabolic coma to wakefulness.

Missing the Diagnosis of Delirium

The "quiet," or hypoactive, delirium is frequently overlooked by physicians and nurses.[22–25] Delirium remains unrecognized by the clinician in as many as 66% to 84% of patients experiencing this complication,[26,27] and it may be attributed incorrectly to dementia, depression, or just an "expected" occurrence in the critically ill, elderly patient.[26] Many clinicians expect delirium to present with agitation or hallucinations, features that are not required for the diagnosis. Other reasons for the lack of recognition of delirium include infrequent cognitive assessments and the fluctuating nature of delirium. The very development of delirium has been associated with fewer interactions and less time spent by nurses and physicians in direct patient care.[28,29]

Geriatric ICU Concerns and Pre-existing Cognitive Impairment

It is estimated that the cost of care for those older than 65 years will increase 10-fold over the next three decades.[30] These data have been used to argue for limiting ICU care provided to the elderly to conserve resources.[31–33] However, a recent report from Angus et al. documented that nearly 60% of all ICU days were incurred by patients older than 65 years.[34] In fact, adults younger than 65 had 37 ICU days per year per 1000 person-years versus 240 for those older than 75 years. The incidence of acute respiratory failure requiring mechanical ventilation rises 10-fold from the age of 55 to 85,[35] resulting in larger numbers of elderly patients treated in ICUs.[36]

Because of these age-related demographics and the relation between pre-existing cognitive impairment and development of delirium, clinicians are likely to discover an increased burden of delirium among hospitalized patients across the country.[37,38] Advanced age and cognitive decline have been found to lead to decreases in the level of interactions and potentially life-saving therapeutic interventions from clinicians and caregivers.[39,40] Nevertheless, more and more elderly patients are being admitted to the ICU,[41] and certainly this will include older patients with pre-existing cognitive impairment ranging from mild to overt dementia. In a cohort investigation, Pisani et al studied the effect of pre-existing cognitive impairment (mostly mild) on ICU outcomes and found that those with and without cognitive impairment had similar outcomes in terms of length of stay in the ICU and the hospital and mortality rate.[42] However, the persistence of delirium symptoms in such patients could strongly affect discharge rates to nursing homes after hospitalization.[24,26]

Prognostic Significance of Delirium

Reports have associated CNS organ dysfunction with complications of mechanical ventilation, including aspiration, nosocomial pneumonia, reintubation, and self-extubation.[43–47] Moreover, in mechanically ventilated neurosurgical patients, the strongest predictor of failed extubation was found to be an abnormal Glasgow Coma Score.[48] In medical ICU patients, Salam et al found important interactions between cognitive dysfunction and the likelihood of failed extubation.[49] CNS "failure" is an important predictor of outcome from sepsis.[2]

In non-ICU populations, the development of delirium in the hospital is associated with an in-hospital mortality rate of 25% to 33%, prolonged hospital stay, and three times the likelihood of discharge to a nursing home.[18,24,50] In a three-site study of medical non-ICU patients, delirium was found to be an independent predictor of the combined outcome of death or nursing home placement.[51] Francis and Kapoor found that the 2-year mortality rate in patients having experienced delirium was 39% versus 23% in controls,[52] but multivariate analysis showed that this was largely explained by baseline cognitive and functional statuses. Perhaps the most convincing report of the independent association between delirium and mortality rate among non-ICU patients was published by McCusker et al,[53] which showed an adjusted hazard of dying of 2.11 associated with the development of delirium. This mortality rate increase has since been shown to be independent of dementia status.[54]

Among ICU patients, there is current evidence that delirium is a predictor of mortality at 6 months following the ICU stay (Fig. 62-1).[55] The development of delirium was associated with a threefold increase in risk of death after controlling for pre-existing comorbidities, severity of illness, coma, and the use of sedative and analgesic medications. These data also showed that delirium is not simply a transition state from coma to normal because delirium occurred just as often among those who never developed coma as among those who did and persisted in 11% of patients at the time of hospital discharge. Further, three recent prospective studies have associated delirium with an increased risk for dementia over 2 to 3 years.[56–58] In light of these findings, future studies should determine whether or not prevention or treatment of delirium changes clinical outcomes, including mortality rate, length of stay, cost of care, and long-term neuropsychological outcomes among survivors of critical illness.

Costs Associated with Delirium in the ICU Patient

Delirium complicates the hospital stay of more than 2 to 3 million elderly patients per year in the United States, involving more than 17.5 million inpatient days and accounting for more than $4 billion in Medicare expenditures.[59] In the only study to date reporting on costs associated with delirium in the ICU, Milbrandt et al found that median ICU and hospital costs were significantly higher for those with at least one episode of delirium versus those with no delirium

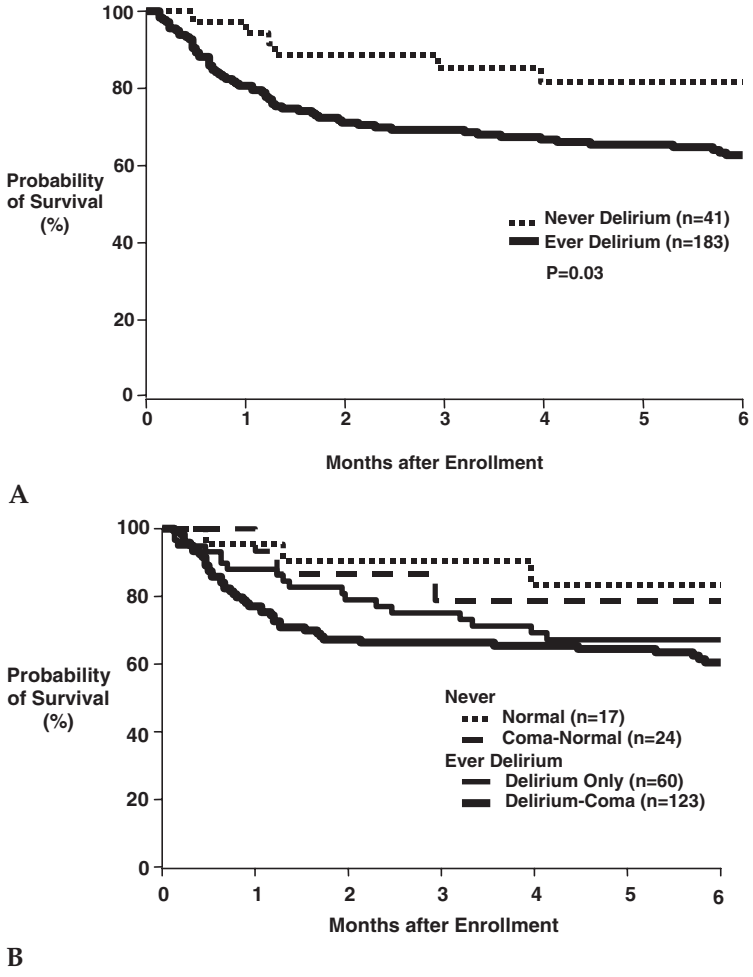

FIGURE 62-1 Kaplan-Meier plots show the relation between delirium and 6-month survival rate. ***A.*** **Never-delirium versus ever-delirium groups (according to whether or not the patient ever developed delirium in the intensive care unit).** ***B.*** **Clinical severity (subdividing the never- and ever-delirium groups to better understand the phenomenology of delirium). The never-delirium group, composed of those who were always normal and those who were comatose and then normal (e.g., deeply sedated and then normal when drugs were stopped) had higher survival rates than the ever-delirium group, which was composed of those with delirium only and delirium and coma.**

(Fig. 62-2).[60] Even after controlling for important potentially confounding variables, such as baseline comorbidities and severity of illness, delirium was associated with a 40% relative increase in ICU and total hospital costs. In addition, the data demonstrated a "dose-response" in which cumulative delirium severity was associated with incrementally higher cost.

The associated annual cost of ICU delirium may be enormous. In the study by Milbrandt et al,[60] delirium occurred in 82% of mechanically ventilated patients and was associated with an incremental increase in ICU cost of more than $9000 per patient. In the United States, there are approximately 880,000 to 2,760,000 ICU admissions annually for respiratory failure requiring mechanical ventilation. Therefore, the estimated number of cases of ICU delirium may range from 721,600 to 2,263,200 per year, with an associated increase in health care costs ranging from $6.5 billion to $20.4 billion. Even if the incidence of delirium from a less severely ill ICU cohort occurred in only 19% of patients,[61] the estimated annual costs would be in the range of $1.5 billion to $4.7 billion. Because some of the additional cost associated with delirium could be attributable to unmeasured differences between patient groups, these estimates represent the upper limit of the cost attributable to ICU delirium. However, even if only 20% of the difference in costs between patients with and without delirium were due to delirium, this would be a significant public health concern, with $300 million to $4 billion in annual attributable costs.

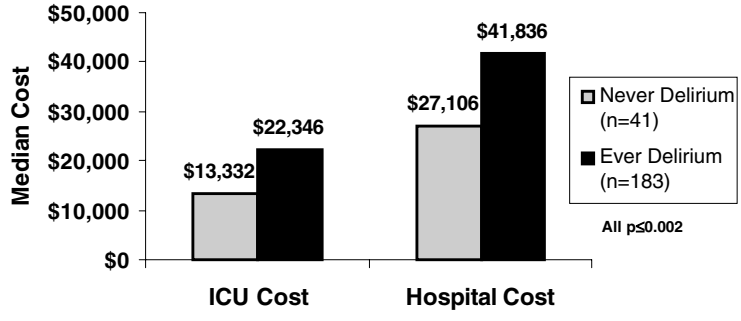

FIGURE 62-2 Median intensive care unit (ICU) and hospital costs per patient. This histogram shows cost according to clinical categorization of ever-delirium versus never-delirium. Delirium was significantly associated with increased ICU and hospital cost.

Risk Factors for Delirium

Only a few studies of ICU patients have studied risk factors for delirium, although many investigations over the past decade, by using a variety of non-ICU cohorts, have identified numerous risk factors for the development of delirium.[50] Patients who are highly vulnerable to delirium may develop the disorder after only minor physiologic stressors, whereas those with low baseline vulnerability require a greater insult to become delirious.[62] It is possible to stratify patients into risk groups depending on the number of risk factors present.[26,62–64] Three or more risk factors increase the likelihood of developing delirium to approximately 60% or higher, and it is a rare patient in the ICU who would not be in the high-risk group. Most ICU patients have more than 10 risk factors for delirium.[17,65]

In practical terms, the risk factors can be divided into three categories: (1) host factors, (2) the acute illness, and (3) iatrogenic or environmental factors (Table 62-2).[4,18,23,26,61,63,64,66–68] Issues that are ripe for study in terms of prevention or intervention have been indicated. In the only ICU cohort risk factor study published to date,[61] factors related to medical history included hypertension and smoking (thereby raising one's awareness of the risks of relative underperfusion of the brain or nicotine withdrawal). During the ICU stay, a dose-dependent risk was found for patients having been treated with opiates.

Psychoactive medications are the leading iatrogenic risk factors for delirium.[24,61,62,69,70] Benzodiazepines, narcotics, and other psychoactive drugs are associated with a 3 to 11 times increased relative risk,[24] and the number and rate of adding psychoactive medications increase the risk of delirium by 4 to 10 times.[24] By coupling these data to knowledge regarding the extreme variability in the pharmacokinetics of sedatives and analgesics according to age, ethnicity, drug metabolizing ability and other factors,[71–74] perhaps the most promising delirium interventions could be centered on delivery patterns of these medications.

Combining Sedation and Delirium Assessments at the Bedside

The SCCM guidelines suggest that all critically ill patients be simultaneously monitored for level of sedation and for delirium.[9] Bedside critical care nurses and the rest of the ICU team need to use data obtained from well-validated, reliable, objective, but brief assessment tools to monitor for both components of consciousness (arousal level and content of consciousness).[75] Neurologic monitoring in the ICU can be streamlined by using a two-step approach to sedation and delirium.

The first step in the neurologic assessment of an ICU patient is to assess that patient's level of consciousness or sedation with an objective sedation assessment. The recommended standard of care is to use objective assessment scales to avoid oversedation and to promote earlier liberation from mechanical ventilation.[9,76–80] Sedation scales help provide a common language for the multidisciplinary team to use when discussing goals and treatments for patients.[80–82] Whereas the Ramsay Scale[83] has been the most widely used instrument for decades in clinical practice and the published literature,[84] other recently developed instruments such as the Sedation-Agitation Scale[85] and Richmond Agitation Sedation Scale[86,87] have been better validated and are being widely implemented.[17,88] Chapter 14 includes a thorough discussion of how to approach sedation in the ICU, but it is appropriate to emphasize the importance of using these instruments to guide patient-targeted or goal-directed sedation. The concept of using sedation scales over time within patients was addressed in the second Richmond Agitation Sedation Scale validation study,[87] in which emphasis was placed on the fact that potent psychoactive medications should not be given without a specific agreed-on target level of effect.

The second step for assessing the brain's function in critically ill ICU patients builds on the level of arousal assessment and involves the delirium assessment. All patients who are responsive to verbal stimuli should be assessed for delirium. The first delirium assessment tools designed specifically for nonverbal, intubated ICU patients were published in 2001.[15,17,89] One of these instruments is the Intensive Care Delirium Screening Checklist,[15] which is used as a screening instrument due to its high sensitivity (99%) and moderate specificity (64%). The other is the Confusion Assessment Method for the ICU (CAM-ICU),[17,89] which has a sensitivity and specificity of approximately 95% and very high interrater reliability ($\kappa = 0.96$). The CAM-ICU was designed to be a serial assessment tool for use by bedside clinicians (nurses or physicians). Thus, it is easy to use, takes only 1 minute on

TABLE 62-2 Risk Factors for Delirium[a]

Host Factors	Acute Illness[a]	Iatrogenic or Environmental
Elderly	Severe sepsis[a]	Sedative and analgesic use[a]
Underlying comorbidities (e.g., heart, liver, or renal failure, diabetes, hypertension)	Acute respiratory distress syndrome[a]	Immobilization (e.g., restraints or catheters)[a]
Pre-existing cognitive impairment or dementia	Multiple organ dysfunction syndrome	Total parenteral nutrition[a]
Hearing or vision impairment[a]	Drug overdose or illicit drugs	Sleep deprivation[a]
Neurologic disease (stroke or seizure)	Acquisition of nosocomial infection[a]	Malnutrition[a]
Alcoholism and smoking[a]	Metabolic disturbance[a]	Anemia (phlebotomy)[a]

[a]Potentially modifiable factors through specific interventions or avoidance.

average to complete, and requires minimal training. Delirium assessment using the CAM-ICU incorporates four key features that comprise delirium as defined by the *Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition* (American Psychiatric Association). These features are (1) change in mental status from baseline or fluctuating course of mental status, (2) inattention, (3) disorganized thinking, and (4) altered level of consciousness. Delirium is present when features 1 and 2 plus features 3 or 4 are present (Fig. 62-3 and Table 62-3). The CAM-ICU has been translated into many languages, and numerous aspects of neurologic monitoring are discussed and available for download from an educational Web site (www.icudelirium.org).

Strategies for Optimal Management of ICU Delirium

PRIMARY PREVENTION AND NONPHARMACOLOGIC APPROACHES

In a trial of 852 general medical patients older than 70 years,[90] strategies for primary prevention of delirium resulted in a 40% reduction in the odds of developing delirium (15% in controls versus 9.9% in the intervention patients). The protocol focused on optimization of risk factors with the following methods: repeated reorientation of the patient by trained volunteers and nurses, provision of cognitively stimulating activities for the patient three times per day, a nonpharmacologic sleep protocol to enhance normalization of sleep and wake cycles, early mobilization activities and range of motion

TABLE 62-3 Features and Descriptions of the CAM-ICU

1. Acute onset or fluctuating course	Absent	Present
A. Is there evidence of an acute change in mental status from the baseline? *or*		
B. Did the (abnormal) behavior fluctuate (i.e., tend to come and go) during the past 24 h or increase and decrease in severity as demonstrated by fluctuation on a sedation scale (e.g., RASS), GCS, or previous delirium assessment?		
2. Inattention	Absent	Present
Did the patient have difficulty focusing attention as demonstrated by scores <8 on the auditory or visual component of the Attention Screening Examination? (Instructions on next page.)		
3. Disorganized thinking	Absent	Present
Is there evidence of disorganized or incoherent thinking as indicated by incorrect answers to ≥2 of the 4 questions and/or inability to follow the commands?		
Questions (alternative sets A and B)		

Set A	Set B
1. Will a stone float on water?	1. Will a leaf float on water?
2. Are there fish in the sea?	2. Are there elephants in the sea?
3. Does 1 lb weigh more than 2 lb?	3. Does 2 lb weigh more than 1 Ib?
4. Can you use a hammer to pound a nail?	4. Can you use a hammer to cut wood?

Other		
1. Are you having any unclear thinking?		
2. Hold up this many fingers. (Examiner holds 2 fingers in front of the patient.)		
3. Now do the same thing with the other hand. (Examiner does not repeat the gesture.)		
4. Altered level of consciousness	Absent	Present
Is the patient's level of consciousness anything other than alert, such as vigilant, lethargic, or stupor (e.g., RASS other than "0" at time of assessment)?		
Alert — Spontaneously fully aware of environment and interacts appropriately		
Vigilant — Hyperalert		
Lethargic — Drowsy but easily aroused, unaware of some elements in the environment, or not spontaneously interacting appropriately with the interviewer; becomes fully aware and appropriately interactive when prodded minimally		
Stupor — Becomes incompletely aware when prodded strongly; can be aroused only by vigorous and repeated stimuli, and as soon as the stimulus ceases, stuporous subject lapse back into the unresponsive state		
Overall CAM-ICU (features 1 and 2 plus feature 3 or 4)	Yes	No

exercises, timely removal of catheters and physical restraints, institution of the use of eyeglasses and magnifying lenses, hearing aids and earwax disimpaction, and early correction of dehydration. Unfortunately, this intervention did not show sustained benefit when the patients were followed to 6 months.[91] Other recent studies of delirium prevention reproduced success only in subgroups such as those without underlying dementia[92] or not at all.[93]

However, this study of primary prevention did not focus on critically ill patients and excluded mechanically ventilated patients. Because ICU studies using the CAM-ICU have documented delirium rates of 70% to 80%, one might view the "room for improvement" in delirium management as far greater for critically ill patients than for general medical patients. Although primary prevention of delirium is preferred, some degree of delirium is inevitable in the ICU. In these cases, the basic tenets of patient management such as restoring sleep/wake cycles, timely removal of catheters, early mobilization, use of a scheduled pain management protocol, minimization of unnecessary noise or stimuli, and frequent reorientation should be applied liberally. Family involvement can be very helpful in reorienting and soothing delirious patients. It is important to teach family members about the fluctuating course of delirium and how they can detect delirium. Preventive and management strategies for delirium in the ICU represent an important area for future investigation.

PHARMACOLOGIC THERAPY

Medications should be used only after giving adequate attention to correction of modifiable contributing factors (e.g., sleep disturbance and restraints) as discussed above and presented in Table 62-2. It is important to recognize that delirium may be a manifestation of an acute, life-threatening problem that requires immediate attention (e.g., hypoxia, hypercarbia, hypoglycemia, metabolic derangements, or shock). After addressing such concerns, delirious patients should be considered for pharmacologic management. Even though the agents used to treat delirium are intended to improve cognition, they all have psychoactive effects that may further cloud the sensorium and promote a longer overall duration of cognitive impairment. Therefore, until outcomes data confirm the beneficial effects of treatment, these drugs should be used judiciously in the smallest possible dose and for the shortest time necessary, a practice *infrequently* adhered to in most ICUs. Some patients will prove refractory to all "cocktail" approaches to sedation and delirium therapy, and these patients should be considered for a trial of complete cessation of all psychoactive drugs.

Benzodiazepines, which are used most commonly in the ICU for sedation, are not recommended for the management of delirium because of the likelihood of oversedation, exacerbation of confusion, and respiratory suppression. However, they remain the drugs of choice for the treatment of delirium tremens (and other withdrawal syndromes) and seizures. The amnestic qualities of benzodiazepines make these agents especially useful when noxious or unpleasant procedures are required. However, it is likely that residual accumulation of these drugs may lead to prolonged delirium long after the drugs have been discontinued. In certain populations, in particular elderly patients with underlying dementia, benzodiazepines may lead to increased confusion and agitation. In such cases, one may try to take advantage of the sedative effects of haloperidol in lieu of continued benzodiazepines. Preliminary results from a prospective, randomized, but unblinded trial of sedation in postoperative cardiac surgical patients showed that those treated with dexmedetomidine, as opposed to propofol or midazolam, were less likely to develop delirium.[94] This work must be confirmed on a larger scale with documented improved outcomes before modifying standard sedation practices.

There are currently no drugs approved by the U.S. Food and Drug Administration for the treatment of delirium. The SCCM guidelines recommend haloperidol as the drug of choice, although it is acknowledged that this is based on sparse outcomes data from nonrandomized case series and anecdotal reports (i.e., level C data).[9,95–103] Nevertheless, haloperidol is a butyrophenone "typical" antipsychotic, which is the most widely used neuroleptic agent for delirium.[104] It does not suppress the respiratory drive and works as a dopamine receptor antagonist by blocking the D_2 receptor, which results in treatment of positive symptomatology (hallucinations, unstructured thought patterns, etc.) and produces a variable sedative effect.[105]

In the non-ICU setting, the recommended starting dose of haloperidol is 0.5 to 1.0 mg orally or parenterally, with repeated doses every 20 to 30 minutes until the desired effect is achieved. In the ICU setting, a recommended starting dose is 5 mg every 12 hours (intravenously or orally), with maximal effective doses usually in the neighborhood of 20 mg/day. This dose range is usually adequate to achieve the "theoretically optimal" 60% D_2 receptor blockade[106–108] and avoid complete D_2 receptor saturation associated with the adverse effects cited below. Because of the urgency of the situation in many ICU patients, due to the potential for inadvertent removal of central lines, endotracheal tubes, or even aortic balloon pumps, much larger doses of haloperidol are often used. Unfortunately, there are few data from formal pharmacologic investigations to guide dosage recommendations in the ICU. Once calm, the patient can usually be managed with much smaller maintenance doses of haloperidol.

Neither haloperidol nor similar agents (i.e., droperidol and chlorpromazine) have been extensively studied in the ICU.[9] Newer "atypical" antipsychotic agents (e.g., risperidone, ziprasidone, quetiapine, and olanzapine) may also prove helpful for delirium.[9,109] The rationale behind the use of atypical antipsychotics over haloperidol (especially in hypoactive/mixed subtypes of delirium) is theoretical and centers on the fact that they affect not only dopamine but also other potentially key neurotransmitters such as serotonin, acetylcholine, and norepinephrine. Adequately powered randomized controlled trials of these agents are not available.

Adverse effects of typical and atypical antipsychotics include hypotension, acute dystonias, extrapyramidal effects, laryngeal spasm, malignant hyperthermia, glucose and lipid dysregulation, and anticholinergic effects such as dry mouth, constipation, and urinary retention. Perhaps the most immediately life-threatening adverse effect of antipsychotics is *torsades de pointes*,[110,111] and these agents should not be given to patients with prolonged QT intervals unless thought to be absolutely necessary. Patents who receive substantial quantities of typical or atypical antipsychotics or coadministered arrhythmogenic drugs should be monitored closely with electrocardiography. Having mentioned these potential

difficulties, antipsychotics (most experience having been accrued with haloperidol) are usually well tolerated from the hemodynamic and respiratory standpoints.

Summary of Key Points on ICU Delirium

Critically ill patients are at great risk for the development of delirium in the ICU. However, this form of brain dysfunction is grossly under-recognized and undertreated. Delirium is mistakenly thought to be a transient and expected outcome in the ICU and of little consequence (i.e., part of the "ICU psychosis"). It is now recognized that delirium is one of the most frequent complications experienced in the ICU; even after adjusting for covariates such as age, sex, race, and severity of illness, delirium is an independent risk factor for prolonged length of stay and higher 6-month mortality rates. In addition, many ICU survivors demonstrate persistent cognitive deficits at follow-up testing months to years later. It is essential for health care professionals to be able to recognize delirium readily at the bedside. The CAM-ICU is a valid, reliable, quick, and easy-to-use serial assessment tool for monitoring delirium in ventilated and nonventilated ICU patients. Delirium is a multifactorial problem for ICU patients that demands an interdisciplinary approach for assessment, management, and treatment. Critical care nurses and physicians should assume a position of leadership in the ICU with regard to delirium monitoring because they are the best-suited members of the ICU team to successfully implement this essential component of patient management, which is now recommended by the SCCM clinical practice guidelines. Although ongoing trials may elucidate the optimal ways to treat delirium, standard pharmacologic and nonpharmacologic management strategies have been reviewed.

Chapter 63

CEREBROVASCULAR DISEASE

VENKATESH AIYAGARI
WILLIAM J. POWERS
MICHAEL N. DIRINGER

KEY POINTS

- *Nonarteriosclerotic causes of stroke occur more commonly in patients admitted to the ICU and should be carefully sought by appropriate diagnostic tests.*
- *In patients with acute ischemic stroke, reduction of systemic blood pressure may carry a risk of producing further neurologic deterioration.*
- *Intravenous tissue plasminogen activator improves outcome in carefully selected patients with acute ischemic stroke when treatment is instituted within 3 hours of onset.*
- *Clinical trials of anticoagulation with heparin or heparin-like drugs in patients with acute cerebral ischemia or infarction have shown no benefit. If other indications for acute anticoagulation are present, these drugs may be given safely.*
- *Emergency neurosurgical intervention should be strongly considered in patients with cerebellar infarction or hemorrhage and consequent brain stem compression.*
- *Early surgical clipping or coiling of ruptured aneurysms removes the risk of rebleeding and facilitates the effective management of delayed vasospasm and hydrocephalus.*

Etiology

Cerebrovascular diseases can be divided into three categories: cerebral ischemia and infarction, intracerebral hemorrhage, and subarachnoid hemorrhage.

Cerebral ischemia and infarction are caused by processes that reduce cerebral blood flow. Reductions in whole brain blood flow due to systemic hypotension or increased intracranial pressure (ICP) may produce infarction in the distal territories or border zones of the major cerebral arteries. More prolonged global reductions cause diffuse hemispheric damage without localizing findings, or at its most severe produce brain death. Prolonged regional reductions can lead to focal brain infarctions. Local arterial vascular disease accounts for approximately 65% to 70% of all ischemic strokes. In most cases, arterial disease serves as a nidus for local thrombus formation with or without subsequent distal embolization. Focal arterial stenosis in combination with systemic hypotension is a rare cause of focal brain infarction. Atherosclerosis is the most common cause of local disease in the large arteries supplying the brain. Disease of smaller penetrating arteries may cause small deep (lacunar) infarcts; it is unclear how often these lacunar infarcts are caused by atherosclerosis, some other arteriosclerotic process of small vessels, or by small emboli arising from more proximal sources. While emboli arising from the heart cause approximately 30% of all cerebral infarcts in a general population, they assume more importance in ICU patients.[1] Atrial fibrillation is the most common cause. Atherosclerotic emboli following heart surgery, infective endocarditis, nonbacterial thrombotic endocarditis, and ventricular mural thrombus secondary to acute myocardial infarction or cardiomyopathy should all be considered in appropriate circumstances. Rarer causes of cerebral infarction must also be considered in the ICU. These include dissections of the carotid or vertebral artery after direct neck trauma, "whiplash" injuries or forced hyperextension during endotracheal intubation, intracranial arterial or venous thrombosis secondary to meningeal or parameningeal infections, and paradoxical embolization from venous thrombosis via a patent foramen ovale.[1]

Hemorrhages into the basal ganglia, thalamus, and cerebellum in middle-aged patients with long-standing hypertension are the most common type of intracerebral hemorrhage. In hypertensive patients with hemispheric lobar hemorrhages and patients without hypertension, other causes should be sought, such as arteriovenous malformations or saccular aneurysms.[2] Amyloid angiopathy becomes increasingly important in patients in the seventh, eighth, and ninth decades; these hemorrhages usually occur in the subcortical hemispheric white matter and may be multiple. Hemorrhage due to anticoagulant and thrombolytic drugs can affect any part of the brain. Rarer causes of intracerebral hemorrhage occurring in patients with other systemic diseases include thrombocytopenia, hemophilia, and disseminated intravascular coagulation (DIC).

Nontraumatic spontaneous subarachnoid hemorrhage (SAH) is almost always due to ruptured saccular aneurysms. Aneurysms may also rupture into the brain parenchyma, producing intracerebral hemorrhage as well. Saccular aneurysms are most commonly located on the large arteries at the base of the brain. Both congenital and acquired factors appear to play a role in the development of aneurysms. Acquired contributing factors include atherosclerosis, hypertension, and hemodynamic stress. In patients with infective endocarditis, mycotic aneurysms of more distal arteries may form and sometimes rupture. Other causes of SAH include ruptured arteriovenous malformations (cerebral and spinal) and fistulae, cocaine abuse, pituitary apoplexy, and intracranial arterial dissection.[3] In some cases, particularly SAH ventral to the midbrain, the cause cannot be determined.

Clinical and Laboratory Diagnosis

The initial diagnostic evaluation of the patient with suspected stroke serves (1) to determine whether neurologic symptoms are due to cerebrovascular disease or to some other condition, such as peripheral nerve injury, intracranial infection, tumor, subdural hematoma, multiple sclerosis, epilepsy, or hypoglycemia; and (2) to distinguish among different types of cerebrovascular disease that require different treatments. The clinical history and examination remain the cornerstone of this process. Cerebrovascular disease typically produces focal brain dysfunction of sudden onset in a single location. The primary exception to this is aneurysmal SAH, which usually presents as a sudden onset of severe headache, with or without nausea, vomiting, or loss of consciousness. In some cases, a less severe aneurysmal hemorrhage may present as a headache of moderate intensity, neck pain, and nonspecific

Copyright © 2005, 1998, 1992 by The McGraw-Hill Companies, Inc. Click here for terms of use.

symptoms. A high index of suspicion is needed in order to avoid missing the diagnosis of SAH. Focal brain dysfunction may not always include an obvious hemiparesis. Neurologic deficits such as neglect, agnosia, aphasia, visual field defects, or amnesia may be the only manifestations of brain infarction or hemorrhage. The clinical distinction between cerebral infarction and intracerebral hemorrhage is unreliable. Both produce sudden focal deficits. Large hemorrhages may produce vomiting or unconsciousness, but so may infarcts in the vertebrobasilar circulation. Multiple small brain infarcts may produce impaired consciousness with minimal or no focal neurologic deficits, thus mimicking metabolic or toxic encephalopathy. The initial neurologic examination provides information about the location of the brain dysfunction and provides a baseline for monitoring the subsequent clinical course. A thorough medical evaluation is necessary to detect systemic diseases that may be the cause of the cerebrovascular problem. Careful examination of the heart is imperative to detect conditions that might predispose to embolization, particularly atrial fibrillation, recent myocardial infarction, and more rarely, infective endocarditis.

X-ray computed tomography (CT) is the diagnostic neuroimaging test of choice for patients with acute stoke. It is rapid and can be performed easily on acutely ill patients. Acute intracerebral hemorrhage is easily identified by noncontrast CT. Intravenous contrast administration increases the sensitivity for detecting diseases that may mimic stroke, such as tumor, chronic subdural hematoma, and abscess. Cerebral infarction may not be demonstrated by CT for several days. If the infarct is small enough, it may never be apparent. Magnetic resonance diffusion weighted imaging is more sensitive than CT for lesion detection in the early period following ischemic infarction. Due to its superior resolution, magnetic resonance imaging (MRI) is also superior for detecting small infarcts (especially those in the posterior fossa) at any time. However, MRI is more cumbersome to perform in acutely ill patients because of longer imaging times, the need for special nonferromagnetic life support equipment, and the necessity of putting the entire body in the scanner. Demonstration of cerebral infarction by neuroimaging is rarely necessary, since the diagnosis can be made reliably by the clinical presentation together with a negative CT scan to exclude hemorrhage and other conditions. Cerebral infarction is most commonly misdiagnosed when there is no clear history of an abrupt onset.

Diagnosis of border zone infarction due to systemic arterial hypotension is almost entirely dependent on the pattern of infarction shown by CT or MRI. Border zone infarctions are often asymmetrical and patchy; rarely is the entire border zone territory between the middle cerebral artery and posterior or anterior cerebral artery involved. Furthermore, the actual location of the border zone varies from person to person.[4] When more than one area of acute infarction has occurred and all infarcted areas are within the border zones, systemic hypotension should be considered as a cause of infarction.

MRI has no advantage over CT in the demonstration of acute intracerebral hemorrhage, but it does have superior sensitivity for detecting subacute or chronic hemorrhage. Noncontrast CT has a sensitivity of >90% for detecting SAH when performed within 24 hours of hemorrhage. There is no role for standard MRI in the initial diagnosis of acute SAH since it is difficult to perform in an acutely ill agitated patient and it does not increase the likelihood of detecting SAH.

In the patient who is awake and alert with acute focal brain dysfunction in whom noncerebrovascular causes can be excluded, the immediate distinction between cerebral infarction and cerebral hemorrhage may not be necessary if no emergent treatment of the stroke is planned. In certain situations, however, differentiation between infarction and hemorrhage may be critical. Patients with ischemic stroke whose time of onset can be determined to be less than 3 hours earlier and whose other medical problems do not preclude thrombolytic therapy, will benefit from treatment with intravenous tissue plasminogen activator (t-PA).[5] In this circumstance, emergency CT to exclude cerebral hemorrhage is imperative, or t-PA cannot safely be given (see the section on treatment below). In the patient with decreased consciousness and a new focal neurologic deficit, emergency CT may be critically important in identifying an intracranial mass lesion that requires emergency neurosurgical intervention.

Except in patients with cerebral venous thrombosis, hematologic evaluation of patients with ischemic stroke is rarely of value. Antiphospholipid antibodies are found in a high percentage of patients with arterial stroke, but they confer neither a worse prognosis nor is there a benefit of long-term anticoagulation.[6] Acquired or hereditary hypercoagulable disorders have not been clearly linked to arterial ischemic stroke, whereas they are clearly of etiologic importance in cerebral venous thrombosis. In patients with intracranial hemorrhage, especially in the ICU, acquired hemorrhagic diatheses (e.g., anticoagulant or thrombolytic drugs, DIC, thrombocytopenia) should always be considered and should be sought by appropriate laboratory testing when clinical suspicion indicates.

Lumbar puncture with cerebrospinal fluid (CSF) examination can be an extremely important test in the evaluation of the patient with apparent stroke, especially in patients with acquired immune deficiency syndrome (AIDS) or when there is infection elsewhere. Meningitis may cause stroke by producing thrombosis of arteries or cortical veins. CSF pleocytosis is common following septic embolism from infective endocarditis and can serve as a valuable clue to its presence. Lumbar puncture is the most sensitive test for detection of SAH; it should be reserved for cases in which there is a strong clinical suspicion and a negative CT scan, or when CT is not available or feasible. CSF xanthochromia can help differentiate SAH from traumatic lumbar puncture. In most patients, conditions that cause increased ICP can be excluded by a careful history and neurologic examination; lumbar puncture can then be performed safely at the bedside without a prior neuroimaging study.

Electrocardiographic monitoring detects previously unsuspected atrial fibrillation in 2% of patients with acute cerebral ischemia.[7,8] This information is clinically useful, since the superiority of oral anticoagulation over aspirin for secondary stroke prevention in this circumstance has been demonstrated.[9] Transthoracic echocardiography can provide evidence of poor left ventricular function, and rarely left ventricular thrombi. In patients without clinical cardiac disease (no previous history or signs or symptoms of cardiac disease, no electrocardiographic [ECG] abnormalities, and normal cardiac silhouette on chest x-ray), significant left ventricular dysfunction is vanishingly rare. Transesophageal

echocardiography has made it possible to identify atherosclerosis of the ascending aorta hitherto detectable only by cardiac catheterization, surgery, or autopsy. Large aortic arch lesions are associated with an increased risk of stroke. The most common lesion detected by echocardiography in patients with stroke who have no other evidence of heart disease is patent foramen ovale with or without atrial septal aneurysm. Although echocardiography can detect these lesions in patients with ischemic stroke, the treatment implications are problematic (see below). ECG abnormalities are extremely common in patients with SAH. However, the clinical relevance of these abnormalities is questionable since they often do not correlate with echocardiographic abnormalities, histopathologic abnormalities, or serum markers of cardiac injury. Approximately 20% of patients with SAH have elevated serum troponin-I levels. Patients with elevated troponin-I levels should undergo echocardiography, as elevated troponin-I levels have been shown to be 100% sensitive and 86% specific for the detection of left ventricular dysfunction by echocardiography.[10]

Cerebral arteriography provides high-resolution images of both extracranial and intracranial vessels, which may occasionally be useful in the identification of causes of cerebral infarction, such as arterial dissection or vasculitis. Magnetic resonance arteriography (MRA), although widely used, is not reliable and can overestimate the degree of stenosis, sometimes even portraying normal vessels as abnormal. In addition, MRA lacks the high resolution of conventional arteriography and cannot be used to exclude small aneurysms or abnormalities in distal arterial branches. In contrast, magnetic resonance venography has supplanted conventional catheter arteriography for the detection of sagittal and lateral sinus venous thrombosis. In hypertensive patients with lobar intracerebral hemorrhage and in nonhypertensive patients with intracerebral hemorrhage in any location, arteriography may demonstrate vascular malformations or aneurysms.[2] Cerebral arteriography plays an important role in the evaluation of the patient with SAH by confirming the existence of an aneurysm and providing the necessary information to plan a surgical approach. If a CT scan demonstrates SAH, a four-vessel angiogram should be performed as soon as possible. A complete study is necessary to look for multiple aneurysms. If arteriography does not reveal a cause for SAH, it should be repeated in 1 to 2 weeks. CT angiography is sometimes used to provide detailed three-dimensional reconstruction of the aneurysm and surrounding vessels to allow precise interventional planning.

Doppler ultrasound of the carotid arteries is useful to prevent subsequent stroke in screening for severe carotid stenosis at the cervical bifurcation in patients who are candidates for carotid endarterectomy. It is important to remember that the reliability of this technique varies from center to center, and that it is insensitive to stenosis above the carotid bifurcation. Patients with transient ischemic attacks (TIAs) who are good surgical candidates should be evaluated immediately since the risk of stroke following TIA can be as high as 1 in 20 within the first 2 days.[11] On the other hand, in patients with a completed stroke, there is usually no urgency in obtaining this information since carotid endarterectomy does not play a role in the management of acute stroke. Transcranial Doppler (TCD) studies can detect stenosis of intracranial vessels, but the value of this information in management decisions remains to be demonstrated.[12] TCD can also detect increases in flow velocity in most patients with arteriographic vasospasm of the middle cerebral artery following SAH (see below). The value of regional cerebral blood flow measurements with positron emission tomography (PET), single photon emission computed tomography (SPECT), stable xenon CT, or MRI in the diagnosis and treatment of patients with cerebrovascular disease remains to be demonstrated. Since the diagnosis of cerebral infarction can be made reliably by means of the clinical picture and a CT scan, it is rarely if ever necessary to demonstrate a defect on a cerebral blood flow study. Furthermore other conditions also may produce focal regional reductions of cerebral blood flow. Cerebral blood flow measurement as an adjunct in deciding the appropriate therapeutic intervention in patients with stroke has not been shown to result in improved outcome. The combination of diffusion weighted imaging (DWI) and perfusion weighted imaging (PWI) in patients with acute ischemic stroke often reveals a central area of restricted diffusion surrounded by a larger area of low perfusion. The diffusion abnormality increases with time. These observations have led to the hypothesis that the area of perfusion-diffusion mismatch indicates tissue destined for infarction that may be salvaged by thrombolytic therapy. This hypothesis remains unproven. Clinical trials are currently under way to determine if treatment decisions based on DWI-PWI magnetic resonance scans lead to better patient outcome.

Treatment

ATHEROTHROMBOTIC INFARCTION

Immediate supportive care of the patient with atherothrombotic infarction requires attention to the patient's airway, breathing, and circulation. Although most patients have preserved pharyngeal reflexes, those with brain stem infarction or depressed consciousness may require intubation for airway protection. Coexisting heart and lung disease is common in patients with atherothrombotic stroke. Respiratory and cardiac function should be assessed fully, and appropriate interventions should be performed to maintain perfusion and oxygenation. The use of supplemental inspired oxygen is rational only if the arterial oxygen content of the blood is decreased. At the time of hospital admission, some patients may have mild intravascular volume depletion. In addition to normal maintenance requirements, careful fluid supplementation may be required. The composition of the intravenous fluid (normal saline solution, one-half normal saline solution, or 5% glucose) makes no difference as long as serum electrolyte and glucose concentrations remain normal. Care should be taken to avoid hypo-osmolarity, which potentially could exacerbate brain edema.

Systemic arterial hypertension is common following acute ischemic stroke. In most cases, blood pressure returns to baseline levels without treatment in a few days. It remains controversial what treatment is appropriate. During the period following acute cerebral infarction, the normal mechanism of cerebral autoregulation of blood flow in response to changes in cerebral perfusion pressure is impaired. Any reduction in systemic blood pressure may cause a decrease in cerebral blood flow, causing further damage in marginally perfused areas adjacent to the infarct. There are no known hazards to

the brain from this spontaneous transient elevation in systemic blood pressure. When systemic hypertension causes organ damage elsewhere (e.g., myocardial ischemia, congestive heart failure, or dissecting aortic aneurysm), careful and judicious lowering of the blood pressure with constant monitoring of neurologic status is indicated. Unfortunately, there are insufficient data to permit designation of any target blood pressure levels as either safe or effective.[13]

The NINDS t-PA Stroke Trial demonstrated that intravenously administered t-PA improves outcome in carefully selected patients with acute ischemic stroke when instituted within 3 hours of onset.[5] Inclusion and exclusion criteria used in this trial are listed in Table 63-1. Owing to the strictness of these criteria, less than 5% of patients initially screened were enrolled. Patients received 0.9 mg/kg (90 mg maximum) of alteplase, 10% given as an initial bolus over 1 minute, followed by a continuous intravenous infusion of the remainder over 60 minutes. The infusion was discontinued if intracranial hemorrhage was suspected. All patients were admitted to a neurology special care area or ICU. Anticoagulant or antiplatelet drugs were not allowed for 24 hours. Blood pressure was monitored every 15 minutes for 2 hours, every 30 minutes for 6 hours, and then every 60 minutes for 16 hours. Blood pressure was kept below 185/110 mm Hg with labetalol or sodium nitroprusside. Symptomatic cerebral hemorrhage occurred more commonly in the group treated with t-PA (6%) than in the control group (<1%). Even taking into account the increased risk of intracerebral hemorrhage, there was no difference in mortality, and more t-PA–treated patients demonstrated an excellent neurologic outcome at 3 months by each of four separate outcome scales.

The use of intravenous t-PA in acute ischemic stroke has been questioned because proof of its efficacy is based only on a single well-conducted trial. Retrospective analysis of small subgroups of patients enrolled <3 hours postevent in other trials have provided supporting evidence, and there are no data to indicate that patients who meet the eligibility criteria for the NINDS trial do not benefit.[14,15] Therefore at this time, t-PA can be recommended for patients who meet the strict inclusion and exclusion criteria of the NINDS trial.[16] The diagnosis of ischemic stroke in this situation rests on clinical evidence; it should be made by a physician experienced in the evaluation of acute neurologic problems to avoid unnecessary administration of an expensive and dangerous drug to patients who will not benefit. If the time of stroke onset cannot accurately be established to be less than 3 hours, t-PA should not be given. For patients who awaken from sleep with a stroke, the time of onset must be taken to be the last time they were awake and known to be in their premorbid state, not the time of awakening. CT signs of early infarction should prompt careful reconsideration of the time of onset, as they rarely occur within 3 hours of onset, but they are not a contraindication to treatment.[17] Facilities must be available for closely monitoring blood pressure and maintaining it below 185/110 mm Hg. Recommended treatment of symptomatic intracerebral hemorrhage following t-PA includes cryoprecipitate and platelet transfusion.[18] In spite of this treatment, mortality at 3 months was 75% in the NINDS trial.[19]

The value of any thrombolytic agent delivered after 3 hours either intravenously or directly by an intra-arterial catheter is not supported by current data.[16] A single trial of intra-arterial pro-urokinase in patients with middle cerebral artery stem occlusion showing a barely statistically significant benefit was not sufficient proof for the drug to be approved for use in the United States.[20] The use of MRI (DWI, PWI, or MRA) or CT (CT angiography or perfusion studies) to identify patients beyond the 3 hour window who might benefit from thrombolytic therapy is the subject of active investigation, but lacks evidence to demonstrate that patient outcome is improved. Owing to its poor safety profile, streptokinase cannot be used as a substitute for t-PA.

Two large studies have shown that 160 or 300 mg/d of aspirin begun within 48 hours of the onset of ischemic

TABLE 63-1 Inclusion and Exclusion Criteria from the NINDS t-PA Stroke Trial

Inclusion criteria

1. Age 18 through 80 years.
2. Clinical diagnosis of ischemic stroke causing a measurable neurologic deficit, defined as impairment of language, motor function, cognition, and/or gaze or vision, or neglect. Ischemic stroke is defined as an event characterized by the sudden onset of an acute focal neurologic deficit presumed to be due to cerebral ischemia after computed tomography (CT) has excluded hemorrhage.
3. Time of onset well established to be less than 180 minutes before treatment would begin.
4. Prior to treatment, the following must be known or obtained: complete blood cell count, platelet count, prothrombin time (if the patient has a history of oral anticoagulant therapy in the week prior to treatment initiation), partial thromboplastin time (if the patient has received heparin within 48 hours of treatment initiation), blood glucose, and CT scan (noncontrast).

Exclusion criteria

1. Minor stroke symptoms or major symptoms that are improving rapidly.
2. Evidence of intracranial hemorrhage on CT scan.
3. Clinical presentation that suggests subarachnoid hemorrhage even if initial CT scan is normal.
4. Female patient who is lactating or known or suspected to be pregnant.
5. Platelet count less than 100,000/μL; prothrombin time greater than 15 seconds; heparin has been given within 48 hours and partial thromboplastin time is greater than the upper limit of normal for laboratory; anticoagulants currently being given.
6. Major surgery or serious trauma, excluding head trauma, in the previous 14 days, or head trauma within the previous 3 months.
7. History of gastrointestinal or urinary tract hemorrhage in the previous 21 days.
8. Arterial puncture at a noncompressible site or a lumbar puncture within the previous 7 days.
9. On repeated measurement, systolic blood pressure >185 mm Hg or diastolic blood pressure >110 mm Hg at the time treatment is to begin, or patient requires aggressive treatment to reduce blood pressure to within these limits.
10. Patient has had a stroke in the previous 3 months or has ever had an intracranial hemorrhage considered to put the patient at an increased risk for intracranial hemorrhage.
11. Serious medical illness likely to interfere with this trial.
12. Abnormal blood glucose (<50 or >400 mg/dL).
13. Clinical presentation consistent with acute myocardial infarction or suggesting post–myocardial infarction pericarditis.
14. Patient cannot, in the judgment of the investigator, be followed for 3 months.
15. Seizure occurred at onset of stroke.

stroke results in a net decrease in further stroke or death of 9/1000.[21] Data from several randomized controlled trials have shown that anticoagulation with heparin, low-molecular-weight heparins, or heparinoids in patients with acute ischemic stroke provides no net short- or long-term benefit in general or in any subgroup.[22,23] Ticlopidine, clopidogrel, and the combination of low-dose aspirin and extended-release dipyridamole (Aggrenox) all have been demonstrated to be modestly effective in the long-term prevention of recurrent ischemic stroke, but there are no data regarding their value during the acute period.[24]

Many drugs aimed at ameliorating ischemic neuronal damage in patients with acute stroke are currently undergoing clinical trials. Physicians treating patients with acute ischemic stroke should be aware of the results of these trials on an ongoing basis.

Cerebral edema is the major cause of early mortality following cerebral infarction; no treatment has been shown by randomized controlled trials to be effective in improving outcome. Mannitol and hyperventilation can temporarily reduce intracranial pressure. They may be of value to the patient with brain stem compression from an edematous cerebellar infarct for whom craniotomy and removal of the edematous tissue may be life-saving. Both hypothermia and hemicraniectomy are sometimes used to treat massive edema from hemispheric infarction. The value of these treatments is unproven, and the proper selection of patients is problematic.[16]

No clinical evidence or pathophysiologic rationale supports routine restriction to bed of patients with acute brain infarction. Prolonged bed rest carries an increased risk of iliofemoral venous thrombosis, pulmonary embolism, and pneumonia. Patients should be out of bed and walking as soon as possible after a stroke. Occasionally, orthostatic hypotension with worsening of neurologic deficits will occur. In these cases, a more gradual program of ambulation should be instituted. In hemiplegic patients, subcutaneous heparin should be administered to prevent iliofemoral venous thrombosis. Alternating pressure antithrombotic stockings may provide benefit as well. In the case of pulmonary embolism or deep venous thrombosis, full anticoagulation with heparin or heparin-like drugs may be instituted without risk to the brain. Fever may occur due to infection or other systemic causes. Central fevers due to hypothalamic disease are an exceedingly uncommon event and the search for other causes should be vigorously pursued. Animal studies have shown that even minor elevations in temperature of a few degrees poststroke can lead to worse brain damage. Maintaining normothermia through the use of antipyretics and cooling blankets makes good sense but is of unproven value. Trials of induced hypothermia with both external and internal cooling are now underway. It is important to remember that dysphagia occurs commonly, even with unilateral hemispheric lesions. Before oral feeding is instituted, each patient's ability to swallow should be carefully checked. Incontinence is also common following acute stroke. Careful attention must be given to the prevention of decubitus ulcers in bedridden patients.

CARDIOEMBOLIC INFARCTION

The basic supportive care of the patient with cardioembolic brain infarction is the same as for atherothrombotic infarction. Intravenous t-PA instituted within 3 hours is effective in selected patients with nonhemorrhagic cardioembolic stroke as well.[5] Patients with ischemic stroke and a cardioembolic source, including atrial fibrillation, do not benefit from acute anticoagulation.[25–27]

OTHER CAUSES OF CEREBRAL INFARCTION

In general, the principles of general care discussed above are applicable to patients with other causes of cerebral infarction. Specific causes may require specific definitive treatments, such as exchange transfusions for cerebral infarction due to sickle cell anemia. The major therapeutic question that arises in dealing with these unusual causes is whether acute anticoagulation will be of benefit. In most cases, this is unknown. Cerebral venous thrombosis can present a particularly difficult situation because of the presence of hemorrhage. Two small controlled trials have demonstrated that anticoagulation improves outcome even in patients with hemorrhagic infarction, although many of those enrolled did not receive anticoagulation within the first few days.[28]

Patent foramen ovale (PFO) is detected more commonly in patients with ischemic stroke than in nonstroke controls and is often the only abnormality found. Based on this finding, it is often concluded that the cause of stroke is paradoxical embolization from deep venous thrombosis. However, in contrast to pulmonary embolization, it is unusual to find a deep venous source in these patients. The risk of recurrent stroke is low and anticoagulation with warfarin does not reduce the risk of long-term recurrence.[29,30] Studies of acute anticoagulation are not available. Acute anticoagulation of spontaneous or traumatic dissections of the carotid or vertebral arteries is often recommended. Data to support this approach are derived only from small nonrandomized, nonblinded studies, and even these data are weak.[31]

INTRACEREBRAL HEMORRHAGE

Supportive care of patients with primary intracerebral hemorrhage (ICH) requires attention to the same basic factors as for patients with cerebral infarction. Any underlying coagulopathy should be corrected as rapidly as possible. Prophylaxis for deep venous thrombosis with low-dose subcutaneous heparin may be instituted safely on the second day after the hemorrhage.[32] Seizures are more common with lobar ICH compared to basal ganglia hemorrhage. While seizures in the acute setting warrant treatment with anticonvulsants, antiepileptic medication should be discontinued after 1 month if seizures do not recur. Prophylactic antiepileptic medications are not recommended.[33]

Systemic blood pressure is often elevated acutely, sometimes to very high levels. Whether acute treatment of hypertension following ICH is beneficial remains to be determined.[13] In patients with small to medium sized hematomas, reductions in blood pressure down to a mean arterial pressure (MAP) of 110 mm Hg or about 20% of the admission MAP do not affect cerebral blood flow in the brain as a whole or in the region around the clot. If ICP is elevated due to large hematomas or hydrocephalus, this lower limit of autoregulation may be shifted to a higher value. Calcium channel blockers and β-blockers have an equivalent minimal effect on CBF within the autoregulatory range of MAP; ganglionic blockers may have a more profound effect on cerebral

blood flow.[34] In patients with increased ICP, the use of systemic antihypertensive agents that cause intracranial vasodilation (e.g., sodium nitroprusside) may further increase ICP. If the ICH is large enough to increase ICP, cerebral perfusion pressure will be reduced, making the rationale for lowering systemic blood pressure problematic. Although rebleeding is now known to occur in up to one third of patients within the first 24 hours, there is no relationship to early arterial hypertension.[13]

The value of ICP monitoring and treatment remains unknown. Corticosteroids do not reduce morbidity and mortality due to edema.[33] Ventriculostomy is of unknown value. In our experience, patients with ventricular enlargement due to intraventricular blood do not appear to benefit from ventriculostomy.[35] Mannitol and hyperventilation can be used effectively to reduce ICP temporarily. This tactic is particularly useful if a definitive surgical intervention is planned.

The primary goal of surgery is to alleviate the effects of the hematoma acting as an intracranial mass lesion, not to reverse the effects of local tissue destruction. Thus surgery has no role in the treatment of small hemorrhages. The value of surgery is best accepted for cerebellar hemorrhages resulting in brain stem compression, although no data other than anecdotal reports are available. Ideally such surgical intervention should be undertaken before brain stem damage occurs. Patients with small cerebellar hematomas (<2 cm) may do well without surgical intervention, or simply with ventricular drainage for hydrocephalus. Those with larger cerebellar hematomas usually undergo surgical evacuation, although no prospectively validated criteria for the necessity and the timing of cerebellar hematoma evacuation are available. Patients with large, deep hematomas arising from the basal ganglia or thalamus do not benefit from surgical intervention. Those with more superficial hematomas and signs of increased ICP may show improvement after surgical evacuation.[35] Intracerebral hematomas due to arteriovenous malformations or ruptured aneurysms require special consideration and careful angiographic studies prior to any surgical approach.

SUBARACHNOID HEMORRHAGE DUE TO RUPTURED INTRACRANIAL ANEURYSM

Aneurysmal SAH remains a devastating neurologic problem, with up to 25% of patients dying within 24 hours with or without medical attention. Of those patients that survive, more than half are left with neurologic deficits as a result of the initial hemorrhage or delayed complications. SAH presents the intensivist with a unique and challenging series of management issues. SAH usually presents as an acute neurologic event which triggers a predictable series of processes that lead to delayed central nervous system and systemic complications. Patients who are minimally affected by the initial hemorrhage can, over the course of hours to weeks, deteriorate due to rebleeding, hydrocephalus, or delayed ischemic deficits caused by vasospasm. Management can be complicated by spontaneous volume contraction, cardiac dysfunction, electrolyte abnormalities, infections, and a catabolic state. The treatment team should include neurosurgeons, radiologists, anesthesiologists, intensivists, and nurses experienced in the management of SAH patients. Because of the complicated nature of their surgical and medical management, SAH patients are best cared for in centers that specialize in this care.

The management of patients following rupture of intracranial aneurysms has changed significantly over the past decades. The calcium channel blocker nimodipine is now routinely used to reduce the impact of vasospasm. Attempts at early obliteration of the ruptured aneurysm with surgical clipping or endovascular placement of detachable coils within the aneurysm have become routine. Hypertensive therapy is now the cornerstone of the management of vasospasm with adjunctive endovascular treatment employed in selected cases. Several new interventions to prevent or to reduce injury from vasospasm are currently under investigation.[36]

INITIAL STABILIZATION AND EVALUATION

Initial evaluation should assess airway, breathing, circulation, and neurologic function. Patients with a diminished level of consciousness often have impaired airway reflexes. In general, patients with a Glasgow Coma Scale score of 8 or less should be intubated. This should be performed under controlled conditions by experienced personnel. Premedication with short-acting agents such as thiopental or etomidate should be used to prevent elevations in blood pressure (BP) with tracheal stimulation so the risk of rebleeding can be minimized.

As soon as the patient is stabilized, a complete neurologic examination, CT, and if indicated, lumbar puncture should be performed. Patients are graded on the basis of clinical and radiographic criteria. The two common clinical grading scales are the Hunt-Hess scale and the World Federation of Neurological Surgeons scale (Table 63-2). The Fisher grade is based on the amount of blood visible on CT scan.[37] These scales predict the likelihood of vasospasm and death.

Routine management of SAH patients usually includes anticonvulsants, steroids, and prophylaxis against deep vein thrombosis (DVT). Anticonvulsants are frequently used in patients with SAH. However, the majority of seizures in these patients occur prior to presentation, and the efficacy of anticonvulsants in preventing subsequent seizures is not conclusively established.[38] Steroids are thought to reduce meningeal irritation and headache and to make the brain less swollen at surgery; however, there are no clear data on their effectiveness. DVT is common in SAH patients, and pneumatic compression stockings are preferred to heparin for prophylaxis because of the risk of intracranial bleeding. Patients require close neurologic and cardiopulmonary monitoring to detect the early complications of hypertension, rebleeding, acute hydrocephalus, pulmonary edema, cardiac arrhythmias, and left ventricular dysfunction.

Routine treatments to reduce the impact of vasospasm include preventing volume contraction and administering nimodipine. Patients should be hydrated with 3 to 5 L of isotonic saline per day. Indicators of volume status should be monitored closely (fluid balance, weight, and in selected cases, central venous pressure or pulmonary capillary wedge pressure) and fluids adjusted accordingly. Several large, prospective, placebo-controlled studies have demonstrated that nimodipine reduces the incidence and severity of delayed ischemic deficits and improves outcome in SAH.[39] It remains uncertain whether this drug acts by causing vasodilation or by exerting direct neuroprotective effects. The recommended dose is 60 mg every 4 hours for 21 days from the time of hemorrhage.

TABLE 63-2 The Hunt-Hess, the World Federation of Neurologic Surgeons, and the Fisher Scales

HUNT-HESS SCALE

Grade	Criteria
I	Asymptomatic or mild headache
II	Moderate to severe headache, nuchal rigidity, with or without cranial nerve deficits
III	Confusion, lethargy, or mild focal symptoms
IV	Stupor and/or hemiparesis
V	Comatose and/or extensor posturing

WORLD FEDERATION OF NEUROLOGIC SURGEONS SCALE

Grade	Glasgow Coma Scale Score	Motor Deficits
I	15	Absent
II	14–13	Absent
III	14–13	Present
IV	12–7	Present or absent
V	6–3	Present or absent

FISHER SCALE (BASED ON INITIAL CT APPEARANCE AND QUANTIFICATION OF SUBARACHNOID BLOOD)

1. No subarachnoid hemorrhage on computed tomography
2. Broad diffusion of subarachnoid blood, no clots and no layers of blood greater than 1 mm thick
3. Either localized blood clots in the subarachnoid space or layers of blood greater than 1 mm thick
4. Intraventricular and intracerebral blood present, in absence of significant subarachnoid blood

At this dose, nimodipine can sometimes reduce systemic BP, an effect that is undesirable in patients with vasospasm (see below). This effect can be ameliorated by increasing fluid administration and by altering the dose to 30 mg every 2 hours, but pharmacologic blood pressure support is necessary in some patients.

EARLY COMPLICATIONS

Hypertension

Elevated BP often initially accompanies acute SAH. Several factors may contribute to increased BP, including headache, elevated ICP in patients with hydrocephalus, increased sympathetic nervous system activity, and pre-existing hypertension. The rationale for treating hypertension is to reduce the risk of aneurysmal rebleeding. There are few compelling reasons not to treat the elevated BP before the onset of vasospasm. As definitive data on optimal BP are lacking, it seems prudent to take the patient's usual BP as a target. When the patient's usual BP is not known, it is probably better to overtreat than to undertreat. There is one important exception—comatose patients in whom CT shows marked hydrocephalus. In such cases BP should be treated very cautiously until the ICP is known, to avoid causing a critical reduction in cerebral perfusion pressure. In patients who present several days after hemorrhage and are at risk for vasospasm, the appropriate management of hypertension is less clear. The benefit of preventing rebleeding must be weighed against the risk of worsening neurologic symptoms by lowering blood pressure in the presence of vasospasm.

The first step in treating elevated BP is to administer analgesics such as morphine or fentanyl. Patients are routinely given nimodipine to prevent vasospasm, and it alone may be adequate to control BP. Otherwise, short-acting agents are preferred, since BP may be labile. Labetalol administered in intermittent intravenous boluses is frequently used, since it appears to have little effect on ICP and is easily titrated. Other useful agents include intravenous hydralazine and enalapril. Sodium nitroprusside is usually avoided because of its tendency to increase ICP and thus reduce the cerebral perfusion pressure. Intravenous nicardipine is becoming more popular in the management of SAH patients.

Rebleeding

Rebleeding is most common in the first 24 hours after the initial hemorrhage. The cumulative risk after 1 week is ~20%, and the risk remains elevated for several weeks.[40] About one half of patients who rebleed die. Measures employed in the hope of preventing rebleeding include avoidance of hypertension, cough, the Valsalva maneuver, and excessive stimulation. Treatment may involve the administration of antitussives, stool softeners, and sedatives when indicated. Antifibrinolytic medications can reduce the risk of rebleeding, but do so at the cost of an increased incidence of hydrocephalus and vasospasm. With the increasingly wide use of early surgery, the use of antifibrinolytics has largely been abandoned.

The timing of surgical obliteration of the aneurysm has changed considerably. Up to the 1970s, surgery was routinely delayed because of reluctance to operate on an edematous brain. Several factors have resulted in a shift to early surgery (days 1 to 3) for patients who have a grade of I to III on the Hunt-Hess scale. These include improved surgical techniques, better results with early surgery in North America,[41] and the necessity that the aneurysm be clipped before hypertensive therapy for vasospasm is administered. The timing of surgery in poor-grade patients (Hunt-Hess grades IV or V) remains controversial, but early surgery is routinely performed in some centers.[42]

In recent years, endovascular techniques for the occlusion of intracranial aneurysms have become possible, allowing craniotomy to be avoided. Electrolytically detachable coils can be placed directly in the aneurysm, where they induce thrombosis. This technique is currently considered appropriate treatment for patients with an aneurysm unsuitable for surgical clipping and those considered to be at high risk for craniotomy.[43] In a recent multicenter randomized trial, 20% of all assessed patients had a ruptured aneurysm that was considered to be amenable to treatment with either surgical clipping or endovascular coiling. Among this subgroup of patients (predominantly of good clinical grade with small ruptured aneurysms of the anterior circulation) the risk of death or dependency at 1 year was significantly lower with endovascular coiling.[44] The long-term risk of rebleeding with this technique and the need for repeated procedures are still under investigation.

Acute Hydrocephalus

Acute hydrocephalus can develop very quickly after SAH. It is most common in patients with intraventricular blood, but can occur in the absence of this factor. The hallmark of symptomatic hydrocephalus is a diminished level of consciousness,

sometimes accompanied by downward deviation of the eyes and poorly reactive pupils. The diagnostic evaluation can be complicated if the patient has received sedative drugs; it is important that analgesics be administered in doses that provide adequate relief from pain, but not excessive sedation. If sedatives are required for agitated patients, judicious administration of short-acting agents is prudent.

Hydrocephalus can be diagnosed reliably with CT and treated effectively with external ventricular drainage. Since less than half of patients with CT evidence of hydrocephalus will deteriorate clinically, ventriculostomy is usually reserved for patients with a diminished level of consciousness.

Cardiac Complications

Cardiac arrhythmias and electrocardiographic abnormalities are common in the first 24 to 48 hours after SAH. Most arrhythmias are benign. More serious arrhythmias include supraventricular and rarely ventricular tachycardia and are associated with hypokalemia.

A significant number of patients have ventricular dysfunction, which can manifest as pulmonary edema or hypotension. Increased serum levels of troponin-I and Swan-Ganz catheter recordings showing elevated pulmonary artery occlusion pressure and decreased cardiac output can serve as surrogate markers of left ventricular dysfunction and should prompt the physician to order definitive tests such as echocardiography or radionuclide ventriculography. Electrocardiographic abnormalities do not always correlate with ventricular dysfunction. Subendocardial myocardial lesions (myofibrillar degeneration and contraction-band necrosis) are seen in patients dying from SAH. These lesions are thought to be due to high levels of circulating catecholamines and/or to cardiac nerve hyperactivity and not to reflect coronary insufficiency. Cardiac pump failure is often transient, hence this condition has been called "stunned myocardium." Though catecholamines have been implicated in the pathogenesis, patients have been successfully treated with inotropes such as dobutamine.[45]

Pulmonary Complications

Pulmonary complications are seen in almost one fourth of all patients with SAH.[46,47] They include pneumonia (arising from acute or subacute aspiration, commonly with nosocomial organisms), cardiogenic pulmonary edema, neurogenic pulmonary edema, and pulmonary embolism. Neurogenic pulmonary edema is thought to be secondary to massive catecholamine release leading to systemic vasoconstriction and a relative shift of the intravascular volume to the pulmonary vasculature. Other possibilities include direct endothelial damage mediated by the sympathetic system and transient cardiac dysfunction. Management of severe pulmonary edema usually involves positive pressure ventilation and diuretics; however, diuretics may not be appropriate for neurogenic pulmonary edema if there is relative intravascular volume depletion.[45] A pulmonary artery catheter often helps guide therapy in such cases.

POSTOPERATIVE MANAGEMENT

Knowledge of the intraoperative surgical and anesthetic course facilitates the postoperative care of SAH patients. Large doses of mannitol may have been administered to shrink the brain and facilitate retraction. This measure can result in postoperative hypovolemia. If temporary clipping of cerebral vessels is required, hypothermia and/or large doses of barbiturates may be employed. These maneuvers may delay emergence from anesthesia and add to the systemic complications of hypothermia. The decision to extubate a postoperative patient must take these factors into consideration. If the aneurysm is successfully clipped, many practitioners will accept higher blood pressures in the postoperative period in anticipation of vasospasm (see below).

HYPONATREMIA AND INTRAVASCULAR VOLUME CONTRACTION

A total of 30% to 50% of SAH patients develop intravascular volume contraction and a negative sodium balance (referred to as *cerebral salt wasting*) when given volumes of fluids intended to meet maintenance needs. Low intravascular volume is associated with symptomatic vasospasm. Hyponatremia develops in 10% to 34% of patients following SAH. Administration of large volumes (5 to 8 L per day) of isotonic saline prevents hypovolemia, but patients may still develop hyponatremia. The degree of hyponatremia appears to be related to the tonicity rather than the volume of fluids administered.[48] Thus administration of large volumes of isotonic saline and restriction of *free water* are usually effective at limiting hyponatremia and preventing hypovolemia. In SAH patients with hyponatremia, the volume of fluids should never be restricted; instead only free water intake should be limited.

VASOSPASM

The term *vasospasm* was originally used to refer to segmental or diffuse narrowing of large conducting cerebral vessels. Recently, this term has taken on multiple meanings. It may refer to angiographic findings, to increased transcranial Doppler velocities, or to delayed ischemic deficits. Angiographic and transcranial Doppler vasospasm occurs in 60% to 80% of patients, whereas clinical vasospasm (or delayed ischemic deficit) occurs in 20% to 40% of patients.

The pathogenesis of vasospasm is complex. Sustained exposure of vessels to extraluminal oxyhemoglobin appears to play an important role in initiating vasospasm. In animal models of vasospasm, vessels demonstrate enhanced responses to vasoconstrictors, as well as structural changes that physically reduce luminal diameter. These changes develop in a delayed fashion after exposure to subarachnoid blood and are self-limited. In addition to changes in the large conducting cerebral vessels that traverse the subarachnoid space, small-vessel reactivity may be impaired as well.[49]

Monitoring for Vasospasm

Serial neurologic assessments are essential in monitoring for vasospasm. These must be performed frequently by physicians and nurses well versed in neurologic examination and the recognition of subtle deficits. The patients with the highest incidence of vasospasm are those with Hunt-Hess grades III through V and Fisher grade 3. These patients are often monitored in the ICU or another special care area during the period of highest risk for onset of vasospasm (days 5 to 10). Clinically vasospasm presents as a decline in the global level of function or a focal neurologic deficit. Patients may initially appear "less bright" and then become progressively less alert and finally comatose. The focal deficits mimic those seen in

ischemic stroke. Middle cerebral artery vasospasm can produce hemiparesis, and if left-sided, aphasia. Anterior cerebral artery vasospasm often manifests as abulia or lower extremity weakness. The focal deficits wax and wane and therefore are not reported by all observers. The symptoms are exacerbated by hypovolemia or hypotension.

Transcranial Doppler ultrasonography detects changes in the blood flow velocity in the proximal portion of the major cerebral vessels. Very high flow velocities (>200 cm/s) in the middle cerebral and intracranial carotid arteries are closely correlated with angiographic vasospasm, while low flow velocities (<120 cm/s) suggest a low likelihood of vasospasm.[50] Patients with rapidly rising velocities are considered to be at highest risk for developing clinical vasospasm. Transcranial Doppler has several limitations. High flow velocities can be due to increased blood flow rather than narrowing of the blood vessel. Distal segments of the major arteries cannot be evaluated. The technique is also operator dependent and adequate "acoustic windows" are required. Therefore, transcranial Doppler velocities should not be used in isolation as an indication for the initiation of aggressive treatments—the clinical course must be considered as well. Angiography may be used to confirm the clinical diagnosis of vasospasm and for endovascular treatment (see below), but it has a limited role in monitoring for vasospasm.

Treatment of Vasospasm

HEMODYNAMIC AUGMENTATION Hemodynamic augmentation for the treatment of vasospasm has been referred to as *hemodilution hypervolemic hypertensive therapy* ("triple H therapy") or as *hypervolemic hypertensive therapy* (HHT). The pathophysiologic rationale is based on the high rate of spontaneous hypovolemia, the association of hypovolemia with delayed ischemic deficits, and the loss of autoregulation of cerebral blood flow in this population.

Most centers continue aggressive hydration during the period of vasospasm risk. Some will increase the rate of fluid administration if transcranial Doppler velocities are rising. The indication for starting aggressive hemodynamic augmentation is usually the onset of clinical symptoms of delayed ischemic deficit. Early descriptions of this therapy emphasized the role of volume expansion, as many of these patients had not been aggressively hydrated before the onset of symptoms. However, if intravascular volume has been maintained before the onset of symptoms, further volume expansion may not be helpful.[51] The optimal intravascular volume is unknown, and achieving cardiac filling pressures that optimize cardiac output has been advocated.

When symptoms persist despite optimal intravascular volume, vasoactive drugs are administered, usually to raise mean arterial pressure (MAP). In most cases, patients will be monitored with an arterial line and a pulmonary artery catheter. The most commonly used agents are dopamine and phenylephrine. Caution must be employed when using dopamine alone, because of a high incidence of tachyarrhythmias. When dopamine is combined with phenylephrine, this is less of a problem. It is best to monitor MAP rather than systolic pressure, because MAP more accurately reflects cerebral perfusion pressure. MAP also varies less than systolic BP with the use of different techniques for measuring blood pressure.

When therapy is initiated, the MAP should be raised to 15% to 20% above baseline rather than to an arbitrary value. If after 1 to 2 hours the delayed ischemic deficit has not resolved, the MAP should be raised further. The MAP is increased progressively until the neurologic deficit is completely resolved or the risk of systemic toxicity becomes unacceptable. Some patients may require a MAP of 150 to 160 mm Hg to completely reverse the neurologic symptoms. Often extremely high doses of vasopressors are required to produce the degree of hypertension desired. The neurologic status should be re-evaluated several times a day to determine MAP goals. Recently, the use of dobutamine to augment cardiac output has been proposed as an alternative to raising blood pressure. Both approaches are reported to produce neurologic improvement. It has not yet been determined whether the optimal therapy is to enhance cardiac output, MAP, or both.

Once instituted, the therapy is generally continued for 3 to 4 days before attempts are made to wean the patient from it. Weaning should be done gradually, with very close monitoring of neurologic status. If the initial attempt at weaning is unsuccessful, a second attempt should be made after 1 to 2 days. The patient usually is weaned from vasoactive drugs first, aggressive hydration being continued for several more days.

Hemodynamic augmentation is not without complications. Early reports indicated high rates of fluid overload, heart failure, and myocardial ischemia. A more recent study indicated that this therapy is safe when administered in a closely monitored setting, even in patients with pre-existing cardiac disease.[52] Cardiovascular monitoring should include continuous display of the electrocardiogram, peripheral oxygen saturation, MAP, and frequent measurements of pulmonary capillary wedge pressure and cardiac output. In patients with a history of ischemic heart disease, daily electrocardiograms and cardiac enzyme measurements may be helpful. Close monitoring of potassium, magnesium, and phosphate levels is important because of large losses in the urine.

ENDOVASCULAR THERAPIES: PERCUTANEOUS TRANSLUMINAL ANGIOPLASTY AND PAPAVERINE Balloon angioplasty can be used to dilate proximal segments of intracranial vessels, but it is not well suited for use in the distal vasculature. The dilatation achieved appears to be long-lasting. Complications that have been reported include artery rupture and displacement of aneurysm clips. In most cases there is clear-cut angiographic improvement, but the clinical efficacy of angioplasty has not been clearly established.[36]

Papaverine is a potent vasodilator that has been used in superselective intra-arterial infusions as an adjunct to angioplasty. The vasodilator effects of papaverine persist for less than 2 hours.[53] Radiographic improvement is usually evident, but the clinical effect is less clear. Complications of papaverine treatment are increased intracranial pressure, tachycardia, arrhythmias, and transient neurologic deficits. These therapies are usually reserved for patients who do not tolerate or do not respond to hemodynamic augmentation.

OTHER POTENTIAL THERAPIES Prevention rather than treatment of the consequences of vasospasm would significantly reduce the morbidity, mortality, and cost of SAH. Intracisternal instillation of thrombolytic agents has been employed in an attempt to dissolve clots around the circle of Willis and thereby decrease vasospasm. A multicenter, randomized, blinded, placebo-controlled study found trends towards

reduction of angiographic vasospasm, reduced delayed neurologic worsening, lower 14-day mortality, and improved 3-month outcome that did not achieve statistical significance in patients treated with intracisternal t-PA. Patients with thick subarachnoid clots had a significant reduction in the incidence of severe vasospasm with intracisternal t-PA.[54]

The degradation of blood deposited during an SAH involves the conversion of oxyhemoglobin to methemoglobin, which releases an activated form of oxygen that catalyzes free radical reactions, including lipid peroxide formation. The 21-aminosteroid, tirilazad mesylate, a potent scavenger of oxygen free radicals, inhibits lipid peroxidation and reduces vasospasm in animal models. A European-Australian multicenter study showed that tirilazad was associated with better outcomes compared to control patients, but this was not confirmed in a subsequent North American study.[55,56] In a multicenter, randomized, double-blind, placebo-controlled trial, nicaraven, a hydroxyl radical scavenger, significantly reduced the incidence of severe vasospasm and poor outcome at 1 month but not at 3 months.[57] Ebselen, another lipid peroxidation inhibitor, did not lower the incidence of symptomatic vasospasm in a controlled study.[58] Other potential therapies being studied include cyclosporine A, high-dose methylprednisolone, serine protease inhibitors, thromboxane A_2 inhibitors, endothelin-1 receptor antagonists, nitric oxide donors, potassium channel activators, and delivery systems capable of slow subarachnoid release of papaverine and calcitonin gene-related peptide.[36]

Chapter 64

SEIZURES IN THE INTENSIVE CARE UNIT

SARICE L. BASSIN
NATHAN B. FOUNTAIN
THOMAS P. BLECK

KEY POINTS

- *Seizures are a relatively common occurrence in the intensive care unit, but may be difficult to recognize.*
- *Seizures that persist longer than 5 to 7 minutes should be treated to prevent progression to status epilepticus.*
- *Three major factors determine outcome in status epilepticus: type of seizure, cause, and duration.*
- *Electroencephalographic (EEG) monitoring to titrate therapy should be implemented in seizing patients who do not awaken promptly after institution of antiepileptics, even if tonic-clonic motor activity resolves.*
- *Lorazepam is a preferred agent for initial treatment, followed by consideration of additional agents for long-term management or to "break'' status epilepticus.*
- *Patients with refractory status epilepticus require intubation, mechanical ventilation, and aggressive treatment with antiepileptics titrated to the EEG.*
- *The underlying cause of the seizure disorder must be sought in tandem with treatment of the seizure disorder itself.*

Seizures are a relatively common occurrence in the ICU, complicating the course of about 3% of adult intensive care unit patients admitted for nonneurologic conditions.[1] Status epilepticus (SE) may be the primary indication for admission, or it may occur in any ICU patient during a critical illness. A seizure may be the first indication of a central nervous system (CNS) complication or the result of overwhelming systemic disease. Seizures in the setting of critical illness are often difficult to recognize and require a complex diagnostic and management strategy. Delay in recognition and treatment of seizures is associated with increased mortality;[2] thus the rapid diagnosis of this disorder is mandatory.

Status epilepticus refers to a protracted seizure episode or multiple frequent seizures lasting 30 minutes or longer. Although conventional definitions of SE have used this time window, clinicians should recognize that most seizures will terminate spontaneously within a few minutes.[3] Recent data suggest that only half of seizure episodes lasting 10 to 29 minutes will stop spontaneously.[4] Therefore seizures that persist longer than 5 to 7 minutes should be treated to prevent progression to SE.[5]

Epidemiology

Limited data are available on the epidemiology of seizures in the ICU. A 10-year retrospective study of all ICU patients with seizures at the Mayo Clinic revealed that 7 patients had seizures per 1000 ICU admissions.[5] Our 2-year prospective study of medical ICU patients identified 35 with seizures per 1000 admissions.[1] The incidence of generalized convulsive SE (GCSE) in the United States is estimated to be up to 195,000 episodes per year,[6] but it is unknown how many of these patients require care in an ICU. The incidence of SE in the elderly is almost twice that of the general population.[7] Eight percent of hospitalized comatose patients in a recent series were found to be in electrographic status epilepticus.[8] Seizures are probably even more frequent in the pediatric ICU, as children in the first year of life have the highest incidence of SE of any age group studied.[5]

Table 64-1 summarizes the most common causes of SE in adults and children in the community. An analysis of 204 cases of SE in Virginia revealed that the primary etiology in children was infection with fever, followed by remote symptomatic

TABLE 64-1 Causes of Status Epilepticus Presenting from the Community

ADULTS		CHILDREN	
Prior Seizures	No Prior Seizures	Prior Seizures	No Prior Seizures
Common causes			
Subtherapeutic anticonvulsant	Ethanol-related	Subtherapeutic anticonvulsant	Febrile seizures
Ethanol-related	Drug toxicity	Intractable epilepsy	CNS infection
Intractable epilepsy	CNS infection		Head trauma
	Head trauma		
	CNS tumor		
Less common causes			
CNS infection	Metabolic aberration	Anoxic brain injury	CNS infection
Metabolic aberration	Stroke	Head trauma	Intractable epilepsy
Drug toxicity		Metabolic aberration	Metabolic aberration
Stroke			
CNS tumor

epilepsy, and subtherapeutic levels of anticonvulsant drugs. In adults, cerebrovascular disease and low antiepileptic drug levels were the most prevalent causes.[5] A recent study from Brazil found anticonvulsant noncompliance to be the main cause of SE in patients with a prior history of epilepsy, and CNS infection, stroke, and metabolic disturbances predominated in the group without previous seizures.[9] A prospective study of neurologic complications in medical ICU patients determined that two thirds of patients had a vascular, infectious, or neoplastic explanation for their seizures;[1] metabolic and toxic etiologies are common in the ICU as well. A review of 100 cases of nonconvulsive SE (NCSE) demonstrated that 14% were due to acute neurologic events, 28% due to acute systemic causes, and 31% due to epilepsy, with the remainder due to multiple causes or a cryptogenic etiology.[10]

A prospective study of neurologic complications in medical ICU patients showed that having one seizure in the ICU doubled mortality.[1] Up to 61% of patients developing SE during hospitalization die.[11] SE in and of itself confers a mortality rate of 26% to adults older than 16 years and 38% to those 60 years and older.[5] Multiple reports corroborate an especially poor outcome in the elderly.[8,12] The mortality rate of SE in children is 3% in the general population and 6% in the ICU.[13]

Three major factors determine outcome in SE: the type of SE, the cause, and the duration. Myoclonic SE following an anoxic episode carries a very poor prognosis for survival. Complex partial SE (CPSE) can produce limbic system damage, usually manifested as a memory disturbance. The mortality of patients with NCSE has been reported between 18%[9] and 57%,[14] and correlates with the underlying etiology, severity of impairment of mental status, and the development of acute complications (especially respiratory failure and infection). Causes associated with increased mortality included anoxia, intracranial hemorrhage, tumor, infection, and trauma. SE in the setting of acute ischemic stroke has a very high mortality, approaching 35%.[15] Prolonged seizure duration is a negative prognostic factor.[16] A study of 253 adult SE patients showed a greater than tenfold increase in mortality rate associated with seizures lasting ≥60 minutes compared with those lasting 30 to 59 minutes.[17]

Classification

The International League Against Epilepsy's (ILAE) classification of seizures is generally accepted. The system allows classification on the basis of clinical criteria without inferring cause. Knowledge of interictal or ictal electroencephalographic (EEG) findings is not necessary to classify seizures except for absence seizures, which are not likely to be a problem in the ICU. The classification system divides seizures into two types: *partial*, which have a focal or localized onset, and *generalized*, in which the cortex of both cerebral hemispheres is involved simultaneously at onset. Partial seizures can further be categorized as *simple*, in which consciousness remains intact throughout the event, or *complex*, in which consciousness is disrupted or altered (but not lost), often resulting in amnesia for the event. Seizures that start locally and then spread to involve the entire cortex are termed *secondary generalized*. Generalized seizures are of two types: *convulsive*, in which tonic, clonic, or myoclonic movements are prominent, and *nonconvulsive*, in which a patient has an altered level of consciousness with or without very subtle motor manifestations.

The clinical manifestation of partial seizures varies with the location of their onset. Motor seizures are usually due to a lesion in the contralateral frontal lobe. Deviation of eyes and head toward the irritative focus is often seen at the onset of seizure activity and is termed *versive* movement. Careful observation of the direction of this initial movement provides important diagnostic information regarding the location of brain pathology. Muscle contractions may be localized to a small region, such as the face or fingers, or be more extensive, involving the entire hemibody. Movements are usually tonic or clonic, but dystonic posturing is also common. Sensory seizures can be primarily auditory, somatosensory, visual, or consist of vague visceral sensations. Patients with complex partial seizures may demonstrate any combination of the above symptoms and have associated motor automatisms, such as lip smacking or swallowing.

Generalized convulsive seizures are usually of the tonic-clonic type. During the tonic phase, initial extension of the trunk is followed by extension of the arms, legs, neck, and back. The respiratory muscles may be involved in the tonic spasm, resulting in cyanosis and decreased oxygen saturation if the tonic phase is long enough, although this is rare. The clonic phase follows and is manifest by repetitive muscle contractions. Fixed and dilated pupils, tachycardia, and hypertension are well described during tonic-clonic seizures. Incontinence usually follows termination of the seizure. The frequency of the clonus eventually wanes and respiration commences when the seizure stops. Patients may initially be deeply comatose but should begin to regain consciousness within 15 to 20 minutes.

Status epilepticus refers to prolonged or serial seizures without interictal resumption of baseline mental status. *Refractory* SE refers to SE that is resistant to treatment with first-line measures and requires more aggressive therapy. Further description of specific treatment modalities will be reviewed below. *Epilepsia partialis continua* is a special type of focal motor epilepsy that consists of near constant muscle contractions of a specific muscle group. These movements can last for months or years without generalizing.

There are theoretically as many different types of SE as there are seizures, since SE is a prolonged seizure. However, SE cannot be classified in exactly the same manner as individual seizures, because seizures are discrete time-limited events with symptomatology restricted to the brief duration of their occurrence. SE, on the other hand, can evolve over time and therefore can have a symptomatology that may encompass more than one seizure type. Furthermore, NCSE can have similar signs and symptoms with different EEG signatures and etiologies. The simplest classification divides SE into generalized convulsive SE and nonconvulsive SE, depending on whether convulsive movements are present. Since NCSE includes everything that is not convulsive, it describes a wide variety of clinical entities and scenarios.

The conventional method of subcategorizing NCSE is to divide it into absence SE and complex partial SE. This works well for patients with a previous history of epilepsy. In this context, absence SE denotes confusion, typically mild, in a patient with generalized, approximately 3-Hz spike-wave discharges on EEG and a history of generalized epilepsy. Complex partial SE denotes confusion, typically waxing and

waning, or recurrent complex partial seizures associated with focal seizures in a patient with focal epilepsy. As defined herein, both types of NCSE imply that the encephalopathy is due to seizure activity. Historically, NCSE was labeled "absence" type if generalized EEG changes were found and "complex partial" if focal EEG changes were found, regardless of whether a history of epilepsy was present.

Many patients with NCSE do not have a history of epilepsy and do not fit into the conventional categorization elaborated above. For example, in a retrospective study of NCSE, we did not find any association between EEG findings and mortality,[9] emphasizing that this categorization is not very useful. This is particularly a problem in ICU patients in whom there are typically numerous factors contributing to encephalopathy. This nosologic uncertainty has given rise to several terms to describe NCSE arising in the ICU, including ICU status, subtle generalized convulsive status epilepticus, EEG status, and status in the critically ill. An important aspect of ICU status is that encephalopathy often has other causes in addition to the seizure activity.

NCSE is of particular importance to the intensivist when it occurs as a sequela of inadequately treated GCSE. After prolonged generalized convulsions, visible motor activity may stop, but the electrochemical seizure continues. Patients who do not start to awaken after 20 minutes should be assumed to have entered NCSE. NCSE following GCSE is a dangerous problem because the destructive effects of SE continue even without obvious motor activity. NCSE in this setting demands emergent treatment guided by electroencephalographic monitoring to prevent further cerebral damage since there are no clear clinical criteria to indicate whether therapy is effective.

NCSE can occur as a late stage of convulsive SE from any etiology, or as an initial form of SE from another cause. Failure to recognize NCSE is common in patients presenting with nonspecific neurobehavioral abnormalities, such as delirium, lethargy, bizarre behavior, cataplexy or mutism.[18] A high level of suspicion for this disorder should be maintained in patients with unexplained alteration in level of consciousness or cognition who are admitted to the ICU.

Two special circumstances with which the intensivist should be familiar are myoclonus and febrile seizures. Brief, shock-like, involuntary muscle contractions constitute myoclonus. Myoclonic jerks are arrhythmic, of variable amplitude, and involve both small and large muscles. In patients with postanoxic coma, myoclonus may be continuous or evoked by stimuli such a noise or touch. While this disorder has been associated with epileptiform discharges in the EEG,[19] not all episodes of myoclonus are epileptic; an EEG can clarify whether it is epileptic in individual cases. Postanoxic myoclonus also occurs in patients who have regained consciousness (the Lance-Adams syndrome); in this setting the myoclonus is probably of cerebellar origin and is not a seizure. Febrile seizures are specific to young children and are usually generalized motor convulsions that occur in association with fever, typically as the temperature is rising. These seizures should not be confused with those that transpire in the setting of fever secondary to infection of the nervous system. Febrile seizures are usually brief, but can be prolonged and recurrent, prompting admission to an ICU.

Clinical judgment is required to classify seizures in the ICU. Patients in whom consciousness has already been altered by drugs, hypotension, sepsis, or intracranial pathology may be difficult to classify using only the ILAE classification because it depends heavily on whether the seizure activity has altered consciousness. However, focal seizure activity on EEG or focal neurologic deficits often helps determine whether the seizure is focal or generalized in onset. The ILAE continues to work towards revising and updating the current classification system. The goal is a multi-axis diagnostic scheme that incorporates anatomic, etiologic, therapeutic, and prognostic implications. For the most recent information regarding this ongoing project, refer to www.epilepsy.org.[20]

Pathogenesis and Pathophysiology

The systemic and cerebral pathophysiology of GCSE can be divided into early and late phases.[21] The early phase of systemic manifestations results from an adrenergic surge and excessive muscle activity.[22] The adrenergic surge causes tachycardia, hypertension, and hyperglycemia. These are augmented by extreme muscle activity that causes hyperthermia and acidosis and can lead to muscle breakdown, rhabdomyolysis, and secondary acute renal failure. This stage is generally well compensated by homeostatic mechanisms so that the excessive demands are met with increased supply or other compensatory mechanisms.

Most facets of GCSE begin to slow down late in GCSE, so only a rare patient continues to have continuous convulsive motor activity for more than an hour. Cessation of continuous motor activity would seem to be a beneficial turn of events, but this is actually coincident with a sharp increase in mortality and in complications. Although systemic factors such as heart rate and blood pressure normalize, they may be inadequate to meet increased demands of intermittent convulsions or electrographic seizure activity, even in the absence of convulsions. Thus mortality increases dramatically for SE lasting longer than an hour.[16] Death may result from a number of causes, but in a prospective study of cardiovascular changes during GCSE 58% of patients had potentially fatal arrhythmias.[23] Patients with atherosclerotic cardiovascular risk factors may have a gradual deterioration in hemodynamic parameters as their cardiovascular reserve is expended, while other patients decline acutely, presumably from arrhythmias.[24]

SE may cause neuronal injury in surviving patients. Some neuronal injury is caused by systemic factors; for example, hyperthermia causes cerebellar neuronal injury. However, neuronal injury continues during electrographic SE, even without motor manifestations or when physiologic parameters are held in the normal range. This is illustrated most clearly in experimental GCSE. Neuronal injury is prominent in the hippocampus and temporal lobe in primates with experimental GCSE. The injury persisted even when muscle activity was eliminated by paralysis, and pulse, blood pressure, temperature, and oxygenation were kept normal.

Neuronal injury during SE is due in part to the excitotoxic effects of glutamate-mediated neuronal seizure activity.[20] Glutamate is the most common excitatory neurotransmitter in the brain. It mediates transfer of information between neurons under normal conditions via several receptors. However, glutamate excessively activates the N-methyl-D-aspartate (NMDA) subtype of receptor in the robust conditions of SE. NMDA receptors have a limited normal function, but during

SE they cause very prolonged depolarization of neurons. This results in intracellular accumulation of calcium and other cellular changes that result in both immediate and delayed cell death.[20]

There are two important clinical implications of the pathophysiology of SE. First, neuronal injury continues during electrical SE even after control of motor manifestations. Therefore it is imperative to exclude ongoing seizure activity if patients are pharmacologically paralyzed after GCSE or do not awaken soon after motor activity stops. These circumstances require EEG monitoring to exclude ongoing seizure activity. Second, pharmacologic treatment is aimed at augmenting inhibition, via drugs that act on γ-aminobutyric acid (GABA), such as barbiturates and benzodiazepines. There will probably also be a role for NMDA antagonists. Ketamine is the only currently available NMDA antagonist, but others are likely to be helpful in the future.

Clinical Manifestations

Three problems complicate seizure recognition in the ICU: (1) occurrence of complex partial or nonconvulsive seizures in the setting of depressed consciousness, (2) masking of seizures by pharmacologically-induced paralysis or sedation, and (3) misinterpretation of other abnormal movements as seizures. ICU patients often have decreased levels of consciousness in the absence of seizures that are ascribable to the underlying disease and its complications.[25] An encephalopathic patient may be unable to appreciate or report symptoms of seizure. Fluctuations in mental status are frequently subtle and may go unrecognized by staff. A decline in baseline alertness may reflect a seizure; an EEG may be required to confirm that one has occurred.

Patients receiving neuromuscular junction blocking agents do not manifest the motor signs of seizures. Patients with refractory intracranial hypertension, severe pulmonary disease, or other critical illnesses may be both paralyzed and sedated, making identification of seizures particularly challenging. Tachycardia and hypertension are signs of seizure that can be misinterpreted as evidence of inadequate sedation. Continuous EEG monitoring is warranted in this population if seizures are suspected.

Patients with metabolic disturbances, anoxia, and other types of nervous system injury may demonstrate abnormal movements that can be confused with seizure. Asterixis, or flapping tremor, is a brief arrhythmic loss of tone that can appear in the setting of hepatic encephalopathy, hypercarbia, drug intoxication, or CNS pathology.[26] Myoclonus in postanoxic coma has been reported in the presence[18] and absence[27] of epileptiform discharges. Therefore EEG is absolutely indicated in this setting to evaluate for ongoing seizures. Action myoclonus in a patient recovering from hypoxic encephalopathy is evoked during movements directed at a target, such as an examiner's finger. It is frequently associated with cerebellar ataxia and postural lapses, which when combined with myoclonus can severely impair ambulation. Myoclonus associated with etomidate is described,[28] but whether it is cortically mediated remains unclear. Brain-injured patients may suffer from so-called "hypothalamic seizures." Tetanus patients do not lose consciousness during their spasms, and describe excruciating pain associated with the sustained whole-body contractions. Psychiatric disturbances in the ICU occasionally resemble complex partial seizures. If doubt about the nature of abnormal movements persists, an EEG should be performed.

Diagnostic Approach

The initial approach to seizure management is the same as that for any other acute medical problem: airway, breathing, and circulation. As described above, generalized convulsive status epilepticus often causes apnea and/or poor oxygen saturation. Hypertension and tachycardia may be marked. However, respiratory and hemodynamic dysfunction is transient, and with seizure termination rapidly returns to normal. Padded tongue blades or similar items should not be placed inside the mouth; they are more likely to obstruct the airway than to preserve it. Medication to treat tachycardia and hypertension before the seizure activity stops is not warranted.

When a patient has a seizure, one has a natural tendency to try to stop the event. This leads to both diagnostic confusion and iatrogenic complications. Beyond protecting the patient from harm, very little can be done rapidly to influence the course of the seizure. The seizures of most patients stop before any medication can reach the brain in an effective concentration. Observation is the most important activity to perform when a patient has a single seizure. This is the time to collect evidence of a partial onset in order to implicate structural brain disease. The postictal examination is similarly valuable; language, motor, sensory, or reflex abnormalities after an apparently generalized seizure are evidence of focal pathology.

Seizures in ICU patients have many potential causes that must be investigated. Drugs are a major cause of seizures in critically ill patients, especially in the setting of renal or hepatic dysfunction. Theophylline can provoke seizures or SE if it has been rapidly loaded or if high concentrations of the drug occur; however, these complications can also arise with normal serum drug levels.[10] Imipenem-cilastatin[29] and fluoroquinolones[30] have the potential to lower the seizure threshold, particularly in patients with impaired renal function. Accumulation of a metabolite of meperidine, normeperidine, causes seizures, even in patients with normal renal function. Sevoflurane, a volatile anesthetic agent, also causes electrographic and clinical seizures without a history of epilepsy or CNS pathology.[31]

Recreational drugs are frequently-overlooked offenders in patients presenting to the ICU. Acute cocaine or methamphetamine intoxication is characterized by a state of hypersympathetic activity followed by seizures.[32] Ethanol withdrawal is a common cause of seizures between 6 and 96 hours after the patient's last drink, but concomitant causes must not be overlooked. Narcotic withdrawal may produce seizures in the critically ill[5] and in newborns of opioid-dependent mothers.[33] Both bupropion hydrochloride[34] and tricyclic antidepressants are associated with seizure in overdose and occasionally at therapeutic doses. In the absence of other clear causes for seizure, a complete toxicology screen should be performed upon admission.

Serum glucose, electrolyte concentrations, and serum osmolality should also be measured. Nonketotic hyperglycemia can precipitate both focal and generalized seizures;[35,36] epilepsia partialis continua was the most common type

seen in a recent series.[37] Seizure activity may infrequently be the first presenting sign of diabetes mellitus. Both severe, rapidly developing hyponatremia and hypoglycemia can cause seizures. The patient's blood glucose concentration should be measured immediately upon presentation, and dextrose and thiamine administered if hypoglycemia is present. Hypocalcemia rarely causes seizures beyond the neonatal period; identifying even moderate hypocalcemia must *not* signal the end of the diagnostic work-up. Hypomagnesemia has an equally unwarranted reputation as the cause of seizures in malnourished alcoholic patients.

The physical examination should emphasize assessment for both global and focal abnormalities of the CNS. Evidence of cardiovascular disease or systemic infection should be sought and the skin and fundi examined closely. Particular attention should be given to the funduscopic examination of infants presenting from the community with seizures, as retinal hemorrhages may be the only evidence of brain trauma induced by child abuse (the "shaken baby syndrome").

New-onset seizures almost always warrant brain imaging. Considering the large number of critically ill patients with neurologic pathology as a primary or contributing cause for seizures, acute brain processes must be ruled out. Computed tomography (CT) scanning is a rapid modality with which the trained clinician can detect acute blood, swelling, large tumors or abscesses, and subacute or remote ischemic strokes. With current technology, there are exceptionally few patients who cannot undergo CT scanning. Magnetic resonance imaging (MRI) is particularly helpful in detecting evidence of acute ischemic stroke, encephalitis, small tumors, subdural empyemas, and cerebral edema. Most cardiac pacemakers are a contraindication to MRI, but many other medical devices, such as inferior vena cava filters, intracranial pressure monitors, and cerebral aneurysm clips, are now manufactured using MRI-compatible material. Patients with altered mental status who need cerebrospinal fluid analysis require imaging of the brain first, to rule out a mass, swelling, or other cause of impending brain herniation. When CNS infection is suspected, empiric antibiotic treatment should be started while imaging studies are being obtained.

In contrast to the patient with a single or a few seizures, the SE patient requires simultaneous diagnostic and therapeutic efforts. Although 30 minutes of continuous or recurrent seizure activity usually defines SE, one should not stand by waiting for this period to pass to start treatment. Since most seizures in critically ill patients stop within 2 to 3 minutes, it is reasonable to start treatment after 5 minutes of continuous seizure activity or after the second or third seizure occurs without recovery between the spells.

THE ELECTROENCEPHALOGRAM

Treatment for recognized SE should not be delayed to obtain an EEG, but such recognition is not always straightforward. A prospective evaluation of 164 patients demonstrated that nearly half manifested persistent electrographic seizures in the 24 hours after clinical control of convulsive SE, and 14% went into electrographic status epilepticus.[38] Subclinical seizures have been observed during aggressive treatment for SE, even in patients treated with high-dose barbiturates to produce a burst-suppression pattern on EEG. These data suggest that EEG monitoring after control of convulsive SE can be essential in directing the course of treatment. Emergent EEG is necessary to exclude NCSE in those patients who do not begin to awaken soon after visible seizure activity has stopped. Patients who develop refractory SE or receive neuromuscular junction blockade require continuous EEG monitoring, since ongoing seizure activity can cause neuronal injury via excitotoxic mechanisms as outlined above.

A variety of findings may be present in the EEG, depending on the seizure type, duration, and level of pharmacologic intervention. Prospective data indicate that EEG patterns may also be helpful in determining prognosis. One study found that the presence of burst-suppression, post-SE ictal discharges, and periodic lateralized epileptiform discharges during the initial 24 hours after control of SE were statistically significantly correlated with mortality and poor outcome.[39] Burst-suppression secondary to pharmacologic coma for treatment of SE must be differentiated from burst-suppression due to widespread cortical injury, or that seen as the last stage of the EEG evolution of SE. The availability of continuous paperless electroencephalographic monitoring allows for detection of seizure activity over a long period.

Management Approach

ISOLATED SEIZURES

Not all patients who have seizures require anticonvulsant therapy. Making the decision to administer anticonvulsants to a hospitalized patient who experiences one or a few seizures mandates consideration of a provisional cause, estimation of the likelihood of recurrence, and recognition of the utility and limitations of anticonvulsants. For example, seizures due to ethanol or other hypnosedative withdrawal do not need chronic treatment, but short-term therapy with benzodiazepines for repeated or prolonged seizures may be warranted (Table 64-2). Seizures caused by metabolic disturbances such as hyponatremia are often refractory to conventional anticonvulsant medications such as phenytoin, and are best treated with correction of the underlying disorder (benzodiazepines may be useful for seizure suppression if needed while the metabolic problem is being corrected). Seizures related to nonketotic hyperglycemia respond best to correction of hyperglycemia with insulin and rehydration.[36]

A patient with CNS disease who has even one seizure should receive anticonvulsant therapy because the risk of seizure recurrence is very high. However, this treatment should be reviewed before discharge. Initiating this treatment after the first *unprovoked* seizure may help delay the appearance of subsequent seizures,[40] but probably does not influence whether epilepsy subsequently develops.[41] Prophylactic therapy in patients at high risk for seizure, especially if his or her condition would be seriously complicated by a convulsion, is not unreasonable. Patients with traumatic brain injury, intracerebral hemorrhages, and subarachnoid hemorrhages are frequently placed on anticonvulsants immediately upon admission, although no prospective randomized trials have proven a positive effect on outcome.

In the ICU setting, phenytoin is often the first drug selected due to ease of administration and rapid assessment of blood levels. While the efficacy of phenytoin in the control of seizures is well established, several inherent properties of the drug limit its tolerability. In order to improve aqueous

TABLE 64-2 Drugs for the Treatment of Acute Convulsive Status Epilepticus

Drug	Dose	Rate	Advantages	Disadvantages
Diazepam	0.15 mg/kg	IV push	Quick onset of action	Respiratory depression
Fosphenytoin	20 mg/kg	<150 mg/min	Easy transition to chronic administration	Delay to onset of action; prolonged loading time; hypotension
Lorazepam	0.1 mg/kg	IV push diluted 1:1	Quick onset of action; may prevent early recurrence	Respiratory depression
Midazolam	0.2 mg/kg	IV/IM push	Can be given IM; quick onset of action	Respiratory depression
Phenobarbital	10–20 mg/kg	50–100 mg/min	Readily available	Prolonged loading time; hypotension
Phenytoin	20 mg/kg	<50 mg/min	Readily available	Prolonged loading time; cardiac arrhythmias; necrosis if extravasation occurs; hypotension; incompatiable with dextrose-containing solutions
Valproate	25 mg/kg	12–200 mg/min diluted 2:1	Appears safe in children	Not well studied in status epilepticus

solubility, phenytoin is suspended in a highly alkaline solution that is comprised of 40% propylene glycol.[42] The propylene glycol vehicle has been linked to hypotension and cardiac arrhythmias during phenytoin infusion; however, phenytoin itself may be partly responsible for hemodynamic instability. The caustic pH of the parenteral formulation can cause injection site reactions that can range from burning at the IV site to necrosis in the event of extravasation.

The phenytoin prodrug, fosphenytoin, is water soluble; therefore the parenteral formulation is more neutral than that of phenytoin and contains no organic solvents. Cardiovascular side effects were initially thought to be less common with fosphenytoin, but subsequent experience suggests that hypotension and arrhythmias may follow its infusion. Pain at the infusion site is significantly less common with fosphenytoin than with phenytoin.[43] In patients without IV access, fosphenytoin can be safely administered intramuscularly. IM doses of fosphenytoin are well tolerated, require no cardiac monitoring, and are completely absorbed. Fosphenytoin is rapidly converted to phenytoin in vivo and free phenytoin levels after fosphenytoin administration are not markedly different compared to phenytoin, although the time to reach the peak level after IM administration is several hours.

A 20 mg/kg loading dose of phenytoin brings most patients to the desired concentration of 20 μg/mL (corresponding to an unbound or free concentration of 2 μg/mL). Fosphenytoin is dosed by phenytoin-equivalent units (PE); therefore no dosage adjustments are needed when converting patients from phenytoin to fosphenytoin. Fosphenytoin can be administered via intravenous infusion at rates of up to 150 mg PE/min, compared with a maximum rate of 50 mg/min for phenytoin. Both of these drug infusions should be started at a lower rate and increased as tolerated. When loading doses of fosphenytoin are given IM, two divided doses of 10 mg/kg each are recommended. After fosphenytoin administration, phenytoin concentrations should not be measured until the biologic conversion to phenytoin is complete and the drug has equilibrated throughout the body, about 2 hours after an intravenous infusion or 4 hours after an intramuscular injection of fosphenytoin. Phenytoin is approximately 90% protein bound in normal hosts, but the unbound fraction is the active component. Patients with renal or hepatic dysfunction or those taking drugs that compete for protein binding may benefit from measuring the free (unbound) serum phenytoin concentration before increasing phenytoin doses due to apparently subtherapeutic total phenytoin concentrations.

The maintenance dose for phenytoin is typically in the range of 5 to 7 mg/kg per day, but is highly variable because of individual differences in metabolism and interactions with other drugs metabolized via the cytochrome P450 system. Maintenance doses can be given either enterally or parenterally. Maintenance doses of IV or enteral liquid suspension phenytoin must be given in twice-daily divided doses since their half-life is less than 24 hours. Extended-release capsules can be given once a day. However, patients often do not tolerate more than 300 or 400 mg of phenytoin enterally in any one dose secondary to nausea. Therefore patients requiring more than this amount in capsules should usually receive divided doses.

Hypersensitivity is the major adverse effect of concern to the intensivist. This may manifest itself solely as fever, but commonly includes rash, eosinophilia, and elevated liver enzymes. Adverse reactions to phenytoin and other anticonvulsants have been reviewed elsewhere.[44]

Phenobarbital remains a useful anticonvulsant for those intolerant to phenytoin or those who have persistent seizures after *adequate* phenytoin administration. The loading IV dose is 15 to 20 mg/kg, and the target serum concentration is 20 to 40 μg/mL. The serum concentration may be altered by hepatic and renal dysfunction. Furthermore, phenobarbital can also induce P450-related metabolism, thereby affecting the metabolism of other drugs that undergo hepatic clearance. Since the usual clearance half-life of phenobarbital is about 96 hours, maintenance doses of this agent should be given once a day. A steady-state level takes about 3 weeks to become established. Sedation is the major adverse effect; allergy to the drug occurs rarely.

Carbamazepine is rarely initiated in the ICU because it is not available in parenteral form and absorption from the gastrointestinal tract is relatively slow. Carbamazepine has significant interactions with many drugs that are used in hospitalized patients, such as corticosteroids, theophylline, warfarin, and cimetidine. Adjusting blood levels of

carbamazepine in the setting of polypharmacy can be unpredictable. Carbamazepine and the newer anticonvulsant oxcarbazepine can both cause hyponatremia with chronic use, probably due to a combination of the syndrome of inappropriate secretion of antidiuretic hormone (SIADH) and salt-wasting nephropathy.

STATUS EPILEPTICUS

Status epilepticus is a medical emergency. While proper diagnosis of the cause is critical, the most important initial goal is to expeditiously stop the clinical and electrographic seizures. The likelihood of successfully treating SE is inversely related to the duration of seizures; the longer seizures last, the more difficult they are to terminate. Aggressive and rapid management of status epilepticus is essential to limit further neurologic and systemic complications.

The conventional agents used for first-line treatment of SE are the benzodiazepines (especially lorazepam, diazepam, and midazolam), phenytoin, and phenobarbital. The Veterans Affairs Status Epilepticus Cooperative Study Group trial compared four regimens for the initial treatment of GCSE and demonstrated that lorazepam was more efficacious than phenytoin, and easier to use than phenobarbital or phenytoin plus diazepam.[45] Lorazepam has been our agent of first choice for terminating SE for many years and remains so with support from this study.

The major advantage of lorazepam over diazepam is its longer duration of action, thereby limiting seizure recurrence. Lorazepam has traditionally been given in 2-mg doses repeated at 5-minute intervals if seizures do not terminate. Since this is often an inadequate dose and valuable time passes before definitive treatment is instituted, we recommend instead a single IV dose of 0.1 mg/kg of lorazepam. If lorazepam is not available, a single IV dose of 0.15 mg/kg of diazepam is an alternative. However, another agent such as phenytoin or phenobarbital should be started immediately, as the duration of action of diazepam against SE is only about 20 minutes. In the event that IV access is unattainable, 0.2 mg/kg of midazolam administered IM will be rapidly and reliably absorbed. The use of midazolam in refractory SE will be discussed below. All benzodiazepines carry a risk of hypotension and respiratory depression. However, these are also sequelae of prolonged or inadequately treated SE. The intensivist should be prepared to intubate or use vasopressors if necessary.

Phenytoin is an effective anti-SE agent; however, the constraint on the rate of intravenous administration is of concern when treating SE. Fosphenytoin may be a better drug for use in SE since it can be loaded up to three times faster, although its 7-minute conversion half-life means that the serum phenytoin level does not reach its target much faster. Phenytoin has a long duration of action when an adequate dose is given (a 20-mg/kg dose produces a serum level above 20 mg/mL for 24 hours). Adding an additional 5 mg/kg if the initial load fails to stop SE may be useful. Intramuscular injection of fosphenytoin in SE patients may be supported by the known pharmacokinetics of this route, but it should not be considered to be acceptable therapy for SE and should be reserved for only those rare circumstances in which IV access cannot be obtained.

Phenobarbital in the management of acute SE is not routinely recommended, except when phenytoin is contraindicated. However, the Veterans Affairs study showed no difference in efficacy between lorazepam and phenobarbital as first-line agents in SE, but phenobarbital took longer to administer.[45] Furthermore, in the patients that did not respond to lorazepam or phenytoin, the response rate to phenobarbital was only 2.1% (unpublished data). We therefore recommend pursuing a more definitive treatment strategy for patients who have entered refractory SE (RSE).

REFRACTORY STATUS EPILEPTICUS

Patients in RSE require doses of medication that are highly likely to cause significant respiratory suppression and hypotension. Therefore mechanical ventilation is necessary, and invasive hemodynamic monitoring is frequently required. Concomitant continuous EEG monitoring is also mandatory to confirm treatment success and monitor depth of sedation. The traditional goal of therapy is burst-suppression pattern on EEG for 12 to 24 hours prior to any attempts to wean medication. Since the available data suggest that successful treatment and improved outcome probably required seizure suppression regardless of background EEG activity,[46] we recommend cessation of electrographic seizures as the goal instead.

High-dose barbiturates, most commonly pentobarbital, are extremely useful in RSE, but side effects can be severe and may limit use (Table 64-3). Hypotension can be refractory to initial resuscitative efforts, and the patient may benefit

TABLE 64-3 Drugs for the Treatment of Refractory Status Epilepticus

Drug	IV Loading Dose	Maintenance Dose	Advantages	Disadvantages
Ketamine	4–5 mg/kg over 2–4 min	1–5 mg/kg per h	Unlikely to cause hemodynamic instability	Not well studied for status epilepticus
Midazolam	0.2 mg/kg IV bolus	0.05–2 mg/kg per h	Fast onset of action	Tachyphylaxis
Pentobarbital	5–12 mg/kg at 50 mg/min	1–10 mg/kg per h	Readily available	Hypotension; immune suppression
Propofol	1–2 mg/kg IV bolus	1–15 mg/kg per h	Easy to adjust	High lipid and calorie content; "propofol infusion syndrome" (metabolic acidosis, and on occasion rhabdomyolysis, with doses greater than 5 mg/kg per h)
Thiopental sodium	75–125 mg IV bolus	1–5 mg/kg per h	Fast onset of action	Can have prolonged effects after extended infusions due to absorption into adipose tissue

from pulmonary artery catheterization to plan fluid and vasopressor management. Pulmonary infection is common due to prolonged intubation and impaired function of both respiratory cilia and leukocytes. The intensivist must be vigilant in monitoring for infection since barbiturate-induced poikilothermia may mask fever. Despite these side effects, barbiturate anesthesia should not be rapidly discontinued if it is successful in terminating refractory SE. Continuing therapy for at least 48 hours, gradual tapering of the infusion dose, and the administration of phenobarbital during the drug taper are recommended.[47] Pentobarbital is loaded at 5 to 12 mg/kg followed by an infusion of 1 to 10 mg/kg per hour. As an alternative, thiopental sodium may be given in 75- to 125-mg IV boluses followed by infusion rates of 1 to 5 mg/kg per hour. Both medications rapidly redistribute into adipose tissue; recovery of consciousness usually takes much longer after thiopental infusions than after pentobarbital. Elimination times can be greatly increased in obese patients after prolonged infusions.

Midazolam is a water-soluble benzodiazepine that has demonstrated high efficacy in refractory SE in adults and children.[48–50] Midazolam is loaded at 0.2 mg/kg followed by continuous infusion of 0.05 to 2.0 mg/kg per hour. Respiratory depression may be encountered less frequently than with other hypnosedatives, but should be anticipated. Since most patients with RSE are already intubated, concern for respiratory effects should not limit use. Clinically significant hypotension is rare even at the very high doses that are often required to address tachyphylaxis.[51] Sedation is quickly reversed after short-term infusions are discontinued. However, terminal half-lives of three to eight times normal have been reported with extended administration.[52] In addition, prolonged elimination times have been associated with critical illness and hepatorenal dysfunction.

Propofol is an intravenous anesthetic agent that acts primarily on the $GABA_A$ receptor. Case reports documenting its efficacy in RSE are abundant, but studies examining direct comparisons with other agents have had mixed results.[53–55] An initial bolus of 1 to 2 mg/kg should be followed with a maintenance infusion at 1 to 15 mg/kg per hour. Propofol is fast acting, highly lipid soluble, and has little propensity to accumulate even with prolonged infusions.[47] Because of its rapid clearance, propofol should not be abruptly discontinued, but instead tapered gradually. Respiratory depression and hypotension are extremely common, especially after the initial bolus. Nutritional support must be adjusted in the setting of propofol infusion due to the high lipid and calorie content of the solution. Acidosis and rhabdomyolysis have been reported in both adults[56] and children.[57] Careful monitoring of creatine kinase and blood pH are prudent.

Alternative regimens with reported success in the termination of RSE include isoflurane, intravenous valproate, ketamine, and topiramate. Further studies are indicated to elucidate the role of these agents in the treatment of seizure emergencies.

Once SE is addressed, one must manage the major systemic complications of SE. Patients with GCSE should be screened for rhabdomyolysis with urine myoglobin and serum creatinine kinase (CK) determination. If myoglobinuria is present or if the CK concentration is more than 10 times the upper limit of normal, rehydration and urinary alkalinization should be instituted.[58] Prolonged or severe hyperthermia should be aggressively treated with cooling blankets, ice packs, or other cooling modalities.

SPECIAL CONSIDERATIONS FOR CHILDREN

Treatment of seizures or SE in critically ill children generally parallels that for adults. Intravenous access is often more difficult to achieve in children. Lorazepam and diazepam can both be administered by the rectal route (usually 0.5 mg/kg *per rectum* for both agents) and midazolam (0.2 mg/kg) via the IM, nasal, or buccal routes. Lorazepam is probably the first-line drug of choice for terminating SE in children as for adults. One study of 86 children presenting with seizure found that those who received lorazepam had a higher incidence of termination of seizure activity and less frequent respiratory depression than those treated with diazepam.[59] Midazolam administered by continuous infusion appears effective in RSE in children.[60–62] Although all eight patients in one study were mechanically ventilated, none demonstrated cardiovascular instability despite midazolam doses resulting in burst-suppression.[59]

As with adults, rapid control of SE in children achieved with benzodiazepines should be followed by administration of a longer-acting agent such as phenytoin (20 mg/kg IV), fosphenytoin (20 mg PE/kg IV), or phenobarbital (10 to 20 mg/kg IV).[63] The rate of conversion of fosphenytoin to phenytoin is probably the same in children as in adults. Intramuscular injection of fosphenytoin may be particularly advantageous for prevention of recurrent seizures in children without IV access. The use of IV fosphenytoin over IV phenytoin is prudent in infants and neonates, whose small limbs are at especially high risk of extensive necrosis and amputation in the event of a phenytoin extravasation.

Intravenous valproate appears to be safe and effective in children;[64] however, more data are needed to fully evaluate its use in pediatric SE.

Chapter 65

INTRACRANIAL PRESSURE: MONITORING AND MANAGEMENT

JEFFREY I. FRANK
AXEL J. ROSENGART

KEY POINTS

- *Intracranial hypertension is the final common pathway of morbidity and mortality for diverse neurologic problems, and its proper treatment requires the timely application of the available therapeutic alternatives when the clinical situation and prognosis warrant and justify treatment.*
- *Anticipating patients at risk for brain swelling is important and allows the development of a strategic plan to limit its severity and facilitate early intervention when possible.*
- *The initial therapeutic focus for intracranial pressure reduction should be the control of factors that can aggravate intracranial hypertension, such as inappropriate head and body position, elevated body temperature, inadequate treatment of pain and agitation, elevated airway pressures, blood pressure fluctuations, seizures, and administration of hypotonic fluids.*
- *The appropriate conventional medical therapies should be selected based on the details of each specific case. It should be clear that brain tissue displacement (BTD) and intracranial hypertension are not synonymous, and the treatment of each of them can be different. Surgical removal of an intracranial mass lesion or expansion of the intracranial compartment should be considered in patients with severe BTD and/or evolving intracranial hypertension.*
- *In the end, the treatment of intracranial hypertension is heuristic, challenging the managing physician's thorough understanding of the cause of the problem and his or her ability to define the human aspects that relate to determining the appropriate level of care for individual patients. In addition, successful management depends on a partnership with nurses founded on comprehensive communication to assist with the accurate translation of the defined care priorities.*

Intracranial hypertension can be the result of a primary central nervous system process, or it can result as a complication of a concurrent systemic illness. Independent of the specific etiology, it is an important and potentially disabling and deadly complication. While it often has important prognostic implications, its successful management can protect the brain from secondary injury and improve outcome.The management of intracranial hypertension is frequently approached in an overly simplistic manner with the sequential application of various intracranial pressure (ICP)–lowering strategies in a cookbook fashion. However, such a simplistic approach to intracranial hypertension can be perilous and potentially aggravate the problem. The management of intracranial hypertension is best tailored to each specific situation. This chapter will introduce the basic principles that should be considered when arriving at an individualized strategic management plan for a patient with brain swelling and/or intracranial hypertension. While some of these concepts and treatment strategies are discussed in Chap. 93 in the context of head injury, we will present a more global view on the management of brain swelling and intracranial hypertension

Cerebral Hemodynamic Considerations

INTRACRANIAL PRESSURE

When it is monitored, the ICP tracing is a ballistic waveform much like the systemic arterial pressure (Fig. 65-1). However, it has a narrow "pulse pressure" and is expressed, by convention, as its mean. The normal mean ICP is generally between 5 and 10 mm Hg, and it will fluctuate at times to higher levels depending on many physiologic factors.

In normal adults, the skull is a rigid container and contains brain parenchyma, fluid (interstitial and cerebrospinal), and blood (arterial and venous). The expansion of any of these compartments or the addition of a space-occupying process can lead to ICP elevation. Table 65-1 lists some of the most common causes of brain swelling. The extent of the ICP elevation depends on many factors, most importantly the patient's intracranial compliance.

INTRACRANIAL COMPLIANCE

Figure 65-2 shows the intracranial pressure-volume curve that diagrammatically describes the dynamic of intracranial compliance. When a process that adds volume to the intracranial cavity evolves, cerebrospinal fluid (CSF) from the hemispheric convexities, basal cisterns, and ventricles (except in hydrocephalus) is passively displaced into the contiguous spinal subarachnoid space. As a result, the ICP only modestly increases during the early stages of the process (A). However, once CSF cannot be passively displaced any further, the ICP rises more sharply as the space-occupying process continues to evolve (B). This relationship between added volume to the intracranial cavity and its matched rise in ICP is referred to as the intracranial compliance. There is decreasing intracranial compliance as the intracranial hemodynamic relationship shifts to the right along the intracranial pressure-volume curve.

The concepts of the intracranial pressure-volume relationships and intracranial compliance can be applied when evaluating brain imaging studies to estimate the likelihood of intracranial hypertension in a patient who suffers a space-occupying intracranial process. For example, Fig. 65-3 shows an axial computed tomography (CT) scan of the brain with brain swelling from a middle cerebral artery territory infarction. As there are still compressible spaces around the swollen brain (e.g., basal cisterns, ipsilateral lateral ventricle, and ipsilateral cortical sulci) on that scan, it is reasonable to expect that the ICP is not yet significantly or persistently elevated. On the other hand, the CT in Fig. 65-4 shows a more extensively swollen brain than in Fig. 65-3, with obliteration of all surrounding CSF spaces. In the example shown in Fig. 65-4 the ICP is likely markedly elevated. While estimating

the likelihood of intracranial hypertension by CT scan appearance is imperfect, it can provide some practically useful direction in management when the clinician is making decisions about whether to begin invasive ICP monitoring or considering other therapeutic maneuvers such as surgical decompression.

CEREBRAL BLOOD FLOW AND CEREBRAL PERFUSION PRESSURE

Alterations in cerebral blood flow (CBF), either too much or too little, can disturb the brain homeostatic mechanisms and lead to cerebral injury. A relatively constant supply of blood to the brain is ensured by cerebral autoregulation, a physiologic phenomenon that allows maintenance of a constant CBF over a wide range of arterial blood pressures. Figure 65-5 graphically depicts this relationship for normotensive patients. In chronic hypertensives, the autoregulatory thresholds are shifted to the right. Relative blood pressure lowering within an autoregulatory range leads to cerebral vasodilation and an increase in cerebral blood volume. Conversely, relative blood pressure elevation within an autoregulatory range leads to cerebral vasoconstriction and a decrease in cerebral blood volume. Such alterations in cerebral blood volume can importantly affect the ICP. In fact, CBF is a critical

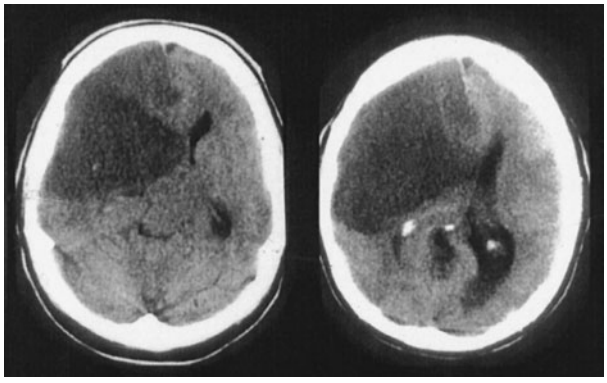

FIGURE 65-4 An unenhanced CT of the brain 96 hours after a right middle cerebral artery territory infarction. There is severe compression of all CSF spaces, an evolving more recent right anterior cerebral artery infarction from right to left subfalcine herniation. This patient has poor intracranial compliance relative to figure 65-3.

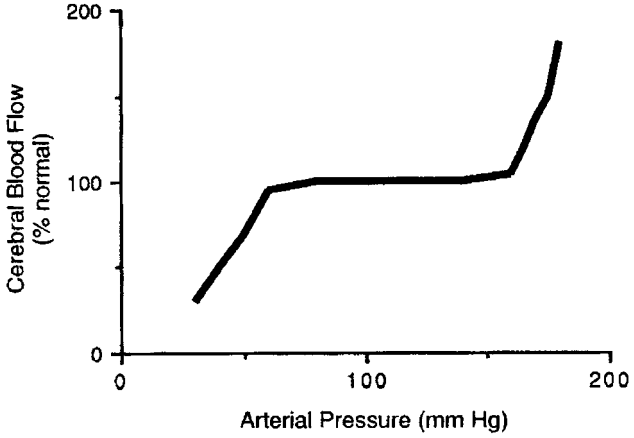

FIGURE 65-5 Cerebral autoregulatory curve demonstrating a constant cerebral blood flow over a range of blood pressures.

determinant of ICP, and its reduction is a major final common pathway for cerebral injury from raised ICP. A practical understanding of these concepts is critical to developing a rational therapeutic plan for patients with intracranial hypertension.

The concept of cerebral perfusion pressure (CPP) is an important guide to management of the dynamic interplay between ICP and blood pressure. By definition, the CPP refers to the difference between the mean arterial pressure (MAP) and the cerebral venous pressure. Since the cerebral venous pressure is approximated by the ICP in most cases, the generally accepted CPP equation is:

$$CPP = MAP - ICP$$

This equation emphasizes the important point that the primary mechanism of cerebral injury from intracranial hypertension is cerebral ischemia from compromised cerebral perfusion. Notably, CBF is not a direct correlate of CPP, since autoregulation allows the CBF to remain constant in normotensive patients once the CPP exceeds approximately 40 mm Hg in previously normotensive patients.

The physiologic relationship between blood pressure, CBF, and CPP are less predictable in damaged brain regions where autoregulation is impaired. In brain regions without intact autoregulation, relative blood pressure lowering or elevation, even within a normal range, can lead to regional cerebral ischemia or hyperemia, respectively. Table 65-2 lists several important factors that influence CBF and ICP. Control or manipulation of these factors constitutes the basis for much of the medical management of raised ICP.

In most situations, it is best to maintain CPP in the 60 to 80 mm Hg range in euthermic patients, but the target CPP

TABLE 65-2 Factors That Influence Cerebral Blood Flow and Intracranial Pressure

Factor	Cerebral Blood Flow	Intracranial Pressure	Effect	Clinical Commentary
Raised intracranial pressure	↓	NA	—	Cerebral injury occurs through ischemia
Cerebral hyperemia	NA	↑	—	Most relevant in pediatric head injury
Hyperventilation	↓	↓	Vasoconstriction	Tromethamine may prolong effect
Hypoventilation	↑	↑	Vasodilatation	Common with posterior fossa pathology
Hypotension	+/−	↑	Vasodilatation	Early diagnosis and treatment imperative
Hypovolemia	+/−	↑	Vasodilatation	Maintain euvolemia
Acidosis	↑	↑	Vasodilation	
Alkalosis	↓	↓	Vasoconstriction	
Hyperthermia	↑	↑	Vasodilation	Linear increase in cerebral blood flow 6% per degree C.
Hypothermia	↓	↓	Vasoconstriction	May have therapeutic value
Hypoxia	↑	↑	Vasodilatation	Significant at $P_{A_{O_2}}$ <50mm Hg
Increased intrathoracic pressure	↓	↑	Cerebral venous outflow attenuation	Occurs with Valsalva maneuver
Pain/arousal	↑	↑	Vasodilatation	Avoid noxious stimuli and treat with analgesics
Volatile anesthetics	↑	↑	Vasodilatation	Alert anesthesia staff to intracranial pressure concerns
Seizures	↑	↑	Increased metabolism and Valsalva	Maintain low threshold for prophylaxis
Positive end-expiratory	↑	↑	Increased thoracic pressure	Variable effect on intracranial pressure

NA, not applicable.

TABLE 65-3 Classification of Cerebral Edema

Type	Location	Site	Blood-Brain Barrier	Probable Mechanism
Vasogenic	Extracellular	White	Disrupted	Increased vascular permeability
Cytotoxic	Intracellular	White or gray	Intact	Cellular failure
Ischemic	Intra- and extracellular	White and gray	Disrupted	Anoxia
Hydrostatic	Extracellular	White and gray	Disrupted	Increased blood pressure
Hydrocephalic	Extracellular	White	Intact	Impaired CSF outflow or absorption
Osmotic	Intra- and extracellular	White and gray	Intact	Relative plasma hypo-osmolality

CSF, cerebrospinal fluid; gray, gray matter, white, white matter.

must be adjusted based on the priorities dictated by each particular clinical situation. For example, when brain hyperemia is one of the causes of brain swelling, maintaining CPP at a lower level can be an important therapeutic strategy. On the other hand, maintaining CPP on the generous side can provide a useful margin of "reserve" when there are plateaus in ICP that can suddenly and unpredictably challenge brain perfusion. Furthermore, higher CPP should be tolerated in circumstances in which blood pressure augmentation is used in selected patients as a treatment strategy for raised ICP based on its ability to cause autoregulatory reflex vasoconstriction, reduced cerebral blood volume, and ICP lowering.

PLATEAU WAVES

One of the most feared and devastating complications of patients with intracranial hypertension and poor intracranial compliance are plateau waves (PW). PW are acute elevations in ICP, at times in the range of 50 to 100 mm Hg, in patients with reduced intracranial compliance. They can last from several minutes to more protracted durations in extreme cases. Resolution of a PW is often as abrupt as its occurrence. While there are many causes of PW, one important mechanism is generalized cerebral vasodilation from an autoregulatory response to a decrement in systemic blood pressure.[1] Other causes include processes that can cause an increase in CBF and/or cerebral blood volume, many of which are listed in Table 65-2. Independent of their mechanism, PW can be disabling or deadly. Since compromised CPP can play a role in the occurrence of the most severe PW, relative blood pressure lowering should be avoided and/or rapidly treated. Similarly, during a PW, maneuvers that accentuate CPP such as blood pressure augmentation will abort the process in many circumstances. Even if blood pressure augmentation does not abort the process, it can prevent cerebral ischemia until other treatment modalities can successfully lower the ICP.

Cerebral Edema, Mass Effect, and Brain Tissue Displacement

CEREBRAL EDEMA

Cerebral edema is defined as an increase in brain water content. The more classic categorization of cerebral edema by etiology differentiates that caused by cellular injury (cytotoxic edema) vs. breakdown of the blood-brain barrier (vasogenic edema).[3] Hydrocephalic edema, ischemic edema (a combination of cytotoxic and vasogenic edema), osmotic edema, and hydrostatic edema have also been characterized as distinct entities by some authors based on their mechanisms and the location of the edema fluid.[3–5] Table 65-3 lists various categories of cerebral edema along with some of their distinguishing characteristics.

Vasogenic edema is comprised of a plasma-derived protein-rich exudate due to an alteration in the blood-brain barrier. It occurs in both gray and white matter, but it tends to predominate within the white matter. Vasogenic edema occurs in variable degrees with brain tumors, abscesses, traumatic brain injury, meningitis, infarction, and hemorrhage. Corticosteroids are useful in reducing vasogenic edema, and their effect is most profound when vasogenic is the main edema etiology, as with brain tumors, and to a lesser degree abscesses.[6] Osmotic agents (see below) have no beneficial effect on the formation or extent of vasogenic edema.[3]

Cytotoxic edema is characterized as an intracellular swelling of neurons, glia, and endothelial cells with an accompanying reduction in the extracellular space. It occurs without a disruption in the blood-brain barrier and is likely due to cellular energy depletion. This results in the failure of the adenosine triphosphate–dependent sodium pump, with resultant accumulation of sodium and water within the cells.[2,3] It occurs in both gray and white matter. Hypoperfusion injuries are most classically associated with cytotoxic edema. They have also been described with Reye's syndrome, diabetic ketoacidosis, and water intoxication. Corticosteroids have no benefit in limiting cytotoxic edema, and osmotic agents have only limited benefit in reducing brain water from cytotoxic edema due to concurrent disruption in autoregulation with most of the processes that cause this form of swelling.[3]

Ischemic edema begins as a cytotoxic edema, and is followed to variable degrees by vasogenic edema.[4] When severe ischemia occurs and is followed by reperfusion, edema formation is biphasic: cells initially take up water and sodium from the extracellular space, but there is no net increase in brain water because there is no blood flow to serve as a source of water. Hours to days after the ischemic insult, the blood-brain barrier becomes disrupted, resulting in increased permeability and rapid accumulation of vasogenic edema. There is no therapy of demonstrated benefit for this process, and steroids have not been shown to be helpful, even though one aspect of this form of edema is vasogenic.[7]

Hydrocephalic edema is defined as an increase in brain fluid caused by the blockage of CSF flow pathways. It occurs in the periventricular white matter in association with hydrocephalus. In this situation the blood-brain barrier remains intact and the edema is in the extracellular space and of the same composition as CSF. Treatment consists of relieving the obstruction to CSF outflow or providing an accessory outflow pathway with a ventricular catheter or shunt.

In general, cerebral edema does not directly affect neural activity. Its main and most severe consequences are due to its mass effect and distortion of surrounding brain tissue. This can cause regional ischemia and result in the development of pressure gradients, leading to devastating brain tissue shifts.[8–10]

BRAIN TISSUE DISPLACEMENT AND HERNIATIONS

It is important to differentiate mass effect and brain tissue displacement (BTD) from intracranial hypertension. As should be apparent from Fig. 65-2, there can be a substantial amount of mass effect without an important global elevation in ICP, and the mass effect alone can cause brain damage through its regional effect on brain perfusion and/or brain tissue displacement (e.g. herniation). BTD is a distortion of brain anatomy, and depression of consciousness is one common sign associated with such distortion. However, depressed consciousness can be a late accompaniment to BTD. Autonomic changes such as increasing blood pressure and exaggeration of the respiratory sinus arrhythmia are also changes that can occur early with evolving BTD, and recognition of these signs can serve as an early warning of this life-threatening phenomenon.[11] The consequences of BTD depend on the extent and duration of the process, and its occurrence alone should not deter attempts to reverse the process.

A more thorough discussion of the clinical signs associated with the various herniation syndromes is covered in Chap. 67 but it is useful to note the relationship between horizontal brain displacement and depressed consciousness. With acute intracranial mass lesions, lateral displacement of posterior brain structures (diencephalon and brainstem) correlate with depression of consciousness. This can be practically quantified by measuring horizontal shift of the pineal gland on noncontrast CT scans. In the classic study describing this important relationship, horizontal shift of the pineal (from midline) by 0 to 3 mm correlated with alertness; 3 to 4 mm with drowsiness; 6 to 8 mm with stupor; and >8 mm with coma.[12] This has clinical applicability in determining the cause of depressed consciousness in individual patients. When the extent of horizontal shift does not readily explain a patient's level of consciousness, other potential etiologic factors should be considered.

The falx cerebri is the dural structure that sagitally divides the left and right hemispheres. The anterior cerebral arteries course inferiorly and parallel to the falx cerebri, and they supply blood flow to the anterior, inferior, and medial frontal lobes. When there is BTD anteriorly, it can lead to herniation of brain tissue under the falx cerebri, *subfalcine herniation*, thereby compressing the anterior cerebral arteries and placing their territory of supply (inferomedial frontal lobes and caudate nucleus) in jeopardy for infarction (Fig. 65-6). Furthermore, subfalcine herniation can lead to obstruction of the outflow of the lateral ventricles (foramina of Monro), leading to obstructive hydrocephalus (usually contralateral to the mass lesion). Since subfalcine herniation is an anterior process, it may not lead to depressed consciousness unless it is very extreme.

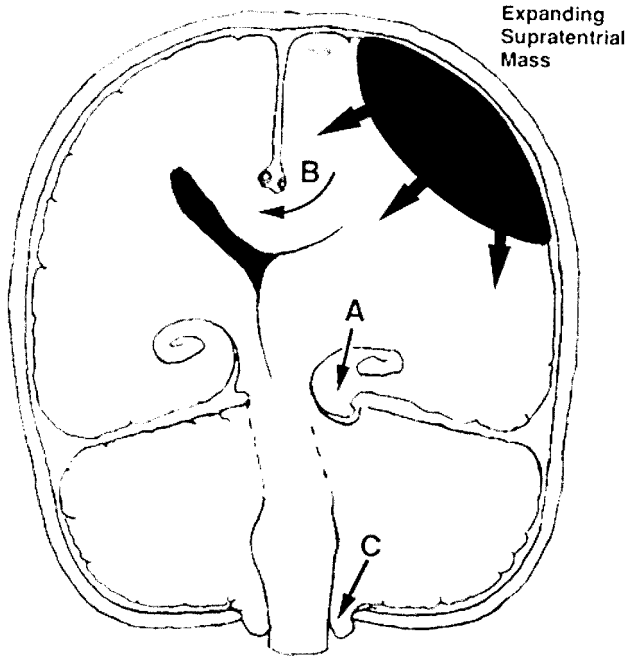

FIGURE 65-6 Shcematic representation of lateral brain tissue displacement from an expanding unilateral supratentorial mass. *A* illustrates the phenomenon of lateral transtentorial herniation. *B* illustrates the phenomenon of subfalcine herniation.

The tentorium cerebelli is the dural structure that divides the supratentorial from the infratentorial space. The space between the lateral midbrain and the medial border of the tentorium cerebelli is called the tentorial incisura, and the posteromedial temporal lobe sits just above this space. When an intracranial mass or brain swelling is posterior it can cause BTD (mainly the inferomedial temporal lobe) through the tentorial incisura, called *lateral transtentorial herniation*. This can lead to compression of the posterior cerebral arteries as they course around the midbrain, placing the brain tissue they supply (occipital lobes, medial temporal lobes, and thalami) in jeopardy for infarction (see Fig. 65-6).

Central transtentorial herniation (Fig. 65-7) is most common with global processes (e.g., global ischemia/infarction, meningitis, or fulminant hepatic failure) and classically occurs as the cerebral hemispheres and basal ganglia exert downward pressure, causing BTD through the tentorial incisura bilaterally. If persistent and extreme, it results in severe brainstem compression with resultant ischemia and hemorrhage, bilateral posterior cerebral artery compression with resultant ischemia/infarction in its territory of distribution, and CSF outflow obstruction with resultant hydrocephalus.

Posterior fossa lesions produce their effects through direct pressure on the medulla, or downward displacement of the cerebellar tonsils (*cerebellar tonsillar herniation*) and lower brainstem through the foramen magnum (see Fig. 65-7). Clinically, these patients develop early depressed consciousness, autonomic disturbances, altered respiratory patterns, and signs of brainstem dysfunction. This type and location of

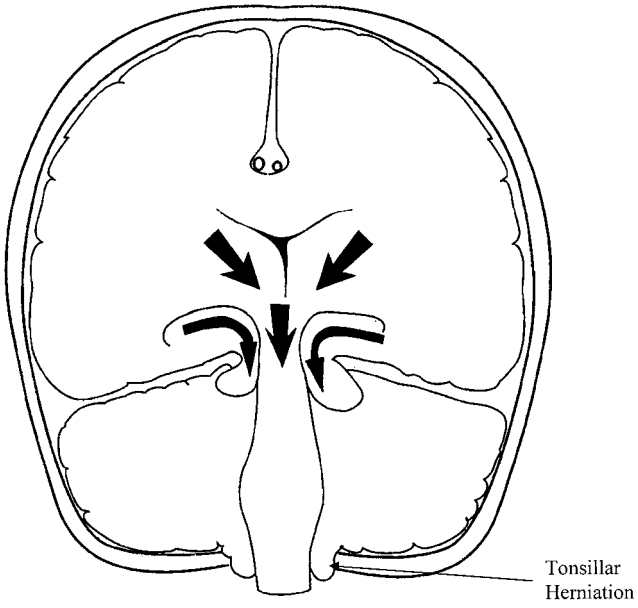

FIGURE 65-7 Schematic representation of central herniation.

BTD causes its damage by severe brainstem and upper cervical spinal cord compression, as well as obstruction of CSF outflow.

As already mentioned, BTD from regional brain swelling can occur even without important ICP elevations, and it can have devastating consequences. For an example, an acute middle cranial fossa process such as an acute temporal hematoma can cause lateral transtentorial herniation without a profound rise in ICP. As a result, successful management of BTD requires strategic consideration of its significance in individual cases. This is particularly important since the treatment for elevated ICP is not necessarily the same as it is for BTD. In fact, in certain cases ICP-directed medical treatments can accentuate BTD.

When a patient at high risk for brain swelling is encountered, a proactive approach to management should begin. This includes developing a monitoring strategy for early detection of the problem and planning the best management approach if it does occur. In at-risk patients without significant brain swelling, invasive ICP monitoring may not yet be appropriate. However, early insertion of an ICP monitor may be necessary if the risk of the problem is very high (e.g., fulminant hepatic failure), serial examination and/or imaging cannot be performed properly or readily (e.g., the intubated and/or heavily sedated patient), and/or the determination of the ICP will translate into important therapeutic changes.

Intracranial Pressure Monitors

It should be clear that the most rational and sophisticated management of intracranial hypertension should be based on continuous ICP and CPP monitoring. While active management of ICP guided by ICP monitoring has not shown a consistent benefit in outcome, it is difficult to study this well in humans for a variety of methodologic reasons. Most experienced physicians appreciate that ICP monitoring has value in

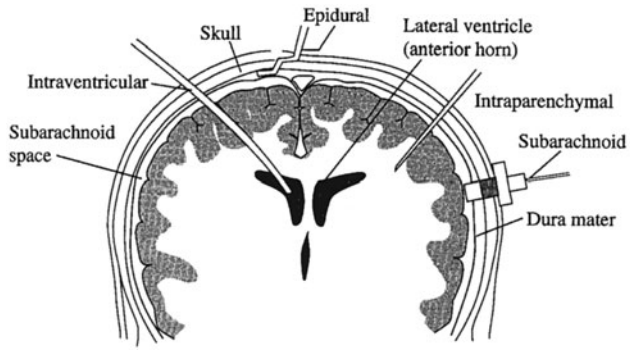

FIGURE 65-8 Various anatomic sites to monitor intracranial pressure.

properly selected patients. In particular, processes associated with life-threatening elevation of ICP, a rapidly expanding intracranial mass, or a disease in which ICP elevation is likely to be progressive and demand proactive preservation of CPP represent some generally accepted indications for monitor insertion.

ICP can be monitored from several intracranial sites (Fig. 65-8). The most commonly employed ICP monitoring devices are ventricular catheters and parenchymal monitors. Both can be readily placed at the bedside with a twist drill by neurosurgeons or experienced neurocritical care physicians. Ventricular catheters have been considered the gold standard for ICP monitoring, based on their reliability and ability to drain CSF, as an alternative for ICP control. It is the most invasive of alternatives, however, and it is associated with higher risks of infection, intracranial hemorrhage, and in our experience, seizures.

Ventricular catheters are ideally placed into a lateral ventricle. In general, right-sided (nondominant hemispheric) placement is usually preferred, since a bleeding complication from the insertion would be less likely to cause language disturbance from this location. Ventricular catheters are then connected to one of the many commercially available closed external drainage systems comprised of a drainage chamber, drainage bag, and an attached transducer. The height of the drainage chamber can be set to allow automatic drainage when the ICP rises above a designated level based on manometric concepts. A ruled measure on the drainage system facilitates accurate drainage chamber height adjustments and a stopcock system between the drainage catheter, drainage chamber, and transducer allows the physicians and nurses to choose between automatic CSF drainage and continuous ICP transduction.

One behavior we often encounter is the simultaneous transduction and recording of the ICP while the CSF chamber is set and open to automatically drain. In this situation, the ICP measure obtained is generally meaningless. For this reason, even when continuous CSF drainage to a determined level is the selected care strategy, the ICP should be transduced with the ventricular drain closed to drainage at least every 30 to 60 minutes for a 5- to 10-minute period with a recording of the ICP and CPP at the end of that time and determination if they are within the desired parameters. This is particularly important since CSF drainage to a set level does not always achieve maintenance of the ICP in the desired range. Some of the factors that limit ICP control by this method are imperfect

ventricular catheter placement, collapse of the ventricle in which the catheter is placed, bubbles within the catheter or fluid column from catheter to transducer, and catheter obstruction.

Several avoidable causes of complications from ventricular drains should be mentioned. Ventricular drains should never be connected to a pressure bag. This can be a deadly error. The only connections to the ventricular catheters should be the drainage system. The drainage system should not be detached or penetrated with a needle except by individuals experienced with the management of ventricular drains. Ventricular drains should be actively closed (via the intervening stopcock apparatus) whenever a change is being made in patient position (particularly involving raising the head of the bed) or during excessive coughing or active endotracheal suctioning. Failure to do this can lead to excessive CSF drainage with dangerous consequences. In addition, ventricular catheters are structurally fragile and they can be readily broken or displaced from their placement within the cranium. All personnel moving patients with ventricular drains (or all other types of ICP monitors or intracranial drains) should be aware of their presence and reminded to take special care in the process. When transporting patients, assigning one individual to have responsibility for the head and maintenance of the monitor integrity is advisable to avoid inadvertent mishaps.

An important risk of infection is associated with their use, and its occurrence in properly handled drains is most often related to its duration of use. Catheter exchange does not have a demonstrated benefit in reducing the infection risk when prolonged external drainage is required, and the practice expands the risk of iatrogenic complications from multiple insertions. Longer subcutaneous catheter tunneling and giving prophylactic antibiotics that target common skin flora likely decrease the risk of infection.[13,14] While newer antibiotic-coated catheters promise a lower risk of infection, their use is not presently an established care standard in most medical settings. Due to the risk of infection with ventricular catheters, each day a patient has one in place should be used to maximize benefit from its placement and/or begin the process necessary to determine the best timing for its safe removal. For a patient on subcutaneous heparin or heparinoids for deep vein thrombosis prophylaxis, it is our practice to hold two doses before removing the ventricular catheter to hypothetically decrease the risk of development of hematoma during removal.

Patients with ventricular drains should have their CSF analyzed at least every other day (we do so daily) for white blood count, protein, glucose, Gram stain, and bacterial cultures. A reduction in CSF glucose to <50% of the simultaneous serum glucose is ominous for infection, particularly when accompanied by a rising CSF white blood cell count, fever, nuchal rigidity, and worsened encephalopathy. However, nuchal rigidity, fever, and worsened encephalopathy can be later findings, and their absence should not delay a real suspicion for early CSF infection. Conversely, a mild elevation in CSF white blood count alone has limited specificity since many processes that require a ventricular drain (e.g., hemorrhage) cause a delayed inflammatory response. We have observed that relative lowering of serum sodium occurs in a respectable number of patients as an early sign of evolving CSF infection in those with ventricular drains. In general, compulsive concern about CSF infection should drive tight monitoring for its occurrence and early empiric treatment when suspected.

Parenchymal monitors offer some advantages over other systems in that they allow rapid and safe placement with accurate measurements and less risk of infection. The presently available parenchymal monitors employ either fiberoptic or strain gauge technology. Their tip can be placed anywhere within the skull, but their most common site is several millimeters into the brain parenchyma through a twist drill hole placed over the convexity. Since the maximal ICP is in the region of an intracranial mass, they are best placed ipsilateral to a mass lesion unless it is deemed unsafe based on the suspected etiology of the process.

Parenchymal monitors are often placed through and secured by a bolt screwed into the cranium after the placement of a small hole with a twist drill; avoidance of kinking is important for fiberoptic catheters since they can break if bent. The monitors based on strain gauge technology can be bent and allow a wider flexibility of placement methods and configurations relative to the fiberoptic systems. However, both technologies are widely used and the selection of monitor type is often based on institutional history and the personal experience and preferences of those who insert them. While ventricular catheters are fluid coupled systems that can be zeroed by nurses at the bedside, parenchymal monitors are zeroed prior to insertion and can only be rezeroed through removing and reinserting them. The advantages of parenchymal monitors over ventricular catheters are to some degree counterbalanced by drift in the ICP readings over time and the inability to drain CSF for ICP control.[15] While these various advantages and disadvantages are important considerations when selecting the ICP monitor type, the anatomy and physiology of the process requiring a monitor often dictate the best monitoring method.

As illustrated in Fig. 65-1, ICP monitors provide a ballistic waveform temporally associated with the systemic blood pressure. Certain characteristics about the ICP waveform can communicate important information about an evolving cerebral process, even when the ICP is not critically elevated. The ICP waveform is comprised of various smaller subwaves. The first two waves observed during systole are referred to as P1 and P2. Normally, each sequential subwave of the ICP waveform is smaller than the one before it, so P1 is usually greater than P2. However, as intracranial compliance decreases, P2 usually becomes greater than P1, even before the ICP is increased to abnormal levels. In addition, fluctuations in the baseline of the ICP waveform with breathing usually reflects a decrease in intracranial compliance, and it can occur and accentuate even before an elevation in ICP. These facts can be helpful in selected situations. For example, when a patient has fulminant hepatic failure, observation of these subtle changes in the ICP waveform can signal the evolution of brain swelling before it is clinically apparent or the ICP has increased.

As mentioned earlier in this chapter, ICP elevation can be imperfectly predicted through analysis of brain imaging studies, usually CT. When the ICP from any monitor type is either much lower or higher than expected clinically and based on imaging analysis, steps should be taken to determine the accuracy of the monitor. At times this requires rezeroing the monitor or replacement, at times even in a new position or location. Blind trust of monitoring information that is

significantly contrary to clinical expectations can lead to mismanagement and avoidable complications.

Management of Intracranial Pressure

While Chap. 93 presents much about the available conventional management strategies for intracranial hypertension when it complicates traumatic brain injury, they are similar for nontraumatic etiologies. The following sections will supplement the information provided in that chapter.

CONTROLLING AGGRAVATING FACTORS

Patient positioning is an important aspect of the care of patients with intracranial hypertension. Lateral head rotation, rotating neck movements, and restrictive devices around the neck (e.g., endotracheal tube neck straps) can compromise jugular venous drainage. The head should be kept in the neutral forward position. Sometimes towel rolls placed on both sides of the head can be useful in maintaining the neutral position. Head elevation lowers ICP by enhancing CSF drainage and maximizing cerebral venous output. CSF and cerebral venous blood are maximally displaced with severe intracranial hypertension, challenging the benefits of head elevation in these patients. The logical approach is to individualize the ideal head and neck position based on clinical observation of the patient and ICP monitoring, when available. When ICP monitoring is not available, head elevations of 30° to 40° allows the most consistent reduction in ICP.[16]

Fevers should be treated aggressively because body temperature elevations increase ICP by increasing cerebral metabolism, cerebral blood flow, and cerebral edema.[17,18] Acetaminophen should be administered (assuming normal hepatic function) and a diligent search made for treatable infection. There should be a low threshold for using empiric antibiotics for the most likely source, even though centrally mediated fevers are often considered in the differential diagnosis in many of these patients. In those resistant to acetaminophen, nonsteroidal anti-inflammatory drugs (e.g., ibuprofen) should be considered when bleeding is not a primary concern. Cooling blankets can be useful, but control of shivering is necessary since it can aggravate intracranial hypertension. Newer intravascular cooling devices provide an exciting alternative to more rapidly and consistently achieve fever control in this brittle patient group.[19] Independent of the cooling method, if shivering complicates its use, it can be controlled with various medications such as meperidine, parenteral sedatives, and neuromuscular paralysis. The key point about fever control in patients with brain swelling and/or intracranial hypertension is that it is essential and requires close follow-up to assure that it is brought under control in a timely fashion.

Coughing and straining against the ventilator increases intrathoracic pressure and can reduce the venous outflow from the intracranial cavity. This can lead to elevation of the ICP. As a result, strategies to decrease these ventilator- or airway-provoked problems can be essential to the management of patients with brittle intracranial hypertension. Some of these strategies include repositioning of the endotracheal tube, inhaled nebulizations that can serve to decrease coughing, ventilator adjustments adapted to the patient's respiratory behavior, or the administration of sedation or nondepolarizing neuromuscular blockers.

Positive end-expiratory pressure (PEEP) will increase ICP only when mean airway pressures are increased, causing transmission to the mediastinum. When pulmonary compliance is reduced as occurs in acute respiratory distress syndrome or pneumonia, the effect of PEEP on ICP is attenuated. It seems fortuitous that the conditions for which higher PEEP levels are often used diminish its deleterious impact on ICP. Probably more important than the effect of PEEP on ICP is its potential effect to decrease cardiac output and blood pressure, with their deleterious impact on cerebral perfusion. In general, the presence of an ICP monitor shifts the concerns about the impact of PEEP from the theoretical to the empiric.

Frequent zealous monitoring of systemic blood pressure is a cornerstone of ICP management in patients with intracranial hypertension. Hypotension will directly cause cerebral vasodilation and increase ICP. A treatment plan should be orchestrated with pressor agents and isotonic fluids at the bedside to allow rapid intervention at the first observation of significant relative blood pressure lowering. However, when cerebral autoregulatory mechanisms are impaired, hypertension may lead to pathologic increases in regional CBF, worsened brain swelling, and aggravation of intracranial hypertension.

Pain and arousal can cause elevated ICP by increasing CBF. As a result, patients with life-threatening intracranial hypertension should generally receive sedatives and analgesics, even if their use risks clouding of the neurological exam. The present availability of short-acting sedatives and analgesics and the ready availability of neuroimaging have simplified the historical reluctance to utilize these classes of agents in the neurologically ill.

Seizures increase ICP by increasing cerebral metabolism and CBF by Valsalva. If the patient is deemed to be at risk, anticonvulsants should be administered promptly. Given the deleterious consequences of seizures and the severity of illness of these patients, drugs that can be parenterally administered with known effectiveness as monotherapy should be used (phenytoin, phenobarbital, or valproic acid). Since hypotension can accompany the administration of phenytoin and phenobarbital, close monitoring of the blood pressure is critical, with preparedness to detect any relative blood pressure lowering and promptly intervene.

MECHANICAL VENTILATION AND HYPERVENTILATION

Hyperventilation induces a rapid and effective reduction in ICP through vasoconstriction induced by hypocapnia-associated CSF alkalosis.[20] The duration of the ICP reduction is variable, but in general, the ICP returns to baseline within hours after commencing hyperventilation, due to normalization of the CSF alkalosis through compensatory adjustments in the bicarbonate buffering systems in the brain and vascular smooth muscle.

When hyperventilation is required for urgent management, it can be accomplished with an ambu mask or mechanical ventilation. Providing a 10- to 12-mL/kg tidal volume at a rate of 14 to 20 breaths/min usually achieves substantial reduction in the partial pressure of carbon dioxide (P_{CO_2}). The ideal P_{CO_2} is variable depending on the clinical situation

and the individual patient's response. One of the most controversial questions is whether excessive hyperventilation can cause cerebral ischemia through extreme cerebral vasoconstriction—a phenomenon suggested by several studies in traumatic brain-injured patients.[21] The most recent work on the subject in patients with severe traumatic brain injury utilizing positron emission tomography demonstrated that hyperventilation can be safely performed (without consequent cerebral ischemia) to a P_{CO_2} of 30 mm Hg, and perhaps to <25 mm Hg in selected patients.[22] Furthermore, it has been shown that hyperoxia can improve oxygen delivery to the brain during hyperventilation.[23]

The potential benefits of hyperventilation must be balanced against some of its potential deleterious consequences, including but not limited to diminished cardiac filling pressures with resultant hypotension, decreased myocardial oxygen supply with an increase in myocardial demand, elevation in mean airway pressure leading to accentuation of intracranial hypertension, electrolyte disturbances (e.g., alkalosis, hypokalemia, and hyperchloremia), and cardiac arrhythmias.[24]

Because hyperventilation is the most rapid way to reduce ICP, it is best kept as a back-up strategy for emergent ICP elevations. A modest goal of 30 mm Hg seems safest with the present state of our knowledge, and preoxygenation may add a layer of protection that is potentially beneficial for ischemia deriving from hyperventilation. Once other ICP-lowering strategies are instituted and controlling ICP and CPP adequately, hyperventilation should be lifted. Gradual withdrawal of hyperventilation is necessary to avoid rebound elevations in ICP as the P_{CO_2} is normalized. We recommend not exceeding P_{CO_2} increases of 2 to 3 mm Hg per hour. When hyperventilation is used for a prolonged period, jugular venous oxygen saturation can be used to monitor for the feared complication of cerebral ischemia due to this maneuver. Inadvertent fluctuations in the P_{CO_2} due to variable ventilation is an important and avoidable cause of ICP plateaus. This is commonly a problem that occurs during patient transport. We recommend using transport ventilators for patients with brittle intracranial hypertension to minimize variations in P_{CO_2} during transport.

Tris(hydroxymethyl)aminomethane (THAM) is a buffer than can be used to correct acidotic states, and it can be used at times to assist in the management of patients with intracranial hypertension. The advantage of THAM is that it alkalinizes without changing plasma sodium or P_{CO_2}. THAM may have a role in limiting rebound ICP elevation during the withdrawal of hyperventilation, or prolonging the benefit of hyperventilation in some patients.[25] It is administered intravenously at a dose of 1 mL/kg per hour. Some of the complications associated with its use include local skin irritation and necrosis, hypoglycemia, and respiratory depression.

CEREBROSPINAL FLUID DRAINAGE

CSF drainage with a ventricular catheter is the primary treatment for hydrocephalus, and it can be a useful treatment strategy for intraventricular hemorrhage, through both CSF drainage and providing access for administration of intraventricular thrombolytic agents. The management of CSF drainage and ventricular catheters is discussed in the section on ICP monitoring in this chapter. While CSF drainage through lumbar puncture should generally be avoided in patients with intracranial hypertension, it is a mainstay of treatment for patients with pseudotumor cerebri (benign intracranial hypertension).

MANNITOL

Osmotherapy is directed at increasing plasma osmolality, establishing an osmotic gradient across the relatively impermeable blood-brain barrier. This favors a net loss of brain water, thereby increasing brain compliance and decreasing ICP. In addition, mannitol, the most widely used osmotic agent, can improve cerebral perfusion through transient hypervolemia and hemodilution, leading to autoregulatory cerebral vasoconstriction, decreased cerebral blood volume, and lower ICP.[26–28] It also can increase CSF absorption.[29] However, most mechanisms of brain injury lead to disruption of the blood-brain barrier and a loss of normal autoregulation. As a result, osmotic agents are less effective in injured brain regions. This is an important consideration when strategizing management in individual patients with unilateral mass lesions and BTD.

Mannitol is typically used in a 20% solution. Its ICP-lowering effect is dose-dependent, and it appears to be maximal with a 1 g/kg dose infused over 30 minutes.[30,31]. The duration of benefit from this high-dose infusion is limited to several hours, and terminal dose-interval ICP elevations beyond the pretreatment baseline are common. Smaller doses of 0.25 to 0.5 g/kg over longer infusion periods (30 to 60 minutes) can be associated with less profound and more lasting ICP benefits within the usual 4-hour dosing interval when multidosing regimens are used. The reduction in ICP after mannitol use should be apparent within 15 minutes, and failure of a response to mannitol is considered ominous, but not hopeless, in our experience.

The goal of osmotherapy should be plasma hyperosmolality with maintenance of adequate intravascular volume. In general, the target osmolality should be in the 300 to 310 mOsm/L range with adequate maintenance intravenous fluid administration. Normal saline should be used for maintenance and replacement fluids. Hypotonic fluids are contraindicated and should be avoided because water accumulation by hyperosomolar brain can aggravate brain swelling and intracranial hypertension. The development of moderate hypernatremia should be expected and tolerated, because administration of hypotonic fluids to correct the hypernatremia is counterproductive and potentially dangerous.

Single doses of mannitol are often effective in reducing ICP and improving intracranial compliance temporarily. When single doses are used, monitoring of the plasma osmolality is unimportant. The benefit of multidosing regimens is more controversial. This is due to some experimental evidence that it can accentuate regional brain water when the blood-brain barrier is disrupted.[32–34] In addition, its disproportionate impact on uninjured brain (relative to injured brain) can potentially accentuate BTD through enhancement of regional intracranial pressure differentials.[35] Nonetheless, mannitol is an effective agent for rapidly reducing ICP in an emergency setting, and it can buy critical time to temporarily stabilize the patient while other treatment strategies are being arranged and commenced.

Rapid diuresis before administration of adequate amounts of replacement fluids can occur in some patients after receiving mannitol. This can lead to systemic hypotension,

emphasizing the need for preparedness when using this treatment modality. We always have pressor agents and replacement fluids readily available at the bedside in patients with increased ICP. Other important complications include electrolyte disturbances (hypernatremia and hypokalemia), prerenal azotemia, and congestive heart failure. Sometimes, pretreatment with a dose of furosemide can circumvent some of the complications of the transient expansion of intravascular volume that occurs immediately after administration of mannitol.

HYPERTONIC SALINE

Hypertonic saline has been used with renewed enthusiasm in patients with brain swelling and intracranial hypertension.[36–39] The osmolality of 3% saline (1026 mOsm/L) is similar to that of 20% mannitol (1375 mOsm/L). The osmolality is much higher with other solutions, such as 7.5% saline (2565 mOsm/L) and 23.4% saline (8008 mOsm/L). Variable formulations of hypertonic saline have been used with different-size boluses (up to 75 mL) with occasional benefit, most recently reported in some patients with traumatic brain injury and cerebral infarction refractory to other modalities. Its use can be associated with the expected complications of hypernatremia, hypokalemia, hyperchloremia, and congestive heart failure. It is an underrecognized part of the ICP-lowering armamentarium. Its use can be a particularly well-suited treatment in patients with volume depletion or renal failure.

LOOP DIURETICS

Loop diuretics such as furosemide can reduce ICP and have been reported in selected series to reduce ICP alone or when used in conjunction with osmotic agents.[40] Diuretics exert their effect through an osmotic gradient caused by a mild diuresis, reduction in CSF formation, and reduction in brain water. They provide another alternative when mild reductions in ICP are desired. However, like osmotic agents, they can produce volume and electrolyte depletion, requiring proper treatment and surveillance for these complications.

CORTICOSTEROIDS

Corticosteroids have been shown to reduce the vasogenic edema associated with brain tumors and abscesses, but their benefit with other processes that can cause intracranial hypertension is less clear.[41] There is generally no benefit consistently demonstrated with intracerebral hemorrhage.[42–45] While it may have a theoretical advantage in certain stages of infarction-related edema, it has not been of demonstrated benefit and has been associated with worse outcomes.[46–49] Dexamethasone is the most commonly used corticosteroid for vasogenic cerebral edema, and there is a wide range of dosing alternatives. We typically use 16 to 24 mg/day of dexamethasone in two to four divided doses in extreme situations. It can be given parenterally or enterally. Higher doses can be safely used for brief periods of time with less clear benefit over more conventional dosing. Potential side effects include gastrointestinal bleeding, hyperglycemia, disturbance in nitrogen metabolism, wound breakdown and poor healing, sleep disturbances, and behavioral disturbances. The hyperglycemia is of particular concern and requires aggressive intervention due to its increasingly recognized negative impact on outcome with most of the processes that can cause intracranial hypertension.

HYPOTHERMIA

There has been renewed interest in moderate hypothermia (32° to 34°C) as an adjunctive therapy for patients with intracranial hypertension. It can lower ICP and improve CPP in some patients, and it theoretically limits hypoperfusion brain injury due to its neuroprotective properties. However, it has not yet been demonstrated to achieve outcome benefit in scientifically valid clinical trials. In spite of the lack of scientific evidence for its benefit to date, those experienced in the management of patients with the problem have used hypothermia with success in selected patients; it is considered a useful "time-buying" trick in refractory cases.

The most classic method for hypothermia induction is with cooling blankets placed above and below the patient with the variable addition of ice-water lavage. However, newer intravascular cooling devices are increasingly available but not yet widely applied.[19] When hypothermia is used, shivering can be a complicating factor when the body temperature gets below 36°C. Since shivering can increase ICP, its occurrence should be anticipated and sedatives and/or narcotics should be rapidly administered and titrated to effect to limit its severity. Rebound intracranial hypertension is an important concern during the rewarming process.[50] When induced hypothermia is terminated, patients should be allowed to passively rewarm with close attention to slow down its pace if the patient develops a rebound increase in ICP. The most common complications of induced hypothermia include pneumonia, cardiac arrhythmia, and coagulopathy.[51]

BARBITURATE COMA

The use of barbiturate coma is an advanced treatment measure aimed at preventing patient demise from uncontrollable intracranial hypertension. While it has been used with variable degrees of success for the treatment of elevated ICP from a variety of causes, there is little evidence that it improves outcome.[52–56] In addition, it is a costly undertaking from an economic and physiologic perspective.

Some of its ICP-lowering benefit may be derived from depression of cerebral metabolism and reduction of CBF in normal areas of brain, with shunting of blood to ischemic areas. In addition, it may limit oxidative damage to lipid membranes and scavenge free radicals, reduce formation of vasogenic edema, attenuate fatty acid release, reduce intracellular calcium, and of course limit external stimuli from causing patient arousal, with the concomitant increases in CBF and cerebral blood volume.[48,54]

The induction of barbiturate coma is a weighty undertaking and demands experience to assure its safe and proper use. The agents most commonly used are thiopental and pentobarbital. Systemic hypotension, complications of prolonged immobility and mechanical ventilation, and immune suppression are the most common deleterious effects of barbiturate therapy. In addition, the need for more frequent transport and invasive line complications are other risks that should not be underestimated in their potential impact.

Pentobarbital coma requires a loading dose of 10 to 30 mg/kg. In our experience, it is best to administer the

pentobarbital in small boluses of 100 to 200 mg every 10 to 20 minutes as tolerated from a blood pressure standpoint. This should be done under electroencephalographic (EEG) monitoring. While each bolus will briefly achieve either a burst-suppression pattern or a flat EEG, usually a more full loading dose is necessary to achieve a sustained effect. A continuous drip of 1 to 3 mg/kg per hour is usually necessary to maintain the desired depth of anesthesia. Optimizing depth of barbiturate therapy should be guided by EEG in these cases, usually titrating a continuous drip to achieve a burst suppression pattern in the 3 to 6 bursts/min frequency. The EEG can be monitored continuously or hourly, and ICU nurses can be taught to interpret burst-suppression frequency as part of the bedside monitoring.

In patients under prolonged barbiturate anesthesia, various strategies must be used to compensate for the loss of ability to do a neurologic examination, and can include continued evoked potential monitoring, serial imaging studies, and numerous other devices that are increasingly becoming available that can track a number of combinations of intracranial factors. The only neurologic exam that is useful in these patients is pupillary dilation, since the barbiturates usually cause bilaterally small pupils. When they become large it can be an ominous sign. However, an important phenomenon has been described in patients under pentobarbital coma: an accentuated ciliospinal reflex that manifests as pupils that are large (>6 mm) and seemingly unreactive to light, usually after a nursing maneuver such as patient turning. It can be misinterpreted as a catastrophic clinical change leading to unnecessary scans. Usually, when it occurs the pupils will react with a sustained intense light stimulus, and it spontaneously abates within minutes after it begins.[57]

As already mentioned, intensive hemodynamic monitoring is required with barbiturate coma. Since volume depletion increases the risk of hypotension from barbiturates, special attention should focus on maintaining intravascular volume with the guidance of invasive monitoring in most cases. The risk of infection and the concurrent disruption in the usual response to infection—fever—requires systematic surveillance for infection with regular cultures (at least every other day) of the endotracheal secretions, urine, and blood drawn through invasive lines.

Hypothermia is common with barbiturates, and in fact we often use barbiturates to facilitate the induction of hypothermia as a treatment modality. While permissive moderate hypothermia is recommended when using barbiturates, extreme hypothermia (<32°C) is associated with numerous complications and should be avoided.

The long half-life of pentobarbital (approximately 24 hours) allows a slow recovery, even when abruptly stopped. Shivering is common during the recovery period from barbiturate anesthesia and may require treatment with narcotics or short-acting sedatives. We prefer to use propofol for this complication. In addition, chaotic EEG patterns are common during this period and often are misinterpreted as status epilepticus.

SURGICAL PROCEDURES

Surgical procedures can be a very important part of the management of patients with intracranial mass lesions, with or without intracranial hypertension. The two primary types of procedures are removal of the primary problem (e.g., hematoma evacuation, neoplasm excision, etc), or creating more room to accommodate an intracranial mass and deter the deleterious effects of BTD by removing skull bone and opening the overlying dura ipsilateral to the mass through hemicraniectomy and durotomy. The application of these surgical alternatives and their timing is heuristic, based on numerous clinical factors, some of which will be discussed in the following section.

General Disease-Specific Comments

While we cannot provide an exhaustive delineation of management recommendations for all causes of intracranial hypertension, in this section we address some disease-specific recommendations for some of the causes most commonly encountered in a medical critical care setting, and not covered in other chapters of this textbook.

HYPERTENSIVE ENCEPHALOPATHY AND ECLAMPSIA

Hypertensive encephalopathy occurs when the blood pressure is elevated beyond autoregulatory thresholds. This leads to an increase in extracellular water, predominantly by hydrostatic mechanisms. In addition, there can be variable degrees of parenchymal hemorrhage, most often localized in the end-arterial border zones along the frontal and posterior parietal convexities (see Fig. 65-9). This is an important reversible cause of brain swelling in which the extent of brain swelling does not necessarily correlate with neuronal injury. Blood pressure lowering is obviously the focus of treatment

FIGURE 65-9 An unenhanced CT of the brain in a patient with the complications of hypertensive encephalopathy. The arrows are pointing to the end-arterial border zones with changes consistent with ischemic and hemorrhagic changes.

of the brain swelling with this disease. However, blood pressure lowering does not achieve immediate resolution of the cerebral edema. So, if the patient already has important intracranial hypertension and diminished intracranial compliance (an estimate guided by clinical and imaging parameters), ICP monitoring is necessary to guide the pace and degree of blood pressure lowering so as to not compromise cerebral perfusion. Any type of ICP monitor can be used, but most often global cerebral edema is associated with a loss of CSF spaces and compression of the ventricles. When that occurs, the ventricular catheters are more difficult to place, their readings are less consistently accurate, and they do not allow enough CSF removal to justify their higher risk. We find parenchymal monitors to be a more rational choice in these cases.

While the mechanism of brain swelling from eclampsia is similar but not exactly the same as hypertensive encephalopathy, the management of intracranial hypertension complicating eclampsia is generally the same. However, the management of eclampsia-associated intracranial hypertension has the added priority of urgent fetal delivery. The presence and suspected severity of intracranial hypertension should be considered when determining the method of delivery and anesthesia. Cesarean section is the preferred mode of delivery in almost all cases. Spinal anesthesia should be avoided due to the risk of precipitating central herniation with CSF drainage. General anesthesia should include close attention to the blood pressure to avoid degrees of lowering that could compromise cerebral perfusion. In general, successful management of intracranial hypertension is best guided with an ICP monitor, and easy and predominantly uncomplicated bedside placement of parenchymal monitors provides little justification for not using them.

Both hypertensive encephalopathy and eclampsia can be associated with ominous clinical presentations and imaging studies. Neither midposition unreactive pupils with extensor posturing nor CT changes suggestive of bilateral end-arterial border zone infarctions with hemorrhage should deter aggressive and optimistic management of such patients. In our experience, both scenarios can potentially lead to good outcomes when treated promptly and aggressively.

FULMINANT HEPATIC FAILURE

Cerebral edema complicates fulminant hepatic failure (FHF) in up to 50% of cases.[58] Similarly to hypertensive encephalopathy and eclampsia, the brain swelling from FHF is global and usually symmetric (Fig. 65-10). Its etiology is thought to be predominantly glial swelling from intracellular glutamine accumulation, but a variety of other mechanisms have been shown to play a variable role in its development.[59–62]

The development of brain swelling from FHF should be anticipated in all patients. Early detection of cerebral edema is imperative in order to pace its development and proactively manage its complications. However, bedside clinical evaluation does not allow its accurate detection due to the worsening hepatic encephalopathy concurrently developing in FHF patients. For example, stage IV encephalopathy patients frequently have diffuse hyperreflexia and increased motor tone with decerebrate posturing in the absence of any cerebral edema. It is not possible to differentiate uncomplicated hepatic encephalopathy from FHF-associated cerebral edema in patients with higher-stage encephalopathy. However, significant cerebral edema most often occurs in patients with higher-stage encephalopathy (III or IV). CT scans should be done in all patients with FHF, particularly those with stage III or IV encephalopathy, to rule out intracerebral hemorrhage and to estimate the presence and severity of cerebral edema. In our experience, patients in the early stages of cerebral edema have their CT scans misread as normal by inexperienced physicians. In addition, the presence of intracranial hypertension has been reported in FHF patients with normal CT scans.[63,64]

FIGURE 65-10 Unenhanced CT of the brain of a patient with cerebral edema from fulminant hepatic failure. Note the attenuation of CFS spaces and the global nature of the swelling.

Once a patient drifts into the higher stages of encephalopathy with FHF, significant cerebral edema and cerebral hypoperfusion can be occurring and be undetectable in the absence of ICP monitoring. So an ICP monitor should be placed prior to stage IV encephalopathy in FHF patients. Often the frequent and severe coagulopathy observed in these patients justifiably demands thoughtful reflection on the risks and benefits of the intervention. However, in our experience, even with coagulopathy, bedside parenchymal monitors can be inserted without significant complications. We prefer to use a parenchymal monitor in the nondominant standard location. We insert it with the administration of 2 units of fresh frozen plasma (FFP) before, 1 unit of FFP during, and 2 units of FFP after the procedure. This should be carried out in collaboration with other caregivers, so invasive line insertions can be coordinated while the FFP infusions are being administered for ICP monitor insertion. Small pediatric patients require a different strategy to minimize bleeding during invasive procedures. While some neuroclinicians prefer to insert ventriculostomies in patients with potential intracranial hypertension (to allow CSF drainage as one therapeutic maneuver to treat plateaus in ICP), this modality carries a higher risk of

hemorrhagic complications and the ventricles collapse (not allowing CSF drainage) in patients with consequential cerebral edema from FHF.

Once an ICP monitor is in place, management should focus on maintenance of adequate cerebral perfusion pressure. Given the likelihood of impaired autoregulation in FHF patients, extremes of blood pressure should be avoided. The patient's blood pressure should be maintained in the mid-normal range for the previously normotensive patient. In addition, normal intravascular volume should be maintained, and a state of readiness for acute response to any systemic hypotension is critical.

In patients with an elevation in ICP and poor intracranial compliance, ICP lowering may be necessary, particularly those with tenuous CPP (<60 mm Hg). Mannitol can be useful in some patients with FHF.[65,66] It should mainly be considered in nonoliguric/anuric patients without significant hypernatremia. We generally use 0.25- to 0.5-g/kg aliquots of mannitol infused over a 20 to 30 minute period. The maintenance intravenous fluid should be isotonic with serum; normal saline is a good choice, with added 5% dextrose and/or potassium, depending on the specific clinical situation.

When using osmotic agents with FHF, the patient is already in quite a hyperosmolar state, so we do not titrate the mannitol to a specific serum osmolality. Rather, it is used intermittently to achieve the desired affect of improved intracranial compliance and ICP lowering. It may lose its effectiveness after several dosings, and so other therapeutic strategies should be considered concurrently. As is typical with the use of an osmotic diuretic, volume depletion can be an important complication with resultant hypotension. Maintaining euvolemia is ideal and requires thoughtful attention to fluid balance and intermittent replacement. Administration of hypotonic fluids such as 50% dextrose without electrolytes (commonly used in FHF in some settings) should be avoided.

Most patients with FHF will develop spontaneous hyperventilation, and this can be related to an increase in circulating free fatty acids and ammonia. While the institution of hyperventilation can be beneficial in lowering ICP acutely, it has no prolonged benefit in FHF as is true with most etiologies of cerebral edema and intracranial hypertension.[67]

Induced hypothermia can be a favorable strategy for both neuroprotection and deterring the development of cerebral edema, but further research is required to clarify its preventive role in this population. A recent study supported the promising role of moderate hypothermia for lowering ICP in patients with FHF.[68] Seven consecutive FHF patients with intracranial hypertension refractory to osmotherapy and ultrafiltration were studied. Moderate hypothermia to 32° to 33°C was achieved with cooling blankets. The mean ICP before and after cooling was 45 mm Hg and 16 mm Hg, respectively. The mean CPP before and after cooling was 45 mm Hg and 70 mm Hg, respectively. The mean CBF before and after cooling was 103 mL/100 g per minute and 44 mL/100 g per minute, respectively.

We induce hypothermia in patients with refractory intracranial hypertension prior to significant cerebral hypoperfusion events. We strive for a body temperature of 32° to 34°C with the use of cooling blankets above and below the patient. Proactive strategies to allow early detection and treatment of fever should be an important part of the care plan for these patients, independent of whether hypothermia is used.

Like most other therapeutic strategies for ICP lowering in FHF, there have been few reliable clinical studies to guide the indications for and use of barbiturate therapy. It has been shown to have an impact on controlling ICP in Reye's syndrome.[69] It probably would be best considered in patients with either refractory intracranial hypertension and/or those with oliguria or anuria. One study of 13 FHF patients with acute renal failure and refractory intracranial hypertension administered thiopental slowly to a maximum of 500 mg to achieve an ICP <20 mm Hg, CPP >50 mm Hg, or until hypotension developed.[70] In each case, the ICP was reduced with the administration of anywhere between 185 and 500 mg (median = 250 mg) of thiopental over a 15-minute infusion period. In eight patients, a constant infusion was required (50 to 250 mg/h) to maintain adequate ICP and CPP. Given the small number of patients and unclearly defined end points, it is difficult to assess the true benefit of the ICP-lowering accomplishments of this strategy. However, unique to FHF, impaired barbiturate metabolism and clearance often precludes the need for a maintenance infusion after the desired effect is accomplished using a loading dose. See the section on treatment recommendations for the management of barbiturate coma elsewhere in this chapter.

GLOBAL CEREBRAL HYPOPERFUSION

The potential benefits of hypothermia on outcome in patients after cardiac arrest is beyond the scope of this chapter and is discussed in Chap. 16. However, when intracranial hypertension does occur as a result of global cerebral hypoperfusion it is a reflection of diffuse neuronal injury. As a result, when secondary intracranial hypertension occurs in this situation, it signals widespread injury and poor neurologic outcome. We strongly discourage aggressive management of this complication in these patients.

LARGE SUPRATENTORIAL HEMISPHERIC INFARCTIONS

While large supratentorial cerebral hemispheric infarctions (LHI) are not common (accounting for less than 10% of all ischemic strokes), they are among the most disabling and deadly. As a result, physicians involved with the management of these patients must be equipped with a contemporary management strategy to minimize disability and mortality in patients in whom survival is desired as the appropriate medical care focus in keeping with the patient's life philosophy. LHI defines a group of patients with disabling strokes, variable degrees of collateral circulation, and brain swelling and life-threatening deterioration from brain herniations and intracranial hypertension.

In addition to the usual priorities of general systemic care (e.g., respiratory, cardiovascular, and nutritional), and general stroke care (e.g., blood sugar control, fever management, and deep vein thrombosis prophylaxis), patients who suffer a LHI should receive thoughtful application of medical treatments and monitoring for optimizing brain perfusion (or avoiding cerebral hypoperfusion), minimizing brain swelling, and limiting brain tissue shifts. There should be early discussion with the patient, family, and surrogate regarding the patient's life priorities as they may apply to practical life-and-death decision making and procedures in the context of the disabling stroke event; a strategic monitoring plan

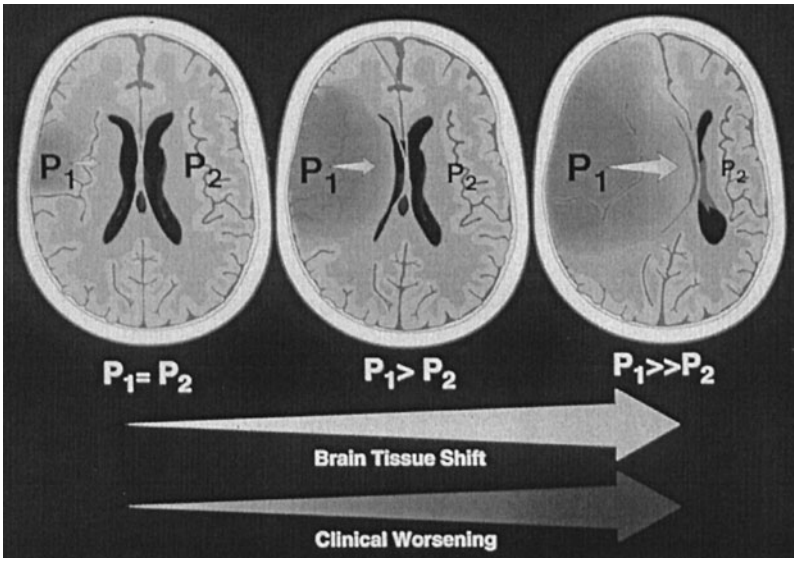

FIGURE 65-11 A schematic diagram demonstrating the concept of evolving pressure differentials with regional brain swelling from large supratentorial hemispheric infarction. Note that the clinical worsening in its early states correlates with brain tissue displacement.

for early detection of deterioration and brain swelling; and engagement of other professionals necessary for the timely application of treatments necessary in the case of significant worsening (e.g., neurosurgeons).

There have been a variety of clinical predictors studied and identified to correlate with fatal outcome from LHI. Some of these factors include high National Institutes of Health Stroke Scale scores, early drowsiness, and early nausea and vomiting.[71–75] The various identified prognostic factors are generally associated with larger infarctions, and not surprisingly, CT and magnetic resonance imaging (MRI) analyses have confirmed a correlation between infarction volume and outcome from supratentorial infarctions.[76,77] While new evolving approaches to predicting brain swelling in patients with LHI are exciting, and our wisdom on their best application will evolve over time, at this point all acute patients with LHI should be considered at risk for severe, life-threatening deterioration. This is supported by the preliminary results of the recently completed HeADDFIRST study, a prospective randomized pilot clinical trial on LHI and surgical decompression. In that study, 65% of the registered patients with at least complete MCA territory infarction (based on acute clinical and CT imaging criteria) developed life-threatening brain swelling and tissue shifts (≥7 mm of anteroseptal shift or ≥4 mm of pineal shift from midline) within 96 hours of stroke onset.[78]

While patients with acute ischemic stroke are a heterogeneous group with variable baseline blood pressure and stroke mechanisms, those patients with LHI more likely have large-vessel narrowing or occlusion, autoregulatory dysfunction, and/or are vitally dependent on collateral circulation. At this point in our understanding, blood pressure lowering should only be done with great reluctance in patients with LHI, with clearly prioritized goals, thoughtful agent selection (to be discussed), and vigilant monitoring to avoid overtreatment. Depending on the extent of brain swelling and the degree of blood pressure lowering desired, it may be rational and appropriate to consider parenchymal ICP or CBF monitoring to avoid exacerbating regional cerebral hypoperfusion. In most cases, we recommend maintenance of the blood pressure at least in the high-normal range with LHI in order to maintain collateral perfusion, since cerebral edema progressively challenges this vital brain-preserving source of cerebral blood flow.

It has been shown that the majority of patients who deteriorate from LHI do not have important ICP elevations or cerebral hypoperfusion as an early contributing factor to their worsening.[35] Their clinical deterioration is mainly due to BTD from evolving brain pressure differentials caused by regional cerebral edema (Fig. 65-11). Indiscriminant administration of mannitol or contralateral ventricular drain insertion and CSF drainage (the ipsilateral ventricle is usually collapsed) can lead to accentuation of the pressure differentials that drive BTD and augment the clinical worsening. However, early ICP elevation, when it does occur with LHI, stratifies the patient to higher risk of death from brain swelling, and younger patients are at higher risk for such early elevations.[35,79] It has not been shown that ICP-focused management (whether or not under the guidance of ICP monitoring) improves the outcome in LHI patients, but it has not been well-studied with appropriate standardized medical treatment protocols. In fact, some of the more widely quoted studies on LHI with aggressive ICP lowering–focused treatment strategies report some of the most dismal outcomes for this disease.[80,81]

We use ICP monitoring in young patients with LHI who already have shown evidence of significant regional brain swelling and compression of ipsilateral cerebrospinal fluid spaces. These patients have declining intracranial compliance and are at risk for ICP plateau waves. The presence of early ICP elevation in the young patient should put everyone on the alert for the escalating risk of death in that individual patient, and this can be factored into decisions regarding treatment escalation and the possible application and timing of surgical decompression. In addition, ICP monitoring in such patients may assist with strategies (positioning and medical) to improve intracranial compliance, and attempt to avoid catastrophic cerebral hypoperfusion during transport and various nursing maneuvers. When ICP monitoring is employed, we recommend using an ipsilateral (to the infarction) parenchymal monitor, since it will be the region of greatest ICP elevation. The ipsilateral placement is because the ICP will be maximal in the region of dominant brain swelling, and the

ventricle ipsilateral to the infarction collapses as swelling progresses, with the various disadvantages mentioned earlier in this section.

When ICP is elevated, medical management alone carries a high mortality. However, with respect to ICP reduction, the application of conventional ICP-lowering strategies can be very helpful early in the course of management. These include: optimizing head and body positioning, avoidance of behaviors that elevate ICP in patients with poor cerebral compliance (fighting the ventilator, agitation, and seizures), tight fever control, hyperventilation, and the administration of mannitol. We rarely administer multidose regimens of mannitol in LHI patients, because its misapplication and overuse has hypothetical dangers in these patients. When ICP elevations are considered important to medically treat in patients with LHI, use of hypertonic saline can also be an effective strategy.

The theme of fluid management in patients with LHI should be avoidance of volume depletion. There is no role for dehydration as a management strategy to limit the development of brain edema. Isotonic fluids (0.9% saline) are generally recommended without clear scientific evidence for their unique advantage for patients with LHI. When patients have been exposed to hyperosomolar treatments, the use of only isotonic fluids is critical, as the hyperosmolar brain may be at risk for worsened cerebral edema when exposed to hypotonic fluids. There is some evidence of a possible benefit of albumin infusions in experimental animals with LHI from MCA occlusion, but this has not been widely applied in humans.[82,83]

The potential for surgical decompression as a method to limit infarct volume and mortality from brain swelling after stroke has been demonstrated in experimental animals and with more recently promising human work.[78,81,84–86] Unfortunately, the selection of patients for this procedure and its best timing are still unclear; the decision making for this step requires a delicate balance between the patient's medical condition, the pace and anticipated severity of clinical progression, the prognosis, premorbid patient wishes, and various ethical and psychosocial issues.

Chapter 66

NEUROMUSCULAR DISEASES LEADING TO RESPIRATORY FAILURE

WILLIAM A. MARINELLI
JAMES W. LEATHERMAN

KEY POINTS

- *Neuromuscular disorders (NMDs) in critical care may be divided into those that precipitate admission to the ICU and those that arise during ICU management; the latter are much more common and significantly influence the pace and extent of recovery from critical illness.*
- *The maximal inspiratory pressure (MIP), maximal expiratory pressure (MEP), vital capacity (VC), and qualitative judgment of oropharyngeal function are the most important parameters to follow in patients with NMDs.*
- *An effective cough is unlikely with a MEP <40 cm H_2O or a VC <30 mL/kg.*
- *Sleep-related deterioration in hypoventilation and hypoxemia is common in patients with respiratory muscle impairment.*
- *Many patients with Guillain-Barré syndrome or myasthenia gravis of sufficient severity to precipitate ICU admission will benefit from treatment with plasmapheresis or intravenous immunoglobulin.*
- *Muscle biopsy is useful in the diagnosis of polymyositis, mitochondrial disease, and other myopathies, and should be considered when electrophysiologic and other testing does not offer a clear diagnosis of peripheral neuropathy or myoneural junction diseases.*
- *Critical illness myopathy and neuropathy should be considered in all patients with protracted critical illness, particularly when multisystem organ failure has been present; avoidance of paralytics, appropriate correction of the metabolic milieu, early physical therapy, and measures to shorten duration of mechanical ventilation may help ameliorate the impact of these acquired NMDs.*

Neuromuscular Disorders in Critical Care

Neuromuscular weakness may result from disorders involving the peripheral nerves, neuromuscular transmission, or skeletal muscles.[1–3] Neuromuscular disorders encountered in the critical care setting may be divided into those that result in ICU admission and those that are acquired during treatment of critical illness. In the first part of this chapter we will address neuromuscular disorders that lead to ICU admission, focusing on Guillain-Barré syndrome (GBS), myasthenia gravis (MG), and dermatomyositis/polymyositis (DM/PM), and concluding with a brief discussion of mitochondrial disease, a recently recognized metabolic myopathy. Subsequently, neuromuscular weakness that is acquired after admission to the ICU will be reviewed. However, before discussing the various causes of neuromuscular weakness, a brief review of respiratory muscle impairment is appropriate, since respiratory failure is the most common reason that patients with a primary neuromuscular disorder are admitted to an ICU.

Although respiratory muscle impairment may occasionally develop rapidly, more often its onset is gradual. Diaphragmatic weakness may be initially manifested by orthopnea or sleep disruption due to nocturnal hypoventilation, without prominent dyspnea.[2] Because there may be a paucity of symptoms, objective testing is necessary. Maximal inspiratory pressure (MIP), maximum expiratory pressure (MEP), vital capacity (VC), and an assessment of oropharyngeal function are the most important respiratory muscle parameters to follow,[4–6] and should be measured frequently in hospitalized patients who have an evolving neuromuscular disorder, with careful attention to serial changes.[7] The most sensitive parameters of respiratory muscle strength are the MIP and MEP. Measurement of MIP and MEP requires a maximal effort at residual volume (MIP) and total lung capacity (MEP), using a bedside manometer fitted with a mouthpiece. Normal values for MIP and MEP are approximately –70 cm H_2O and 100 cm H_2O, respectively, for women, and approximately –100 cm H_2O and 150 cm H_2O, respectively, for men.[5] An effective cough is unlikely when the MEP is <40 cm H_2O, and there is risk of hypercapnia when the MIP is less negative than –20 cm H_2O. In the early stages of respiratory muscle weakness, arterial blood gas and VC measurements are commonly normal. The normal VC in adults is approximately 50 mL/kg, and elimination of secretions with coughing is impaired when the VC declines to <30 mL/kg. Serial VC measurements that decline to <15 to 20 mL/kg increase the likelihood that ventilatory assistance will be necessary.[1,8] Sleep-related deterioration in hypoventilation and hypoxemia are common in patients with respiratory muscle impairment, particularly during rapid eye movement sleep.[2] When the supine VC is <60% of the predicted value, or the MIP is less negative than –34 cm H_2O, sleep-disordered breathing is common.[9]

Bulbar muscle impairment may significantly increase the risk for aspiration-related respiratory failure. Unfortunately, bulbar muscle impairment is commonly unrecognized, resulting in increased risk of morbidity and mortality.[8] Intact musculature involving the mouth, pharynx, palate, tongue, and larynx are necessary for effective oropharyngeal function.[10] The assessment of oropharyngeal function is primarily based on clinical observation, and early consultation with an experienced speech pathologist is recommended to assess the patient's ability to perform the complex and coordinated action of swallowing.

Neuromuscular Disorders Leading to Intensive Care Unit Admission

Many patients who present to the ICU as a result of an underlying neuromuscular disorder will have a previously defined diagnosis. However, when a patient presents with recent onset of acute or subacute bilateral muscle weakness, a broad differential diagnosis must be considered (Table 66-1). An initial approach to differential diagnosis is based on the patient's history and a careful neurologic exam that attempts

TABLE 66-1 Causes of Acute and Subacute Bilateral Weakness

Syndrome/Level of Abnormality	Representative Disorders
Basilar artery occlusion	Embolic, thrombotic, vasculitic
Myelopathy	Cord compression (e.g., abscess, neoplasm, disc herniation, trauma)
	Transverse myelitis
Central nervous system infections	Poliomyelitis
	West Nile virus
Central nervous system toxins	Neurotoxic fish poisoning
Peripheral nerve disorders	Guillain-Barré syndrome
	Diphtheria
	Heavy metal toxicity
	Vasculitic neuropathy
Disorders of neuromuscular transmission	Myasthenia gravis
	Eaton-Lambert syndrome
	Botulism
	Tick paralysis
	Organophosphate poisoning
	Penicillamine toxicity
Myopathic disorders	Dermatomyositis/polymyositis
	Metabolic myopathy (e.g., mitochondrial disease)
	Toxic myopathy (e.g., corticosteroid injury, rhabdomyolysis)
Electrolyte disorders	Periodic paralysis
	Hypophosphatemia
	Hypokalemia

to define the principal level of abnormality (Table 66-2). Additional diagnostic tests such as nerve conduction studies and an electromyogram (EMG) are often needed to more reliably establish the underlying disorder. Although lesions involving the upper and lower motor neuron may occasionally be responsible for new-onset weakness that necessitates ICU admission, the latter is more often due to diseases that effect the peripheral nerves (e.g., GBS), neuromuscular junction (e.g., MG), or muscles (e.g., PM/DM).

GUILLAIN-BARRÉ SYNDROME

Guillain-Barré syndrome is an acute inflammatory demyelinating polyneuropathy that most often presents with ascending symmetrical weakness.[1,8,11] Weakness typically evolves over days to weeks, although a subset of patients experience a rapid decline in function over hours. Excluding trauma, GBS is the most common cause for acute flaccid paralysis in previously healthy people.[1] The ascending weakness is accompanied by depressed or absent reflexes. Sensory involvement is common, and many patients experience peripheral paresthesias as their initial symptom. In addition, an aching discomfort in the lower back and legs is common in the early phase of the syndrome. Autonomic dysfunction is common in patients with GBS, resulting in brady- or tachyarrhythmias, orthostatic hypotension, hypertension, or abnormal sweating.[8] Although bowel and bladder function are usually preserved,[12] ileus and bladder dysfunction can occur. Variants from the usual GBS presentation may be encountered, including

TABLE 66-2 Differential Diagnosis of Neuromuscular Disorders Leading to ICU Admission

Level of Abnormality	Presentation	Representative Disorders	Nerve Conduction	Electromyography
Upper motor neuron	Weakness	Cortical	Normal	Normal
	Spasticity	Subcortical		
	Hyperreflexia	Brain stem		
	Sensory/autonomic changes	Spinal cord lesions		
Lower motor neuron	Weakness	Poliomyelitis	Normal	Denervation
	Flaccidity	Post-polio syndrome

the Miller-Fischer variant, with ataxia, ophthalmoparesis, and areflexia.[1,11,13]

For unclear reasons, GBS appears to be more common in young adults and in the elderly. A preceding infectious syndrome with respiratory or gastrointestinal symptoms, usually occurring 1 to 4 weeks prior to the onset of neurologic symptoms, has been noted in approximately two thirds of patients.[1,11,14] *Campylobacter jejuni* and cytomegalovirus infections are the most commonly identified triggers for GBS.[11,14] However, a diverse and seemingly unrelated group of triggers have been identified, including infections, vaccination, general surgery, epidural anesthesia, thrombolytic agents, drugs, neoplastic disease (Hodgkin's disease), sarcoidosis, and connective tissue diseases.[1,8]

A diagnosis of GBS is based on the clinical presentation and electrodiagnostic studies compatible with a demyelinating polyneuropathy.[1,11] Elevated cerebrospinal fluid protein levels are commonly noted after the first week of symptoms and may be associated with a limited mononuclear pleocytosis (<10 cells/cm^3). Diagnoses other than GBS should be more aggressively considered if: (1) reflexes remain intact despite weakness (areflexia is present in ~90% of patients when weakness is fully developed); (2) the distribution of weakness is highly asymmetric; (3) fever is present during the initial presentation; or (4) the electrodiagnostic features are not indicative of an acquired demyelinating polyneuropathy.[1] A rapidly progressive spinal lesion is the most important potentially reversible process to be excluded in a patient who presents with ascending weakness.[12]

Respiratory failure occurs at the time of initial presentation in 10% of patients, and eventually develops in up to 43% of patients during the course of their disease.[1,15] All aspects of respiratory muscle function—inspiratory strength, expiratory strength, and upper airway protection—may be impaired.[8,16] Progression to respiratory failure was predicted in one retrospective study by the presence of a VC <20 mL/kg, MIP less negative than –30 cm H_2O, and MEP <40 cm H_2O ("20/30/40 rule").[17] Inability to cough markedly increases the risk for intubation.[15] In addition, multivariate analyses have also indicated that a time from onset to admission of less than 7 days, inability to stand, and inability to lift the head or elbows are all associated with an increased risk for mechanical ventilation.[15] The risk of intubation is increased by the dysautonomia of GBS, because of an exaggeration of the hypotensive response to sedative agents, and a markedly increased risk of arrhythmias, most often bradyarrhythmias.[8,10]

Guillain-Barré syndrome is a monophasic illness with a fairly predictable natural history; at least 90% of patients reach the nadir of their neuromuscular impairment by 4 weeks.[8] Most patients recover from their illness, with two thirds experiencing mild residual deficits, and 10% to 20% of patients recovering completely.[1] The remaining 3% to 8% of patients will die as a result of pneumonia, acute respiratory distress syndrome, sepsis, pulmonary emboli, and cardiac arrest.[1,18,19] Deaths appear to be more common in the elderly, particularly in patients with pre-existing pulmonary disease.[18] In addition, the mortality and morbidity of GBS is strongly associated with the need for and duration of mechanical ventilation. The mortality rate of patients with GBS who require mechanical ventilation may be as high as 20%.[20] Mechanical ventilation for more than 2 weeks has been found to be the strongest predictor of major morbidity by multivariate analysis, with lower respiratory tract infection being the most common complication.[21]

Treatment of GBS involves either plasmapheresis or intravenous immune globulin (IVIg). Plasma exchange was demonstrated to improve strength and reduce the incidence of respiratory failure in three multicenter trials conducted in the 1980s.[22–24] Two exchanges may be needed in patients with mild impairment, whereas four exchanges are optimal in those with more severe impairment.[25] Albumin is as effective as fresh frozen plasma as a replacement fluid during plasma exchange, and is associated with fewer adverse reactions.[26] IVIg has also been shown to be an effective therapy for GBS.[27] The mechanism by which IVIg benefits patients with GBS is not fully defined, but neutralizing neuromuscular blocking antibodies by a dose-dependent process appears likely.[28] A randomized, multicenter, international trial compared plasma exchange, IVIg, or plasma exchange followed by IVIg in 379 GBS patients who had marked weakness and whose symptoms had been present for 14 days or less.[21] There were no differences among the three treatment groups with regard to either the duration of mechanical ventilation or functional outcome 4 weeks after therapy. It was therefore concluded that IVIg and plasmapheresis are equally effective therapies, and that their combined use offered no additional benefit.[21] Because of its ease of administration and acceptable side effect profile, IVIg is often preferred. In addition, IVIg may be superior to plasmapheresis in patients with *Campylobacter jejuni* infections and antibodies to peripheral nerve gangliosides.[2,29] Screening for IgA deficiency is recommended prior to treatment with IVIg to reduce the risk of anaphylaxis during infusion. Although frequently used in the past, corticosteroids have not been shown to be beneficial in patients with GBS.[1,11,13]

MYASTHENIA GRAVIS

Myasthenia gravis is an acquired autoimmune disorder of neuromuscular junction transmission characterized by muscle weakness, progressive muscle fatigue with repetitive use, and improvement in strength after rest.[3,30] The incidence of MG is highest in younger women or older men. Generalized weakness with fatigability involving the trunk and extremity muscles is noted in approximately 85% of patients and may be the dominant complaint.[3] Ocular muscle involvement, including ptosis and diplopia, are common at presentation. Bulbar muscle impairment results in dysphonia and difficulty with chewing and swallowing. The immunopathogenesis of MG has been well defined, with identification of autoantibodies that bind to the acetylcholine receptor resulting in a significant reduction in the number of available receptors at the neuromuscular junction, thereby impairing neuromuscular transmission.[3]

Although isolated involvement of the respiratory muscles may occur, respiratory muscle impairment typically presents along with generalized muscle weakness.[31,32] Upper airway obstruction with abnormal vocal cord adduction during inspiration has also been described.[33] Lower respiratory muscle impairment is evidenced by a significant reduction in VC, MIP, and MEP. Approximately 15% to 27% of patients experience "myasthenic crises," a rapid and severe decline in respiratory muscle function that is associated with a mortality of

4% to 13%.[34–36] Multiple triggers for myasthenic crises have been identified, including infection, electrolyte abnormalities, withdrawal of anticholinesterase drugs, and the use of drugs that impair neuromuscular transmission, with infection being the most common identifiable precipitating factor. However, a trigger for the myasthenic crisis cannot be found in nearly a third of patients.[35] In a retrospective study of 73 episodes of myasthenic crises progressing to intubation, 50% of patients were extubated within 2 weeks, and the median ICU and hospital stays were 14 and 35 days, respectively.[35] Three independent predictors of prolonged intubation were identified in this study: (1) preintubation serum bicarbonate ≥30 mg/dL; (2) peak VC <25 mL/kg on day 1 to 6 postintubation; and, (3) age >50 years. Cardiac dysrhythmias are a common cause of death in patients with myasthenic crises, and continuous cardiac rhythm monitoring is strongly recommended.

In patients with a compatible clinical presentation, the diagnosis of MG centers on three principal studies: (1) a positive anticholinesterase test (rapid and transient improvement in strength after administration of edrophonium); (2) presence of acetylcholine receptor antibodies in the serum; and (3) electrophysiologic studies that are indicative of a disorder of the neuromuscular junction, with a decremental response in compound action potentials to repetitive nerve stimulation.[3] Acetylcholine receptor–binding antibodies are identified in approximately 88% to 93% of patients with generalized MG, and in approximately 71% of patients with symptoms limited to ocular muscle involvement.[37] One diagnostic strategy that has been recommended begins with an edrophonium test, followed by a repetitive nerve stimulation test and measurement of acetylcholine receptor antibodies.[3] Single-fiber EMG may be obtained if the diagnosis remains undefined.

Conditions associated with MG include thymic hyperplasia or thymoma, and autoimmune conditions such as rheumatoid arthritis, lupus, thyroiditis, and Graves disease.[3] Thyroid function testing should be obtained in all patients with MG. Thymic abnormalities are present in the majority of patients with MG, with thymic hyperplasia being most common and thymoma identified in 10% to 12% of patients.[3] The association with thymic abnormalities has led to the use of a chest computed tomographic (CT) or magnetic resonance imaging (MRI) scan as a screening tool in patients with MG.

The treatment of MG includes anticholinesterase medications to increase the concentration of acetylcholine available for receptor binding, immunosuppressive therapy, and thymectomy.[3,38,39] The first line of therapy is use of an anticholinesterase agent, most commonly pyridostigmine. Respiratory muscle function improves in approximately 50% of patients treated with anticholinesterase medications.[2,40] Muscarinic side effects include abdominal cramping with frequent defecation, increased urinary frequency, bronchospasm, bradycardia, fasciculations, increased oral secretions, and excessive lacrimation. Less commonly, these agents produce a cholinergic crisis, with increased bulbar and lower respiratory muscle weakness during the early phase of treatment. The clinical manifestations of a cholinergic crisis may overlap with those of a myasthenic crisis, making a clear distinction difficult; withholding anticholinesterase medications for 4 to 10 days may be necessary.

Most patients respond to anticholinesterase therapy, but their response is usually incomplete and symptomatic relapse during therapy is common. Unfortunately, increasing the dose of drug often leads to significant side effects.[3,38,39] Thus the majority of patients require additional therapy with immunosuppressive agents. Corticosteroid use results in a remission or marked improvement in approximately 75% of patients with MG, and these are the most commonly used agents. Azathioprine has a more delayed onset of action, usually requiring at least 3 months of therapy, thereby limiting its use as a primary agent for initial therapy. Cyclosporine reduces acetylcholine receptor antibody production, but toxicity limits its use. Cyclophosphamide has also been beneficial in patients who were refractory to other agents, but toxicity remains a significant concern.

Plasma exchange and IVIg are commonly used for intensive short-term therapy.[41,42] Plasma exchange removes acetylcholine receptor antibodies rapidly, commonly resulting in an improvement in strength within several days. Typically, 2- to 4-liter exchanges are performed two to three times per week over a 10- to 14-day period. IVIg also results in a rapid improvement in most patients. Plasma exchange should be considered as an initial intervention in patients with myasthenic crisis, with IVIg reserved for possible use after a course of plasma exchange.[38]

Thymectomy has been associated with clinical improvement and remission in patients with MG, and is generally recommended for patients with thymomas between the ages of puberty and approximately 60 years.[3,38,43] However, adequate prospective studies demonstrating a clear benefit from thymectomy are unavailable. Because postoperative decline in ventilatory function is common, thymectomy should not be performed as an emergency procedure in patients with significantly impaired ventilatory function (VC <2 L). Plasma exchange should be considered preoperatively in patients with significant ventilatory impairment.

Alternative therapeutic strategies should be considered in MG patients who are refractory to conventional therapy. For example, high-dose cyclophosphamide followed by granulocyte colony-stimulating factor therapy was reported to be effective in three patients with MG refractory to conventional immunosuppressive therapy, plasma exchange, and thymectomy.[44] In addition, lymphocyte depletion therapy with the human-mouse chimeric monoclonal antibody rituximab was associated with clinical improvement and reduction in the acetylcholine receptor antibody titer in a patient who developed MG after bone marrow transplantation.[45,46]

Disorders of neuromuscular transmission that may mimic MG include Eaton-Lambert syndrome (usually associated with small-cell carcinoma), botulism, tick paralysis, organophosphate toxicity, and a myasthenic-like syndrome induced by penicillamine.[3] Botulism results in a toxin-mediated irreversible inhibition of neuromuscular transmission, resulting in an acute symmetric descending paralysis beginning with bulbar impairment.[2,47] The early bulbar involvement of botulism may initially be confused with the Miller-Fischer variant of GBS, which predominantly involves the bulbar musculature.[1,13] Botulism is most commonly associated with food-borne and intestinal sources. Wound-related illness may also occur, especially in parenteral heroin users. Bioterroism remains a serious concern as another potential source of botulism. Tick paralysis typically affects children

more than adults and is manifested by an ascending paresis or paralysis caused by a tick-borne neurotoxin.[48] A high index of clinical suspicion is critical for establishing a diagnosis of tick paralysis. Treatment of tick paralysis is centered on a careful physical exam (including scalp, ears, axilla, buttocks, perianal skin, and labia) to identify and remove all ticks and their body parts, along with close observation and supportive care. In North American tick paralysis, significant improvement in neuromuscular strength usually occurs within several hours of tick identification and removal.

DERMATOMYOSITIS AND POLYMYOSITIS

Dermatomyositis and polymyositis are idiopathic inflammatory disorders which usually present with progressive symmetrical muscle weakness over several months.[49,50] Less commonly, there is an acute presentation with rapidly evolving muscle weakness. Of the major muscle groups, the shoulder and pelvic girdle muscles are most often affected. Neck flexion muscles are weakened in up to 50% of patients, but facial muscles are usually spared. Pharyngeal muscle involvement may present with dysphonia or dysphagia. Myalgias and muscle tenderness occur in up to 50% of patients. An immune-mediated mechanism is strongly supported by the association of PM/DM with other autoimmune diseases, and by the frequent presence of autoantibodies in serum.[50]

Diagnostic criteria for PM/DM include the presence of symmetrical proximal muscle weakness, elevated skeletal muscle enzymes, and compatible findings on electromyography and skeletal muscle biopsy.[49–51] Characteristic dermatologic findings are present in dermatomyositis, including heliotropic changes of the eyelids and Gottron sign, a characteristic symmetric erythematous rash over the extensor surfaces of metacarpophalangeal, interphalangeal, elbow, and knee joints. Creatine phosphokinase (CK) elevation is the most consistent indicator of muscle inflammation. However, other muscle enzymes (aldolase, aspartate aminotransferase, alanine aminotransferase, and lactate dehydrogenase) may also be elevated. Electromyography typically reveals features of a generalized myopathic disorder, but findings may be normal in 10% to 15% of patients. Muscle biopsy is the most definitive test, demonstrating variable degrees of type I and II fiber necrosis and inflammation.

Respiratory and cardiovascular complications of DM/PM are the main concerns in the ICU.[49,52,53] Respiratory complications with DM/PM include respiratory muscle weakness, interstitial lung disease, pneumonia resulting from aspiration or immunosuppression, and drug-induced lung disease. The presence of dysphagia suggests pharyngeal muscle dysfunction, which greatly increases the risk for aspiration, the most commonly reported pulmonary complication of DM/PM. Respiratory muscle dysfunction with inspiratory and expiratory muscle involvement has been reported in up to one third of patients. Interstitial lung disease has also been identified in nearly one third of patients with DM/PM,[54] with nonspecific interstitial pneumonitis being the most common underlying histopathologic lesion.[55] Typical findings on high-resolution chest CT include reticular and ground-glass opacities in the lower lung fields, variable presence of consolidation in the lung periphery, and the absence of a fibrotic honeycomb-like appearance.[56] An analysis of 70 patients with DM/PM and diffuse interstitial lung disease found a musculoskeletal presentation in 36%, pulmonary presentation in 30%, and a combination of musculoskeletal and pulmonary symptoms in 21%.[55] When presentation is with pulmonary disease alone, treatment with corticosteroids may suppress or obscure musculoskeletal symptoms, thereby delaying the diagnosis of DM/PM for weeks to years.[55] Cardiac features include tachyarrhythmias, conduction abnormalities, myocarditis, or heart failure with a dilated cardiomyopathy. Chronic pulmonary hypertension may result from several mechanisms, including underlying cardiomyopathy, chronic hypoxia associated with either chronic hypercapnic respiratory failure or interstitial lung disease, or the development of a primary pulmonary hypertension–like syndrome.

Most patients with DM/PM respond to corticosteroids, with normalization in muscle enzymes by 4 to 6 weeks and improvement in muscle strength within 2 to 3 months.[38,49,50] Therapy with corticosteroids is usually initiated at a dosage of 0.5 to 1.5 mg/kg prednisone, with gradual tapering after a complete response has been demonstrated. However, the clinical course of DM/PM is quite variable, ranging from a relatively indolent course to a relentlessly progressive process that is unresponsive to therapy. Symptom duration of greater than 6 months before diagnosis, severe symptoms, and the presence of dysphagia are clinical predictors of poor outcome in DM/PM.[57,58]

Alternative immunosuppressive agents, including methotrexate, azathioprine, or cyclophosphamide, should be considered in patients with poor prognostic markers or a limited response to corticosteroids.[58] These immunosuppressive agents, particularly methotrexate or azathioprine, may also be used if there is corticosteroid intolerance and for long-term maintenance therapy. Alternative therapy with IVIg, cyclosporine, tacrolimus, alkylating agents, and tumor necrosis factor inhibitors has been used for patients whose symptoms are unresponsive to standard treatment. In one study of 35 patients with PM who were refractory to therapy with prednisone and at least one additional immunosuppressive agent, significant improvement in strength was noted in 71% of patients after treatment with IVIg; all patients had a significant reduction in CK values.[59] IVIg has also been reported to be beneficial in the management of life-threatening esophageal involvement in DM/PM.[60] Pharyngeal muscle involvement in DM/PM usually responds to corticosteroid therapy. However, surgical division of the cricopharyngeal muscle may be necessary for severe cricopharyngeal achalasia that is refractory to immunosuppressive therapy. Cardiac complications are managed with appropriate pharmacologic therapy and insertion of a pacemaker-defibrillator should be considered in the event of serious conduction abnormalities or ventricular dysrhythmias.

MITOCHONDRIAL DISEASE

Mitochondrial disease may present with diverse manifestations in the critical care setting, including respiratory muscle impairment. This increasingly recognized metabolic myopathy appears to result from acquired mutations of genes coding for critical proteins in glycolysis, fatty acid oxidation, or oxidative phosphorylation.[61–63] Clues to the possible presence of this interesting disorder include unexplained dyspnea progressing to respiratory failure, sedative-related respiratory failure out of proportion to the sedative dose administered,

respiratory failure with persistent unexplained lactic acidosis, prolonged paralysis following use of neuromuscular blockade, and unexplained difficulty with weaning from mechanical ventilation.[61,64,65] An elevation in the lactate:pyruvate ratio of greater than 20 is frequently present in patients with abnormalities in glycolysis. Reduction in carnitine levels may be identified in patients with a disorder in fatty acid oxidation, reflecting abnormalities in carnitine palmitoyl transferase enzymes. Muscle biopsies are usually diagnostic, demonstrating characteristic findings on light and electron microscopy. Care for patients with these unique disorders is primarily supportive, including treatment of precipitating infections and withholding sedatives and neuromuscular blockers. A diet high in carbohydrates may be of benefit in patients with abnormal carnitine palmitoyl transferase enzyme function.

Neuromuscular Disorders Acquired in the Intensive Care Unit

Acquired neuromuscular disorders have become increasingly recognized over the last two decades as a major cause of morbidity related to critical illness. Currently, acquired disorders are a much more common cause of severe generalized weakness in the ICU than are primary neuromuscular disorders.[66] Although ICU-acquired muscle weakness is usually reversible, respiratory muscle involvement may lead to prolonged mechanical ventilation and delayed weaning. Once patients are successfully extubated, they often require prolonged physical rehabilitation and may be unable to perform basic activities of daily living for weeks to months.[67] Of greater concern, recent studies have documented the persistence of significant weakness up to several years after hospital discharge, indicating that in some cases severe ICU-acquired weakness may result in permanent disability.[68–71] Without question, the medical, economic, and psychosocial costs of ICU-acquired neuromuscular weakness represent a major problem in the current practice of critical care medicine.

CAUSES OF INTENSIVE CARE UNIT–ACQUIRED WEAKNESS

Three basic causes of ICU-acquired neuromuscular weakness have been identified: (1) persistent blockade of the neuromuscular junction after discontinuing a neuromuscular blocking agent (NMBA), (2) a sensorimotor axonal polyneuropathy, and (3) an acute myopathy.[72–74] Although the clinical setting and physical examination may be of some help in elucidating the underlying cause of muscle weakness, in most cases diagnosis has been made by electrophysiologic studies, sometimes supplemented by biopsy of muscle or nerve. As will be discussed below, elucidation of the underlying cause of weakness is not always easy, and combined disorders of muscle and nerve may occur.[75]

PERSISTENT NEUROMUSCULAR JUNCTION BLOCKADE

Residual blockade of the neuromuscular junction after discontinuation of an NMBA is rarely responsible for persistent neuromuscular weakness in the ICU.[66] One possible exception is the use of vecuronium in patients with renal failure, in which case accumulation of the active metabolite 3-desacetylvecuronium may result in paralysis that is prolonged for several days.[74] If residual neuromuscular paralysis is a consideration, a repetitive nerve stimulation protocol should be performed to see if there is a progressive decrement in the compound muscle action potential (CMAP) that would indicate residual blockade at the neuromuscular junction.

CRITICAL ILLNESS POLYNEUROPATHY

In the 1980s Bolton and colleagues reported on a group of critically ill patients who developed generalized weakness after several weeks in the ICU.[72,76] Affected patients, most of whom had underlying sepsis, often underwent neurologic evaluation because of difficulty in weaning from mechanical ventilation or because of diffuse limb weakness. Distal muscles were often affected most prominently, but cranial nerves did not appear to be involved. Sensory examination was difficult to perform, but deep tendon reflexes were either reduced or absent in most cases.[72,76] Electrophysiologic evaluation with electroneurography (ENG) and EMG suggested that weakness was due to an axonal sensorimotor polyneuropathy. Key findings included a reduction in the CMAP in response to stimulation of motor nerves, often accompanied by a decrease in the sensory action potential (SAP) when sensory nerves were stimulated. The EMG revealed spontaneous fibrillations and positive sharp waves that were attributed to denervation. Survivors had improvement in their electrophysiologic studies over several months that paralleled clinical recovery. Autopsy findings included grouped fiber atrophy in muscle and axonal degeneration with loss of myelin in nerves, with distal segments most severely affected.[76] Neither muscle nor nerve showed inflammation.[76]

Numerous additional studies dealing with critical illness polyneuropathy have been published in the last 20 years, and the reported findings have been similar to those initially described, including the diffuse distribution of weakness (other than the facial muscles), frequent difficulties with weaning, and occurrence in the setting of sepsis and systemic inflammatory response syndrome (SIRS), often with multiorgan dysfunction. The pathogenetic mechanism of acquired polyneuropathy in critical illness is not understood. It has been suggested that the peripheral nervous system may be one of the many target sites for tissue damage in the setting of sepsis, and that lack of effective vascular autoregulation and increased microvascular permeability could result in neural edema and capillary occlusion, thereby damaging peripheral nerves.[72,77] As with other types of organ dysfunction in SIRS, neuronal injury may be cytokine-mediated.[77]

INTENSIVE CARE UNIT–ACQUIRED MYOPATHY (CRITICAL ILLNESS MYOPATHY)

Severe ICU-acquired myopathy was first reported 25 years ago,[78] with numerous individual case reports and case series having been published subsequently.[79–81] Myopathy most often occurred in the setting of mechanical ventilation for severe airflow obstruction, and affected individuals had typically been treated with concomitant corticosteroids and NMBAs. However, myopathy has also been documented in patients treated with corticosteroids without paralysis, and in critically ill septic patients who received neither corticosteroids nor NMBAs.[73,82–85] Some authors have attempted to subdivide the acute myopathy that develops in the ICU into a "critical illness myopathy" associated with hypercatabolic

(generally septic) states, a "thick filament myopathy" related to corticosteroids and (usually) NMBAs, and a "necrotizing myopathy" characterized by prominent myonecrosis.[73] However, it is not clear that these are really distinct entities, and a recent editorial suggested the term *critical illness myopathy* be used as the sole descriptor for all instances of ICU-acquired myopathy.[86]

Like critical illness polyneuropathy, acute myopathy is usually manifested by generalized muscle weakness that becomes apparent once withdrawal of sedation allows an assessment of neuromuscular function. Although reflexes may be depressed or absent if myopathy is severe, sensation is intact. In severe cases, patients are unable to move their limbs, resulting in the commonly used descriptor "acute quadriplegic myopathy." On occasion, patients may not open their eyes in response to verbal commands, giving the impression of coma. When less severe, patients may have predominantly distal weakness, and both foot drop and wrist drop are common. In contrast to the frequent diaphragmatic involvement in critical illness polyneuropathy, asthmatic patients who develop myopathy often have relatively well-preserved inspiratory muscle function despite near-quadriplegic limb weakness.[80]

Serum creatine kinase (CK) levels may be elevated or normal, and can neither establish nor exclude an underlying myopathy as the cause of muscle weakness. The EMG reveals either normal or decreased CMAP amplitudes, depending on the degree of muscle involvement. Like critical illness polyneuropathy, needle EMG often reveals spontaneous fibrillations and positive sharp waves in resting muscle. However, with voluntary contractions there is a characteristic myopathic pattern of abundant low-amplitude, short-duration polyphasic units with early recruitment.[87] Pathologic findings in acute myopathy have been variable, with fiber atrophy and vacuolization in the absence of inflammation being the most common finding.[73] Although necrosis may be prominent, more often it is minimal or absent.[73] A key finding on electron microscopy is a selective loss of myosin, with relative sparing of actin and Z bands.[73] This pattern is very characteristic of ICU-acquired myopathy and is rarely seen in other disorders of muscle. A reduction in the myosin:actin ratio has also been documented by electrophoresis of needle aspirates of muscle, potentially offering a minimally invasive technique of diagnosing acute ICU-acquired thick filament myopathy.[88]

The underlying reason for the often near-quadriplegic muscle weakness in ICU-acquired myopathy is uncertain. Although myosin loss may interfere with normal contractility, another potential mechanism of weakness may be temporary muscle inexcitability. In a study of patients with severe ICU-acquired myopathy related to corticosteroids and NMBAs, Rich and colleagues found that they were unable to induce an action potential even when the muscle was stimulated directly.[89] Muscles later regained their ability to generate an action potential during clinical recovery.[89] In a subsequent study, inability to induce an action potential by direct muscle stimulation was also documented in a more heterogenous group of patients with ICU weakness, including a number of patients who were septic and had not received corticosteroids or NMBAs.[90] Studies in experimental animals suggest that muscle inexcitability may be due to impairment of sodium fast channels.[91]

POLYNEUROPATHY, MYOPATHY, OR "POLYNEUROMYOPATHY"

Differentiation of an axonal motor polyneuropathy and severe myopathy by EMG often rests upon the pattern of recruitment seen with voluntary muscle contraction, and inability to cooperate with the voluntary portion of the needle EMG may preclude reliable diagnosis. Marked reduction in sensory nerve amplitudes would indicate neuropathy, but tissue edema may limit the accuracy of sensory ENG, and it has been claimed that 40% to 60% of patients with critical illness polyneuropathy have normal sensory exams. Furthermore, the routine histopathologic findings in muscle biopsy specimens may be similar in myopathy and critical illness polyneuropathy. Therefore, a diagnostic dilemma is presented by patients who have a normal sensory ENG (or in whom sensory evaluation cannot be performed) and are unable to perform voluntary muscle contractions.

A recent study evaluated eight critically ill patients in whom a standard ENG/EMG and muscle histopathology could not differentiate a pure motor axonal neuropathy and a primary myopathy.[92] In all cases electron microscopy revealed a profound selective loss of myosin and normal sural nerve histology, indicating the presence of a primary myopathy rather than motor neuropathy as the cause of weakness.[92] A similar conclusion was reached when direct muscle stimulation was used to differentiate motor neuropathy and myopathy.[93] As noted earlier, muscle inexcitability has been documented in acute myopathy, but a motor neuropathy should not preclude generation of a normal CMAP in response to direct muscle stimulation. In a study of 22 consecutive patients in whom standard ENG/EMG was nondiagnostic, all but 1 patient had evidence of myopathy by direct muscle stimulation and quantitative EMG.[93] Another group has noted that with use of direct muscle stimulation they have never been able to document a single case of pure axonal motor neuropathy, and suggest that previously reported patients given the latter diagnosis almost certainly had a myopathy.[94] Direct muscle stimulation could eventually prove to be useful in the investigation of severe weakness in the ICU, because coma or deep sedation does not preclude its use.[84] It should be appreciated, however, that this technique is not as well-standardized as the routine EMG, and individual laboratories may need to establish their own normative data.

Recently, it has been suggested that some patients with ICU-acquired weakness have both an axonal polyneuropathy and myopathy. In one study muscle and nerve biopsies were performed in 24 patients with ICU-acquired weakness, all of whom had ENG/EMG evidence suggestive of polyneuropathy.[95] All but one had pathologic evidence of a myopathy and one third also had an axonal lesion. The authors concluded that polyneuropathy and myopathy often coexist. A recent prospective study of ICU-acquired paresis found that 22 patients in whom ENG/EMG could be performed uniformly had evidence of a sensorimotor axonal neuropathy, but each of the 10 patients who also underwent muscle biopsy had evidence of myopathy (type II fiber atrophy with myosinolysis).[96] This again suggested that both polyneuropathy and myopathy may coexist and together contribute to ICU-acquired weakness.

Although clarification of the underlying mechanisms of ICU-acquired weakness may be important from a research

perspective, it is uncertain how it will affect individual patients in the ICU since there is no specific therapy. Indeed, it has been suggested that electrophysiologic and pathologic studies are of little practical value in the evaluation of weakness that is clearly acquired after the onset of critical illness, and that a purely clinical approach is adequate to define the presence of a critical illness weakness syndrome.[97] From a practical standpoint, the primary concern with omission of electrophysiologic studies would be missing a rare case of the Guillain-Barré syndrome, a disorder with specific therapy that may be triggered by acute nonneurologic critical illness (see above). In addition, the prognosis for recovery may be different with a pure myopathy and a severe axonal polyneuropathy (see below).

INTENSIVE CARE UNIT–ACQUIRED WEAKNESS: INCIDENCE AND RISK FACTORS

A number of studies have attempted to define the incidence of ICU-acquired weakness and the risk factors for its development. In general, two types of patient cohorts have been examined: those with status asthmaticus, and a more general ICU population in which sepsis, SIRS, and multiorgan failure were dominant.

STATUS ASTHMATICUS

Asthmatic patients who developed acute myopathy have uniformly received systemic corticosteroids while undergoing mechanical ventilation, and in the great majority of cases neuromuscular paralysis had been used to facilitate mechanical ventilation.[79–81] Two large retrospective studies found an identical 30% incidence of myopathy among mechanically ventilated asthmatic patients who had received an NMBA.[80,98] The risk of myopathy increases with the duration of paralysis. One prospective study found a striking relationship between the duration of paralysis and incidence of myopathy.[79] In a second retrospective study the mean duration of paralysis for patients who developed myopathy was 3.2 days, and 90% of patients had been paralyzed for more than 24 hours.[80] A third study also reported a mean duration of paralysis of 3 days among asthmatic patients who developed myopathy.[98] Although it was initially believed that myopathy may be related to use of steroidal NMBAs (vecuronium and pancuronium), the incidence of myopathy is similar with atracurium (a nonsteroidal NMBA) and vecuronium.[80]

These reports, as well as numerous additional publications, have suggested that mechanically ventilated patients with status asthmaticus who are treated with corticosteroids should be at minimal risk of developing acute myopathy as long as they have minimal or no exposure to NMBAs. Unfortunately, the data linking use of NMBAs with acute myopathy has been based almost entirely on retrospective analyses. In the single prospective study of myopathy in status asthmaticus, patients were uniformly paralyzed.[79] More recently, myopathy has been reported in mechanically ventilated patients with airflow obstruction who received corticosteroids and deep sedation, without paralysis.[83] Furthermore, our recent unpublished clinical experience has included a number of patients who developed severe myopathy despite minimal or no exposure to NMBAs. Therefore, while prolonged paralysis appears to increase the risk of myopathy in status asthmaticus, avoidance of NMBAs does not eliminate the risk of neuromuscular weakness.

In experimental animals a thick filament myopathy analogous to that seen in humans with status asthmaticus can be produced by combined denervation and corticosteroids, but not by either intervention alone.[99] Denervation results in a marked increase in the number of cytosolic corticosteroid receptors, but a similar effect is seen after limb immobilization by pinning and casting.[100,101] It is possible that the apparent enhancement of corticosteroid myotoxicity by prolonged paralysis in individuals with status asthmaticus is related to the induction of total muscle inactivity rather than denervation per se. This could explain the occurrence of severe myopathy in corticosteroid-treated patients who underwent deep sedation for many days.[83]

Sepsis, Systemic Inflammatory Response Syndrome, and Other Causes of Critical Illness

A number of studies have attempted to identify the incidence and risk factors for ICU-acquired weakness among populations of medical and surgical patients who had prolonged critical illness, usually as a result of sepsis and SIRS. The reported incidence of ICU-acquired weakness has varied widely due to differences in diagnostic criteria and case mix. A recent study prospectively screened 95 consecutive patients who had remained mechanically ventilated for 7 days and subsequently became sufficiently awake that they could answer simple questions.[96] Based on a complete clinical and electrophysiologic neuromuscular evaluation 1 week after awakening, clinically significant ICU-acquired paresis was diagnosed in 25% of patients.[96] Another prospective study found an incidence of 33% among patients who had been mechanically ventilated for more than 4 days.[102] When focusing on patients with sepsis and multiorgan failure, the incidence of clinically significant ICU-acquired neuromuscular disease appears to be much higher (70% to 82%).[103,104]

A variety of risk factors have been associated with risk for the development of weakness during critical illness. Sepsis is believed to be a major risk factor for ICU-acquired weakness. Although some studies found Acute Physiology and Chronic Health Evaluation (APACHE) II scores to be of no prognostic utility, a recent study found higher APACHE III score and presence of SIRS increased the risk of neuromuscular complications.[102] Duration of mechanical ventilation has also been associated with increased risk, as has the presence of multiorgan dysfunction.[96]

Despite their putative role in status asthmaticus–related myopathy, the contribution of corticosteroids and NMBAs to weakness that occurs in a mixed ICU population, in which sepsis, SIRS, and multiorgan dysfunction predominate, is uncertain.[105] Although one multicenter prospective study found corticosteroid therapy to be a strong risk factor for ICU-acquired paresis,[96] most studies have not found a relationship between corticosteroid use and ICU-acquired weakness.[105] Similarly, most studies involving mixed ICU populations have found no relationship between NMBA use and persistent muscle weakness.[95,102]

OUTCOME

The rate of recovery from ICU-acquired weakness has varied greatly in different series. When weakness occurs in the setting of severe asthma treated with corticosteroids and NMBAs, recovery may require several weeks, but near-normal muscle function is sometimes evident within 10 to 14 days after severe quadriparesis.[87] A much longer recovery time has been found in studies involving a more diverse group of critically ill patients. In the first large study of critical illness polyneuropathy, survivors recovered over 3 to 6 months.[76] A recent prospective study of ICU-acquired paresis reported a median recovery time of 21 days, and a number of patients did not achieve near-normal muscle function for 2 to 3 months.[96] Another prospective study found that all survivors had recovered by 2 to 3 months.[104]

Although earlier studies suggested that ICU-acquired weakness is nearly always reversible, more recent studies have found that long-term, perhaps permanent, disability does occur. An evaluation of 109 survivors of acute respiratory distress syndrome found significant functional limitation at 1 year that was attributed in large part to muscle wasting and weakness.[71] A second study found that one third of patients who had spent more than a month in the ICU had persistent muscle weakness 1 to 5 years after discharge.[68] An evaluation of 19 patients who had been admitted to a rehabilitation unit due to severe ICU-acquired weakness found that one-third had persistent quadriparesis 2 years after discharge.[69] Finally, 11 of 13 patients in one study had incomplete recovery by clinical and electrophysiologic criteria 1 to 2 years after ICU discharge.[70] Together, these studies suggest the disturbing possibility that some patients with severe ICU-acquired weakness may never fully recover, and that the persistent muscle weakness may have a profound impact on overall function and quality of life.

TREATMENT AND PREVENTION

There is no specific treatment for ICU-acquired muscle weakness other than physical rehabilitation. Unfortunately, it may not be possible to easily prevent this complication in patients with either severe sepsis and multiorgan failure or severe, protracted status asthmaticus that requires use of corticosteroids and either prolonged deep sedation or neuromuscular paralysis. In essence, the risk of neuromuscular weakness may be largely determined by the severity and duration of the underlying illness, whether it be sepsis syndrome or status asthmaticus. Nonetheless, to the extent that near-total muscle inactivity may contribute to myopathy, it is possible that risk of the latter might be decreased by maintaining as much muscle activity as is safely possible. A group of researchers recently found that mandated withdrawal of sedatives to determine ongoing need helped avoid oversedation and shortened the total time of mechanical ventilation, without increasing the risk of complications.[106] It is possible that periods of sedation withdrawal could decrease the incidence of myopathy by permitting increased muscle activity, avoiding oversedation, and shortening the duration of ventilatory support. Finally, one large randomized study found that tight glycemic control improved overall outcome among surgical critically ill patients, including a significant reduction in the incidence of muscle weakness,[107] suggesting an additional strategy for prevention of ICU-acquired neuromuscular weakness.

Chapter 67

COMA, PERSISTENT VEGETATIVE STATE, AND BRAIN DEATH

AXEL J. ROSENGART, ROBERTA L. NOVAKOVIC, AND JEFFREY I. FRANK

KEY POINTS

- *The neuroanatomy of coma can be divided into three major categories: diffuse brain dysfunction or bithalamic injury, primary brain stem disorders, and secondary brain stem compression from supratentorial and infratentorial mass lesions.*
- *Most cases of coma are due to metabolic disorders or exogenous drug intoxication.*
- *Patient evaluation must follow an orderly sequence, beginning with vital signs, general physical examination, and neurologic examination.*
- *The most important single sign distinguishing toxic-metabolic coma from primary brain disease is the presence of pupillary light responses.*
- *The neurologic examination of the patient in coma is brief and focuses on (1) level of consciousness, (2) pupils, (3) eye movements, (4) motor responses, and (5) respiratory pattern.*
- *Computed tomographic (CT) scanning of the brain is the most valuable acute test to rule out structural causes of coma.*
- *Hypoxic-ischemic encephalopathy after cardiopulmonary arrest or shock states may be ameliorated by aggressive measures to increase cerebral blood flow after resuscitation.*
- *Serial neurologic examination over the first 72 hours is most helpful to determine the prognosis for patients with atraumatic coma; for anoxic brain injury, failure to recover pupillary responses or corneal reflexes in the first 24 hours is a poor prognostic sign.*
- *As therapies aimed at cerebral resuscitation and preservation following acute injury are developed and proved efficacious, prior guidelines for determining prognosis will require redefinition and reconfirmation.*
- *The Uniform Determination of Death Act states that "an individual who has sustained either (1) irreversible cessation of circulatory and respiratory functions, or (2) irreversible cessation of all functions of the entire brain, including the brain stem, is dead."*
- *The determination of death by brain criteria is based on clinical examination, and in most cases does not require confirmatory tests. However, the cause of coma must be known, and the cause must be sufficient to explain irreversible cessation of whole brain function.*

Normal and Impaired Consciousness: A Conceptual Approach

Consciousness is a difficult term to define, and even more complicating is the fact that many different meanings and classification systems exist for the various states of decreased level of consciousness, such as drowsiness, stupor, and coma. For practical reasons, however, in the evaluation of consciousness most clinicians give greater weight to the patient's responses and behavior than to what the patient says. Hence, consciousness can be defined in its simplest form as the patient's *awareness of self and environment* and the *responsiveness to his or her needs and external stimulation*. The level of consciousness used in clinical practice refers to the state of arousal and should be separated from the *content* of consciousness, which describes various forms of cognitive behaviors and thinking. An awake person is fully responsive (alert) to stimuli and is able to specify an awareness of self and environment.

Impaired consciousness is generally categorized by the level of responsiveness to external and internal stimuli (Table 67-1). *Drowsiness* ("lethargy") is a state of reduced physical and mental activity and a drowsy person can often not sustain wakefulness without external stimulation. It is similar in appearance to light sleep and almost always accompanied by reduced attention and concentration span and mild confusion. A *stuporous* patient requires repeated, stronger stimuli to arouse and quickly drifts back to persistent inactivity when the stimulus is withdrawn. When aroused, this patient may or may not open his or her eyes and partially respond to requests. At times restlessness and motor stereotypes are observed. *Sopor*, the Latin word for deep sleep and a term used in some European countries, denotes an intermediate state between stupor and coma. *Coma* (from the Greek *komas*, or deep sleep) is a state of unresponsiveness in which the patient is incapable of arousing to external or internal stimuli (lack of alertness). The degree of coma can vary from lighter stages (also denoted as *semicoma*) with observed changes in autonomic function or brief moaning to strong stimulation, to the deepest stage with absence of any brain stem responses (e.g., pupillary and corneal reflexes), cyclic autonomic activity, and motor tone. *Sleep* and pathologic states of consciousness undeniably share some common features; for example, the sleeping person is not aware of him- or herself and in this respect is unconscious. Of course, the important difference is that a sleeping person can be aroused to full consciousness. Furthermore, electrodiagnostic evaluation differs in the two conditions (see below) and cerebral glucose uptake does not decrease during sleep but does so in coma. For in-depth discussions of this topic the reader is referred to the major textbooks in neurology and to the seminal work by Plum and Posner.[1]

A *vegetative state* can follow coma and identifies a state in which brain stem and diencephalic (thalamic) activity is present to a degree that clinical signs of arousal are observed.[2] This condition is without meaningful mental function. The patients often show blink responses to light; intermittent eye movements (sometimes erroneously interpreted as following objects or looking at family members); stimulus-sensitive automatisms such as swallowing, bruxism, and moaning, as well as primitive motor responses and cycles of sleeping and waking. However, despite the appearance of wakefulness, the

TABLE 67-1 Clinical Levels of Altered Consciousness

Terms	Eyes	Arousability	Content
Lethargy	Closed	Arousable	Mildly impaired
Stupor	Closed	Arousable with effort	Markedly impaired
Coma	Closed	Unarousable	Not applicable
Akinetic mutism[a] (abulic state, coma vigil)	Open	Wakeful	Impaired
Locked-in syndrome[b]	Open	Wakeful	Normal

[a] Secondary to bilateral frontal/basal forebrain dysfunction.
[b] Secondary to basis pontis dysfunction.

patient's cerebral function remains severely impaired with total inattention and unawareness. If this state is long-lasting it is referred to as *persistent vegetative state* (PVS) and is used as a descriptive clinical syndrome rather than a disease-specific entity. The most common causes include cardiac arrest, head trauma, and various causes of thalamic necrosis. Vegetative states can also be seen in the terminal phase of degenerative illnesses such as Alzheimer's disease. Ambiguous terms for PVS such as apallic syndrome and neocortical death should be avoided.[3,4] *Minimal conscious state* can be diagnosed in patients displaying inconsistent behavioral evidence of awareness of the environment, but they cannot communicate and are unable to follow instructions reliably[5] (Table 67-2).

Clinical practice teaches that *consciousness* should be viewed as a continuum between different pathological conditions and not as an all-or-none phenomenon,[1] and that it is frequently difficult to identify definite signs of conscious perception of environment and self in patients with severe brain injuries. The latter limits the diagnostic certainty of remaining brain function on clinical grounds since the identification of consciousness relies purely on the deduction whether consciousness is present or absent in a particular patient.[2]

Recent data obtained in patients with PVS helps to reveal the critical brain areas involved in consciousness. Extensive loss and severe neuronal damage is causally related to loss of consciousness in patients with PVS, a finding supported by a study identifying decreased cortical radiolabeled flumazenil uptake (a benzodiazepine antagonist and neuronal marker).[6] In corroboration, several studies consistently identified decreased cerebral glucose metabolism and blood flow.[7,8] However, brain regions with the most consistent decrease in cerebral glucose consumption in patients in PVS are the polymodal association areas of the frontal, temporal, and parietal lobes[9]; interestingly, normal subjects display higher brain metabolism during wakefulness than in sleep in similar regions.[10] Furthermore, thalamocortical disconnections can be identified using auditory and sensory external stimulations.[11]

Some carefully performed studies identified patients with PVS who activate primary and associative cortex, depending on the complexity and familiarity of the test stimuli.[12,13] It is, however, unclear whether the identified activations represent consciousness since no conclusions to the connectivity of thalamocortical brain regions and larger neuronal networks can be drawn. Similarly, brain plasticity with recovery of functional thalamocortical connections and reestablishment of neuronal networks may allow certain patients to regain consciousness after severe brain injury and PVS.[9] In recent years we have gained much insight into which brain areas seem necessary for conscious experience; however, future research should broaden our knowledge about what form of brain activity in these areas confers consciousness.

Impaired Consciousness: An Anatomic Approach

Because coma is a sleeplike state, it is not surprising to find that the neuroanatomy of coma is closely related to brain stem centers that regulate daily cycles of wakefulness and sleep: the reticular activating system (RAS). In animals the RAS lies within the center of the brain stem, extending from the midbrain into the hypothalamus and thalamus.[14,15] Electrical stimulation of this region in a sleeping animal produces arousal, and ablation causes coma. Lesions in the pathways of the brain stem reticular formation or RAS have the greatest impact on changes in consciousness.

TABLE 67-2 Characteristics of the Persistent Vegatative State (PVS) and Related Conditions

Condition	Self-Awareness	Sleep-Wake Cycles	Motor Function	Experience Suffering	EEG Activity
PVS	Absent	Intact	No purposeful movement	No	Polymorphic delta or theta, sometimes slow alpha
Coma	Absent	Absent	No purposeful movement	No	Polymorphic delta or theta
Brain death	Absent	Absent	None or only spinal reflex movements	No	Electrocerebral silence
Locked-in syndrome	Present	Intact	Quadriplegia and pseudobulbar palsy; eye movements preserved	Yes	Normal or minimally abnormal
Akinetic mutism	Present	Intact	Paucity of movement	Yes	Nonspecific slowing

SOURCE: Adapted from ref. 8 with permission.

The RAS is a loosely organized core of polysynaptic neurons reaching in the brain stem from the lower medulla through the paramedian pons to central midbrain. At the diencephalic level it includes several functionally related nuclei in the thalami (especially the medial thalamus) and cerebral projections are prominent to the inferomedial frontal lobes, but also reach almost all cerebral cortex. The essential role of the RAS is arousal and maintenance of wakefulness; injury leads to reduction or failure of arousal. As the brain stem RAS receives direct spinothalamic information, incoming sensory stimulations are not only projected to the sensory cortices, but are also needed to activate the brain stem RAS for the maintenance of consciousness. Within the brain stem and thalamus the RAS is confined to rather small anatomic areas; therefore even small lesions can severely impair arousal and consciousness. In contrast, RAS fibers are sparse and spread out as they move towards the cerebral hemispheres, hence only larger cortical lesions will lead to impaired consciousness at that level.

Lesions in the medulla and lower pons need to be quite large to induce significant coma (loss of awareness) since the RAS is rather thinned in these regions. More commonly, lesions in the *ventral pons* (such as basilar artery occlusions) lead to severe motor pathway injury sparing somatosensory and ascending RAS (arousal) systems. This state is referred to as *locked-in syndrome* or de-efferented state, as the patient has preserved consciousness. However, the patient cannot speak or respond and is unable to move cranial, trunk, or extremity muscles, but retains the ability for vertical gaze and eye blinking. In contrast, vascular occlusions of the top of the basilar artery or the posterior cerebral arteries result in injuries to the *midbrain* or *medial thalami* which lead to significant impairment of consciousness but no or only minimal focal neurologic findings.

Traumatic brain shearing injury can lead to slit-like hemorrhages and ischemia or inflammatory to necrotizing lesions of the midbrain, resulting in impaired consciousness. Cerebral masses can produce either direct or indirect (uncal or tentorial herniation) displacement and torsions of the midbrain and reduced alertness. *Akinetic mutism* refers to patients who are silent and apathetic with greatly reduced activity and no focal findings on examination. A number of pathologic lesions have been described, often associated with inferior frontal lobe damage bilaterally. Sudden injury to either or both cerebral hemispheres may produce impaired consciousness, indicating that wakefulness has no hemispheric dominance and requires some cerebral function. Bilateral, extensive acute or subacute damage to the cortex and white matter, for example due to trauma, hypoxia, or infection, impairs activation of the upper RAS, leading to impaired consciousness. Notably, even large cortical (lobar) areas can be injured and initially not affect consciousness at all until secondary injury from swelling and bleeding occurs, as evidenced by patients with penetrating wounds of the cerebral hemispheres who remain fully awake. Similarly, degenerative disorders such as Alzheimer's disease generally do not or only minimally affect the RAS since these patients remain fully awake. *Hypersomnia* refers to a condition of excessive drowsiness and sleep. It may occur in the setting of narcolepsy, hypothalamic disorders, sleep disorders, or psychiatric illness.

Several categories of consciousness-impairing mechanisms and lesions can be defined. First, one cause is an easily identifiable mass lesion compressing the upper RAS either directly or indirectly (such as tumor, abscess, meningitis, or hemorrhage); second, discrete lesions of the upper brain stem (examples are outlined above) may be the cause; and third, a larger group of patients includes those in whom suppression of the RAS is induced by metabolic derangements, toxic states, or seizures. Such functional causes of coma may be reversible by correcting the underlying metabolic derangement or removing the offending drug. "Metabolic" coma is likely the most common etiologic category resulting in impaired consciousness in medical critical care units.

The neuroanatomy of consciousness is not linked to any specific motor, sensory, or cognitive function. Coma and specific focal signs of neurologic damage may occur together or independently. Therefore, patients in coma can be divided into two major clinical categories: coma with or coma without focal neurologic signs. This simple division is often the best way to identify primary neurologic disease as the cause for coma.

Examination of the Comatose Patient: A Clinical Approach

Acute depression in level of consciousness is a critical, life-threatening emergency that requires a systematic approach for evaluation of etiology. The variety of causes of coma are myriad. Therefore, a reliable history should be obtained from family, witnesses, or medical personnel, and examination should seek representative localizing neurological and general physical findings.

HISTORICAL FEATURES

Clues can be ascertained from the onset of coma. An acute onset in a previously healthy individual may indicate a cerebral vascular etiology (i.e., subarachnoid hemorrhage, intracerebral hemorrhage, or hemispheric or brain stem stroke), generalized epileptic activity, traumatic brain injury, or drug overdose. Likewise, a subacute deterioration may point to systemic illness, evolving intracranial mass, or a degenerative infectious or paraneoplastic neurologic disorder. Moreover, the duration of a comatose state should be documented because it may have predictive value for prognosis in certain causes.

GENERAL CLINICAL FEATURES AND PROTOCOL

Frequently the etiology of acute depression in consciousness in the hospitalized patient includes sepsis, acid-base and electrolyte disorders, or hepatic, renal, or cardiac failure. Therefore careful physical examination is performed with attention to vital signs, spontaneous breathing pattern, and careful auscultation of the lungs and heart (Table 67-3). Airway patency and protective reflexes should be assessed. Emergency measures should be taken to ensure vital functions continue despite an obscure diagnosis. Furthermore, laboratory studies should be obtained to exclude metabolic and endocrine causes.

During evaluation, core body temperature is an important clue. Hypothermia can be seen in drug overdose, brain death, or acute spinal cord transection. Moreover, hyperthermia can be seen in infection; traumatic brain injury; subarachnoid,

TABLE 67-3 Useful Physical Examination Findings in Comatose Patients

Exam Focus	Specific Features	Suggested Condition
Skin	Petechiae, splinter hemorrhage	Coagulopathy; SBE
	Icteric	Hepatic encephalopathy
	Needle tracks	Drug overdose or withdrawal
	Cyanotic	CO_2 narcosis
Lymph nodes	Adenopathy	Infectious etiologies; immunocompromised hosts
Head	Contusion; postauricular ecchymosis (Battle's sign)	Trauma
	VP shunt	Hydrocephalus; shunt malfunction
Eyes	Periorbital ecchymosis (raccoon eyes)	Trauma
	Papilledema	Increased intracranial pressure
Ears	Hemotympanum	Trauma
Nose	Excessive discharge	Trauma
Neck	Stiff	Subarachnoid hemorrhage, infection
	Enlarged thyroid	Dysthyroidism
Cardiovascular	Arrhythmia, etc.	Hypoxic/iechemic encephalopathy
Abdomen	Small hard liver	Hepatic encephalopathy
Misc.	Acetone, alcohol breath	Ketoacidosis; alcohol intoxication
	Fever	Infection
	Tongue laceration; incontinence	Postictal state

SBE, subacute bacterial endocarditis; VP, ventriculoperitoneal.

intracerebral, or pontine hemorrhage; and hypothalamic dysfunction.

NEUROLOGIC EXAMINATION

The neurologic exam in a patient with depressed level of consciousness can be a valuable tool to localize the etiology. The important neurologic features include (Table 67-4): (1) respiratory pattern, (2) pupillary size and reactivity, (3) eye position and movements, (4) corneal reflexes, and (5) motor function.

Assessment of Consciousness

The determination of the level of consciousness depends on analyzing arousability and content (see Table 67-1). Initially, observe whether the patient appears asleep or wakeful with spontaneous eye opening. In a sleeping patient, quantify how much stimulation is required to arouse the patient. Attempts should be made to elicit a behavioral response by verbal command alone. If no response is obtained, then physical stimulation should be used, first by shaking the patient. Then noxious stimulation can be applied by digital pressure to the supraorbital nerves or nailbeds of the fingers or toes. Purposeful attempts by the patient to remove the offending stimulus indicate preservation of brain stem function and intact connections to the appropriate cerebral hemisphere. Eye opening, either spontaneous or in response to stimulation, indicates preserved function of the RAS in the upper brain stem and hypothalamus. Once aroused, the patient's ability to remain wakeful and respond coherently is determined.

TABLE 67-4 Neurologic Assessment of the Comatose Patient

- Level of consciousness

  - Facial symmetry
- Motor function
  - Posturing
  - Tone
  - Spontaneous movements
  - Withdrawal to noxious stimulus
  - Deep tendon reflexes

Lethargy (or drowsiness), stupor, and coma represent different points on a continuum of decreasing levels of consciousness. Patients in these states appear to be sleeping with eyes closed. In contrast, patients with akinetic mutism and locked-in syndrome appear to be awake with eyes opened.

The Glasgow Coma Scale (Table 67-5) is used to assign a numerical description of consciousness. The scale was devised to evaluate patients with head injury and is most reliable and reproducible in trauma patients.[16,17] Its application in nontraumatic conditions is less reliable, but it is still the most widely used clinical scale to evaluate the level of consciousness. Furthermore, it provides a reproducible tool to monitor progression.

Respiratory Control

The cerebral cortex and forebrain are important in the control of regular respiration. Patients with isolated brain injury uncomplicated by other critical medical illnesses may have characteristic breathing patterns that aid in neuroanatomic localization (Fig. 67-1). However, these patterns are not reliable in patients with multiple organ system failure who are receiving mechanical ventilation. Nevertheless, a discussion is warranted.

Cheyne-Stokes respiration is a periodic breathing pattern in which periods of hyperpnea regularly alternate with apnea

[a] The lower the GCS score, the more severe the head injury.

in a smooth crescendo-decrescendo pattern. This neurogenic respiratory alteration occurs with damage to the cortex and forebrain bilaterally, or secondary to cardiac or respiratory failure. It is the result of the loss of frontal lobe control over respiratory patterns with excessive dependence on blood CO_2 levels to trigger brain stem respiratory centers.

Midbrain and upper pontine lesions may cause a central neurogenic hyperventilation syndrome with persistent deep hyperventilation. It can only be diagnosed with arterial blood gas measurements, since hyperventilation also occurs secondary to hypoxemia and acidemia. Likewise, metabolic disorders, especially the early stages of hepatic coma, cause central neurogenic hyperventilation.

Lesions of the middle or lower pons are characterized by deep prolonged inspiration followed by a long pause referred to as *apneustic breathing*. Most patients with this respiratory pattern require early intubation and mechanical ventilation.

Ataxic and irregular periodic breathing occurs with lesions in the dorsomedial medulla and may be accompanied by hypersensitivity to respiratory depressants. These patterns are not compatible with sustained life.

When assessing a comatose patient, the rate and pattern of respiration should be observed. In addition, vomiting and hiccups should be noted because they may result from intrinsic brain stem pathology or transmitted pressure on the brain stem. Furthermore, spontaneous yawning may occur in comatose patients. The neurogenic networks for this complex respiratory response are integrated in the lower brain stem.

Pupillary Size and Reactivity

In one study of 346 comatose patients, the pupillary reflex was shown to be the strongest prognostic variable for awakening when compared with evoked-potential studies.[18] Pupillary size is controlled by the autonomic nervous system and is dictated by the balance between sympathetic and parasympathetic input to the pupillary dilators and constrictors, respectively. The parasympathetic efferents to the pupil originate from the Edinger-Westphal nucleus in the upper midbrain and travel with the ipsilateral third cranial nerve (oculomotor). Dysfunction within this pathway will produce unopposed sympathetic input to the pupil and relative pupillary dilation ipsilateral to the lesion. The sympathetic efferents to the pupil originate in the hypothalamus, descend through the brain stem and cervical spinal cord, and exit the upper thoracic spinal cord (T1 to T3 levels). From this point they ascend the carotid sheath and follow the vasculature to the pupil. Any disruption of the sympathetic fibers along this loop can lead to unopposed parasympathetic pupillary activity and subsequently an ipsilateral small (miotic) pupil.

A light stimulus to one eye produces constriction of the ipsilateral pupil (direct response) and contralateral pupil (consensual response), through a network of connections. Table 67-6 summarizes the pupillary changes commonly seen in coma and their significance.

Small reactive pupils may be due to a toxic-metabolic disturbance. Very small pupils (pinpoint) that react to naloxone are characteristic of narcotic overdose. Pinpoint pupils that are poorly reactive are characteristic of pontine dysfunction. Lesions rostral or caudal to the midbrain may disrupt descending sympathetics and produce small pupils.

Bilateral, widely dilated, fixed pupils are due to sympathetic overactivity from an endogenous cause (seizures or severe anoxic ischemia) or exogenous catecholamines (dopamine or norepinephrine) or atropine-like drugs.

Since the midbrain is the one location in the brain stem where parasympathetic and sympathetic pupillary fibers are adjacent, a midbrain lesion classically results in intermediate pupil size. Such pupils are seen in brain death and severe midbrain injuries.

A unilaterally dilated, unreactive pupil in a comatose patient may be caused by herniation of the ipsilateral temporal uncus through the tentorium, which compresses the ipsilateral oculomotor nerve and its parasympathetic fibers. In this

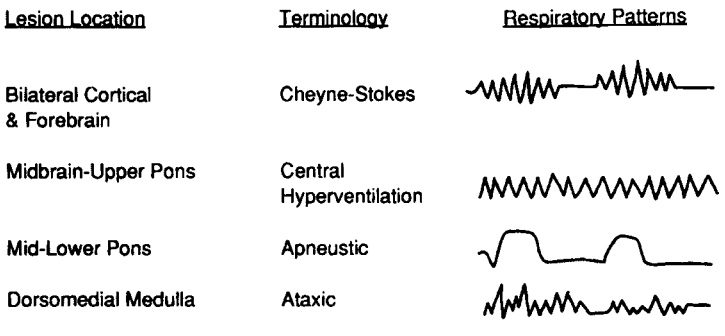

FIGURE 67-1 Respiratory patterns in coma.

TABLE 67-6 Pupillary Changes in Coma

Size	Reactivity	Comments
Bilateral		
Normal or small	Normal	Toxic-metabolic disturbance
Midposition (3–5 mm)	Poor	Midbrain dysfunction; drugs (glutethimide [Doriden])
Small (pinpoint)	Poor	Pontine dysfunction; drugs (narcotics)
Large	Poor	Toxic-metabolic disturbance (anoxia); drugs (anticholinergics)
Unilateral		
Large	Unreactive	Ipsilateral midbrain pathology or compression of ipsilateral CN III: uncal herniation, posterior communicating artery aneurysm
Small	Minimal	Ipsilateral sympathetic dysfunction

setting, the large pupil is eventually accompanied by other evidence of cranial nerve (CN) III disruption (i.e., ipsilateral eye deviation inferolaterally). In the setting of head trauma, this implies an ipsilateral epidural, subdural, or intracerebral hematoma. In nontraumatic conditions, it usually occurs with large cerebral infarcts, spontaneous intracerebral hematoma, or supratentorial brain tumors.

Eye position and Movement

The eye muscles are controlled by three sets of cranial nerves, CN III, CN IV (trochlear), and CN VI (abducens), their nuclei being located in the upper midbrain, lower midbrain, and pontomedullary junction, respectively. Proper eye movement control requires a network of interconnections between these nuclei so that the eyes move conjugately. This interconnection is referred to as the medial longitudinal fasciculus (MLF), which is also integrated with the vestibular nuclei and allows for reflex conjugate eye movement in response to positional head changes.

Figure 67-2 displays the relevant anatomy accounting for horizontal conjugate eye movements. Each frontal eye field controls gaze to the contralateral side by stimulating the contralateral pontine paramedian reticular formation (PPRF) at the pontomedullary junction. Lesions of the frontal eye fields or the PPRFs lead to conjugate eye deviation, provided that the MLF is intact. Therefore, a lesion of the right frontal eye field or left PPRF impairs leftward gaze, and thus the eyes conjugately deviate to the right. In short, the eyes turn toward the lesion with frontal eye field dysfunction and away from the lesion with PPRF dysfunction. In contrast, MLF lesions are manifested as poor adduction of the eye ipsilateral to the MLF lesion. Spontaneous "roving" eye movements in all directions in the comatose patient demonstrate integrity of a significant portion of the brain stem. If no spontaneous eye movements are observed, the intactness of the interconnections

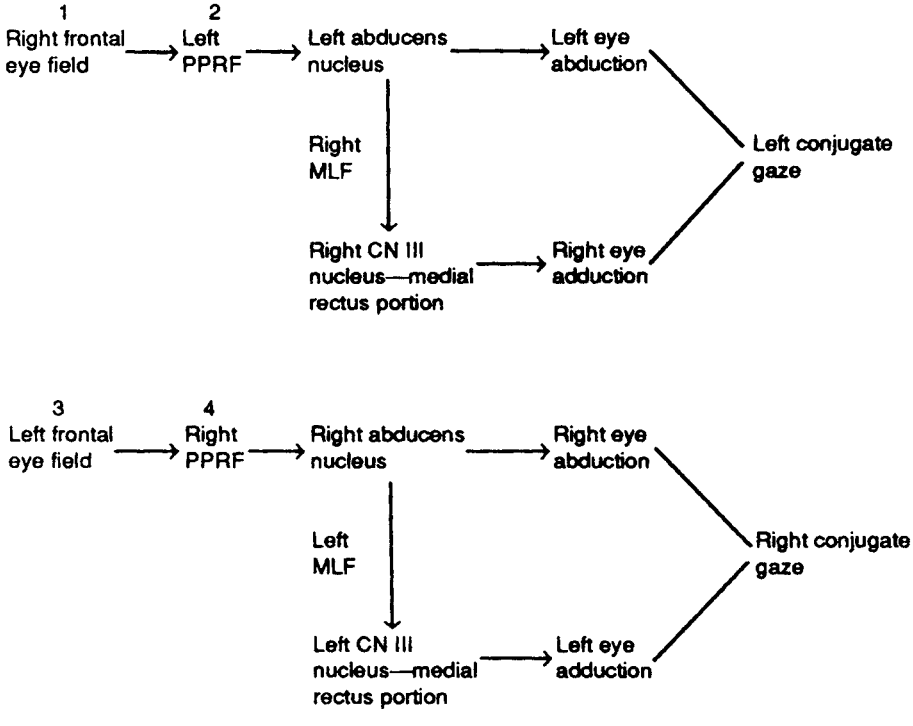

FIGURE 67-2 Schematic representation of the neurologic pathways controlling horizontal conjugate gaze. PPRF, pontine paramedian reticular formation; MLF, median longitudinal fasciculus; CN III, third cranial nerve; 1–4, sites of possible pathologic lesions (see text).

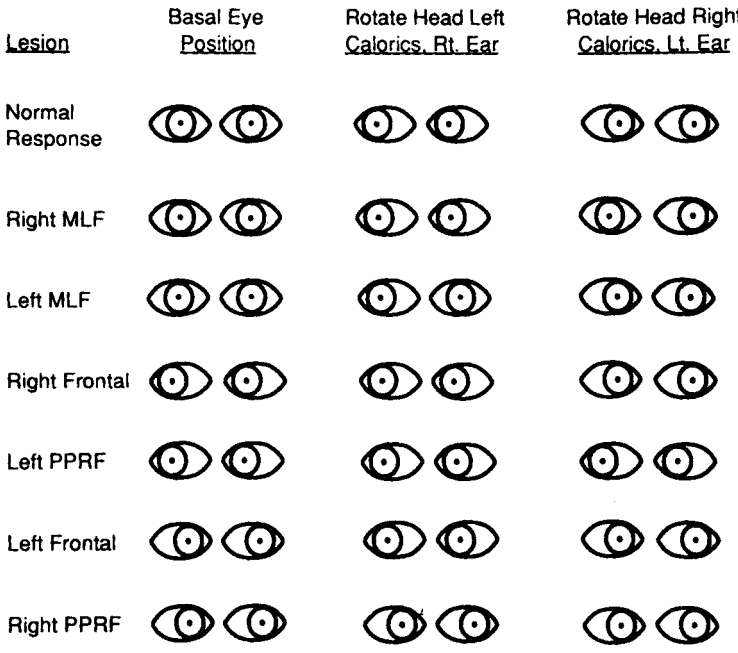

FIGURE 67-3 Eye positions in the doll's eye maneuver and with cold caloric testing in coma. MLF, median longitudinal fasciculus; PPRF, pontine paramedian reticular formation.

responsible for eye control is in question. Since comatose patients are unable to follow commands, maneuvers that take advantage of vestibular input to ocular control must be utilized.

An oculocephalic reflex (doll's eye maneuver) is performed by rapidly rotating the head from side to side and observing the patient's eye positional changes (Fig. 67-3). The normal response in the comatose patient with intact brain stem is for the eyes to remain fixed on the same point in space. Thus when the head is turned rightward, the eyes move to the left. When the head is turned leftward, the eyes move conjugately to the right. If a comatose patient does not have normal doll's eyes, a disruption of brain stem ocular and vestibular connections may be present. Of course, in the setting of trauma, the head should not be rotated due to the possibility of cervical spine injury. In this situation or when doll's eye maneuvers are inconclusive, cold water calorics are helpful.

Oculovestibular reflexes (cold water caloric testing) depend on vestibular system stimulation by altering endolymphatic flow in the semicircular canals. The change in endolymphatic flow is achieved by instilling ice-cold water in the external auditory canal, thereby cooling the mastoid process, and in turn the semicircular canal. Prior to performing this test, the external auditory canal should be examined to confirm intactness of the tympanic membrane and remove any impacted cerumen. The head should then be elevated 30 degrees. A functional apparatus for instilling the water is a butterfly catheter (with the needle removed) connected to a syringe containing approximately 100 mL of cold water.

The responses to cold water in patients with various lesions are summarized in Fig. 67-3. In normal wakeful patients the response is horizontal nystagmus, with the slow phase toward and the fast phase away from the stimulated side and with minimal eye movement from the midline. With diminishing consciousness in patients without structural brain stem damage, the fast phase of the nystagmus disappears, and the eyes tend to deviate conjugately toward the stimulated side. Structural brain stem disease eliminates the caloric response, as does inner ear disease, deep drug coma, and anticonvulsant drug overdose. In order to ensure proper interpretation of cold water caloric testing, the opposite side should not be stimulated until 5 minutes after the initial side.

Corneal Reflex

The corneal reflex is an important protective mechanism for the cornea. it is a blinking reflex triggered when the cornea is presented with a noxious stimulus. The afferent limb is via the trigeminal nerve (CN V), and the efferent limb is via the facial nerve (CN VII). Although corneal reflexes assess brain stem function, they have limited localizing value.

Motor Function

The corticospinal tract predominantly originates from the frontal cortex and descends ipsilaterally through the corona radiata, the posterior limb of the internal capsule, and the cerebral peduncle of the midbrain and consolidates in the pyramids, the ventral swellings of the medulla. The pyramidal fibers decussate to the contralateral side at the junction of the medulla and spinal cord to form the lateral corticospinal tract.

Observation is the key to the motor examination in the comatose patient. The patient is observed for spontaneous movements or maintenance of particular postures. Lesions involving the corticospinal tract generally lead to diminished contralateral spontaneous activity. Upper midbrain or more rostral lesions may lead to decorticate posturing characterized by flexion of the contralateral arm at the elbow and hyperextension of the leg. Central midbrain and high pontine lesions, with a relatively intact brain stem inferiorly, may lead to decerebrate posturing characterized by contralateral arm and leg extension. Such posturing may also be caused by structural lesions or metabolic insults and it is often mistaken for seizure activity. The patient should be observed for

the presence of tremor, myoclonus, or asterixis, because these may be associated with toxic-metabolic encephalopathies.

After observing for spontaneous movements and posturing, motor tone should be assessed by passive flexion and extension of the extremities. Tone may be increased or decreased, depending on the location of the motor system involvement. Afterward, noxious stimuli should then be applied to each limb and the supraorbital regions. Purposeful movement upon noxious stimulation suggests intactness of motor tracts to that limb, whereas decorticate or decerebrate posturing in response to noxious stimuli has the localizing significance mentioned above.

Acute corticospinal tract lesions may cause hyporeflexia because hyperreflexia may not occur for days to weeks after the injury. However, a Babinski sign, which is characterized by extension of the great toe and fanning of the other toes upon lateral plantar stimulation, may be present acutely with corticospinal tract lesions. Complete bilateral paralysis without any response to noxious stimuli usually indicates a grave prognosis. However, spinal cord injury and neuromuscular transmission blockade must be excluded because they may produce a similar state of complete paralysis.

Differential Diagnosis of Coma

Alcoholism, cerebral trauma, and cerebrovascular diseases account for a majority of comatose patients. Other major causes for admission include epilepsy, drug intoxication, diabetes, and severe infection. In the university hospital setting Plum and Posner[1] found one-quarter of comatose patients to have cerebrovascular disease, 6% were the consequence of trauma, all "mass lesions" (i.e., tumors, abscesses, hemorrhages, and infarcts) accounted for less than one-third, while subarachnoid hemorrhage, meningitis, and encephalitis accounted for another 5%. The majority of cases were the consequence of exogenous (drug overdose) and endogenous (metabolic) intoxications and hypoxia.

When the examination leads to the conclusion that the central neuraxis is affected at multiple levels or diffusely, the etiology is most likely of toxic-metabolic origin. Metabolic causes and toxic ingestions account for the largest number of patients with depressed consciousness (Table 67-7). The single most important sign distinguishing metabolic from structural coma is the presence of the pupillary light response.[19,20] In metabolic coma, confusion and stupor commonly precede symmetrical motor signs. Asterixis, myoclonus, tremor, and seizures are common. Central hyperventilation occurs frequently.

Supratentorial mass lesions causing compression or displacement of the upper brain stem (Table 67-8) usually present with focal neurologic signs that are asymmetrical. Neurologic dysfunction usually progresses in a rostral-caudal fashion, and the examination usually points to one anatomic area of the brain stem at a given point in time.

Subtentorial masses or *destructive lesions* causing coma usually are associated with brain stem dysfunction or sudden onset of coma. Brain stem signs always precede or accompany the onset of coma and always include abnormalities of eye movements. Cranial nerve palsies are usually present. Irregular respiratory patterns are common and usually appear at the onset of coma.

Psychiatric causes
Lethal catatonia
Hysterical coma
Malingering

SELECTED CAUSES OF COMA

Metabolic derangements, cerebrovascular diseases, head trauma, and drug intoxications are reviewed in Chaps. 62, 63, 93, and 102.

Hypoxic-ischemic encephalopathy is the most common and most devastating cause of coma in most critical care units. The term is a pathologic diagnosis that refers to the effects of various degrees of global brain ischemia, sometimes complicated by hypoxemia. Cardiac arrest is the most common cause of global brain ischemia.[21–24] Each year there are 200,000 attempts at cardiac resuscitation, and only 70,000 are successful. Of the early survivors, 30% leave the hospital, but only 10% resume their former lifestyle because of permanent neurologic deficits. Other important causes of global brain ischemia include severe hypotension, cardiac failure, strangulation, cardiopulmonary bypass, status epilepticus, diffuse cerebral arteriosclerosis, increased intracranial pressure, cerebral arterial spasm, closed head trauma, and hyperviscosity.

Hypothermia and heat stroke
Traumatic brain injury/contusions
Osmotic demyelination syndrome
Progressive hydrocephalus
Leukoencephalopathy (chemotherapy or radiation)

The degree of neuronal injury in this condition depends on the degree of mismatch between metabolic demand and delivery of substrate (oxygen and glucose) to the brain.[25] For example, the brain can tolerate 45 minutes of total circulatory arrest with complete recovery if hypothermia to 18°C is induced. Conversely, a brain with metabolic activity that is eightfold above normal during status epilepticus will sustain neuronal damage after 2 hours, even with perfect maintenance of arterial oxygenation, glucose, and blood pressure.

The neurologic syndromes that follow cardiac arrest and resuscitation are diverse and depend on the duration of ischemia (time from arrest to cardiopulmonary resuscitation [CPR]), adequacy of CPR, underlying cardiovascular disease, degree of arterial atherosclerosis, adequacy of postresuscitation cerebral perfusion, and whether the patient is cooled following arrest (see Chap. 16). Patients in coma less than 12 hours after resuscitation usually make an excellent recovery. Those in coma more than 12 hours have permanent neurologic deficits due to focal or multifocal infarcts of the cerebral cortex in arterial border zones. They may be left with permanent amnesia, dementia, bibrachial or quadriparesis, cortical blindness, seizures, myoclonus, and ataxia.[26,27] If the coma persists for 1 week, recovery is rare, and most patients remain in a PVS due to laminar necrosis of the cerebral cortex with preservation of brain stem function.[28,29]

Early in the course of hypoxic-ischemic encephalopathy, specific neurologic signs can predict outcome with a high degree of reliability. In a study of 210 patients, the absence of pupillary responses on the first day after CPR predicted poor outcome.[30] None of 52 patients recovered, and only 3 regained consciousness. No patient who lacked corneal reflexes after the first day ever regained consciousness. After 3 days, a lack of purposeful motor responses predicted poor outcome in all patients (PVS or severe disability). Certain early signs were associated with good recovery. At 1 day, the following signs were associated with at least a 50% chance of regaining independent function: verbal responses of any type, purposeful eye movements or motor responses, normal ocular reflexes, and response to verbal commands.

The cause of hypoxic-ischemic encephalopathy is not a simple response to circulatory arrest. Evidence has accumulated that the brain can tolerate a longer period of ischemia than previously thought if certain conditions are met. After a 10-minute period of global brain ischemia, if the circulation is adequately restored, there is marked hyperemia, subsequently followed by a delayed, progressive fall in cerebral blood flow to levels considerably below prearrest values.[31] In some cases, cerebral metabolism remains high in the face of low blood flow, a situation that worsens the effects of the initial ischemia. There is experimental evidence suggesting that if cerebral blood flow can be maintained at a hyperemic level, the brain can recover.[32] It appears that some of the damage is due to a lack of adequate reperfusion after resuscitation, the no-reflow phenomenon. The mechanisms of delayed hypoperfusion and no-reflow are poorly understood but may be due to diffuse arterial spasm, calcium influx, vasoconstrictor prostaglandins, and intravascular coagulation. Even when adenosine triphosphate levels recover promptly as evidence of successful reperfusion, neurons show progressive morphologic damage, suggesting that injury may be in large part due to reperfusion rather than ischemia, per se. Persistently impaired protein synthesis following reperfusion may prevent the cell from repairing damage. In addition, apoptotic pathways appear to be activated, triggering neuronal death. In addition, other biochemical changes are initiated after ischemia that can cause delayed neuronal injury: elevation of intracellular calcium, release of neurotoxic excitatory amino acids (glutamate and aspartate), reoxygenation injury from superoxide formation, and brain lactic acidosis.[33,34]

The pathophysiology of altered cerebral blood flow and meta- bolism following CPR is complex and points to several windows of opportunity where the devastating effects of global brain ischemia may be ameliorated. Calcium channel blockers such as nimodipine, nicardipine, and lidoflazine are being investigated, experimentally and clinically, to determine if they can prevent neuronal damage following global brain ischemia and improve cerebral perfusion after resuscitation. Excitatory amino acid antagonists (MK-801) may be effective at preventing delayed neuronal injury after ischemia.[31] Free radical scavengers and excitatory amino acid antagonists have also been considered as potentially useful to improve

outcome after brain injury; to date, despite some promise in animal models of central nervous system (CNS) injury, these agents have not shown benefits in clinical trials. The mechanism of benefit from induced hypothermia following anoxic brain injury is unknown, and this topic is further considered in Chap. 16.

DIAGNOSTIC PROCEDURES IN EVALUATING THE COMATOSE PATIENT

Keeping in mind the preceding differential diagnosis for states of coma, the sequence of diagnostic studies becomes clear. Rapid identification of metabolic or toxic causes of coma is determined by laboratory testing of blood, urine, gastric aspirate, and cerebrospinal fluid (CSF) (Table 67-9).

A variety of diagnostic tests are useful in evaluating comatose patients. *Computed tomographic* (CT) scanning of the head is useful in detecting changes in brain density. It is utilized mainly to detect focal brain disease, being most sensitive for diagnosing acute hemorrhage, which appears as an area of increased density. Conversely, infarction shows up as an area of lucency, subtly apparent at least several hours after onset. Neoplasms and abscesses are lucent on CT but often accumulate IV contrast material due to alterations in the blood–brain barrier. CT is the test of choice in acute trauma because it provides detailed images of bony structures of the skull base.[35] It may also show parenchymal shifts and effacements of CSF spaces, suggesting the presence of increased intracranial pressure or the presence of hydrocephalus. In addition, CT can be performed easily and rapidly in critically ill, intubated, and artificially ventilated patients.

Magnetic resonance imaging (MRI) is the most sensitive method to image the brain and define diverse pathologies. The image resolution is much better than CT, and it allows images of the central nervous system in multiple planes. MRI is particularly helpful for imaging posterior fossa structures, which often are poorly visualized on CT due to bony artifact. MRI frequently displays pathologic processes earlier than CT does, which may be critical for prompt initiation of appropriate therapy, as in herpes encephalitis.

Lumbar puncture and CSF examination are essential in the diagnosis of meningitis and encephalitis. On occasion, CSF analysis is more sensitive than CT in documenting subarachnoid hemorrhage. The major contraindication to performing a spinal tap is cerebral edema. Since processes associated with cerebral edema represent several of the etiologic considerations in the comatose patient, CT should generally be performed prior to the spinal tap in comatose patients. If it is essential to obtain CSF in states associated with intracranial masses and intracranial hypertension, ventriculostomy may be performed safely and provides an excellent tool for subsequent monitoring and treatment of intracranial hypertension.

Electroencephalography (EEG) measures brain wave activity. It is useful in detecting focal cerebral dysfunction, seizures, encephalitis, and diffuse metabolic encephalopathy, although it is nonspecific with regard to cause (i.e., uremia vs. hepatic failure).[36,37] A rare patient in coma from nonconvulsive status epilepticus will be identified by EEG.[38] It can be used as objective verification of brain death, but this application is less popular in contemporary practice.[39]

Evoked-potential studies (visual, auditory, and somatosensory) have been used extensively for assessment of brain function in comatose patients with acute brain injury, with the hope that they would provide information about prognosis.[37,39] In general, they are no more useful than the clinical examination, except for somatosensory evoked potential (SSEP). The absence of cortical waves in SSEPs performed early after onset of hypoxic-ischemic coma has a high specificity for predicting the likelihood of nonawakening. SSEPs are resistant to sedative drug intoxication and may be present in drug overdose states that cause an "isoelectric" EEG. The persistence of cortical SSEPs in comatose patients with head trauma predicts potential recovery in about one-third of patients; the absence of SSEPs predicts poor outcome in the vast majority.[37,40] Recently one study showed promising potential with more specific tests looking at the role of late auditory (N100), cognitive evoked potentials (mismatch negativity; MMN), and middle latency auditory evoked potentials (MLAEPs) for prognosis of awakening in a cohort of 346 comatose patients.[18] The strongest prognostic variable was pupillary reflex (estimated probability 79.7%), and the estimated probability rose to 87% when N100 was present, and to 89.9% when MLAEPs were present. Interestingly, when MMN was present, 88.6% of patients awakened and no patient with MMN became permanently vegetative.

In a recent small study of 34 patients with anoxic coma admitted over a 2-year period to an intensive care unit, the predictive value of combined clinical exam, SSEP, and EEG was evaluated.[41] On day 3 or thereafter, patients with extensor motor response to pain or worse and a "malignant" EEG (low amplitude, less than 50 μV, delta rhythm, nonreactive; or burst-suppression; or suppression $<$20 μV, alpha/theta coma, nonreactive; or epileptiform discharges with burst-suppression), or those patients with flexor posturing or worse and bilaterally absent SSEPs invariably had poor outcome. However, some patients with initially malignant EEG and normal SSEPs may recover and should be supported until their prognosis becomes more definitive.

TABLE 67-9 Emergency Laboratory Tests for Nonstructural Coma

1. Venous blood: hemoglobin, white blood count, platelets, glucose, electrolytes, calcium, blood urea nitrogen, creatinine, osmolality, coagulation studies, liver function tests, muscle enzymes, thyroid and adrenal functions, toxicology screen, blood cultures
2. Arterial blood: pH, P_{CO_2}, P_{O_2}, carboxyhemoglobin, ammonia
3. Urine: toxicology, microscopic examination
4. Gastric aspirate: toxicology
5. Cerebrospinal fluid: cell count and gram stain, protein, glucose, culture, counterimmunoelectrophoresis, viral and fungal antigens, and antibody titers

Treatment of Coma

Treatment must be instituted immediately, even when the diagnosis is uncertain, to prevent further brain damage secondary to complications. Oxygenation must be ensured, and airway protection is essential. All patients in coma should have a cuffed endotracheal tube placed quickly; the need for mechanical ventilation is determined by the degree of spontaneous breathing and the need for therapeutic hyperventilation. Trauma patients with suspected cervical spine injuries may need emergency tracheostomy to avoid extension of

the neck during endotracheal tube placement (see Chap. 35). Subsequent ventilator adjustments are determined by arterial blood gases.

Arterial blood pressure must be maintained. Hypotension causes secondary brain ischemia. Intravascular volume replacement with blood or isotonic solutions often requires hemodynamic monitoring. The goals are to attain normal intravascular volume with normal central venous pressure, mean arterial pressure, and blood osmolality. Excessive volume replacement can aggravate intracranial hypertension, especially if hypotonic solutions are administered and serum osmolality falls. Inadequate intravascular volume will cause a fall in cardiac output and worsen brain ischemia. Inotropic and vasopressor drugs are administered as needed.

As part of the initial management of all patients with coma, glucose should be given (50 mL of 50% glucose) as soon as blood is sent to the laboratory. Although there is a theoretical risk of hyperglycemia causing brain lactic acidosis during ischemia, the risk of damage from hypoglycemic coma is much greater and requires emergency treatment. Thiamine (100 mg IM or IV) is administered with the glucose to avoid Wernicke-Korsakoff syndrome. Seizures, regardless of cause, must be stopped (see Chap. 64). Intracranial hypertension, if present, should be treated aggressively using intracranial pressure monitoring as a guideline for treatment.[35,42] Details of intracranial pressure monitoring and treatment are described in Chap. 65.

Systemic infections, especially gram-negative sepsis, can cause stupor or coma on a toxic basis and must be promptly treated. Severe acid-base disorders, while rarely responsible by themselves for coma, can worsen the overall situation by causing secondary cardiovascular and respiratory failure. Rapid correction of severe acidosis or alkalosis may be helpful.

Hyperthermia can accompany a variety of pathologic states, either infectious or secondary to hypothalamic or brain stem damage. A 1°C elevation in body temperature will increase cerebral tissue metabolic demand by 10%. Therefore, hyperthermia can itself exacerbate the harmful effects of ischemia, hypoxia, or hypoglycemia. Hyperthermia should be aggressively treated. Mild therapeutic hypothermia was first proposed as a treatment for brain trauma in the late 1950s. Hypothermia can lower ICP, alter chemical pathways that could contribute to injury, and modulate apoptosis, but the mechanism of benefit seen in animal models remains unknown. Large trials in patients with traumatic brain injury have been conflicting[43,44] while benefit seems established following out-of-hospital cardiac arrest.[45,46]

Specific antidotes may be effective in coma secondary to drug intoxication. Details of treatment for drug overdose are described in Chapter 102. Other than general measures, as outlined above, treatment depends on accurate diagnosis of cause and specific directed treatment.

Prognosis and the Persistent Vegetative State

While it is possible to describe broad prognostic likelihoods for patients with nontraumatic coma, particularly postanoxic brain injury (see above), there are no precise tools to determine which patients with coma will evolve to vegetative state. Generally, the clinical course and long-term outcome of vegetative state depends in part on the etiology of the brain injury. A useful classification in this regard describes three broad categories: (1) acute traumatic and nontraumatic brain injuries, (2) degenerative and metabolic brain disorders, and (3) severe congenital malformations of the CNS. Recovery of consciousness from a posttraumatic PVS is unlikely after 12 months for both children and adults. For nontraumatic PVS, recovery after 3 months is exceedingly rare. Patients with degenerative disorders or congenital abnormalities are very unlikely to recover consciousness after several months of PVS. For all patients remaining in PVS, life span is substantially reduced and generally ranges from 2 to 5 years. Survival beyond 10 years is extremely unusual. Life expectancy is largely influenced by the complications accompanying chronic care of these individuals.

Patients who recover consciousness after severe head trauma are often left with marked disabilities. The overall main costs of disability from brain injury are loss of employment. Only about half of all patients with full time employment prior to the severe head injury event were able to return to full time employment,[47] most of them at lower occupational status. In a group of severely brain-injured young men, however, the re-employment rate can be significantly improved by using on-site training accompanied by a job coach, as well as continuing long-term support with use of behavioral and cognitive training strategies.[48,49]

Declaration of Death Using Neurologic Criteria

In recent years, the success rate of organ transplantation has increased dramatically, and transplantation has become standard therapy for patients with end-stage kidney, heart, and liver disease. Unfortunately, thousands of critically ill patients will not receive needed organs due to a lack of understanding of the concepts and criteria for the declaration of death. We are wasting a rare and precious resource because health professionals, as well as the public, have been misinformed about definitions and procedures necessary to declare death in the setting of massive, irreversible brain damage[50,51] (see also Chap. 91).

Although specific protocols for the determination of death vary slightly from institution to institution, guidelines in the United States were firmly established by the President's Commission in 1981 and have been uniformly accepted by the American Medical Association, American Academy of Neurology, and American Bar Association.[52–54]

The Uniform Determination of Death Act states that "an individual who has sustained either (1) irreversible cessation of circulatory and respiratory functions, or (2) irreversible cessation of all functions of the entire brain, including the brain stem, is dead. A determination of death must be made in accordance with accepted medical standards." In 1987, the state of New York adopted the preceding statement as the legal definition of death. Since that time, this definition has been widely adopted throughout North America and Europe.[55,56]

However, confusion still surrounds (1) the definition of death and (2) the criteria for determining death in a patient who has stable cardiovascular function but irreversible cessation of brain function. Part of this confusion arises from the

continued use of the ambiguous term "brain death," implying that there is more than one type of death. If health professionals are confused about this concept, it is no surprise that the public remains uncertain about the terminology.

The medical and legal definitions of death are clear: brain death and cardiac death are the same. Dissenting opinions from the strict religious orthodoxy of Roman Catholicism and Orthodox Judaism persist, however, due to individual interpretations and applications of religious beliefs and laws. It is unlikely that there will ever be a unanimously accepted definition of death, due to diverse religious and ethical opinions. However, time has brought about increasing acceptance that the irreversible cessation of brain function is a mechanism of death.

The core of the clinical diagnosis of brain death is to establish unresponsiveness and brain stem areflexia. The preconditions are that (1) the cause of coma is known and (2) the cause is adequate to explain the irreversible cessation of whole brain function.[57,58] In almost all cases, cerebral circulatory arrest from intracranial hypertension is the mechanism. Confirmatory tests are appropriate in selected cases, particularly for posterior fossa processes that can cause devastating brainstem dysfunction without hemispheric injury. Careful attention to these preconditions will alert the intensivist to special circumstances that require re-evaluation and confirmatory tests. In the press for organ procurement, the cautious physician may be perceived as delaying the transplant process to ensure that the diagnosis of death is unequivocal.

The President's Commission's recommendations grew out of studies at Harvard Medical School in the 1960s and extensive collaborative studies sponsored by the National Institute of Neurological Disorders and Stroke in the years 1971 and 1972.[59,60] These clinical studies were performed before the availability of CT imaging, making the cause of coma and anatomic extent of brain damage uncertain in many cases. Therefore, the use of routine EEG became a standard part of many determination-of-death protocols. With the ability to directly visualize the extent of brain damage in comatose patients by CT, the determination of irreversibility became more precise. To this day, however, there continues to be unnecessary reliance on confirmatory laboratory tests rather than the use of objective clinical criteria. In contemporary practice, the use of transcranial Doppler to verify cerebral circulatory arrest is more relevant than EEG.

In most states in the United States and many countries around the world, clinical criteria are sufficient to diagnose brain death. Confirmatory tests are reserved for situations in which there is uncertainty regarding cause and reversibility of coma. However, there is no doubt that the diagnosis of brain death requires diagnostic respect from the physician and its proper pronouncement is best verified by physicians experienced with the diagnosis.

CLINICAL DIAGNOSIS

It is important to keep a structured approach in mind when approaching a patient with the possible diagnosis of brain death. First, imperative prerequisites that should be fulfilled prior to determination of brain death include (1) irreversible brain catastrophe which involves both the cerebral hemispheres and the brain stem; (2) core temperature $>32^{\circ}C$; (3) no evidence of intoxication, poisoning, or the use of paralytics, anesthetics, or sedatives; and (4) no confounding medical conditions such as severe endocrine, electrolyte, and acid-base disturbances. CT scan may or may not show abnormalities consistent with brain death. For example, following cardiopulmonary arrest the CT may show abnormalities only visible to the expert and may be interpreted as normal by those who are less experienced. On the other hand, a significant and easily identifiable mass lesion seen on CT scan does not necessary imply brain death. As a rule, if the brain CT is discrepant with the clinical diagnosis of brain death, a repeat study is warranted; if the repeat CT scan remains discrepant, the search for other confounding factors should be intensified.

The examination of a potentially brain dead patient should be methodologic as well as documented in detail: Identify the lack of consciousness (coma), verify the patient's core temperature and ventilator dependency, test and describe that no movements and brain stem reflexes are present (including absence of pharyngeal and tracheal reflexes), and demonstrate the lack of spontaneous respiration to increasing arterial carbon dioxide levels (*apnea test*). The apnea test demonstrates the lack of ventilatory drive while the patient remains oxygenated; a patient fails the apnea test when an increase of arterial CO_2 to 60 mm Hg (from a baseline range of 35 to 45 mm Hg) or a 20 mm Hg increase from the pre–apnea test baseline arterial CO_2 has been documented.[61] The successful performance of an apnea test requires a specific methodology to minimize hypoxemia during testing and proactively manage hypotension to assure study completion. For these reasons, it should only be done by physicians experienced with the test. Generally, failure to adequately perform an apnea test (e.g., because of hypotension or a marked drop in oxygenation) should indicate the need for another confirmatory test.

*Certain spinal movements and reflexe*s can be observed in brain-dead patients without casting doubt on the diagnosis. They may be especially prominent during apnea testing, and physical stimulation of the patient. They are often short-lasting and symmetric. Well-known but rather uncommon in its complete form is a brief attempt of the body to sit up to about 60° with raising of both arms (Lazarus sign). A convenient classification of spinal movements and reflexes seen in brain-dead patients[61] by body region includes but is not limited to: cervical region (tonic neck reflexes or head turning), upper extremities (flexion-withdrawal or extension pronation or flexion), trunk (opisthotonic posturing, flexion, or abdominal reflexes), and lower extremities (plantarflexion, triple flexion, or Babinski sign). Observation of any of these movements should lead to verification that they are compatible with the diagnosis of brain death (by an experienced physician) and preparation of the family of their mechanism and relevance.

CONFIRMATORY TESTING

Generally, confirmatory testing is recommended in children less than 1 year old and in situations in which adequate clinical testing cannot be performed. Lack of cerebral blood flow, that is, *cerebral circulatory arrest*, can be documented by standard arterial angiography, transcranial Doppler, or radionuclide scan, and there is some, but limited, experience with magnetic resonance imaging/angiography and CT angiography. Four-vessel cerebral angiography may be performed in clinically dead patients who have an uncertain diagnosis.[57]

Complete absence of cerebral circulation is an absolute confirmation of brain death. The major use of the technique is for rapid diagnosis of death in patients whose clinical examination is obscured by hypothermia or drug intoxication. Transcranial Doppler sonography is a noninvasive bedside technique that can measure, in a qualitative fashion, blood flow in the proximal portions of the main cerebral arteries. An ultrasonic probe is placed over the temporal bones (usually) and the direction and velocity of blood flow can be measured. A number of investigators have shown that absence or reversal of diastolic flow in the cerebral arteries can be demonstrated in patients who meet the traditional criteria for brain death;[62] the operator-dependent sensitivity ranges from 90% to 99%, and the specificity is 100%.[63] About 10% of patients cannot be insonated because of excessive skull thickness. Radioisotope brain scanning can accurately document absent brain blood flow in the cerebral hemispheres, but not in the vertebrobasilar circulation.[64] Some institutions have portable units that can be brought to the bedside in the ICU. Because this technique does not image the posterior circulation, the clinical diagnosis of brain stem areflexia becomes even more important. In situations of suspected or known drug intoxication, isotope brain scanning is not helpful, since it will not answer the question of whether brain stem areflexia is due to drug effect or irreversible damage. Xenon-enhanced CT and ^{99m}T-HMPAO single photon emission computed tomography (SPECT) are noninvasive techniques for accurately measuring brain blood flow in all arterial territories. It has been used in young children and infants with great reliability to confirm the clinical criteria of death.[65] Particularly in children it can overcome many of the problems associated with EEG and cerebral angiography. Unfortunately, the technique is only available in a referral center.

Absence of any electrical activity on a 30-minute EEG with increased sensitivity settings is consistant with brain death and has a reported sensitivity and specificity of about 90%.[66] If the cause of coma is clearly established from anatomic imaging studies of the brain, and clinical criteria are met that all brain functions are absent, EEG confirmation is not necessary.[67] Apneic coma and an isoelectric EEG in the face of normal brain imaging studies are strongly suggestive of sedative drug intoxication, and appropriate toxicology studies must be performed.

NEUROLOGIC STATES RESEMBLING BRAIN DEATH

As correct identification and verification of brain death is rather difficult and complex and misjudgment may have great negative impact, not only on the patient, but also on the family and the diagnosing medical doctor. The diagnosis should only be made by a physician with experience in careful neurologic examinations, interpretations of brain imaging studies, and skilled evaluation of confirmatory studies used to diagnose brain death. Misleading diagnoses may lead the superficial examiner to believe that the patient is brain dead, but often the history and examination together reveal details inconsistent with the diagnosis of cerebral perfusion arrest. For details, the reader is referred to current textbooks in neurology and a recent monograph by Wijdicks.[61] Examples of disorders potentially mimicking brain death include but are not limited to severe hypothermia, acute metabolic coma (e.g., endocrine and organ failure, among others); poisoning (via drugs such as antidepressants, anticonvulsants, analgesics/sedatives, and many more, or via toxins and poisons); locked-in syndrome, akinetic mutism, and possible PVS, as well as peripheral nerve disorders in which the patient may appear brain dead, but is fully awake.

Critical Care Aspects of Brain-Dead Patients

It is well known that brain injury can have immediate and delayed systemic effects on multiple organs. Hence, it is not surprising that brain-dead patients will experience significant effects on overall body function. Generally, vascular motor tone and cardiac stability and performance decreases, pulmonary edema, disseminated intravascular coagulation, and hypothermia may occur, and severe electrolyte and fluid balance disturbances are noted. Up to one-quarter of all potential donor organs are rejected because of the detrimental impact of these changes, which are commonly associated with inadequate medical management (see Chap. 91).

Since the determination of any brain dead patient as a medically suitable organ donor is only done by organ procurement organizations, all brain dead patients should be managed as potential organ donors. This requires proactive anticipatory care to avoid the expected systemic complications that can sabotage the success of organ donation once a family approves. A brief discussion of some of the more important management issues follows.

1. *Maintain hemodynamic stability*. The initial response of brain injury is massive discharge of catecholamines leading to hypertension and tachycardia and not infrequently myocardial injury. In brain death, hypotension and hypovolemia associated with electrolyte and temperature disturbances will lead to systemic vascular instability. Target hemodynamic goals in these patients could be simplified to maintain systolic blood pressure at about 100 mm Hg, heart rate <100 beats per minute, and urine output >100 mL/h. For fluid resuscitation, boluses of either 5% albumin or crystalloid infusion are recommended, the particular choice depends on the treating physician's preference and individual patient's sensitivity to low osmotic pressure–mediated tissue edema. For heart-lung donors we prefer use of colloids to reduce the risk of precipitating acute heart failure, especially in patients with brain injury–related myocardial abnormalities. Inotropic support is indicated for a volume-resuscitated patient with systolic blood pressures <100 mm Hg; principally, any vasopressor agent can be used; however, ideally use the lowest dose possible to avoid further organ impairments. We commonly initiate treatment with low-dose dopamine to stabilize cardiac function and blood pressure while dilating renal, mesenteric, and coronary vasculature. However, if myocardial contractility is already impaired, dobutamine in combination with dopamine would be an appropriate first step. Blood loss is treated with transfusions to a target hematocrit of about 30%. Consumption of blood factors and platelets due to disseminated intravascular coagulation (aggravated by massive release of brain thromboplastin) can be rapid and replacement may become increasingly difficult.

2. *Manage diabetes insipidus*. Posterior lobe pituitary injury and necrosis leading to diabetes insipidus (DI) in brain-injured and brain-dead patients is common and should be recognized immediately. Helpful clinical parameters supporting the diagnosis of DI include (1) hypotonic polyuria, identified by urine output >4 mL/kg per hour and urine specific gravity <1.005; (2) urine osmolality <300 mOsm/L; and (3) plasma osmolality >300 mOsm/L (may be confounded by the use of osmotic diuretics). Diabetes insipidus will invariably lead to dehydration, hypernatremia, and vascular collapse. Therapy is simplified by early recognition of DI and includes hypotonic fluid resuscitation on a volume-to-volume basis, and desmopressin acetate, for example, as an initial bolus of 0.3 μg IV, and then as an adjusted dose guided by clinical and laboratory parameters (e.g., titrate urine output to 2 to 3 mL/kg), given approximately every 6 hours to a total 24-hour dose ranging from 10 to 40 μg. Infusion of aqueous vasopressin can be used alternatively (start at 3 U/h); however, the infusion should be stopped prior to surgical organ recovery to diminish the dose-dependent effects on systemic vascular constriction. Recently, the addition of thyroid hormone replacement was shown to have a vasopressor-supporting effect.[68] The management of diabetes insipidus can be complex, and is best guided by those experienced with brain death management.
3. *Maintaining normothermia*. Adverse effects of hypothermia are well known and include reduction of cardiac output and peripheral vascular resistance leading to arrhythmia and hypotension, hypoxia, hyperglycemia, and coagulopathy. Brain-dead patients have lost their ability to control body temperature and are hence dependent on ambient temperature and the temperature of the infusion products they receive. For these reasons (as well as for the establishment of the diagnosis of brain death) the core temperature should be kept constantly above 36°C using conventional methods.
4. *Maintain glucose and electrolyte balance*. Hypernatremia (e.g., from untreated DI) in excess of 155 mEq/dL may lead to a higher incidence of graft loss after liver transplantation and should therefore be treated aggressively.[69] Certainly, electrolytes need to be evaluated and supplemented as needed, at least every 2 to 4 hours, especially with aggressive fluid resuscitation and treatment of DI, as hypernatremia, hypokalemia, hypocalcemia, and hypomagnesemia are common. Hypophosphatemia is frequently observed in brain-dead patients, and if untreated, may lead to hemolysis, rhabdomyolysis, and platelet dysfunction. Glucose, potassium, and ketones should also be checked regularly, as hyperglycemia due to relative insulin resistance, and use of steroid-, pressor-, and glucose-containing solutions is frequent in these patients. Often an insulin infusion is required to maintain blood glucose levels between 150 and 200 mg/dL.

The proper diagnosis and management of brain death is complex and requires expertise and respect for the diagnosis as a real mechanism of death. The need for proper diagnosis supersedes whether or not the patient will become an organ donor. However, the sensitive and thoughtful management of the patient and family can at least keep the opion of organ donation open; a decision to be finalized between organ procurement, and, usually, families. This is one situation in which proper management can potentially save several lives.

Chapter 68

ANEMIA AND BLOOD TRANSFUSION

JUDITH A. LUCE

KEY POINTS

- *The current practice of transfusion in the ICU is conservative, reflecting a balance between the benefits and adverse consequences of transfused blood.*
- *Anemia developing in the ICU should not be attributed solely to phlebotomy; red cell loss, destruction, or underproduction should also be considered.*
- *Evaluation of the basis for anemia, beginning with analysis of the blood smear, reticulocyte count, and red cell indices, may lead to easier management of the anemia and may prove useful in overall treatment.*
- *For most critically ill patients, a transfusion target for hemoglobin of 7 to 9 g/dL is at least as safe as a higher threshold of 10 to 12 g/dL; the lower value may be superior.*
- *Transfusion is rarely associated with life-threatening complications such as transfusion-related acute lung injury, major hemolysis, or lethal infection.*
- *Erythropoietin and oxygen-carrying blood substitutes remain unproven for critically ill patients.*
- *Massively transfused patients are at risk for hypothermia and dilutional coagulopathy.*

Red blood cells are the most efficient vehicle by which oxygen is delivered to the tissues of whole organisms. The evolution of red cells and the circulatory system allowed for the development of larger, more complex organisms with higher levels of activity. Deficiency in the number and in the local delivery of red blood cells causes relative oxygen deficiency in tissues. Oxygen deficit causes metabolic insufficiency, with inadequate energy production to sustain activity, or even life. Hemoglobin, the complex molecule contained within human red blood cells, has unique properties in and of itself, allowing for the efficient uptake of oxygen in an oxygen-rich environment, and the efficient divestiture of oxygen in an oxygen-poor environment. The whole organism also has evolved to attempt to regularly recycle and reuse the important portions of the hemoglobin molecule, thus reducing the need for ongoing sources of iron. Anemia, the lack of red blood cells in normal volumes, is therefore a disorder that threatens the homeostasis of the entire organism, and when it occurs in the setting of already life-threatening illness, anemia is a potential contributor to mortality.

Blood transfusion has long been recognized as a potential remedy for blood loss, although the first efforts to transfuse blood from animals to human beings or from one human to another were marred by the lack of knowledge of the unique antigens on the surface of red blood cells and the immune response to them. Once a systematic approach to the collection, storage, cross-matching, and transfusion of blood was developed, enthusiasm for transfusion reached its peak. Tempered by the recognition of new transmissible illnesses, by the increasing limitations of the blood supply,[1] and by the awareness of the limitations of aggressive transfusion, modern critical care practice has evolved to a more conservative approach to the use of transfusion as a remedy for anemia in critically ill patients.

Anemia in the ICU

The frequency of anemia in critically ill patients has been studied in a variety of settings, all with the conclusion that it is a common problem that tends to worsen with severity of illness and duration of stay in the ICU. Up to 40% of patients admitted to the ICU in one large sequential cohort study were bleeding on admission,[2] and 40% to 50% require blood transfusion during their ICU stay.[3] By day two in the ICU, nearly 95% of patients are anemic.[4] Trauma patients are subject to higher rates of transfusion, 55%, than medical patients in one comparative study, even though these patients had lower rates of comorbid illnesses.[5]

In these studies, anemia has been defined in various ways, mostly as any deviation from the normal hemoglobin content of blood for men and women. The severity of anemia, however, may vary, and the data on the effects of anemia show that severity is an important marker of both concomitant complications and outcome. Hemodilution in laboratory animals is a relatively well tolerated phenomenon; acute hemodilution results in evidence of myocardial dysfunction and tissue ischemia demonstrable only at hemoglobin levels of 3 to 5 g/dL. Normal human volunteers also appear to tolerate hemodilution to levels of 5 g/dL.[6] However, in animal models of coronary ischemia, and in acute hemodilution in humans with coronary disease, hemoglobin levels of 7 to 10 g/dL may produce evidence of further ischemia and of depressed ventricular function.[7] Conversely, the normalization of hematocrits with transfusion and erythropoietin in patients with chronic anemia and coronary disease in one randomized trial did not result in an outcome benefit.[8]

Measurement of the effects of severe anemia in the critically ill is not straightforward. The assessment of the consequences of anemia is complicated in severely ill patients who cannot report the usual symptoms of anemia—dyspnea, fatigue, lightheadedness, angina, or claudication. The usual signs of end-organ problems due to poor oxygen delivery may also be difficult to interpret: tachycardia and tachypnea have many other causes, cardiac ischemia may be multifactorial, and physical signs of poor organ perfusion may result from a variety of other conditions.

Guidelines for the evaluation of the physiologic impact of anemia are based on what is known of the physiology of anemia. In the absence of adequate delivery of red cells over a given volume of perfused tissue, oxygen extraction rises. Thus the delivered oxygen content may remain constant, but the mixed venous oxygen content will fall compared to normal. Low mixed venous oxygen saturation, usually below 70%, is often employed as a marker of anemic physiology. Under normal circumstances, peripheral oxygen extraction is about 25%, so the ratio of oxygen saturation in mixed venous blood to that delivered ($S\bar{v}_{O_2}/Sa_{O_2}$), and the oxygen extraction ratio (Sa_{O_2} minus $S\bar{v}_{O_2}$ divided by Sa_{O_2}) all have been

Copyright © 2005, 1998, 1992 by The McGraw-Hill Companies, Inc. Click here for terms of use.

shown to provide indirect clues to the presence of tissue oxygen delivery problems.[9]

To make matters more complicated, there are numerous case reports of patients tolerating severe anemia in the postoperative setting in Jehovah's Witnesses, in patients with renal failure, and in situations in which matched blood could not be obtained. These reports were compiled in a formative review by Hébert and colleagues for the Canadian Guidelines on Blood Transfusion.[10] This qualitative review concluded that there was little evidence of perioperative mortality when the preoperative hemoglobin concentration was above 8 g/dL and the estimated blood loss at surgery was less than 500 mL. However, patients having the same hemoglobin level and either older age (>50 years) or greater blood loss were subject to greater mortality.[11] Hemoglobin levels below 8 g/dL are accompanied by a rise in mortality.[12]

Risk factors for adverse outcomes from anemia have been examined in a number of recent publications, and these risk factors are more prevalent in patients in the ICU.[13–15] Most of the evidence for these adverse risk factors is empiric, retrospective, and cohort based. ICU admission alone is a risk factor for poor outcome, as are advanced age and underlying cardiac, cerebrovascular, or respiratory insufficiency.[16,17] In particular, the Carson series of Jehovah's Witnesses allows for a calculation of the relative risk according to perioperative hemoglobin levels: The odds ratio for mortality in patients having a hemoglobin of 6 g/dL preoperatively is 2.5 times the risk of a nonanemic patient, but the mortality rises from 2.5- to 16-fold in the presence of cardiac disease. A retrospective review of Medicare data for patients having myocardial infarction showed that transfusion was associated with lower 30-day mortality in patients having hematocrits of 27% or lower, and with higher mortality in patients having admission hematocrits of 36% or more.[18] Perioperative transfusions after hip fracture were associated with no difference in outcome for patients with hemoglobin levels of 8 g/dL or greater. While overall severity of illness appears to be a risk factor, most of the other studies involving patients in the ICU are too small to examine the independent effects of age, cardiac and cerebrovascular disease, and degree of blood loss.

CAUSES OF ANEMIA IN THE ICU

RED CELL LOSS OR DESTRUCTION

Hemorrhage is the most common cause of anemia in the ICU; those losses arise from surgical intervention or from medical causes of bleeding, and are the sole contributor to anemia in up to 20% of anemic patients in the ICU (Table 68-1).[4] The severity of red cell loss, and the resultant need for transfusion, is also dependent on the degree of underlying illness in a particular patient, as well as the type of surgery being performed, and the exact medical cause of bleeding. Underlying conditions such as renal failure, nutritional failure, liver disease, and drug effects have been shown to increase the risk of bleeding in critically ill patients.[2]

Red cell losses attributable to phlebotomy can be considerable; when originally reported, they probably amounted to the equivalent of two units of red blood cells in an average ICU patient.[19] Phlebotomy losses are greatest in the first few days of ICU admission. Following the initial publications regarding the extent of red cell loss, a variety of conservation measures have been employed, including microanalytic techniques, continuous arterial sampling, the use of external oxygen monitoring, and increasing nursing precautions for blood loss at phlebotomy or other patient procedures.[20] Early closure of burns reduces red cell loss dramatically. Recently published prospective series suggest that the fraction of red cell loss attributable to "medical vampires" has been reduced to less than 20% of all calculated red cell loss.[21]

Red cell destruction also occurs in critically ill patients, although is it a less common cause of red cell loss than is blood loss. Intravascular events that cause mechanical shearing and red cell destruction include disseminated intravascular coagulation (DIC), thrombotic thrombocytopenic purpura (TTP), and endovascular devices, especially newly placed endovascular grafts and older mechanical cardiac prosthetic valves. Thermal destruction of red cells may occur in particular situations, including malfunctioning blood warmers, patients with thermal injuries and with heat exposure, but not in patients with high fever only.

Immune-mediated red cell destruction is also less common than blood loss, but often unrecognized. Autoimmune hemolytic anemia is a very rare event in a critically ill patient, but may be seen in patients with the acquired immunodeficiency syndrome (AIDS), autoimmune diseases, and lymphomas. More common is alloimmunization due to transfusion; delayed red cell hemolysis due to delayed transfusion reactions is often unrecognized and may occur in one in 4000 red cell transfusions.[22] The estimates of red cell sensitization for patients undergoing coronary bypass surgery, for example, are a risk of approximately 1% per unit of red cells transfused.

TABLE 68-1 Causes of Anemia in the ICU

Loss of red blood cells
Hemorrhage
Surgery
Nonsurgical
Phlebotomy
Extracorporeal circuits: hemodialysis, membrane oxygenator, hemofiltration, plasmapheresis
Wounds and burns (until covered)
Immune-mediated hemolysis
Autoimmune
Drug-induced
Infection-related
Nonimmune hemolysis
Endovascular devices
Thrombotic thrombocytopenic purpura, hemolytic-uremic syndrome
Metabolic defects (e.g., glucose-6-phosphate dehydrogenase deficiency)
Underproduction of red blood cells
Anemia of chronic disease
Suppression of erythropoietin production
?Suppression of response to erythropoietin
Alterations in iron metabolism and delivery
Nutritional failure
Bone marrow suppression
Immune
Drugs, toxins

While critically ill patients are less likely to experience primary immunization to homologous red cell antigens than are either healthy volunteers or less sick patients,[23] nonetheless, prior exposures to homologous red cells may predispose to delayed transfusion reactions even though the patient is at the time quite severely compromised.

Drug-induced red cell destruction may occur by several mechanisms: glucose-6-phosphate dehydrogenase (G-6-PD) deficiency is the most common cause of metabolic hemolysis. In the presence of oxidative stress from drugs such as sulfas, primaquine, nitrofurantoin, phenazopyridine, and dapsone, G-6-PD-deficient patients may experience intravascular hemolysis, occasionally on a large scale with accompanying hyperbilirubinemia and hemoglobinuria. But other minor metabolic abnormalities, unstable hemoglobin molecules, and red cell membrane defects may also be associated with hemolysis under the stress of critical illness. More commonly, drugs bound to the red cell membrane act as antigens and stimulate an immune response or form an immune complex which then binds to the red cell surface as a by-stander site. The result is immune-mediated, usually extravascular, hemolysis and anemia. Because the antibodies only bind when the drug is present, this particular form of immune-mediated hemolysis is particularly reversible with the cessation of the drug. Other drugs such as methyldopa are capable of inducing autoantibodies; still others cause hemolysis by unknown mechanisms. Common causes of drug-induced immune hemolysis include penicillins, cephalosporins, quinine and related drugs, sulfas and sulfonylureas, and procainamide.

Another rare cause of red cell destruction in critically ill patients is sepsis due to a variety of infectious agents that can cause hemolysis. Malaria is usually recognizable by history and blood film examination. Babesiosis is a tick-borne intracellular parasite that may also be recognized on peripheral blood smear. *Bartonella bacilliformis* adheres to red cell membranes and induces their destruction in the spleen and reticuloendothelial system. Massive intravascular hemolysis may occur in patients with *Clostridium perfringens* sepsis, due to the formation by the organisms of lysolecithins and resulting red cell membrane proteolysis. Overwhelming infections with the DNA viruses Epstein-Barr, herpes, and cytomegalovirus are associated with hemolysis, probably due to immune complexes. Hemolysis has also been observed in varicella, influenza, measles, and coxsackievirus infections. Mycoplasma infections are commonly associated with the formation of cold agglutinins; occasionally these produce overt cold-mediated hemolysis. Infections with enterotoxin-inducing species of *Escherichia coli* and other enteric organisms trigger hemolytic uremic syndrome.

RED CELL UNDERPRODUCTION

The humoral response to stress and infection includes the production of a wide variety of inflammatory cytokines that have an adverse effect on red cell production, erythropoietin production and responsiveness, iron metabolism, and the reticuloendothelial system. The end result of this adaptation to stress and infection is the characteristic anemia of chronic disease (ACD). The laboratory phenomena associated with the anemia of chronic disease have all been observed in critically ill patients, and evolve rapidly at the onset of severe illness such as sepsis and multiorgan failure.[24] The anemia of chronic disease may also be present prior to ICU admission, as it is a common manifestation of inflammatory and neoplastic disease.

Inflammatory cytokines cause suppression of marrow production of red cells. This phenomenon is seen in a wide variety of illnesses, including minor viral infections. Ordinarily it is brief in duration and produces only a small impact on red cell mass. In critical illness, however, marrow suppression is combined with other disorders of red cell synthesis to produce more profound and durable anemia. One phenomenon that has been documented in the anemia of chronic disease is shortening of red cell lifespan. There is no evidence that this is directly immune-mediated, nor that the red cells themselves are abnormal. The current theory is that the 20% to 30% reduction in lifespan is a result of exaggerated surveillance by an activated reticuloendothelial system.[25,26]

Underproduction of erythropoietin has also been documented in critically ill patients. This may be a direct consequence of hepatic or renal failure, but is more often related to suppression of production of erythropoietin and perhaps to relative refractoriness of the marrow to its effects. Serum erythropoietin levels below those expected for the degree of anemia have been demonstrated in critically ill patients.[27,28] What is more controversial is whether pharmacologic erythropoietin treatment has a significant impact on overall outcomes (see below).

Another phenomenon observed in critically ill patients and in patients with chronic disease is abnormal iron metabolism. Iron has two sources: dietary iron is absorbed in the small intestine, transferred across the epithelial cells and into the bloodstream to the carrier molecule transferrin, where it is made available to the marrow storage cells. Iron is also recycled from senescent red cells by macrophages. Transferrin and ferritin are the molecules that deliver stored iron to developing erythrocytes. In chronic illness, ferritin levels are usually normal or elevated, but iron transport via ferritin into developing erythrocytes is suppressed, probably by responses to inflammation within the macrophages themselves. Transferrin production and transfer of iron from macrophages to transferrin is also often suppressed, and serum iron and iron binding capacity levels are low as a consequence. The result is that although iron absorption is normal, iron reuse from storage is suppressed, and overall production of red cells declines.

While the suppressive effects of the anemia of chronic disease are likely to be the most important elements causing prolonged anemia in the ICU, a variety of other causes of red cell underproduction should be assessed and treated in critically ill patients. Nutritional factors are particularly important, as they lend themselves to obvious solutions. Underlying nutritional deficiency may antedate entry into the ICU, particularly in the elderly, in alcoholics, and in patients with underlying gastrointestinal or other conditions that predispose to undernutrition. Folic acid, vitamin B_{12}, micronutrients (copper, selenium, and zinc) and calorie malnutrition all may cause anemia or perpetuate it in a critically ill patient.[29] Bone marrow suppression from drugs is important in cancer patients, but should be evaluated in patients taking suppressive therapies for autoimmune diseases, and in patients on chronic nonphenothiazine antipsychotic medications and phenytoin. The presence of pancytopenia should prompt an evaluation

of the peripheral blood smear for evidence of disruption of marrow architecture, and perhaps bone marrow biopsy to evaluate the anemia.

EVALUATION OF ANEMIA IN THE ICU

Patients with anemia upon admission to the ICU should have the same considerations of cause as any patient admitted to the hospital. A medical history may disclose the underlying conditions, the duration of the anemia, and prior evaluation. Patients having unknown causes or new onset of anemia upon ICU admission should be thoroughly evaluated at the onset of their stay, since the underlying cause may both prove useful in the overall treatment of the patient, and will certainly assist in the management of the anemia during the ICU stay. Patients who acquire their anemia during the ICU stay have a slightly different set of conditions to consider.

The work-up of anemic patients should begin with the evaluation of the peripheral blood smear and the reticulocyte count. Normal to low reticulocyte counts should be expected in patients sick enough to merit ICU admission, and thus a high reticulocyte count should prompt an evaluation for chronic hemolysis or other red cell destruction. Patients' mean corpuscular volume (MCV) should also be evaluated; frankly megaloblastic red cells have a limited differential diagnosis, as do frankly microcytic red blood cells. Most patients, however, will have normal red cell volumes. The evaluation of both the peripheral blood smear and the MCV are complicated by the addition of transfused red blood cells. Pancytopenia should prompt a still different set of diagnoses, including bone marrow disorders and marrow toxins.

The evaluation of hemolysis also begins with the peripheral blood smear. Red cell fragmentation and distortion, producing schistocytes and teardrop cells, are indications of intravascular events or intramedullary events that mechanically fragment red cells, and suggest the diagnosis of DIC, TTP, or marrow infiltration.

Most patients will prove to have normochromic, normocytic anemia with a low or normal reticulocyte count and no obvious alterations in red cell morphology on peripheral blood smear. Such patients are likely to have the anemia of chronic disease. This may antedate ICU admission and be due to underlying chronic illness, or may appear in the ICU as a consequence of acute illness and marrow suppression, combined with steady blood loss. Whether such a patient requires some other confirmatory test to prove the presence of ACD is controversial. For example, critically ill patients (and many other categories of chronically ill patients without renal failure) display erythropoietin levels that are below the range considered normal for their degree of anemia. However, measuring erythropoietin levels is expensive, often not readily available, and is not considered a standard for the evaluation of ACD in the ICU. Similarly, the iron transport protein ferritin should be normal or elevated in ACD, and low when ACD is accompanied by iron deficiency. However, serum iron levels themselves are often low, and transferrin levels low in ACD in the ICU. These common indices of the suppression of red cell production are in themselves only suggestive of ACD and are not widely used to make a diagnosis. Hence, the diagnosis of ACD is usually one of exclusion. The extent to which testing for other causes of anemia is undertaken depends on the clinical situation.

TRANSFUSION THERAPY IN THE ICU

INDICATIONS FOR TRANSFUSION

In spite of a long tradition of transfusion of red blood cells in critically ill patients, the precise indications for transfusion remain a source of controversy, and specific transfusion practices may vary widely among clinicians. Prior to the major randomized studies of transfusion policies, survey studies of transfusion practice showed that about half of ICU patients were receiving red cell transfusions,[30] and another showed that if the ICU stay was longer than a week, the rate of transfusion was 85%.[31] Total numbers of transfusions were high, and ICU practice was characterized by high rates of transfusions.[32]

There have been only ten randomized trials of transfusion policy in the ICU, and only one of these was large enough to draw specific, statistically significant conclusions.[33] The Canadian Critical Care Trials Group compared a liberal (target hemoglobin 10 to 12 g/dL) with a restrictive (target hemoglobin 7 to 9 g/dL) red cell transfusion policy in patients stratified for disease severity. At 30 days from randomization, the restrictive strategy was at least as good as, if not better than ($p = 0.11$) the liberal strategy, and overall hospital mortality was significantly lower for the restrictive strategy group ($p = 0.05$). For patients under 55 years of age and for patients with lower (≤ 20) Acute Physiology, Age, and Chronic Health Evaluation (APACHE) II scores, the restrictive strategy was clearly superior. In addition, liberal transfusion was not associated with shorter ICU stays, less organ failure, or shorter hospital stays; longer mechanical ventilation times and cardiac events were more frequent in the liberal strategy group. A later subgroup analysis of patients having cardiovascular disease, while small enough to have statistical doubt, suggested that for patients with severe ischemic coronary disease a more liberal transfusion strategy was probably appropriate.[34] The Canadian study has highlighted the many and complex issues involved in transfusion decision making in the ICU.

Since the publication of the Canadian study, several large reports have examined utilization of red cell transfusions in critical care units. Vincent and colleagues[3] surveyed European ICUs, and found that transfusion rates for 3534 patients were 37% during the ICU stay and 12.7% after the ICU stay. The mean pretransfusion hemoglobin level was 8.4 g/dL. Corwin and colleagues[35] studied 284 ICUs in the United States a year later and found great similarity: nearly 50% of patients received transfusions, and the mean threshold hemoglobin level was 8.6 g/dL. A single large Scottish teaching hospital reported a more parsimonious practice; the rate of transfusion was still 52% in its ICU patients, but the total volume of blood used was slightly smaller and the mean pretransfusion hemoglobin was only 7.8 g/dL.[36] All of these authors have concluded that ICU practice has not fully embraced the guidelines of the Canadian clinical trial. In contrast, eighteen hospitals in Australia and New Zealand have reported on transfusion in 1808 consecutive ICU admissions, and although the authors found a median pretransfusion hemoglobin of 8.2 g/dL, the rate of transfusion was lower, at only 19.7% of patients, 60% of whom were bleeding.[37] The "inappropriate" transfusion rate was 3%. The authors speculate that the practitioners may have been influenced by the publication of the Canadian study and their own regional survey of transfusion practices. Nonetheless, they agree that full implementation

of the Canadian guidelines in their clinical setting might be controversial.

COMPONENTS AVAILABLE FROM THE BLOOD BANK

Whole Blood and Red Cell Products

Whole blood, approximately 450 to 500 mL obtained by phlebotomy, is generally stored in an acid-citrate-dextrose medium, and is most often available only for replacement during acute hemorrhage, where transfusion requirements are likely to be large. Because most donated units of blood are separated into components rather than remaining as whole blood, whole blood has become less available.

Fresh whole blood, which has been removed from donors within a few hours of its use, has not been shown to be more effective than stored whole blood, and is only very rarely available, in part because complete infection testing may take several days. Whole blood that has been stored less than 10 days does exhibit longer red cell survival than blood that has been subjected to longer storage, and there is some evidence that the red cells in whole blood have slightly longer survival than red cells that are stored as packed red blood cells. Patients who are at high risk of clinical problems from the transfusion of hemolyzed or senescent red cells may be candidates for blood that has been stored for a shorter time period. Such patients include those with anticipated difficulty clearing bilirubin, such as neonates.

Packed red blood cells (PRBCs) consist of essentially all of the red cells in a unit of whole blood, with platelets and plasma largely removed, so that the resulting cells are at a hematocrit of about 70%. Their higher viscosity may result in longer transfusion times.

Red blood cells store well when frozen, usually in glycerol. Their shelf life is vastly extended, and they can be shipped with little risk of loss. Rare donor types may be stored in one institution and made available nationwide to other blood banks. Frozen red cells are no less likely to transmit most diseases than refrigerated stored red cells. Preparation for transfusion of frozen red cells consists of careful thawing and dilution and recentrifugation in order to remove the glycerol. Opening and manipulating the stored red cells results in a short shelf life; they must be used within 24 hours in order to avoid the risk of bacterial contamination.

"Washed" red cells are produced by recentrifugation in saline solution in order to remove plasma and contaminating white blood cells. They must also be used rapidly after washing, and because of this and the cost of the washing procedure, most institutions use white blood cell filters to prevent febrile transfusion reactions prior to considering the washing procedure. Washing does permit the administration of red cell transfusions to patients with a history of major allergic responses to plasma transfusion (see below).

Irradiation of blood products renders the lymphocytes nonviable, and is used to prevent graft-versus-host disease (see below). Irradiated red cells have a normal life span, do not require expedited handling, and may perhaps be less likely to transmit viral disease.

One blood conservation strategy that is probably underused, although it is currently estimated to be the source of approximately 7.5% of all transfusions, is autologous predeposit of whole blood. Designated donor blood, which has not been shown to be safer than volunteer donor blood, comprises 1% to 2% of all transfusions. Whole blood from autologous predeposit or from designated donors is tested and stored in the same fashion as donor blood. Institutional guidelines vary with respect to the handling of autologous units that test positive for transmissible diseases. While federal regulations allow the storage and use of such units of blood, many institutions either label it with biohazard labels or do not allow its use at all in order to attempt to avoid the potential for clerical error and transfusion to another patient (see section on risks, below). Unfortunately, wastage of both autologous and designated donor blood is approximately 50%, higher than that for volunteer donor blood (about 15%). This observation suggests that overcollection may be occurring.

Red blood cells are customarily stored for 72 to 90 days; during that time they gradually become deficient in 2,3-diphosphoglycerate (2,3-DPG), and a small fraction of stored cells also gradually lyse, releasing potassium, hemoglobin, and red cell stroma into the pack. Red cell senescence is accelerated in storage, and the survival of red cells held in storage is shorter than normal. Altered conditions of storage, such as the addition of alanine, that improve red cell survival unfortunately diminish 2,3-DPG levels, and vice versa. Individual blood bank policies and practices with respect to preservation solutions vary. Usage of red cells beyond the storage limit can result in higher risks of bacterial transmission.

Heat and mechanical fragmentation both can disrupt stored red cells. Blood warmers must be checked for temperature accuracy, since exposure to temperatures over 42°C can result in significant hemolysis of red cells. Attempts to restore the 2,3-DPG levels of stored red cells are not necessary, as the cells rapidly replete when transfused. However, citrate toxicity, which results in hypocalcemia, may be seen when large volumes of blood are administered over a very short time (more than a liter in an hour or two). The intravenous administration of calcium gluconate is recommended for treatment of this problem.

Platelets, Plasma, and Other Products

Platelets do not survive refrigeration, and therefore platelets are removed from fresh whole blood and stored at 22°C under continuous agitation. They may also be obtained by pheresis of a single donor, which harvests about the same amount as five to six units of platelets. Stored platelets are viable for up to a week, and transfused platelets last up to 72 hours in normal recipients.

Platelets pheresed from a single donor may be used to reduce the risk of immunization of recipients who are repeatedly exposed to platelet transfusions. Platelets may be matched to specific platelet antigens or to human leukocyte antigen (HLA) haplotypes; both techniques may be used to successfully give platelet transfusions to recipients who have already become sensitized to random donor platelets.

Plasma may be stored whole, usually as fresh frozen whole plasma. Each unit of plasma from the blood bank is about 200 to 250 mL. Fresh frozen plasma must be thawed carefully, and thawed plasma is rarely kept in storage in blood banks. Cryoprecipitate is prepared from fresh plasma by freezing, then slow thawing to 60°F. The resulting flocculant precipitate contains factor $VIII_C$/von Willebrand factor (vWF), fibrinogen (about one-third of that in the unit of blood), and fibronectin. Commercial cryoprecipitate is lyophilized after the precipitate is harvested. Both of these plasma products have long shelf lives, though shorter half lives once transfused

than their native counterparts. When made into cryoprecipitate, a unit of plasma yields about 80 to 100 units of factor $VIII_C$/vWF and about 200 to 300 mg of fibrinogen. Cryoprecipitate can be reconstituted in extremely small volumes, making it useful when volume overload is a concern.

Specific coagulation factors may be manufactured from pooled plasma or as recombinant DNA products. The latter are more expensive, but appear to have fewer complications, including sensitization and disease transmission. These include human recombinant factor VIII, factor IX, activated protein C, and activated factor VII.

Commercial preparations of plasma also include plasma products that are free of immunoglobulins, that consist of activated or non-activated liver-dependent clotting factors (prothrombin complex), and fibrin "glue" or fibrin sheets.

RISKS OF TRANSFUSION THERAPY

Cross-Matching and Sensitization

Red cells are cross-matched by mixing recipient serum with type-specific (ABO and Rh) donor cells at two different temperatures (major cross-match) and donor serum with recipient red cells (minor cross-match). This takes time, and only under desperate circumstances should this step be omitted. Cross-matching may be complicated by a variety of problems. Nonspecific cold agglutinins are seen in a host of medical conditions, and they cause difficulty matching at room temperature and sometimes at 37°C. Cold agglutinins are usually not associated with serious hemolytic reactions in vivo, but they make cross-matching difficult and they may mask the presence of other antibodies. The warm antibodies seen in autoimmune hemolytic anemia are usually IgG, are associated with autoimmune disease and certain malignancies, and make conventional cross-matching of red cells very difficult because they react with almost all red cells. The procedure for cross-matching in patients having warm antibodies involves eluting the warm antibodies from the patient's plasma so that a cross-match may be performed. If antibody elution is not available, the consensus is that blood banks should provide the best possible match of type-specific blood, knowing that hemolysis may be no greater than it is endogenously. Surface antigens are weakly expressed in neonates, the extremely elderly, and massively transfused patients, making cross-matching difficult. Larger volumes of blood will be needed to cross-match these patients.

In spite of cross-matching, sensitization to homologous blood transfusion occurs, and may become a clinical problem for repetitively transfused individuals, especially those who have rare blood types. The risk of sensitization to red cells is estimated at 1% per transfusion episode; in contrast, the risk of platelet sensitization is 5% to 10% per pooled random donor transfusion episode. Recipient sensitization to leukocyte antigens also occurs during red cell transfusion and may be the basis for some febrile reactions, but is otherwise usually of little clinical significance. On the other hand, the presence of leukocyte antibodies in the donor plasma, the presumed cause of transfusion-associated lung injury, can be prevented only by much more complex leukocyte typing.

Hemolytic Transfusion Reactions

Intravascular hemolysis of transfused red blood cells is caused by complement fixation and rapid intravascular destruction of ABO incompatible red cells, or by the same process in a previously sensitized patient with a high-titer antibody such as anti-Kell or antibodies to Rh system components. The syndrome that results from massive intravascular hemolysis is due to the release of red cell stroma, which causes cytokine, bradykinin, and granulocyte mediator release. Hypotension, capillary leak, and oliguria are manifestations that follow very rapidly after the onset of intense intravascular hemolysis. The most feared complications are disseminated intravascular coagulation, acute renal failure, and the acute respiratory distress syndrome (ARDS). The majority of acute hemolytic transfusion reactions are caused by clerical or nursing error, and fortunately, deaths are rare.

The treatment of hemolytic transfusion reactions is supportive. Early recognition of the syndrome and stopping the offending transfusion are critical. Recognition may be difficult during general anesthesia, and the symptoms at the bedside may also be initially confusing. The decision to stop a transfusion is often difficult unless the findings are very extreme. Most clinicians believe that supporting high urine output is important during the resuscitation of these patients, but that diuretics should be used only if the patient shows intravascular volume overload. The use of mannitol is controversial. There is no role for steroids, antihistamines, heparin, colloid, or other specific pharmacologic interventions. Treatment of the complications should be vigorous, as the majority of patients survive the event.

Delayed Transfusion Reactions

Red cell sensitization may result in an antibody response that is initially weak and does not persist. However, the patient's next exposure to that red cell antigen will arouse an anamnestic immune response, and higher titers of antibody may occur fairly rapidly after transfusion. If an extremely brisk anamnestic response produces antibodies capable of fixing complement, patients may have intravascular hemolysis of the transfused cells within a few days of transfusion. These delayed transfusion reactions usually produce jaundice, and elevated lactate dehydrogenase (LDH) and low haptoglobin levels, but may occasionally be severe and result in oliguria. If the antibody does not fix complement, extravascular hemolysis of the transfused red cells will occur. This type of delayed transfusion reaction is often subtle, but results in elevations in LDH and indirect bilirubin, occasionally the appearance of spherocytes in the peripheral blood smear, a positive direct antiglobulin (Coombs) test, and falling hemoglobin levels. Documentation of such a reaction is important so that future transfusions are more carefully screened.

Other Types of Transfusion Reactions

Febrile transfusion reactions are most often attributed to the presence of granulocytes in transfused blood, although they may also be caused by plasma factors such as exogenous immunoglobulins or rarely by bacterial pyrogens. Benign febrile transfusion reactions may be distinguished from the fever associated with intravascular hemolytic transfusion reactions by the lack of hypotension, chills, or other signs of hemolysis, and by the generally delayed onset of fever compared to hemolytic transfusion reactions. Febrile reactions are usually treated with acetaminophen or aspirin; use of these drugs and occasionally antihistamines for prophylaxis is also common. Patients who have repeated febrile reactions should receive leukocyte-filtered blood.

Urticarial transfusion reactions are thought to be caused by plasma components. One rare subset of patients with congenital IgA deficiency (about one in 650 to 900 persons) may have anaphylaxis due to plasma exposure, but in general urticarial reactions are not accompanied by a risk of anaphylaxis. Urticarial reactions are usually treated with antihistamines and may be treated prophylactically. IgA-deficient patients may be transfused with washed packed red blood cells, or failing that, with IgA-deficient red cells. Products such as platelets must be from IgA-deficient donors. Patients who have repetitive urticarial reactions in spite of prophylaxis may need to receive related-donor blood products.

Transfusion-related acute lung injury (TRALI) is an uncommon syndrome that is due to the presence of leukocyte antibodies in transfused plasma. TRALI is believed to occur in approximately one in every 5000 transfusions. Leukoagglutination and pooling of granulocytes in the recipient's lungs may occur, with release of the contents of leukocyte granules, and resulting injury to cellular membranes, endothelial surfaces, and potentially to lung parenchyma. In most cases leukoagglutination results in mild dyspnea and pulmonary infiltrates within about 6 hours of transfusion, and spontaneously resolves; occasionally more severe lung injury occurs as a result of this phenomenon and ARDS results.[38] Leukocyte filters may prevent TRALI for those patients whose lung injury is due to leukoagglutination of the donor white blood cells, but because most TRALI is due to donor antibodies to leukocytes, filters are not helpful in TRALI prevention. Transfused plasma (from any component source) may also contain antibodies that cross-react with platelets in the recipient, producing usually mild forms of posttransfusion purpura or platelet aggregation after transfusion.

Another nonspecific form of immunologic transfusion complication is mild to moderate immunosuppression consequent to transfusion. This effect of transfusion is not completely understood, but appears to be more common with cellular transfusion and may result in both desirable and undesirable effects. Mild immunosuppression may benefit organ transplant recipients and patients with autoimmune diseases; however, neonates and other already immunosuppressed hosts may be more vulnerable to infection, and cancer patients may possibly have worse outcomes postoperatively.[39]

Graft-versus-host disease (GVHD) occurs when immunocompetent lymphocytes are transfused into an immunoincompetent recipient. The lymphocytes proliferate and respond to recipient HLA antigens. The syndrome presents as fever, skin rash, and liver function abnormalities occurring 2 to 6 weeks after transfusion. Graft-versus-host disease is highly lethal in reported cases outside of the transplantation situation; it is very morbid in transplant settings as well. GVHD primarily occurs in organ transplantation, leukemia, and other severely immunosuppressed patients, but it has been reported following cardiac surgery and in neonates. GVHD has been reported only once in a patient with the acquired immunodeficiency syndrome (AIDS). The correct diagnosis is made by recognizing the syndrome and obtaining a skin biopsy. Prevention in the non–bone marrow transplant setting is to irradiate every cellular blood product before use. Treatment of active graft-versus-host disease involves further immunosuppression with cyclosporine, antithymocyte globulin, steroids, and cytotoxic drugs. Critically ill adult patients who are receiving blood transfusions from family members should have those related donor products irradiated.[40]

In order to reduce the risks of immunosuppression and GVHD, cytomegalovirus (CMV) transmission, and perhaps of alloimmunization, leukocyte reduction through the routine use of white blood cell filters has been undertaken. Several randomized trials of leukoreduced transfusions in critically ill patients have been published, but none of the trials has been large enough to demonstrate benefits unequivocally, and most are negative. However, the largest prospective study performed to date was a Canadian sequential cohort study that has shown some potential benefits to routine leukoreduction.[41] The study closely followed 6982 patients using routine practice, followed by the institution of universal leukoreduction in all blood banks and follow-up of 7804 patients' outcomes. The main outcome measure was all-cause in-hospital mortality, which was reduced during the leukoreduction period compared to the previous period (odds ratio [OR] 0.87; 95% confidence interval 0.75 to 0.99). The second outcome measure, nosocomial infections, was not changed by leukoreduction, although the frequency of fevers and the use of antibiotics were reduced. The cost effectiveness of this strategy has yet to be analyzed.

Risks of Disease Transmission

Hepatitis transmission from blood transfusion is rapidly becoming a rare event. Nucleic acid testing for hepatitis B is universal. The current estimate of the risk of hepatitis B is less than 1 in 200,000.[42] Nucleic acid–based screening tests for hepatitis C provide excellent protection. It detects more potentially infectious units of blood than the enzyme-linked immunosorbent assay (ELISA) test, and is thought to have the potential to reduce the rate of posttransfusion hepatitis to less than the current 5% nationwide.[43] Individuals who have an acute hepatitis-like illness after transfusion should be tested for hepatitis C; however, since the antibody screen is not 100% sensitive. The vast majority of individuals infected do develop antibodies within the first 6 months after transmission. Many of those people may lose their antibodies later on, hence the less-than-perfect screening test. Posttransfusion hepatitis may be caused by other as yet poorly characterized hepatitis viruses, but it is an uncommon event when donor screening by questionnaire and serology is performed.

AIDS transmission is also an unusual event. Both nucleic acid–based tests and HIV antibody tests are routinely used, and the most recent estimates of risk nationwide are less than one in two million.[44] Human T-lymphocyte virus (HTLV) I/II is also tested using ELISA antibody detection, and the total number of cases related to transmission of this virus in the U.S. is fewer than two dozen annually. Transfusion-associated HIV is more rapidly lethal than most community-acquired cases. Acute HIV infection is characterized by fever, adenopathy, and pancytopenia. For all disease testing, repetitively tested volunteer donor blood has been shown to have a higher safety profile than family donors or designated donors.

Cytomegalovirus transmission remains a clinical problem. Forty to sixty percent of adults in the U.S. are antibody-positive for CMV; most, however, are not infectious. Clinical studies have estimated transmission to occur in 3 to 12 recipients/100 units of blood transfused. Rises in antibody titers or seroconversion have been shown in up to 30% of transfused surgical patients. More than 90% of

seroconverters/titer increases are asymptomatic, but in vulnerable recipients, CMV produces acute illness. Neonates, premature, or low birth weight infants are at highest risk; 13% to 37% acquire CMV, and up to one in four dies of it.[44] Bone marrow transplant recipients have a high rate of early death due to CMV pneumonitis, although most of this is thought to represent endogenous reactivation of virus replication. Other vulnerable patients include cancer patients, AIDS patients, seronegative pregnant women, and splenectomy patients. Symptomatic acute cytomegalovirus infection results in a clinical syndrome that resembles infectious mononucleosis. Treatment of cytomegalovirus disease is marginally effective; drugs used in infected patients are mostly suppressive unless remission of the immunosuppression occurs. White blood cell filters, chemoprophylaxis for seropositive patients, and use of seronegative blood products for others are important and useful strategies in the bone marrow transplant setting, and transmission is prevented in neonates by the use of seronegative donor blood products.[45]

Blood may be contaminated by bacteria at the time of collection. This is a rare event, at a rate of 0.21 per million units of red cells transfused, but it is fatal in about one third of recipients, especially if the contaminating organism is a gram-negative rod.[46] Contamination is more than twice as likely from platelets or plasma. Other blood-borne diseases that may be transmitted by transfusion include parvovirus B19, Epstein-Barr virus, human herpesvirus-8 (HHV-8), malaria, brucellosis, trypanosomiasis, syphilis, toxoplasmosis, West Nile virus, the severe acute respiratory syndrome, and possibly variant Creutzfeldt-Jakob disease (or bovine spongiform encephalopathy).

THE MASSIVELY TRANSFUSED PATIENT

Patients suffering rapid blood loss require massive transfusion, generally defined as replacement of the entire blood volume within a 24-hour period, or equaling 50% of the blood volume in 3 hours. Typical conditions leading to massive transfusion include polytrauma, peripartum hemorrhage, gastrointestinal blood loss, aortic aneurysmal rupture, and perioperative bleeding. These patients are considered separately because the large volume of blood required leads to complications not generally associated with blood transfusion, most notably a severe coagulopathy. Moreover, management may benefit from a style that relies on prevention and empiricism as well as on laboratory testing.

Coagulopathy accompanying massive transfusion is multifactorial, including contributions from direct loss, consumption, and dilution of clotting factors and platelets; hypothermia as cool fluids are infused; and shock-related hepatic dysfunction leading to impaired clearance of activated coagulation factors and their breakdown products. It is generally believed that early detection and prevention of coagulopathy is more effective than later treatment by interrupting a vicious cycle that, if not avoided, culminates in a hypothermic, acidemic patient who responds very poorly to aggressive resuscitation. Early studies implicated thrombocytopenia as being the predominant early consequence of massive transfusion, but more recent studies show that a coagulation factor deficit is the earlier derangement. Hypocalcemia can contribute to coagulopathy during truly massive transfusion (greater than 100 mL/min), but this is not often seen because citrate can be rapidly metabolized by the liver.

Initial priorities in the massively bleeding patient include achieving hemostasis when this is possible; obtaining large-bore intravenous access (number and caliber are more important than location); assessing the need for intubation and mechanical ventilation; and infusing sufficient quantities of fluid (generally normal saline). Fluid warmers should be used early in anticipation of heat losses, not only when core temperature falls to abnormal levels. Packed red blood cells should be infused rapidly, dictated by the clinical assessments of blood loss, intravascular volume, and measured hemoglobin concentration. Laboratory tests of hemoglobin, coagulation parameters, platelets, and fibrinogen are indicated, but given the delay in obtaining results and preparing and transporting blood products, cannot provide the sole basis for plasma and platelet transfusion in all patients. Instead some centers have empiric guidelines recommending transfusion of fresh frozen plasma and platelets in some proportion to the amount of blood transfused once the patient is deemed to be "massively transfused." Such a formulaic approach has not been shown to improve outcomes and is strongly discouraged by many, but others attribute their unusually good outcomes in massively bleeding patients to such protocols. The roles for cryoprecipitate, prothrombin complex concentrates, and recombinant activated factor VII remain to be determined.

Some patients transfused massively will suffer uncommon complications such as abdominal compartment syndrome (see Chap. 42); electrolyte derangements such as hypocalcemia, hyperkalemia, or hypomagnesemia (see Chap. 76); and transfusion-related acute lung injury (see Chap. 38), although this is difficult to diagnose in a patient also at risk of fluid overload and aspiration.

ALTERNATIVES TO USE OF BLOOD BANK PRODUCTS

Presurgical storage, or autologous blood donation, makes up approximately 7.5% of all transfusions, although recent studies suggest that autologous donation is underused. Generally, practice has been to have patients donate a unit every 2 to 3 weeks prior to surgery, while taking oral iron and perhaps erythropoietin. There is some evidence that more units may be predeposited with the concomitant use of erythropoietin, although the ultimate clinical impact of such use is unknown. Patients do present for surgery slightly anemic. The FDA permits the use of autologous units that are hepatitis- or HIV-infected; individual institutions may not wish to assume the risk of handling such units and may reject such autologous donors. If used, this infected donated blood should be labeled as a biohazard and handled with extreme caution.

Designated donors, usually members of a patient's family, are often requested by physicians and patients as sources of blood products, usually with the idea that designated donors are less likely to have infectious diseases. Unfortunately, the published data demonstrate that in comparison to regular volunteer donors who have been screened, designated donor blood is more likely to test positive for infectious diseases. Designated donor blood is not necessarily safer than volunteer donor banked blood.

With the availability of recombinant human erythropoietin and its success in increasing hemoglobin concentration in patients with renal failure and bone marrow failure due to HIV infection or chemotherapy, the use of erythropoietin to reduce blood transfusions in critically ill patients seemed obvious. In the past decade, six randomized studies have

evaluated exogenous administration of recombinant human erythropoietin (rHuEPO) to decrease red cell transfusions in the ICU.[47] They have varied with respect to dosage regimens, the dose of concurrently administered iron, patient characteristics (trauma, medical, and surgical), and transfusion thresholds. Although the use of rHuEPO does increase hemoglobin levels compared to concurrent or historical controls, the rate at which hemoglobin rises is slow, measured over a period of weeks, not days. The largest study conducted to date using the best methodology administered weekly rHuEPO and found a 19% decrease in transfusion requirements.[48] Reduced ICU length of stay was shown in only one study of surgical/trauma patients. Reduced hospital stay after ICU discharge was found in another study of severely ill patients (APACHE II score >22), a potentially important non-ICU outcome. A variety of other outcomes were measured in these studies, but none was significantly altered by rHuEPO use. No adverse events were associated with rHuEPO use, although these studies were not designed to evaluate safety, and the target hemoglobin was higher than that used in the Canadian transfusion trial. There are to date no published cost-effectiveness analyses.

Artificial blood substitutes are still in development. Perfluorocarbon products are chemically inert polyfluorinated hydrocarbons that are insoluble in plasma, but in which oxygen is soluble. They are produced as emulsions with surfactants and added hydroxyethyl starch and they need to be stored frozen. The oxygen delivery capability of these products is good, but the use of perfluorocarbons is limited by less efficient oxygen uptake, which requires 100% inspired oxygen delivery. In addition, the total dose and carrying capacity are limited, so that at the maximum dose, the contribution to the total hematocrit by perfluorocarbon, or "fluorocrit," is very low. Finally, these drugs are short-acting, with a half-life of only about 24 hours.[49,50]

Hemoglobin conjugated to polysaccharide is available in a variety of forms, although all have drawbacks with respect to oxygen-carrying capacity, reactions, vasoconstriction, and shorter half-lives. None is currently marketed for use in critical care.

Hemodilution and intraoperative autologous transfusion are other surgical techniques used to avoid transfusion. Hemodilution lowers blood viscosity, thought to be an advantage by some. While there are no formal randomized trials of hemodilution, there are ample nonrandomized studies in cardiac bypass surgery, orthopedic surgery, and Jehovah's Witness patients to suggest that hemodilution techniques are safe and can result in saving blood transfusions.[51] Intraoperative scavenging and reuse of red cells using cell saver technology has become widespread practice in major surgeries such as cardiac and vascular procedures. It remains controversial in trauma or "dirty" operative fields, however. A large number of published nonrandomized series attest to the relative safety of most "washing" cell savers now in use, although the research methodology does not allow for unequivocal demonstration of benefit for their use.[52] One systematic review of the available trials in abdominal aortic aneurysm repair does not clearly demonstrate an advantage with respect to the use of blood products,[53] while an overall review of cell salvage use supports safety and the potential for decreasing red cell use. The use of heparin, antibiotics, filters, and other adjuncts to cell salvage is not standardized.

Additional savings in blood loss have been made with the use of continuous intra-arterial monitoring devices, laboratory microtechniques, and concerted nursing efforts in intensive care units to reduce the number and volume of phlebotomies.

Chapter 69
BLEEDING DISORDERS

JOSEPH M. BARON
BEVERLY W. BARON

KEY POINTS

- *Assessment of the patient with a bleeding diathesis requires careful history-taking and bedside evaluation and comprehensive baseline coagulation testing.*
- *Uncomplicated vascular injury related to trauma or surgery should be eliminated as the primary cause of bleeding before the possibility of a coagulopathy is invoked.*
- *Consideration of coagulation abnormalities should include vascular disorders, platelet problems, impairment of the fibrin generation cascade, and excessive fibrinolytic activity.*
- *Disseminated intravascular coagulation may present with either thrombotic or bleeding problems. Awareness of the possibility of this diagnosis and prompt, appropriate laboratory confirmation may improve treatment selection and outcome.*
- *Invasive procedures in critically ill patients with coagulopathies need to be performed with special caution to prevent complications. Some guidelines are presented.*

Introduction to Bedside and Laboratory Diagnosis of Coagulopathies

Accurate diagnosis of the mechanism of a bleeding disorder is based on careful history-taking and bedside evaluation of the patient, coupled with appropriate confirmatory laboratory testing.[1] Information obtainable from the patient or others about a pre-existing congenital or acquired bleeding diathesis, medications being taken, recent surgery or pregnancy, and underlying disturbed organ function (e.g., hepatic or renal insufficiency) will facilitate the diagnostic process and provide the basis for directing empirical urgent therapy should it be necessary before laboratory testing can be completed.

Careful physical examination may clarify whether observed bleeding is strictly a local problem, i.e., limited to one site and not out of proportion in severity to that expected from an observed injury or fixed lesion, or is due to a systemic bleeding diathesis, which should be suspected if multiple bleeding or bruising sites are present and cannot be accounted for by the extent or severity of known trauma. In some patients with a single mechanism of systemic coagulopathy, it may be possible to distinguish a vascular or platelet disorder, which is characterized by immediate bleeding (prolonged, continued bleeding after onset and dominant petechial/mucosal manifestations), from a problem of fibrin generation (a cascade disorder) or of fibrinolysis, which is typified by delayed bleeding (rebleeding after initial hemostasis and prominent ecchymoses or deep muscle and joint hemorrhage). Complex coagulopathies, such as disseminated intravascular coagulopathy (DIC), may have features of both categories. The presence of findings such as splenomegaly or telangiectases also may be helpful clues.

Several generalizations based on data from the history and physical examination may help in directing the workup and treatment of bleeding problems. The first consideration in the evaluation of a bleeding patient—before a coagulopathy is invoked as a contributing cause—is to exclude uncomplicated vascular injury (related to trauma or surgery) that would be amenable to surgical hemostasis techniques. Second, brisk bleeding is almost never due to spontaneous hemorrhage caused by a coagulopathy alone. Third, clinically significant bleeding often is the result of the coexistence of trauma or a potential bleeding lesion (e.g., a peptic ulcer) with a coagulopathy that may antedate the lesion or may develop while the lesion is present. Fourth, initial and follow-up laboratory screening of critically ill patients for the presence of a potential bleeding diathesis is important in predicting and preventing bleeding complications during interventions such as line placements and surgical procedures.

Systematic laboratory evaluation of the patient with a coagulopathy[2] is facilitated by consideration of the factors necessary for normal clot formation and degradation (Table 69-1). An appropriate screening laboratory survey for a hemostatic disorder in the critically ill patient would include a complete blood count including platelet count; review of a peripheral smear for the presence of schistocytes and for the evaluation of platelet number, clumping, size, and appearance; rapid screening of in vitro platelet function[3] and measurement of bleeding time (unless the platelet count is less than 50,000/μL); prothrombin time (PT), activated partial thromboplastin time (PTT), thrombin time (TT), and functional fibrinogen level; and the level of fibrin degradation products (FDPs) as well as D-dimer assay. These tests should be done simultaneously rather than sequentially in the critically ill patient.

The initial response to vessel injury with formation of the platelet plug depends on normal vascular and platelet function. Defects in these components are reflected in a prolonged bleeding time. Platelet dysfunction (e.g., aspirin effect, von Willebrand's disease) may be sorted out by in vitro platelet function screening.[3] Formation of the definitive fibrin clot requires proper functioning of the clotting factor cascade (Fig. 69-1). Clotting times that are measured in vitro, such as the PT, PTT, and TT, are useful in combination for the detection of significant abnormalities in this pathway. The TT depends on the final step of the cascade (conversion of fibrinogen to fibrin) and, therefore, is sensitive for the detection of fibrinogen abnormalities and inhibitors acting at this level (e.g., heparin). The fibrin plug must be maintained for long enough to permit repair of vascular injury, or delayed or secondary bleeding may occur. Excessive fibrinolysis leading to premature clot instability and lysis is detected by FDP and D-dimer testing.

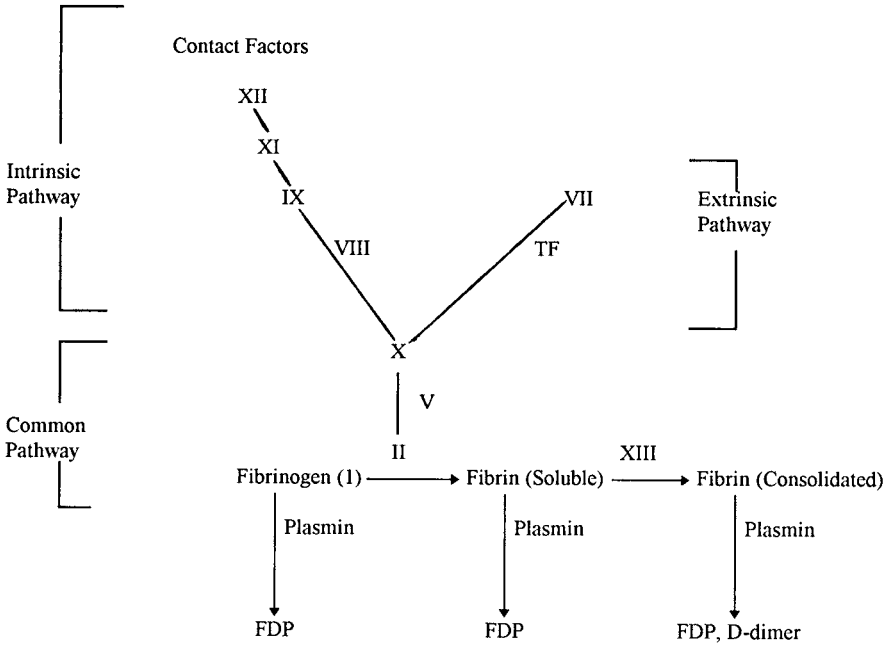

FIGURE 69-1 Fibrin generation cascade and fibrin degradation. TF = tissue factor; FDP = fibrin degradation products.

FDPs result from fibrinogenolysis and fibrinolysis, but the D-dimer is a unique product of plasmin degradation of fibrin. Thus elevated D-dimer levels imply that clotting (fibrin formation) has taken place prior to plasmin activity. Screening profiles of a number of common coagulopathies are given in Table 69-2.

Vascular Disorders

VASCULITIS[4]

Patients with vasculitis due to any of a variety of causes (e.g., drugs, infections, neoplasms, or systemic connective tissue

TABLE 69-2 Screening Coagulation Test Profiles in Selected Typical, Fully Manifest Bleeding Disorders

Disorder	Platelet No.	Bleeding Time	PT	PTT	TT	FDP Level	D-Dimer Level	Other
Vasculitis	N	I	N	N	N	N	N	Palpable purpura
Telangiectasia	N	N	N	N	N	N	N	Cutaneous and visceral lesions
Immune thrombocytopenia	D	I	N	N	N	N	N	Antiplatelet antibodies
Thrombotic thrombocytopenic purpura	D	I	N	N	N	N	N	Schistocytes, renal failure
Thrombocythemia	I	I or N	N	N	N	N	N	Large platelets
Thrombocytopathy	I, N, or D	I	N	N	N	N	N	Impaired platelet aggregation
Hypofibrinogenemia	N	N	I	I	I	N	N	Liver dysfunction
Hemophilia A	N	N	N	I	N	N	N	Low VIII:C levels
von Willebrand's disease	N	I	N	I	N	N	N	Low levels of VIII:C, and ristocetin cofactor
Vitamin K deficiency	N	N	I	I	N	N	N	
Advanced liver disease	N or D	N or I	I	I	I	I	N or I	Elevated VIII:C level, short euglobulin lysis time
Disseminated intravascular coagulation	D	I	I	I	I	I	I	Schistocytes, low fibrinogen and VIII:C levels, normal euglobulin lysis time
Heparin therapy	N	N	I	I	I	N	N	Low antithrombin III level, positive circulating anticoagulant test
Warfarin therapy	N	N	I	I	N	N	N	Negative circulating anticoagulant test
Thrombolytic therapy	N	N	I	I	I	I	I	Low fibrinogen level, short euglobulin lysis time

ABBREVIATIONS: N, normal; I, increased; D, decreased; TT, thrombin time.

diseases) may have an increased risk of bleeding complications owing to vascular fragility resulting from the inflammatory changes in vessel walls. Cutaneous rashes secondary to allergic drug reactions may have a significant vasculitic component. Vasculitis may be suspected by finding so-called palpable purpura—small hemorrhagic areas that are infiltrated and become palpable—in contrast to the typically flat purpura of thrombocytopenia.

Cutaneous vasculitis, such as that associated with drug rashes, may cause a prolonged bleeding time and may compromise the safety of even a small surgical incision through involved areas. A positive diagnosis of vasculitis may be made by a small punch biopsy of a purpuric lesion. Management consists of removing possible offending agents, treating underlying disorders (if possible), minimizing skin trauma, and administering anti-inflammatory agents such as corticosteroids, if not contraindicated by other clinical circumstances.

VASCULAR MALFORMATIONS

A variety of vascular malformations may bleed when traumatized or entered inadvertently during closed-space biopsies. Hereditary hemorrhagic telangiectasia (Osler-Weber-Rendu disease) may be associated with cutaneous, mucosal, or deep visceral malformations. Usually there is no laboratory evidence of a coagulopathy. A family history (the disorder has autosomal dominant inheritance) and careful inspection of cutaneous and mucosal sites for blanching "spiders" may suggest the diagnosis. Unfortunately, rare patients have only unsuspected deep visceral malformations, which may bleed. The disorder occasionally coexists with von Willebrand's disease or hemophilia A.

Patients with congenital cavernous hemangiomas may have a coagulopathy related to consumption of platelets and clotting factors in stagnant vascular spaces (Kasabach-Merritt syndrome).[5] There may be physical findings and laboratory features of DIC.

MICROCIRCULATORY OBSTRUCTION

Leukostasis secondary to very elevated myeloblast levels in acute nonlymphocytic leukemias may lead to small-vessel obstruction and resulting purpura.[6] Brain, lung, and skin are particularly well recognized sites of clinical importance. Similar vaso-occlusive sequelae may be seen in DIC, thrombotic thrombocytopenic purpura (TTP), heparin-induced thrombocytopenia, and fat embolism after long-bone fractures.

Platelet Disorders

THROMBOCYTOPENIAS (TABLE 69-3)

The platelet count is the result of a balance between the rate at which platelets are produced and the rate at which they are removed from the circulation. Bone marrow normally has a six- to eightfold reserve production capacity for the formed elements released into the blood, which can help to compensate for shortening of the normal platelet life span of about 10 days. Although there is no simple, readily available test for the rate of platelet production corresponding to the reticulocyte count as an indicator of new red blood cell (RBC) production, the rate of platelet production can be estimated roughly from evaluation of Wright-stained peripheral blood smears for young (large, basophilic) platelets and from particle counter estimates of mean platelet volume.

UNDERPRODUCTION STATES

Hypoplastic Marrow

Lack of platelet production, either as an isolated problem or as a factor contributing to thrombocytopenia, is suspected when decreased overall cellularity or a selective decrease in

TABLE 69-3 Thrombocytopenias in the Critically Ill

Mechanism	Selected Specific Causes
Underproduction of platelets	
Bone marrow hypoplasia/aplasia	Drugs and chemicals (cytotoxic chemotherapy, ethanol, benzene, chloramphenicol, thiazides)
	Radiation therapy
	Infections (viral hepatitis, cytomegalovirus, tuberculosis)
Ineffective bone marrow	Myelophthisic (metastatic cancers, tuberculosis)
	Megaloblastic (folic acid, B12 deficiencies)
	Primary marrow diseases (leukemia, myeloma)
Shortened platelet survival	
Immune thrombocytopenia	Drugs (rifampicin, methicillin, sulfonamides, barbiturates, diphenylhydantoin, quinidine, α-methyldopa, thiazides, furosemide, gold salts, heparin, trimethoprim-sulfamethoxazole)
	Lymphomas
	Collagen vascular diseases (systemic lupus erythematosus)
	Viral infections, including HIV-1
Intravascular consumption	DIC
	TTP
	Cardiopulmonary bypass
	Hemodialysis
Sequestration	Hypersplenism (cirrhosis, lymphoma)
Hemodilution	Massive transfusion

ABBREVIATIONS: DIC, disseminated intravascular coagulation; TTF, thrombotic thrombocytopenic purpura; HIV-1, human immunodeficiency virus type 1.

megakaryocyte number and size is found on bone marrow examination. A variety of suppressive factors may cause a generalized decrease in marrow mass or a selective decrease in megakaryocyte number. These include chemicals, both therapeutic drugs and environmental toxins; infectious agents, including bacteria, viruses, fungi, and mycobacteria; immune processes, in which the marrow may be inhibited by either a humoral or a cell-mediated mechanism; radiation injury; and idiopathic hypoplastic or aplastic marrow. Marrow hypoplasia will be evident on examination of a bone core biopsy. Care should be taken not to sample marrow that is in the port of prior radiotherapy. Hypoplasia is expected in such an area and may be misleading if interpreted as representing the status of the full marrow.

Ineffective Marrow

Ineffective marrow states are characterized by normal or increased cellularity but lack of release of precursors into the blood. Measurement of the reticulocyte response to anemia is a convenient way to monitor marrow "effectiveness" in this circumstance. A common cause of ineffective marrow function is folate deficiency causing megaloblastic hematopoiesis. The finding of hypersegmented polymorphonuclear leukocytes or ovalomacrocytes and the lack of a reticulocyte response in conjunction with thrombocytopenia should suggest this mechanism. Increased metabolic requirements, decreased folate intake in the diet, and therapy with certain chemotherapeutic agents predispose an individual to folate deficiency. Of course, vitamin B_{12} deficiency needs to be considered at the same time because of hematologic features identical to folate deficiency. Ineffective marrow function is also a feature of various myelophthisic conditions in which marrow may be replaced by tumor or granuloma or is impaired functionally by metabolic disturbances such as azotemia or hypothyroidism. A variety of inflammatory conditions may cause increased or decreased platelet counts via mechanisms not clearly defined.

SHORTENED PLATELET SURVIVAL

The survival of platelets in the blood is usually shortened in patients who are ill. Fever, bleeding, and sepsis, in general, predispose to shortened platelet survival; some specific circumstances include immune-mediated platelet removal by the reticuloendothelial system, hypersplenism, and consumptive coagulopathy. An otherwise uncomplicated shortened platelet life span can be suspected from the findings of a low circulating platelet count, normal or (usually) increased numbers of megakaryocytes on bone marrow examination, and the presence of large, basophilic platelets on a blood smear (indicative of effective marrow release of platelets).

Immune Thrombocytopenic Purpura (ITP)
