The typical critically ill patient is unable to complain of the usual symptoms of PE, has numerous explanations for tachycardia and tachypnea, is hemodynamically unstable, and is a poor candidate for transport for radiographic studies. For that reason, it is important to have a clear sense of the probability of PE in any given patient. Such a judgment is complex, and validated algorithms for determining prior probability in critically ill patients are not available. Synthesis of the patient's cardiopulmonary physiology, combined with an assessment of risk factors, is all the clinician has to go on. Obviously, there is no substitute for experience in managing these very difficult patients. In the following sections, the contribution of various tests in evaluating suspected PE is discussed. An approach to diagnosis is summarized in Fig. 27-5.

RISK FACTORS

Since the symptoms, signs, and laboratory findings of PE are usually nonspecific, delay before pursuing a diagnosis in a patient with classic, unmistakable clues risks missing this potentially lethal disease. However, since nonspecific indicators of potential PE are ubiquitous, indiscriminant pursuit of the diagnosis is prohibitively costly and dangerous. Most patients with PE have identifiable risk factors (Table 27-4). Absence of such risk factors should lead the physician to seek alternative explanations for the patient's findings other than thromboembolism. On the other hand, when numerous risk factors are present, the diagnosis should be more seriously considered.

TABLE 27-4 Risk Factors for Pulmonary Embolism

Epidemiologic factors: Obesity, prior thromboembolism, advanced age, malignancy (especially adenocarcinoma), chemotherapy (particularly thalidomide), estrogens
Venous stasis: Immobility, paralysis, leg casts, varicose veins, congestive heart failure, prolonged travel, and use of muscle relaxants
Injury: Postsurgical, posttrauma, postpartum
Hypercoagulable states: Proteins C and S and antithrombin III deficiency, activated protein C resistance, antiphospholipid antibody syndromes, polycythemia, macroglobulinemia
Indwelling lines: Central venous and pulmonary artery catheters

DIAGNOSTIC TESTS

The gold standard for the diagnosis of PE has long been the pulmonary angiogram. However, its use in critically ill patients is limited by invasiveness, expense, need for dye infusion, and the risks attendant to transport out of the ICU. In many patients, the pulmonary angiogram can be replaced by its noninvasive cousin, the helical computed tomography (CT) angiogram. Helical CT angiography is rapidly replacing both the ventilation-perfusion ($\dot{V}/\dot{Q}$) lung scan and pulmonary angiography in the diagnosis of PE. The limitations of pulmonary angiography and $\dot{V}/\dot{Q}$ scanning, combined with residual doubts regarding the reliability of helical CT angiography, have led to attempts to supplant or augment these tests with alternatives. These include noninvasive leg studies, MRI imaging of the thorax, and various blood tests such as the D-dimer assay. An integrated approach to the diagnosis of PE is described in Figure 27-5.

COMPUTED TOMOGRAPHY AND MAGNETIC RESONANCE IMAGING

Advances in CT and MR imaging have rekindled great interest in the potential for these relatively noninvasive studies to replace the $\dot{V}/\dot{Q}$ scan and pulmonary angiogram as diagnostic procedures of choice.

Magnetic resonance imaging and angiography (MRA) technology has progressed greatly in the past 10 years, with rapidly improving resolution and speed of image attainment. MR does not require iodinated contrast, making it ideal for patients with renal insufficiency, or for those who should not be exposed to ionizing radiation. Among initial reports in 1997, one study listed a sensitivity of 100% and specificity of 95% when MRA was performed in 30 patients undergoing pulmonary angiography for suspected PE.[33] Three of the 22 "negative" MRAs were also termed "poor quality," yet were considered negative readings for calculation of sensitivity and specificity. A larger (118 patients) study with an arguably less selected group of patients found the sensitivity of MRA to be 77% but with a wide 95% confidence interval; specificity was better, at 98%.[34] In both studies, MRA proved difficult either due to patient factors that made them ineligible for magnetic resonance (9% to 15% of eligible patients), or due to poor image quality (6% to 9%), which made the study uninterpretable. Thus while promising, MRA has not yet attained a sensitivity that allows one to rule out PE.

CT scanning has received even more attention and is widely used. Helical CT angiography produces a two-dimensional image of the lung and its vessels at very small collimator, or slice thickness. It has been shown to detect central emboli—out to fourth-division vessels—with a high degree of reliability. Like MRI, helical CT angiography is minimally invasive and may provide alternative diagnoses in the work-up of PE. It does, however, require the injection of intravenous contrast, it is expensive (though less so than either MR or pulmonary angiography) to perform and interpret, and it can be difficult to perform in patients who are unable to hold their breath or are hemodynamically unstable. The most significant criticisms of this technique have been its inability to detect emboli to the level of subsegmental arteries and its variation in interobserver interpretation.

In a prospective trial of 42 patients with suspected PE who underwent helical CT angiography followed by pulmonary angiogram, all 23 patients with a normal CT were found to have a negative pulmonary angiogram, for a sensitivity of 100%.[35] The test likewise appeared to be extremely specific, with only one false-positive, for a reported specificity of 96%. However, with further studies, a range of sensitivity emerges of 53% to 100%, and of specificity between 81% and 100%. Two well-performed recent reviews[36,37] of the CT data came to similar conclusions: that the available literature on CT in the diagnosis of PE remains limited by small studies with incomplete use of a reference standard; that the sensitivity and specificity of CT in diagnosing PE are as yet undetermined; and that the safety of withholding anticoagulation based on a negative CT study is untested and unknown. Both studies raised concerns that interobserver variation and the potential inability of CT to reliably determine subsegmental PEs might preclude its usefulness as a diagnostic test. It is interesting to recall that in PIOPED, subsegmental PEs accounted for 6% of the PEs detected, and that the interobserver agreement for pulmonary angiograms among these small PEs was wider than that of larger PEs (66% for subsegmental PEs compared to 90% for segmental and 98% for lobar PEs).[38] It would appear that subsegmental PEs are challenging to diagnose even by pulmonary angiography, and that the clinical significance of such clots remains difficult to ascertain.

One recent study may shed some light on the safety of withholding anticoagulation following negative CT scan.[39] One hundred seventeen patients in whom PE was suspected but who were found to have a negative helical CT angiogram were followed for a mean duration of 21 months. The study population was elderly (mean = 65 years) and with frequent comorbidity; 70% of patients had known cardiac or respiratory disease. The recurrence rate for PE was 4.5%, based on three patients who died of unknown cause within 1 month of their initial suspected PEs, and two cases of repeat presentation with suspected PE which was confirmed by imaging. One of the patients who died was receiving anticoagulation for severe cardiac insufficiency; excluding his death yields a recurrence rate of 4.9%. If one were to consider the three unexplained deaths—two were older than 90 years with significant comorbidities—as not being due to recurrent PE, the recurrence rate would fall to 1.8%. For pulmonary angiogram, the reported rate of recurrence of PE following a negative study ranges from 0.6% to 4.9%. Thus it may be that helical CT angiography, while by no means a perfect test, has a PE recurrence rate similar to that of pulmonary angiography following a negative study, and is therefore adequate grounds for withholding anticoagulation. Further investigations to confirm or contrast the above findings are necessary to validate this claim.

Both CT and MRA have the advantage of being able to diagnose alternative conditions that may explain the patient's symptoms. Both are less invasive and less expensive than pulmonary angiography, and are probably easier than $\dot{V}/\dot{Q}$ scan to perform in a critically ill patient. Yet lacking comprehensive prospective studies using angiography as a gold standard—lacking PIOPED—both MRA and CT may remain suspect to some practitioners.

NONINVASIVE LEG STUDIES

Noninvasive leg studies include impedance plethysmography (IPG), phleborheography, venous Doppler, and B-mode ultrasound scanning of leg veins. The technical details of these procedures and differences between them are beyond the scope of this chapter, but which particular test to choose is largely a function of local expertise. Both IPG and venous ultrasonography are extremely helpful in assessing a patient with symptomatic proximal deep vein thrombosis. In this population, across numerous studies venous ultrasonography has a sensitivity of 97%, a positive predictive value (PPV) of 100%, and a negative predictive value (NPV) of 100%;[40] IPG was similar though slightly inferior, with a sensitivity of 92%, PPV of 78%, and NPV of 96%.[40] Falsely abnormal results on IPG can be seen with nonthrombotic compression of the vein, increased central venous pressure, and chronic obstructive pulmonary disease.[41] The troublesome aspect to both of these imaging modalities is their performance in asymptomatic patients, particularly asymptomatic patients with high clinical probability of thromboembolism. Patients with symptomatic DVT are far more likely to have a proximal than a distal, or isolated calf vein, DVT.[42,43] In contrast, among asymptomatic patients screened for thromboses, the majority—almost two thirds—are distal.[44,45] When the natural history of postoperative deep vein thrombosis was studied in 1969, approximately 20% of distal DVTs subsequently extended into the proximal veins, and while nonextending distal DVT caused no clinical cases of pulmonary embolism, 4 of 9 cases with proximal DVT did cause PE.[45] Subsequently, studies have observed that distal clots which subsequently progress tend to do so within a week of presentation,[46] and that proximal extension of distal DVT after more than a week is unusual,[40] spurring the evaluation of serial noninvasive leg studies for the diagnosis of proximal DVT. In evaluating the safety of withholding anticoagulation following a negative test, both IPG and venous duplex appear to have similar rates of subsequent DVT (1.5% to 2%) during the 6 months following a negative test.[40] However, pooling data from combined studies of IPG, 4 of 1625 patients (0.25%) with an initial negative IPG died from PE during serial testing or follow-up, whereas one of 1747 patients (0.06%) with initial negative venous ultrasound died of PE.[40]

Precisely because PE more commonly follows asymptomatic, rather than symptomatic, DVT,[38] noninvasive leg studies cannot make or exclude the diagnosis of PE. Moreover, the ultrasonic characteristics of any thrombus appear to predict poorly the likelihood of associated PE.[47] Nevertheless, the wide availability of accurate noninvasive leg studies provides a simple method for managing many patients who cannot be transported or who have nondiagnostic helical CT angiography. In patients with angiographically proven PE, 43% to 57% will have detectable DVT.[48,49] In some patients, diagnostic testing can be avoided by performing serial noninvasive leg studies. Demonstration of venous thrombosis provides grounds for treatment (usually anticoagulation), so the question of PE may cease to be important. On the other hand, failure to detect DVT may sufficiently reassure the intensivist that neither further diagnostic measures nor empirical treatment is urgently needed. The rationale for this approach is that if deep venous thrombosis cannot be detected, the likelihood of re-embolism is very low. Furthermore, if deep venous thrombosis develops, or a subclinical thrombosis propagates to the proximal deep veins, serial testing will reveal it before it has much chance to embolize. In ambulatory patients, this strategy is effective (Table 27-5). It is important to note that this approach has not been validated in critically ill patients and does not take into account the role of upper extremity thrombosis.

TABLE 27-5 Serial Leg Studies in Patients with Suspected Venous Thromboembolism

	N (%)
Initial negative IPG	1114
Positive IPG, days 2–5	23 (2.8)
Positive IPG, days 6–10	6 (0.7)
Thromboembolism at 3 mo	11 (1.0)
Fatal PE at 3 mo	1 (0.1)

ABBREVIATIONS: IPG, impedance plethysmography.
NOTE: 380 of these patients had suspected PE, the remainder having suspected DVT only. Patients were not critically ill. Anticoagulation was withheld while serial studies were performed. Data abstracted from references 46 and 50–52.

VENTILATION-PERFUSION LUNG SCAN

$\dot{V}/\dot{Q}$ scanning traditionally was the initial test of choice in the evaluation of PE, but two important studies have led to a sobering reappraisal of this test.[38,48] $\dot{V}/\dot{Q}$ scans can be extremely helpful to the clinician when they provide either a high probability result—with an attendant specificity of 85%, confirming the diagnosis—or a normal result, when the diagnosis of PE is virtually excluded.[38] Although 15 of 100 patients with "high probability" $\dot{V}/\dot{Q}$ scans will not have PEs, the risk of treating them is felt to be less than the risk and cost of performing pulmonary angiography in all 100 patients. The frustration with $\dot{V}/\dot{Q}$ scanning stems from the large number of tests which yield either intermediate probability or indeterminate results. Scans of intermediate probability indicate a substantial likelihood of PE (about 40%) necessitating further evaluation to prove or exclude the diagnosis. Among patients with low probability scans, the prevalence of PE ranges from 16% to 40%, necessitating further diagnostic work-up in all but those deemed to have a low clinical likelihood of PE, among whom only 4% of patients had PE. Thus the $\dot{V}/\dot{Q}$ scan results, which are sufficient in themselves to terminate the evaluation (because PE is either highly likely or has been reliably excluded) include all normal scans, all high probability scans, and low probability scans in patients with a low clinical pretest probability of PE. Unfortunately, a minority of patients fall into these three categories, so that for the majority of patients undergoing $\dot{V}/\dot{Q}$ scan, it prompts further testing.

How useful the ventilation-perfusion scan is when applied to the subset of critically ill patients remains an open

question. In a retrospective analysis of the PIOPED database, 223 patients were defined to be "critically ill" (room air Pa_{O_2} <50 [$n = 89$]; mechanically ventilated [$n = 46$]; hypotensive, but not ventilated [$n = 3$]; or physically in an ICU, but not ventilated [$n = 85$]).[53] While it is difficult to know precisely how ill these patients were (no severity of illness scores were reported), only 29 of 223 had a high probability result, and no critically ill patients had normal or near normal scans. Sixteen critically ill patients had the combination of low clinical pretest probability and low probability scan. Thus even in this group of ICU patients presumably stable enough to be enrolled in a clinical trial and in whom the scan could be performed, the test was definitive in only 20%. Although the investigators concluded that the sensitivity and positive predictive value of the $\dot{V}/\dot{Q}$ scan were similar in "critically ill" and "non–critically ill" patients, it is clear that the $\dot{V}/\dot{Q}$ scan is not helpful in the majority of patients. Given the surging popularity of CT scanning, combined with ever better CT and MR detectors, there seems to be little role for perfusion or ventilation-perfusion scanning in critically ill patients.

OTHER NONINVASIVE MEANS OF DIAGNOSIS

The most recent potentially useful blood test is the D-dimer assay. Very low levels of D-dimer argue against a diagnosis of PE, with a sensitivity of 95% and a negative likelihood ratio of 0.9 to 0.13 using the widely available quantitative rapid enzyme-linked immunosorbent assay (ELISA).[54] Essential to the use of a D-dimer test in diagnosing patients with thromboembolic disease is an assessment of clinical pretest probability; one clinical prediction rule for DVT found a prevalence of DVT of 6%, 9%, and 28% in patients whose clinical prediction rule was low, intermediate, or high, respectively.[55] Converting the prevalence to odds, and applying the D-dimer test with a 0.9 negative likelihood ratio, posttest probability is as low as 0.006 for the initial low-probability patients, whereas it is an order of magnitude greater (0.03%) in the high-probability patients. If one were to imagine extremely high-risk patients, with a pretest probability of 80%, the posttest probability of PE could be as high as 0.28 despite a negative D-dimer result. D-dimer assays can be considered unidirectional, in that a negative result can be extremely useful, yet a positive result has little effect on the likelihood of either DVT or PE.[54] This fact unfortunately limits the utility of the D-dimer test in the critically ill population, in whom so many patients will have a positive D-dimer level. For example, in a retrospective analysis of patients with severe sepsis randomized to undergo aspirin versus placebo, 100% of patients had an elevated D-dimer.[56] On the other hand, when D-dimer testing was applied to patients with cancer suspected of having deep vein thrombosis, it proved to be an effective test, with a 98% sensitivity, a 97% negative predictive value, and a negative likelihood ratio of 0.03.[57] Despite concern that the high prevalence of thromboembolic disease in a population with cancer would limit the utility of D-dimer, the test performed well and allowed outpatient evaluation in 29% of the patients studied.

The combination of pulse oximetry and static compliance of the respiratory system yielded a very high sensitivity and specificity for PE in critically ill trauma patients.[58] In patients with COPD, capnography during a prolonged passive exhalation had a negative predictive value of 100% when values of arterial P_{CO_2} and end-maximal expiratory P_{CO_2} were nearly equal.[16] Combining steady-state end-tidal alveolar dead space fraction and D-dimer was also quite sensitive in diagnosing PE in hospitalized, though not critically ill, patients, with a sensitivity and negative predictive value of 98%.[17] The proper place of each of these tests depends on further study.

PULMONARY ANGIOGRAPHY

Pulmonary angiography is considered the definitive test for the diagnosis of PE. Positive findings include an intraluminal filling defect or a cutoff of a 2-mm or larger vessel seen in more than one view. Experienced radiologists agree on 98% of studies showing lobar embolism.[59] However, agreement falls to 90% with segmental embolism, and only 66% in those with subsegmental clots. Thus even this test has limitations. Its sensitivity is sufficiently high to occasionally detect embolism even weeks to months after the acute episode. The earliest documented resolution of an angiogram to normal following a pulmonary embolus is 1 week, although faster resolution has been seen in animal studies.[60] Thus this test can reliably exclude embolism if a negative study is obtained even a week following the onset of symptoms.[61] Since it is invasive, costly, riskier than CT angiography, and requires the presence of an interventional radiologist (rather than a CT technician), it is usually reserved for patients in whom the diagnosis cannot be made or excluded by less invasive means. However, pulmonary angiography is safer than generally appreciated. Mortality is around 0.2% as shown in several large series.[62,63] Several patients who have died had severe pulmonary hypertension and cor pulmonale at the time of the procedure, leading some to conclude that pulmonary hypertension is a contraindication to pulmonary angiography. The degree of risk in such patients was directly addressed in one review of pulmonary angiography.[63] Elevated pulmonary systolic pressure (greater than 70 mm Hg) and elevated right ventricular diastolic pressure (greater than 20 mm Hg) were identified as risk factors. However, even in these sickest patients the mortality was only 2%. In patients with severe chronic pulmonary hypertension who are being considered for surgical endarterectomy (admittedly a different population) angiography has been performed quite safely.[64] Nonionic, low osmolality contrast agents improve image quality and may be able to reduce risk even further.

EMPIRICAL DIAGNOSIS

Occasionally, an empirical diagnosis of PE seems clear cut to the managing physician. No alternative diagnoses may seem plausible, or further diagnostic steps seem risky or unnecessary. Although this approach may appear attractive, it rarely proves correct. First, the clinical diagnosis is simply too unreliable, even for the most experienced clinician. Second, one can always expand the differential diagnosis to include alternative causes. Finally, the doubt that lingers after an empirical diagnosis too frequently haunts subsequent management. Progression of symptoms or signs despite therapy raises questions about failure of treatment or the need for alternative treatments. Complications of treatment (usually hemorrhage due to heparin, occasionally thrombocytopenia) create

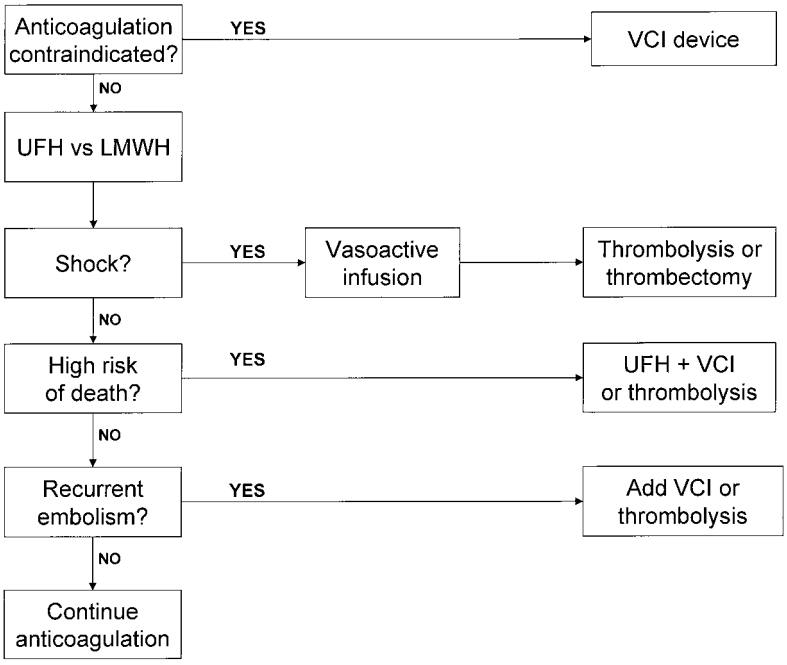

FIGURE 27-6 Treatment of PE in critically ill patients. UFH, unfractionated heparin; LMWH, low-molecular-weight heparin; VCI device, vena cava interrupting device.

uncertainty about the necessity of the toxic therapy, or precipitate more diagnostic interventions in a newly unstable state. Since critically ill patients are more likely to have complications of therapy, empiricism is rarely appropriate.

Treatment

The majority of patients with PE will not die from the clot that leads to diagnosis. As long as re-embolization is prevented, the patient will survive, while intrinsic fibrinolysis restores pulmonary blood flow. Therefore the primary goal of all therapies for PE is to prevent re-embolization. Some patients, however, survive the initial embolus yet remain in shock. These patients, who are overrepresented in ICU populations, may succumb to the initial embolus. Additional therapy to hasten clot resolution, aimed at more promptly restoring the circulation, is useful in such patients. Supportive care, anticoagulation, vena caval interruption, thrombolysis, fluid and vasoactive drug administration, and rarely surgical embolectomy all must be considered in the treatment of this disease. An integrated approach to the treatment of PE is presented in Figure 27-6.

RISK ASSESSMENT

Having made a diagnosis of PE, the clinician and patient face numerous potential therapies and outcomes. Pulmonary embolism is spectacularly inconsistent in its clinical presentation, and can range from asymptomatic or mildly symptomatic dyspnea to profound shock due to right ventricular dysfunction. Several characteristics of each presentation can allow the clinician to identify patients with the poorest prognosis, who almost certainly benefit from close observation in a monitored setting, and who may benefit from a more aggressive therapeutic approach. Equally important, the clinician may also identify those patients at low risk for complications, in whom a strategy of anticoagulation alone, potentially as an outpatient, will suffice. The Geneva prognostic index, generated from a prospective study of 296 patients with PE admitted through the emergency room, identified six predictors of adverse outcome, defined as death, recurrent thrombotic event, or major bleeding.[65] Hypotension imparted an odds ratio of 15; cancer of 9.5; and prior DVT, DVT by ultrasound, heart failure, and hypoxemia odds ratios of between 2.6 and 3.8. Cardiac biomarkers have also become potential prognostic indicators; when elevated, both troponin T and troponin I portend a high risk for complications, and troponin I was significantly associated with increased overall mortality in one study.[66] Low brain natriuretic peptide (BNP) was positively associated with survival, and high BNP with higher mortality and PE-specific mortality in another study of 110 normotensive patients with PE.[67] As previously discussed, echocardiographic evidence of right ventricular dysfunction clearly identifies a subgroup of patients with PE at high risk of shock or death.[31] To date no data have shown a decreased mortality or decreased recurrence of thromboembolic events by adopting a more aggressive treatment strategy for patients deemed to be high risk, and we do not advocate basing therapeutic decisions, such as whether or not to use thrombolytic medications, on such criteria. However, it seems prudent to use a careful risk assessment of death, recurrence, or major bleeding when contemplating which patients may benefit from outpatient therapy, treatment on the general ward, or surveillance in an ICU.

SUPPORTIVE CARE

OXYGEN AND BED REST

Patients typically present with hypoxemia, which responds well to oxygen therapy since the underlying pathophysiology is usually $\dot{V}/\dot{Q}$ mismatch. Bed rest, once advocated as the standard of care in treating venous thromboembolic disease, has recently been called into question by two randomized

prospective studies.[68,69] Both studies found that allowing patients with DVT to ambulate on day 2—compared to imposed strict bed rest for between 4 and 10 days—failed to increase the incidence of PE as detected by $\dot{V}/\dot{Q}$ scanning. Ambulating patients wore thigh-length compression stockings and walked up to 4 hours per day. Admittedly, the applicability of these studies to an ICU population may be problematic, as patients were excluded if they had clinically overt PE, free floating thrombus, pregnancy, renal insufficiency, or were unable to ambulate. Many of our ICU patients, and all patients with symptomatic PE, would have failed to qualify for these studies. Bed rest may have advantages to the critically ill patient beyond the theoretical advantage of reducing clot dislodgment. By reducing oxygen consumption ($\dot{V}_{O_2}$) and thus $\dot{Q}_T$ to their absolute minimum, bed rest—combined with sedation and mechanical ventilation in selected patients—is indicated in the treatment of patients with PE and shock.

SPECIFIC THERAPIES

ANTICOAGULATION

Unfractionated Heparin (UFH)

Heparin has long been the mainstay of therapy for PE, although its pre-eminent role in treating thromboembolic disease has lately been challenged by newer medications. Unfractionated heparin is a mixture of acidic glycosaminoglycans typically extracted from porcine intestinal mucosa, with a variable molecular weight of between 5000 and 30,000 da, depending on its clinical preparation.[70,71] Along with a coumarin derivative, it was the first anticoagulant to be prospectively shown to decrease mortality and recurrent PE, decreasing mortality by 25%.[72] While it has proven effective, it requires monitoring of coagulation parameters as well as dose adjustment due to unpredictable plasma levels even within individuals. Although a recent study has shown that UFH given subcutaneously is as effective and safe as fixed dose nadroparin,[73] UFH is generally given by continuous intravenous infusion and we expect this practice to continue. These limitations functionally restrict the use of heparin to the hospital setting. Heparin essentially catalyzes the effect of antithrombin to rapidly inhibit several of the factors from the intrinsic and common coagulation pathways, factors Xa, IXa, XIa, and XIIa.[70] It also inhibits the activation of factors V and VIII by thrombin.[71] Heparin is cleared rapidly from the plasma by binding to cell surface receptors on endothelial cells and reticuloendothelial elements,[70] and its clearance is not affected by renal or hepatic insufficiency.

In dosing heparin, a singular concept emerges: one must give enough heparin to surpass a minimal level of anticoagulation in order to prevent further thromboembolism. This threshold level appears to be doses at which the activated partial thromboplastin time (aPTT) is at least 1.5 times control[74] (or alternatively at which a heparin level of 0.2 to 0.4 U/mL by the protamine sulfate assay or 0.3 to 0.6 IU/mL by amidolytic anti-Xa study is reached), and it should be reached as quickly as possible. When continuous intravenous heparin was compared with intermittent subcutaneous heparin in the treatment of proximal deep vein thrombosis, only 1 of 61 patients who achieved an aPTT of greater than 1.5 times control suffered recurrent venous thromboembolism (VTE). In contrast, 13 of 53 patients whose aPTT was below 1.5 times control for 24 hours had recurrence, independent of the method of administration of heparin (relative risk = 15:1).[74] Rapid, adequate anticoagulation is facilitated by a weight-based nomogram.[73,75] Heparin is typically initiated with a bolus of 80 U/kg followed by a continuous infusion of 18 U/kg per hour. For most patients, oral anticoagulation (coumadin) is begun within 3 days of initiating heparin.

While the evidence supporting a lower therapeutic limit for heparin of 1.5 times control as judged by the aPTT is quite strong, the conventional upper limit (2.5 times control) is arbitrary. For years it had been assumed that the risk of hemorrhage was significantly related to the level of the aPTT, but one trial has cast doubt on this assumption.[76] In this study, hemorrhagic complications were related to underlying predisposing factors (eg, recent surgery, ulcer disease, or cancer) rather than to supratherapeutic levels of the aPTT. Patients were initially treated with heparin plus warfarin or with heparin alone. Of 99 patients in the combined treatment group, 69 (69%) had aPTT levels greater than 2.5 times control for more than 24 hours. In contrast, in the heparin only group, 24 of 100 patients (24%) had supratherapeutic aPTT levels. Bleeding complications were similar in the two groups (combined therapy, 9.1%; heparin alone, 12.0%). In addition, bleeding complications were seen in only 8 of 93 patients with supratherapeutic aPTT regardless of therapeutic arm, compared with 13 of 106 patients without such elevation. These findings refute an association between modestly elevated aPTT and hemorrhage, and combined with the importance of prompt, adequate anticoagulation, suggest the value of an approach that aims to assure enough heparin in the first hours of treatment, rather than to avoid too much.

Complications of Heparin

Complications of heparin, in addition to hemorrhage, include heparin-induced thrombocytopenia (HIT), osteoporosis, hypersensitivity, and (rarely) hyperkalemia. The most important complication of heparin is bleeding. In a pooled analysis of its use in deep venous thrombosis, major bleeding (bleeding greater than 1 L, bleeding requiring blood transfusion, or intracerebral bleeding) was reported in 2 of 59 patients (3%).[77] In a group of 121 patients given heparin for all indications, 8% developed major hemorrhage (fatal, life-threatening, potentially life-threatening, or bleeding leading to reoperation or requiring at least three units of blood).[78] When heparin dosing is guided by nomogram as described above, the risk of hemorrhage was 9% to 12%.[76] Hemorrhage typically occurs from the gastrointestinal or urinary tract, or from surgical incisions. Less common sites of serious bleeding include the retroperitoneum, adrenal glands, soft tissues, nose, and pleural space. Intracranial hemorrhage is uncommon in patients anticoagulated with heparin.

The approach to treatment of the patient who bleeds on heparin depends on the severity of bleeding. When bleeding is minor, simply stopping the heparin may be sufficient. Bleeding related to needlesticks may respond to sustained direct pressure. When hemorrhage endangers life or organ function, a more aggressive approach is mandatory. Transfusion of fresh frozen plasma is usually ineffective since circulating heparin inhibits the function of transfused factors. Protamine sulfate is an antidote to heparin. The dose of protamine depends on heparin levels, and is therefore related to

dose, route of administration, and time since the last dose. When hemorrhage immediately follows a bolus of heparin, sufficient protamine to completely neutralize the heparin (1 mg protamine per 100 U heparin) should be administered. In the more usual situation in which heparin therapy is ongoing, the dose of protamine should be based on the approximate half-life of heparin (90 minutes). Since protamine is also an anticoagulant, the dose should be calculated to only half-correct the estimated circulating heparin. Protamine has been known to cause hypotension, shock, dyspnea, and pulmonary hypertension upon intravenous injection. The incidence is reduced by giving the drug very slowly (no more than 50 mg in 10 minutes). When protamine is administered, a physician should be present in case of an anaphylactoid reaction. Alternatives for the treatment of underlying conditions should be considered once heparin is stopped. For example, the patient with pulmonary embolization should have vena caval interruption with a percutaneous filter (see below).

Thrombocytopenia is a relatively common complication of heparin administration, typically occurring after several days of therapy. In large series, roughly 1% to 3% of patients given full-dose intravenous heparin have developed thrombocytopenia.[79] Interestingly, in our experience at a tertiary care center where many of our patients are repeatedly exposed to heparin, the incidence of heparin-induced thrombocytopenia seems to be much higher. The mechanism in most patients is thought to be related to specific IgG directed against heparin. Thrombocytopenia is less commonly seen with highly purified low-molecular-weight heparins, suggesting that higher-molecular-weight components may be responsible. It is also rare in patients given prophylactic, minidose heparin, occurring in only one of 348 patients.[80] The onset of thrombocytopenia is usually on the third to fifteenth day (mean = day 10), but it can occur after several hours in patients previously sensitized. The severity of thrombocytopenia is variable (commonly to 50,000/mm^3), but can be severe (<5000/mm^3). Most patients remain asymptomatic, but some suffer major arterial or venous thrombosis, or life-threatening hemorrhage. Rarely, this syndrome is associated with skin bullae that progress to necrosis ("heparin necrosis"). These may occur at sites of injection or at distant sites. Any time heparin is given, it is prudent to measure platelet counts on a daily basis. An otherwise unexplained drop in platelet count of 30% has been suggested as the threshold that should prompt discontinuation of heparin,[80] although there are few data upon which to base this. Heparin-dependent IgG should be sought in the patient's serum, since a positive result may simplify management decisions. None of the available assays are fully sensitive, so a negative test is no guarantee against recurrent thrombocytopenia or thrombosis if the patient is rechallenged with heparin.

Low Molecular Weight Heparin

The promise of low molecular weight heparins (LMWHs) is a simple, once or twice daily therapy for venous thromboembolism that does not require monitoring of anticoagulant effect. As a class, the LMWHs encompass a number of fragments of unfractionated heparin which are on average 5000 da in molecular weight. The different LMWHs have been depolymerized by various means, and thus differ in their pharmacokinetic and pharmacodynamic properties.[70] One LMWH may not be interchangeable with another. LMWHs achieve excellent bioavailability when given subcutaneously (about 90% of that achieved with an equal intravenous dose), have a long half-life (2 to 4.4 hours), correlate well between anticoagulant response and body weight, and have equal or better antithrombotic effects than unfractionated heparin. There have now been numerous trials comparing LMWHs (subcutaneously or intravenously) with unfractionated heparin in both DVT and PE.[81–85] In an early meta-analysis pooling the results of over 2000 patients, LMWHs appeared superior with regard to venographic score improvement, recurrence rate of VTE, and hemorrhage. There is also a trend towards an all-cause mortality benefit for LMWHs.[81] Similarly, a recent meta-analysis of LMWH compared to unfractionated heparin for the treatment of PE found non–statistically-significant decreases in recurrent symptomatic VTE, PE, and bleeding complications.[86] With such data, groups such as the American College of Chest Physicians now recommend that clinicians use LMW heparin over unfractionated heparin.[71]

Aspects of caring for critically ill patients may limit the full implementation of such recommendations in the ICU. Many patients with critical illness have coincident renal failure, bleeding diatheses, or need for ongoing invasive procedures, all of which make unfractionated heparin, which can be quickly discontinued and rapidly cleared from the body, preferable. Conversely, certain situations appear to be ideally suited to the use of LMWH, such as in the long-term treatment of cancer patients with venous thromboembolism.[87,88] As stated, the incidence of HIT is lower with LMWH than with unfractionated heparin, although in many trials of LMWH for DVT or PE, the incidence of HIT was sufficiently low in both arms to preclude a statistical comparison. In orthopedic and surgical studies as well as the initial industry-sponsored trials of various LMWHs, the incidence of HIT varied between 0% and 0.8% of patients, compared with approximately 3% of patients treated with unfractionated heparin.[89] However, antibodies from patients with previous HIT cross-react with every commercially available LMWH, therefore LMWHs cannot be safely used in a patient known to have HIT.[89]

Alternatives to Heparin

Neither heparin nor low molecular weight heparin can be used in patients with HIT; furthermore, no safe dosing regimen has been approved for LMWH in the presence of renal failure. Current alternatives to heparin include selective factor Xa inhibitors, direct thrombin inhibitors, and oral anticoagulants.

Direct thrombin inhibitors include the hirudin family, first isolated from leeches, and the argatroban family of active-site inhibitors. The advantage of such agents over unfractionated heparin is their ability to inhibit fibrin-bound thrombin with a predictable dose response, and their inability to produce HIT.[70] Hirudin and its derivatives, especially lepirudin and bivalirudin, are potent anticoagulants which have been proven more effective than enoxaparin, a LMWH, in DVT prophylaxis of patients undergoing hip replacement.[90] The risk of life-threatening bleeds appears to be equal between hirudin and heparin,[90,91] although an increased risk of moderate bleeding was observed with hirudin.[91] aPTT must be monitored with hirudin agents (goal aPTT = 1.5 to 2.5 times control). Dosages must be adjusted for renal insufficiency. The agents are approved for use in patients with HIT,

but they have not been extensively studied in prospective comparison to heparin or LMWH in treatment of pulmonary embolism.

Additional direct thrombin inhibitors are the class represented by argatroban, melagatran, and the new oral agent ximelagatran. Argatroban is an effective anticoagulant in patients with HIT, and has been licensed for use in this capacity.[70] Like the hirudins, argatroban has not been studied in any randomized trials in PE, but it appears to be as safe or safer than heparin when given to patients with myocardial infarcation.[92] It is cleared principally by the biliary system and the dose needs no adjustment for renal failure. Monitoring of both the aPTT and the prothrombin time (PT) is recommended. Ximelagatran, an oral prodrug converted to melagatran, does not require monitoring. Having been proved favorable in preventing DVT following total knee replacement compared to both coumadin[93] and enoxaparin,[94] ximelagatran was tested for secondary prevention of DVT. In this study, the oral drug was compared to warfarin therapy for patients who had already received 6 months of oral anticoagulation with coumadin.[95] Recurrent thromboembolism was significantly reduced in the ximelagatran group (2.8% vs. 12.6% in the warfarin group, $p < 0.001$), with similar rates of major bleeding. Three cases of fatal pulmonary embolism were diagnosed in the warfarin group, compared to none in the ximelagatran group, though overall mortality was equivalent between groups. Ximelagatran has been shown to cause elevated liver aminotransferases, especially in the first 4 months of therapy; in this study, all cases of elevated alanine aminotransferase were transient, and no case (out of 600) progressed to hepatic failure.[95]

Among the newest of antithrombotic agents approved for the prophylaxis of DVT and pulmonary embolus is fondaparinux, a novel synthetic drug inhibiting factor Xa. By binding to antithrombin with tight affinity and inducing a conformational change, fondaparinux facilitates the binding of antithrombin with factor Xa, thus blocking the common pathway of coagulation.[70] It has been approved by the FDA as a subcutaneous injection of 2.5 mg once daily for use in DVT and PE prophylaxis in patients undergoing orthopedic surgery for hip fracture, hip replacement, or knee replacement, after several randomized controlled trials found superior reduction of DVT for fondaparinux compared to enoxaparin.[96] A study comparing fondaparinux and heparin for pulmonary embolism found the new agent to be as effective and safe as heparin, with a nonsignificant trend toward fewer recurrences of VTE in the fondaparinux group.[97] Bleeding events were similar, and no difference in mortality was detected. HIT has not been observed with fondaparinux use. A number of additional anti–factor Xa agents are in development, but they have not yet been widely tested in humans. While fondaparinux shows promise in the acute treatment of PE, more studies are necessary before recommending that factor Xa inhibition replace our traditional anticoagulant strategies.

Warfarin anticoagulation should be instituted in the first few days (5 mg PO qhs for the first 2 days, then adjust the dose to achieve an International Normalized Ratio [INR] between 2.0 and 3.0) and continued to overlap with heparin therapy for at least 5 days. If the patient is clinically unstable or likely to require ongoing invasive procedures, heparin or a rapidly adjustable agent such as lepirudin or argatroban should be used preferentially, to facilitate rapid adjustment of anticoagulation if necessary.

VENA CAVAL INTERRUPTION

Occasionally patients have compelling reasons that preclude anticoagulation, or continue to embolize despite adequate anticoagulation. As most thromboemboli originate in the legs, pelvis, or inferior vena cava (IVC),[98] inferior vena caval interruption (VCI) has the potential to prevent subsequent embolization. Conventional indications for the use of VCI in patients with venous thromboembolism have included contraindications to anticoagulation, hemorrhage following anticoagulation, failure of anticoagulation to prevent recurrent embolization, and prophylaxis of extremely high-risk patients. Only one randomized prospective trial has evaluated using VCI to prevent PE.[99] This trial randomized 400 patients with proximal DVT who were at risk for PE to receive a vena caval filter or standard anticoagulation. Over the first 12 days, the vena caval filter group had significantly fewer cases of PE (1.1% vs. 4.8%, $p < 0.03$). However, over the subsequent 2 years, during which all patients were anticoagulated for at least 3 months, the rates of PE, major bleeding, and death were similar in both groups. Moreover, the vena caval filter group actually had a significantly higher rate of recurrent DVT, with a nearly twofold increase in odds ratio for DVT compared to the no-filter group. Thus VCI appeared to be a successful short-term strategy to prevent PE, but came at the expense of increased long-term DVT and a trend toward increased thromboembolic disease. This landmark study prompted widespread discussion on two fronts: whether anticoagulation should be considered for all patients receiving a vena caval filter, and whether a temporary or retrievable filter might be more successful.[100] Unfortunately, no prospective trial evaluates either question. Progress has been made in the technology of retrievable filters, and small case series of several different types of temporary filters have been published.[101,102] Whereas initially, temporary filters had to be removed within a 2-week period in order to minimize the risk of endothelialization, newer filters have been retrieved after up to 134 days without complication.[101]

As VCI devices have evolved, they have become smaller and more easily placed. As physicians have become more experienced with them, they have become safer as well, although published complication rates have varied widely, from 2% to 19%.[101] Proposed indications for VCI continue to expand as the technology improves,[100] yet caval filters are probably underutilized in the sickest patients. Those with critical cardiopulmonary compromise may be least able to tolerate the admittedly low risk of heparin failure. Patients who survive sublethal embolism but remain hemodynamically compromised may benefit from VCI since recurrent embolism, while unlikely, will be fatal. In addition, some patients have such a predictably high risk of venous thromboembolism that VCI may be indicated even before any thrombosis is detected. For example, we have placed caval filters prophylactically in patients with severe COPD and proximal venous thrombosis and in a woman with Crohn's disease complicated by toxic megacolon and ARDS on her way to the operating room. Additional potential indications include extensive free-floating vena caval thrombus (since the efficacy of heparin in this setting is controversial), pre–pulmonary embolectomy, and as primary treatment in patients with malignancy (since

anticoagulants seem less effective and less safe in this setting). The advent of safe, effective retrievable filters may greatly expand our use of VCI.

Complications include filter fracture (occasionally with embolization of fragments), improper placement of the filter, venous thrombosis at the insertion site (seen in 8% to 25%[103]), caval occlusion (which is now far less common than when the Mobin-Uddin "umbrella" filters were in use), inadvertent dislodgment by guidewires during central venous catheterization, and erosion or perforation of the caval wall and other viscera. A final point about VCI is that while it prevents most recurrent emboli, it does not treat the (presumed) leg source. Therefore, when these devices are used, concomitant anticoagulation is necessary (unless the indication for VCI is contraindication to anticoagulation). The significance of upper extremity sources of thromboemboli in ICU patients, who often have central catheters, is unknown but probably small. Nevertheless, inferior VCI would clearly be ineffective so that when the clinical presentation suggests an upper source, due consideration should precede placement of this device. Filters have been placed in the superior vena cava and in the suprarenal IVC with apparent safety, but the experience is limited.

THROMBOLYTIC THERAPY

It has been clear for more than three decades that thrombolytic therapy more rapidly lyses pulmonary emboli and improves hemodynamics.[104] However, 7 days after therapy, patients given thrombolytic therapy cannot be distinguished from those treated only with heparin on the basis of clinical findings or lung perfusion.[105] Combined with the clearly increased risk and cost of thrombolytic agents, this has led to a general skepticism about the value of thrombolytic therapy for the treatment of PE. In a survey of pulmonary physicians, only 11% would give thrombolytic therapy for a large PE without hypotension, severe hypoxemia, or right ventricular strain.[106] However, nearly all would give thrombolytics to a patient with shock due to PE, and there is now convincing data to support this approach. For example, when patients with massive PE were given alteplase (1 mg/kg over 1 hour) in an uncontrolled trial, there was significant clinical improvement in 11 of 15 with shock.[107]

In another study comparing alteplase (100 mg over 2 hours) and heparin, right ventricular function assessed echocardiographically improved more rapidly in patients given alteplase.[108] This more rapid hemodynamic improvement could translate into improved survival in critically compromised patients. Furthermore, of the 55 patients treated with heparin alone, 5 suffered recurrence (2 fatal) within 14 days, whereas none of 46 patients given alteplase recurred. Finally, one very small (eight patients) randomized clinical trial comparing thrombolysis (streptokinase, 1,500,000 U over 1 hour) with heparin in patients with massive embolism and hypoperfusion showed a mortality benefit for thrombolytic therapy; all four patients receiving heparin alone died, while there were no deaths in the streptokinase group.[109]

Recently, the debate over thrombolytic therapy has moved from discussion of massive PE to that of submassive PE: PE which has not yet provoked hypotension, but for which the risk for death is high. Data from echocardiographic studies show an indisputably higher mortality in patients with moderate RV dysfunction.[30] The utility of echocardiography in prognostication has led to great interest as to whether echocardiographic criteria should be used routinely to guide the use of thrombolytic therapy.[110,111] Two studies address this question. In a retrospective cohort study of patients with radiographically large emboli and right ventricular dilation (but without hypotension or shock), those who received thrombolytic therapy had better pulmonary perfusion on day one, but this advantage disappeared by day seven.[112] Mortality was 6% in the thrombolytic group compared to no deaths in the heparin group, and severe bleeding in the thrombolytic group approached 10%, with intracranial bleeds in 4% of patients. In a second, prospective study, patients with acute PE and right ventricular dysfunction (but without shock) were randomized to heparin plus alteplase or heparin plus placebo.[113] While there was no difference in mortality between groups, the alteplase group had a significantly lower rate of treatment escalation, mostly consisting of secondary thrombolysis for worsened symptoms. No significant difference in bleeding was found between groups, which was surprising, as previous studies have never failed to show an increased risk of major hemorrhage with thrombolytic therapy compared to heparin. In a large prospective registry of over 2400 patients with PE, the rate of major hemorrhage in patients receiving thrombolytics was almost 22%, and intracranial bleeds were noted in 3%.[114] The retrospective, nonrandomized nature of the first study raises concerns for its validity, but the latter has also been cited as potentially flawed in its design, both in its definition of "right heart dysfunction" and its use of secondary thrombolysis based on vague clinical criteria.[115] As no mortality benefit has yet been established for patients with submassive PE who receive thrombolysis, we advocate restricting thrombolytic therapy for those patients with clinically apparent shock.

The optimal regimen for thrombolytic therapy has not been established. A number of approaches are listed in Table 27-6.[104,107,109,116–118] There has been a general trend towards bolus, as opposed to long-duration, infusion, based on both animal studies and human trials in patients with myocardial infarction showing increased efficacy and reduced hemorrhage. Yet the increasing benefits of front-loaded regimens

TABLE 27-6 Alternative Thrombolytic Strategies in Acute Massive Pulmonary Embolism

[a] Urokinase, 4400 U/kg bolus, followed by 4400 U/kg per hour for 24 hours[104]
Urokinase, 1,000,000 U bolus over 10 minutes, followed by 2,000,000 U over 110 minutes[116]
Urokinase, 15,000 U/kg bolus over 10 minutes[117]
rt-PA, 0.6 mg/kg bolus over 2–15 minutes [118]
rt-PA, 1 mg/kg over 10 minutes [107]
[a] rt-PA, 100 mg over 2 hours [116]
Streptokinase, 1,500,000 U over 1 hour[109]
[a] Streptokinase, 250,000 U over 30 minutes, followed by 100,000 U/h for 24 hours

[a] Approved by the Food and Drug Administration.
ABBREVIATIONS: rt-PA, recombinant tissue plasminogen activator.
NOTE: Heparin is infused at 1300 U/h when the activated prothrombin time falls below twice normal, then adjusted to keep the aPTT between 1.5 and 2.5 times control.

TABLE 27-7 Contraindications to Thrombolytic Therapy

Absolute
Recent puncture in a noncompressible site
Active or recent internal bleeding
Hemorrhagic diathesis
Recent central nervous system surgery or active intracranial lesion
Uncontrolled hypertension (BP >180/110 mm Hg)
Known hypersensitivity, or for streptokinase, use of streptokinase within 6 months
Diabetic hemorrhagic retinopathy
Acute pericarditis
Recent obstetric delivery
History of stroke
Relative
Trauma (including cardiopulmonary resuscitation) or major surgery within 10 days
Pregnancy
High likelihood of left heart thrombus
Advanced age
Liver disease

NOTE: See text for discussion about "absolute" contraindications.

has a limit as demonstrated in a comparison of alteplase, 0.6 mg/kg (maximum dose = 50 mg) over 15 minutes versus 100 mg over 2 hours, in which there was no significant difference in efficacy or rate of hemorrhage.[119–121] The particular thrombolytic agent is probably not of much importance. In a head-to-head comparison of alteplase (100 mg over 2 hours) and urokinase (1,000,000 U over 10 minutes followed by 2,000,000 over 110 minutes), the two regimens yielded similar efficacy and safety.[122] A powerful case can be made that streptokinase is the agent of choice since it is the one agent for which a mortality benefit has been shown,[109] and it is fourfold cheaper than any of the current alternatives. Careful attention should be given to selecting patients appropriately to reduce the rate of hemorrhagic complications (Table 27-7). Especially important is a concerted effort to avoid invasive procedures, including arterial blood gases, arterial catheters, central venous punctures, and pulmonary angiograms, where possible.[123]

Various measures of the lytic state correlate poorly with both efficacy and incidence of bleeding, so that outside of clinical research protocols, routine monitoring is not indicated. When streptokinase is given, the manufacturer recommends that the thrombin time be assayed at 4 hours to ensure that a lytic state is achieved. An adequate lytic state can be assumed if the thrombin time is prolonged above the normal limits of the laboratory, or if the fibrinogen level is reduced. Clinical monitoring should include serial neurologic examinations to detect central nervous system hemorrhage and frequent vital signs to detect gastrointestinal or retroperitoneal hemorrhage. Patients who have undergone catheterization should have the groin puncture examined, and preferably have repeated measurements of thigh girth. Huge volumes of blood can be lost into the thigh and groin, especially in obese patients, with little external evidence of bleeding.

After the thrombolytic agent is discontinued, heparin is typically begun (without a bolus) when the thrombin time or the aPTT falls to less than 2 times control. Heparin is begun as an intravenous infusion at 1300 U/h and titrated to a PTT of 1.5 to 2.5 times control.

No advantage to infusing the thrombolytic agent directly into the pulmonary artery has been shown in controlled trials despite claims of benefit in small case series.[124] Investigational approaches include pharmacomechanical thrombolysis[125] and augmentation of cardiac output to enhance thrombolysis.[126]

Thrombolytic Therapy following Surgery

Although recent surgery is generally included among the absolute contraindications to thrombolytic therapy, there is an evolving literature supporting its use. For example, 13 patients with angiographically confirmed embolism within 2 weeks of major surgery (mean = 9.6 days) were given a modified regimen of urokinase (2200 U/kg directly into the clot, followed by 2200 U/kg per hour for up to 24 hours).[127] Complete lysis was achieved in all and there were no deaths or bleeding complications. In another report, two patients in shock due to PE were given bolus regimens of urokinase (1,200,000 U) or alteplase (40 mg, followed by another 40 mg over 1 hour) only 2 days after lung resection.[128] There was prompt clinical improvement, although one patient had delayed hemorrhage. Finally, nine patients were treated with urokinase (1,000,000 U over 10 minutes, followed by 2,000,000 U over 110 minutes) following neurosurgery (mean = 19 days following surgery).[129] All of the patients survived their acute episode of PE and no intracranial hemorrhage occurred, although one patient developed a subgaleal hematoma. These reports suggest that recent surgery is a relative, not an absolute, contraindication, and that the risks and benefits should be considered on an individual basis.

Complications

The greatest limitation of the thrombolytic drugs, and the factor which has limited their acceptance for the treatment of venous thromboembolism, is the consequential incidence of bleeding. In patients treated for pulmonary embolism the risk of major hemorrhage is reported to be around 15%,[107] but these data were gathered in an era of frequent pulmonary angiography. As mentioned, intracranial bleeds have been observed in as many as 4.7% of patients,[112] although larger series report a 3% incidence.[114] When serious bleeding occurs, the lytic agent should be immediately discontinued, and reliable, multiple, large-bore catheters secured. Direct compression of bleeding vessels may stop or slow ongoing blood loss. If heparin has been given, it too should be stopped and consideration given to reversing heparinization with protamine. Most patients will be adequately managed without the transfusion of clotting factors. If it becomes necessary to reverse the lytic state, cryoprecipitate, which contains fibrinogen and factor VIII (both of which are consumed by plasmin) is the preferred blood product.[130] The initial dose is 10 units, after which the fibrinogen level should be assayed. Fresh frozen plasma (as a source of factors V and VIII), platelets, and fibrinolytic drugs (e.g., epsilon aminocaproic acid 5 g over 30 minutes) all may play a role in the critically bleeding patient.

Allergic Effects

Allergic reactions, including skin rashes, fever, and hypotension are rare except with streptokinase. Mild reactions can be treated with antihistamines and acetaminophen. More

severe reactions should prompt the addition of hydrocortisone. Hypotension usually responds to volume administration.

FLUID, VASOACTIVE DRUGS, AND NITRIC OXIDE

Volume administration with saline or colloid has generally been advocated in patients with PE and shock on the grounds that it will increase filling pressures and thereby augment $\dot{Q}_T$. However, in a patient with elevated right heart pressures and a grossly distended right ventricle, it is possible that further distention of the right ventricle during volume administration will increase myocardial oxygen consumption, yet fail to increase $\dot{Q}_T$ and oxygen supply. In addition, to the extent that fluids increase right ventricular end-diastolic volume, the interventricular septum will bulge further to the left, impede left heart filling, and further compromise $\dot{Q}_T$. Experimental studies to determine the effect of fluids have shown a detrimental effect on hemodynamics.[131] Therefore, volume administration should not be routine therapy unless the patient is clearly hypovolemic. When fluids are given, central venous catheterization (to measure venous oxyhemoglobin saturation and changes in right atrial pressure) and echocardiography may provide useful guidance. These issues are further discussed in Chapter 26.

There is also controversy regarding the use of vasoactive drugs to treat the hypoperfusion caused by PE. Successful use of vasoconstrictors, inotropes, and vasodilators has been reported. Since no controlled studies in patients have been performed, it is hard to give firm recommendations. However, the pathophysiology of this form of shock, the results of some animal experiments, and limited human data (all discussed in Chapter 26) provide some guidance. When any of these drugs are used, serial assessment of the effect of the intervention is mandatory. Any drug which does not result in the intended salutary effect should be discontinued promptly.

The vasoactive drug of choice, based on the largest published experience in patients, is dobutamine.[132] Dobutamine is infused beginning at 5 μg/kg per minute and increased to effect. If dobutamine is ineffective or incompletely effective, norepinephrine should be tried. The rationale for the use of this vasoconstrictor is based on the assumption that right ventricular ischemia is the fundamental problem leading to shock. A vasoconstrictor that increases systemic arteriolar tone could raise aortic pressure and augment coronary blood flow, without increasing right ventricular load. In animal models of sublethal PE, norepinephrine was shown to be superior to no therapy, to volume administration, and to isoproterenol in the maintenance of cardiac output as well as in survival time.[133] Infusion is initiated at 2 μg/min and adjusted (up to 30 μg/min) based on the hemodynamic response. In the clinical setting, hypoperfusion may have additional contributors such as left ventricular dysfunction or ischemic heart disease, so that a vasoconstrictor might be less beneficial than in controlled animal experiments. If dobutamine and norepinephrine fail to improve cardiac output, epinephrine may succeed.[134] Finally, nitric oxide, which can lower the pulmonary artery pressure, boost cardiac output, and improve oxygenation, can be tried if available.[135,136]

EMBOLECTOMY AND MECHANICAL THERAPIES

Surgical embolectomy is a major procedure rarely resorted to in most institutions. In part, this is related to the availability of other, more benign, therapies such as heparin and thrombolysis. Additionally, it takes time to organize a surgical team, operating room, cardiopulmonary bypass and so on, by which time the patient is often hemodynamically improved or moribund. Yet embolectomy has its advocates, who maintain that thrombolytic therapy is often contraindicated in patients who could benefit from it, the operative mortality for embolectomy is now acceptable, and chronic cor pulmonale can be averted.

In one institution's review of 87 patients with PE, 34 were treated with heparin, 28 with streptokinase, and 25 with embolectomy.[137] Pretreatment embolic scores were most severe in the embolectomy group. Hospital mortality in the heparin, streptokinase, and surgery groups was 6%, 21%, and 20%, respectively. However, cumulative survival at 5 years was 68%, 64%, and 80%, a trend favoring embolectomy. However, most late deaths were due to malignancy, not recurrent PE or chronic pulmonary hypertension. Although the authors recommended surgical embolectomy for all patients with emboli in the main pulmonary arteries based on their results, regardless of the hemodynamic impact, this study was not randomized and the possibility seems large that the long-term benefit for embolectomy was related to selection of patients. A more recent trial showed that surgical embolectomy was comparable to thrombolytic therapy in patients with massive PE.[138]

Mortality due to embolectomy appears to be in the range of 30% to 40%, but may be as low as 8% in those who have not sustained cardiac arrest preoperatively.[139,140] Even if this lower number reflects improvements in anesthetic or operative technique, this mortality is still comparable to that of patients with massive embolism treated less invasively.[141] The argument that embolectomy might reduce the long-term consequences of chronic pulmonary hypertension lacks force, even though this complication is more common than previously thought.[142] Thus it has never been demonstrated in a well-performed trial that embolectomy confers any advantage over thrombolytic therapy, or for that matter heparin. The population of patients who might benefit from embolectomy appears to be those who meet the following criteria: those with a hemodynamically significant embolism, in whom thrombolytic therapy is contraindicated; and in a center with a rapidly responding cardiopulmonary bypass team and a surgeon experienced in the technique of embolectomy.

Several new devices have been tested which aim to remove pulmonary emboli less invasively than the direct surgical approach. For example, a 10F suction catheter, inserted through a jugular or femoral venotomy and advanced into the pulmonary artery has been used to extract clot.[143] Eleven of eighteen patients improved immediately. Suction embolectomy was more likely to be successful in patients treated promptly after hemodynamic deterioration. More recently, patients with shock underwent mechanical fragmentation of their massive PE with a rotational pigtail catheter, followed by thrombolytic therapy.[144] Nine of ten patients survived, and 6 of the survivors achieved hemodynamic stability within 48 hours of the procedure. Alternative methods to re-establish pulmonary artery patency include endovascular stents,[145] but experience with all of these techniques is limited.

Special Considerations

PREGNANCY

The pregnant woman who may have PE presents unique challenges.[146] Pregnancy is thought to be a risk factor for venous thrombosis, and PE is the second leading cause of death among gravidas (next to trauma).[147] The addition of the fetus, as well as anatomic considerations, leads to several key differences in management.

DIAGNOSIS

Diagnosis can be more difficult because of reluctance to perform potentially risky procedures, particularly involving diagnostic radiology. However, it is important not to lose sight of the risk of failing to make the diagnosis. Thus when the diagnosis is seriously considered, it should be pursued. $\dot{V}/\dot{Q}$ scans probably pose little risk to the fetus. The estimated radiation dose is small, and the risk is clearly less than that of missing a diagnosis.[148] Impedance plethysmography is also less useful in pregnancy due to mechanical compression of the IVC by the enlarged uterus, especially in the third trimester. A positive result in the first two trimesters is sufficient basis on which to anticoagulate, but may not be in the last trimester unless the vascular laboratory has particular expertise in pregnancy.[149] The risk of helical CT angiography is not known, but when indicated, it should not be withheld out of concern for fetal radiation exposure. The maternal risks of undiagnosed and untreated PE are clear. A diagnosis of thromboembolism in pregnancy has serious implications for the mother, not just in the current pregnancy, but during any subsequent pregnancies. Because of the risk of heparin-induced osteoporosis and the remaining uncertainties about effective prophylaxis against recurrence during future pregnancies, the diagnosis of thromboembolism should never be made lightly in a gravida, but instead should be based on solid evidence.

TREATMENT

The use of heparin in pregnancy is no different than in the nonpregnant patient. Heparins do not cross the placenta, and pose a low risk to the fetus. However, warfarin, which is teratogenic, should not be instituted. Rather, long-term treatment should consist of subcutaneous heparin[150] or LMWH.[151] LMWHs are preferred in that they have a lower incidence of both bleeding and of heparin-induced thrombocytopenia.[151] Osteoporosis is a serious complication of full-dose heparin during pregnancy, with fractures occurring in 2% of women.[152] There are indications that bone mineral loss is reversible,[153] but several cases of debilitating back pain have been reported. Low molecular weight heparins, when prospectively studied, do not appear to accelerate bone mineral density loss.[154] Thrombolytic therapy risks spontaneous abortion and uterine bleeding. Nevertheless, several case reports of the successful use of thrombolytic treatment of PE have appeared. Vena caval interruption requires some modification as well. The left ovarian vein (a potential source of clot) drains into the left renal vein. Therefore, when a caval filter is placed, it should be inserted to a suprarenal position, rather than below the renal veins. Again, several cases of successful use of these devices have been described. Pregnancy may be an ideal situation for the temporary vena caval interruption device.

CHRONIC OBSTRUCTIVE PULMONARY DISEASE

Patients with COPD are at increased risk for PE. In addition, their preexisting respiratory compromise and abnormal pulmonary vasculature leave them particularly vulnerable to the cardiopulmonary consequences of PE. Ironically, diagnosis of PE in the setting of COPD is unusually difficult. Patients commonly complain of dyspnea, chest pain, cough, and anxiety, and occasionally note hemoptysis and leg swelling. Their examinations, chest radiograms, ECGs, and arterial blood gas values are usually abnormal at baseline. $\dot{V}/\dot{Q}$ scans are most often unhelpful. For example, in PIOPED 108 patients were identified as having COPD (although objective data were available in only 43).[155] Scans were intermediate probability in a full 60%. Only 20 patients (19%) had results which made pulmonary angiography unnecessary by being normal, high probability, or low probability paired with a low pretest clinical estimate. Nevertheless, for the occasional patient, $\dot{V}/\dot{Q}$ scanning obviated pulmonary angiography.

When patients with COPD present with symptoms that are atypical for their usual exacerbation, particularly when the Pa_{CO_2} is reduced from previously elevated values, it is worth considering the diagnosis.[156] Positive leg studies may provide a rationale for anticoagulation and obviate the need for further investigation, although this approach has been called into question.[41] CT angiography or pulmonary angiography may be necessary to establish a diagnosis. The physician and patient may be in the unfortunate position of having to repeatedly consider an invasive procedure or risk a missed diagnosis. In fact, it is in just this type of situation that PEs go undiagnosed. There is no simple answer to this problem and PEs will continue to be underdiagnosed until better, less invasive tests are available.

PATIENTS WITH COAGULATION OR PLATELET DISORDERS

The risk of venous thromboembolism in patients with chronic liver disease or marked thrombocytopenia is not known. While it seems sensible to conclude that the risk must be lower than if clotting and platelet function were normal, PEs occur even when the bleeding tendency is severe.[157,158] Therefore, when the clinical presentation strongly suggests PE, thrombocytopenia and coagulopathy should provide little reassurance, and diagnostic testing is indicated. Patients with chronic renal failure—excepting those with nephrotic syndrome—do seem to be at a remarkably low risk of venous thromboembolism, so alternative diagnoses should always be sought.

Prophylaxis against Venous Thromboembolism

A discussion of prophylaxis has been left to the end of the section on thromboembolism because here it is particularly easy to emphasize several points. PE is common, lethal, usually missed, difficult to evaluate, and costly to treat. Critical illness makes these statements especially true, therefore the goal must be to prevent this disease. A full treatment of

prophylaxis is beyond the scope of this chapter, but a few points are worth making. Prophylaxis in the ICU is discussed further in Chapter 10.

Over the last 20 years, a large volume of information regarding the risks and benefits of numerous prophylactic strategies has been collected. The greatest accumulated experience is with low-dose heparin, typically 5000 U administered subcutaneously either bid or tid both in surgical and medical patients. Other methods of thromboprophylaxis are also available, and may have a role in special subsets of patients, patients in whom heparin is ineffective or contraindicated, or those who are at unusually high (or low) risk of VTE. These alternatives include low molecular weight heparins (LMWHs), adjusted-dose heparin, aspirin, warfarin, dextrans, antiembolism stockings, intermittent pneumatic (or sequential) compression cuffs, and vena caval interruption. In some patients combined prophylaxis is superior. For example, the combination of minidose heparin and intermittent pneumatic compression was more effective than minidose heparin alone in patients following cardiac surgery.[159] In trauma patients[160] and in patients suffering hip fracture, LMWH is superior to low-dose heparin. In many settings the optimal approach has not yet been clarified and there are far fewer data regarding medical patients than surgical patients. Nevertheless, for most patients at risk of VTE, some method which is both safe and effective is available. In one survey of 152 medical ICU patients, only 33% were given prophylaxis and there was a mean delay of 2 days before prophylaxis was prescribed, although risk factors were identified in 87% of patients.[161] In the absence of a contraindication, nearly all critically ill patients should receive minidose heparin. When heparin is unsafe (e.g., neurosurgical patients), alternative methods of prophylaxis, such as intermittent pneumatic compression cuffs, should be instituted. In some patients at very high risk of thromboembolism, such as those with acute spinal cord injury, minidose heparin is ineffective and LMWH is preferred.[83] In most patients, however, the increased cost of LMWHs is not matched by clearly incremental efficacy or improved safety.[83] Finally, although controversial, some patients at extremely high risk of PE should have consideration given to prophylactic insertion of vena caval filters (see above).

Air Embolism

The syndrome of air (or gas) embolism results when air enters the vasculature, travels to the pulmonary circulation, and causes circulatory or respiratory embarrassment. It is uncommonly recognized in critically ill patients, but is quite likely underdiagnosed.

PATHOPHYSIOLOGY

The syndrome is triggered when a gas, usually air, enters a vessel, typically a vein. It travels with the venous return to the right heart and lungs, where it may have circulatory or respiratory consequences. Occasionally, air reaches the arterial circulation leading to systemic manifestations. Although air embolism is often abrupt and short-lived, intriguing cases of continuous streaming of bubbles in mechanically ventilated patients have been reported.[162] At times, such embolism may persist over many days.

ENTRY OF AIR INTO THE VASCULATURE

Development of air embolism requires an abnormal communication between air and the blood vessel. In addition, there must be a pressure gradient to favor entry of air into the vessel, rather than bleeding from the vessel. Trauma, surgical incisions, and intravascular catheters create the most common sources of air entry. In addition, there are more subtle paths through which air can reach the vasculature, such as in damaged, mechanically ventilated lungs of patients with ARDS. The driving gradient for air entry may be provided by air under pressure, as during positive pressure ventilation or high pressure wound irrigation. Alternatively, the air may be at atmospheric pressure, but the intravascular pressure is subatmospheric. For example, any vein which is above the heart by an amount exceeding the right atrial pressure is likely to be at less than atmospheric pressure (and therefore appears collapsed). Table 27-8 lists some of the causes of the air embolism syndrome.

CIRCULATORY CONSEQUENCES

Massive air embolization can fill the right heart, impede venous return, and thereby stop circulation; thus sudden death is one of the possible outcomes. It is estimated that >100 mL of air must be acutely infused to arrest circulation. Most often, however, air passes through the right heart into the lungs. There it raises PA pressure, but has predominantly respiratory consequences. Since unilateral experimental air embolism causes pulmonary hemodynamic changes similar to bilateral embolism, humoral or reflex vascular changes

TABLE 27-8 Etiology of Air Embolism

Surgery and Trauma Related	Nonsurgical
Neurosurgery, especially upright	Cardiopulmonary resuscitation
Liver transplantation	Gastrointestinal endoscopy
Total hip replacement	Barotrauma
Harrington rod insertion	Positive pressure ventilation

Retrograde pyelography	
Hemodialysis	
Percutaneous lithotripsy	

probably account for some of the increase in pulmonary vascular resistance. In an experimental canine model of massive air embolism, systemic hypotension and pulmonary hypertension were attenuated by pretreatment with an intravenous endothelin-receptor antagonist.[163] Such work suggests that the circulatory effects of air embolism may be due to cytokine release following release of endothelin—a potent pulmonary vasoconstrictor—and that the activation of the cyclooxygenase pathway may contribute. One case study described a patient with suspected air embolism who developed the systemic inflammatory response syndrome,[164] perhaps lending further credence to the idea that air in the circulation causes downstream humoral, not simply mechanical, consequences.

RESPIRATORY CONSEQUENCES

Air is carried into the pulmonary vasculature where it embolizes in pulmonary arterioles and capillaries. The abnormal air-blood interface is thought to denature plasma proteins, creating amorphous proteinaceous and cellular debris at the surface of air bubbles.[165] This debris attracts and activates white blood cells, facilitating injury to the pulmonary capillaries. Endothelial injury increases capillary permeability, which leads to alveolar flooding. The resulting noncardiogenic pulmonary edema accounts for the majority of symptoms and signs due to air embolism (see Chap. 38). In addition, air embolization leads to bronchoconstriction, a point which may be useful in diagnosis.[166]

Although the dominant gas exchange abnormality is hypoxemia, carbon dioxide elimination is impaired as well. As pulmonary vessels become occluded, alveoli subtended by them are ventilated, but unperfused. This increment in dead space may be signaled by a drop in end-tidal CO_2, if this is being monitored. In the patient with fixed minute ventilation (e.g., if the patient is on a muscle relaxant), P_{CO_2} will rise. Either of these may lead to suspicion of the diagnosis.

EXTRATHORACIC MANIFESTATIONS

Air embolism is occasionally accompanied by systemic findings. If air directly enters the pulmonary veins, as may occur in patients being mechanically ventilated with acute lung injury, bubbles pass directly to the arterial circulation. However, since air typically enters a systemic vein, the arterial circulation is protected from embolization by the filtering effect of the pulmonary circulation. Nevertheless, bubbles can pass to the left side of the heart via the foramen ovale, which is probe patent in up to 30% of people. This type of foramen ovale does not ordinarily allow right-to-left shunting, due to the higher pressures in the left atrium. However, after significant embolization to the pulmonary circulation, right heart pressures rise, reversing the interatrial gradient. This allows bubbles to pass directly from the right to left atrium, then to the systemic circulation. Even in the absence of a foramen ovale, air can reach the arterial circulation since the lungs do not fully filter air, especially when a large amount is embolized. Air may pass through large extra-alveolar vessels or through the pulmonary capillaries themselves. In animal experiments, the threshold rate of venous air infusion that overwhelms pulmonary filtering is 0.30 mL/kg per minute.[167] For a 70-kg man, this value translates to only 21 mL/min.

Once air reaches the arterial circulation, peripheral embolization leads to ischemic manifestations in the brain, heart, skin (livedo reticularis),[168] and other organs. Some of the ischemic manifestations in the periphery are probably mediated by polymorphonuclear leukocytes and oxygen radicals, as is the injury in the lung.[169]

TABLE 27-9 Manifestations of Air Embolism

Dyspnea, hypoxemia
Confusion, stroke, or peripheral embolization
Hypotension and shock
Diffuse alveolar infiltrates
Increment in airway pressures
Increased dead space and rising minute ventilation
Abrupt fall in end-tidal CO_2
Detection of air by echocardiography, Doppler monitor, or radiography

PRESENTATION

Air embolism is usually recognized when it presents as acute hypoxemic respiratory failure. As noted above, it may also manifest as an acute hypoperfusion state or as peripheral embolization. The chest x-ray shows diffuse alveolar filling. We have seen one case in which intracardiac and intra-arterial air was grossly evident on the chest radiograph. Increased dead space may be indicated by increased $\dot{V}_E$, increased P_{CO_2}, or decreased ET_{CO_2}. Rarely, echocardiography will demonstrate residual air (or ongoing embolization) in the heart. Precordial Doppler monitoring during high-risk surgery is well suited for detecting air (Table 27-9).

A diagnosis of air embolism is usually considered when air is witnessed to enter an intravascular catheter. It is also likely to be considered in extremely high-risk settings such as upright neurosurgery. However, if air embolism is only considered when it is grossly apparent, many episodes will go unappreciated. It should also be included in the differential diagnosis of patients with hypoperfusion, systemic embolization, obtundation, and respiratory failure, especially when more likely causes are lacking. It is also worth emphasizing that many cases are related to central lines, not only during placement, but while the catheters are in place (catheter disconnection, hub fracture, or gas in the line), while being changed over a wire, and after they are removed (through a persistent cutaneous tract).

The differential diagnosis of air embolism includes other forms of noncardiogenic pulmonary edema, as well as cardiogenic edema. Thus volume overload, sepsis, and gastric acid aspiration must be excluded.

MANAGEMENT

The goals of treatment are to prevent re-embolization while supporting respiration and circulation. In most cases, resolution is prompt. The source of air entry should be identified and closed if possible. Alternatively, the gradient favoring air entry can be lessened, as for example by saline administration to raise intravascular pressures. When air embolism complicates positive pressure ventilation, it is advisable to lower airway pressures by lowering tidal volumes, reducing positive end-expiratory pressure (PEEP), or intentionally hypoventilating. Oxygen hastens the reabsorption of air from bubbles, so all patients with significant air embolism should receive 100% oxygen during the initial resuscitation.[170]

In certain situations, it may be possible to retrieve air from the venous circulation or right heart, especially intraoperatively when a catheter is in place for that purpose. However, this should not be routinely attempted in other settings because significant amounts of air cannot usually be removed. Positional maneuvers to prevent air from embolizing to the lungs (such as head down left decubitus) are largely unproved. Similarly, the distribution of arterial emboli seems little affected by the Trendelenburg position, since the force of arterial flow greatly outweighs the buoyancy of the bubbles.[171]

Standard treatment is similar to that of any patient with ARDS. Mechanical ventilation to reduce the work of breathing, with oxygen and PEEP to maintain arterial saturation are usually necessary. Although the pulmonary edema is not related to hypervolemia, the degree of lung leak is probably sensitive to filling pressures. Therefore we reduce filling pressures to the lowest value that allows an adequate $\dot{Q}_T$ (see Chap. 38).

In animal experiments, corticosteroids given before embolization, or shortly following embolization, reduce the degree of lung injury. In high-risk neurosurgical patients on steroids, the incidence of the syndrome seems less than in similar patients who are not so treated, suggesting a prophylactic benefit in human beings as well. Nevertheless, no clear treatment role for these agents has been demonstrated, and they should not be routinely given. Potential future therapies include other anti-inflammatory drugs and agents directed against oxygen free radicals.

Hyperbaric treatment is of theoretical benefit since compression reduces the size of bubbles. This reduces the surface area for activation of white blood cells and can thereby limit pulmonary and systemic injury. Such therapy is standard when the mechanism of gas embolism is decompression, such as in professional and recreational divers. It is not routinely used in other critically ill patients, however. Since patients usually respond readily to standard supportive measures, and since the syndrome typically resolves in only 24 to 48 hours, it is unlikely that hyperbaric treatment will find a prominent role in treatment. It is probably better to keep patients in the ICU where they remain under the watchful eye of the health care team, rather than to risk transport for an unproven treatment. When such patients are transported by air, a pressurized craft flying at low altitude should be requested.

Fat Embolism

The fat embolism syndrome (FES) is associated with fat particles in the microcirculation of the lung. It consists typically of lung dysfunction, neurologic manifestations, and petechiae, usually following a latent interval. It is most common following long bone fractures, typically presenting as dyspnea and confusion. However, FES is seen after other forms of trauma and in several nontraumatic conditions as well. For example, FES has been proposed as a major cause of the acute chest syndrome in patients with sickle cell disease[172](see Chap. 108). After long bone or pelvic fracture, the incidence of the syndrome is at least 10% when evidence for it is prospectively sought,[173] although serious clinical manifestations are seen in only 1% to 3%. Since the clinical presentation is usually mild, FES is often unrecognized. Even when lung injury is obvious, its cause may be attributed to infection, aspiration, or traumatic ARDS, rather than to fat embolization. Some of the causes of FES are presented in Table 27-10.

TABLE 27-10 Causes of Fat Embolism Syndrome

Traumatic fat embolism
Long bone fracture (especially femur)
Other fractures
Orthopedic surgery
Blunt trauma to fatty organs (e.g., liver)
Liposuction
Bone marrow biopsy
Nontraumatic fat embolism
Pancreatitis
Diabetes mellitus
Lipid infusions
Sickle cell crisis
Burns
Cardiopulmonary bypass
Decompression sickness
Corticosteroid therapy
Osteomyelitis
Alcoholic fatty liver
Acute fatty liver of pregnancy
Lymphangiography
Cyclosporine infusion

PATHOPHYSIOLOGY

NONTRAUMATIC EMBOLISM

Fat globules are seen in pulmonary (and other) vessels at autopsy and can be found in venous blood. In contrast to traumatic embolism, the fat is probably not derived from bone marrow, but rather arises from lipids in the blood. Serum from acutely ill patients has the capacity to agglutinate chylomicrons and very low density lipoproteins, as well as liposomes of nutritional fat emulsions.[174] It has been proposed that C-reactive protein (CRP), which provokes the calcium-dependent agglutination of each of these lipid-containing substances, may underlie nontraumatic FES. Since CRP is dramatically elevated in trauma, sepsis, and inflammatory disorders, this provides a mechanism for fat embolization.

An alternative, but less attractive, hypothesis implicates the liberation of free fatty acids (FFAs) from fat stores. Although FFAs are known to injure the pulmonary vascular endothelium, their concentration in the systemic circulation during critical illness does not rise sufficiently to account for lung injury. An understanding of the pathophysiology is potentially valuable in the search for prophylactic and therapeutic approaches to these patients, since corticosteroids, for example, may ameliorate the toxic effect of embolized fat but act to mobilize FFA.

TRAUMATIC EMBOLISM

Fracture of bone releases neutral fat which embolizes into the pulmonary vasculature. The derivation of this fat from bone is supported by the finding of coincident particles of bone marrow at autopsy in patients with long bone fractures and by echocardiographic studies showing frequent, often dramatic embolism at the time of medullary reaming.[175] Local hydrolysis of fat by lung lipase releases toxic FFAs, which generate endothelial injury. Systemic findings in FES

probably relate to passage of venous fat emboli across the pulmonary circulation, although serum-derived fat may play a role. Elevated right heart pressures following embolism may open a probe patent foramen ovale, causing severe, even fatal systemic embolism.[176] Further, fat can cross the pulmonary circuit even in the absence of a right-to-left shunt, as has been shown in experimental animals.[177] Fat was able to traverse the pulmonary microcirculation even though 15-micron radiolabeled microspheres could not, perhaps due to enhanced deformability of fat emboli.[177]

CLINICAL MANIFESTATIONS

Following injury, there is usually a latent interval of 12 to 72 hours before the syndrome becomes evident. The dominant findings are related to lung injury. Patients with FES present as ARDS, with dyspnea, hypoxemia, and a diffuse lung lesion. In addition, there is often confusion, obtundation, or coma, signs due to cerebral fat embolism rather than coincident hypoxemia. The typical neuropathologic findings include fat microemboli and diffuse petechial hemorrhagic infarcts. Petechiae are also seen on the skin, particularly over the upper chest, neck, and face. On funduscopic examination, embolized fat may be detected in retinal vessels (Purtscher's retinopathy). Often thrombocytopenia and anemia are present. Rare patients will develop a full blown acute right heart syndrome[176] (see Chap. 26).

The diagnosis is usually based on the clinical findings in a patient at risk for FES. Fat globules in the urine are neither sensitive nor specific for the diagnosis of FES. Attempts have been made to find alternative, objective means of diagnosis, since this might be useful in devising prophylactic or therapeutic strategies. Fat can be detected in bronchoalveolar lavage specimens in many patients following trauma, but this finding appears not to be a reliable means of diagnosis.[178] Fat can also be seen in spun samples of blood withdrawn from a wedged pulmonary artery catheter, but this finding is also not clinically useful.[179]

PROPHYLAXIS AND TREATMENT

The substantial incidence of the syndrome and the large number of patients with a well-defined risk factor (long bone fracture) have provided the opportunity to evaluate prophylactic approaches. The least controversial strategy has involved a shift toward early fixation of long bone fractures, even in patients with multiple trauma. Early fixation decreases the incidence of FES, as well as of ARDS and pneumonia, and reduces length of stay.[180–182] Orthopedic surgery, and particularly total hip arthroplasty, carries a high risk of fat embolism, which has been demonstrated by transesophageal echocardiography to occur during the preparation of the femur and insertion of the femoral component. Specific surgical techniques, such as using bone vacuum with the preparation of the femur,[183] have shown decreased fat emboli detected by transesophageal echocardiography, although the clinical significance of such of echo-detected emboli is less clear. More controversial is the use of prophylactic corticosteroids. Nearly all trials of methylprednisolone, in both high (7.5 mg/kg every 6 hours) or low dose (1.5 mg/kg every 8 hours), have shown a reduction in the incidence of the FES, as well as less severe hypoxemia.[184–186] Nevertheless, concerns regarding the risk of infection and impairment of wound healing have limited the routine use of these drugs. Since most cases of FES are mild and the great majority of patients recover, an acceptable prophylactic regimen would have to be quite safe and inexpensive.

Once the syndrome becomes evident, treatment is that of ARDS (see Chap. 38). Prevention of re-embolization by fracture fixation should be attempted, and supportive management with oxygen and PEEP initiated. It has been suggested that corticosteroids may be of benefit even once the syndrome is established, but it is not clear that the benefits outweigh the risks, and we do not recommend them. No clear role has been established for glucose and insulin, heparin, ethanol, and albumin, despite studies seeking a useful therapy for FES.

Chapter 28
PERICARDIAL DISEASE

ISRAEL BELENKIE

KEY POINTS

- *Accurate hemodynamic assessment of seriously ill patients requires an understanding of the concepts of transmural (effective) filling pressures and ventricular interaction.*
- *A systematic approach to the assessment of a patient with a low cardiac output and increased right atrial pressure will result in the correct determination when pericardial disease is a contributing factor.*
- *Echocardiography is the most important test for the initial evaluation of patients with pericardial disease.*
- *Pericardial drainage should be performed without delay in patients with cardiac tamponade. Volume loading or inotropic agents are not effective therapies for tamponade.*
- *Conditions such as localized tamponade and constrictive pericarditis must be considered in patients without a good alternative explanation for low cardiac output.*
- *Although rare, the possibility of purulent pericarditis should be considered in patients who are most susceptible.*
- *Anticoagulation is not contraindicated in pericarditis.*

A pericardial cause of otherwise unexplained low cardiac output should always be considered in critically ill patients. Pericardial inflammation or infection may also deserve consideration. This chapter focuses largely on the hemodynamic implications of constraint to ventricular filling and the approach to diagnosis and treatment of pericardial disease. The goals are to provide the reader with tools to assess the potential for suspected or known pericardial disease to relieve a patient's condition. The reader should refer to standard cardiology texts to learn the details of specific causes of pericardial disease (Table 28-1).

Physiology of Constraint

PERICARDIAL CONSTRAINT

The key to understanding pericardial physiology is to understand transmural pressure. The ventricles distend in proportion to transmural pressure, not to intracavitary pressure; this is frequently overlooked because changes in intracavitary pressure often (but not always) reflect changes in transmural pressure. Effective distending pressure is the *pressure difference* across the chamber wall, that is, transmural pressure.[1] This principle is rarely important with respect to systolic pressures[2] but may be critical with respect to diastolic pressures.[3] If left ventricular end-diastolic pressure (LVEDP) is 12 mm Hg, then LVEDP is 12 mm Hg greater than atmospheric pressure. However, if pericardial pressure is 4 mm Hg, then transmural LVEDP, the effective distending pressure, is 8 mm Hg. Further, if LVEDP increases to 15 mm Hg and pericardial pressure increases to 7 mm Hg, then transmural LVEDP remains 8 mm Hg and left ventricular end-diastolic volume (LVEDV) does not change.

VENTRICULAR INTERACTION

Ventricular interaction can be defined as the complementary change in right ventricular (RV) and left ventricular (LV) volumes such that, when right ventricular end-diastolic volume (RVEDV) increases, LVEDV decreases, and vice versa. Ventricular interaction involves the septum moving toward the left or right ventricle and is modulated by external constraint that is pericardial or due to other mediastinal structures. The pericardium, in the short term, is effectively nondistensible; thus, the heart is surrounded by an effectively unyielding sac. Therefore, RVEDV can increase only "at the expense" of LVEDV. This interaction can occur because the septum is elastic and moves leftward or rightward with small decreases or increases in the difference between LVEDP and right ventricular end-diastolic pressure (RVEDP; i.e., the trans-septal gradient is equal to LVEDP minus RVEDP). When the pericardium is opened and the lungs are held back from the heart, ventricular interaction is substantially less; when pericardial pressure is very low, ventricular interaction is also diminished.[4]

EXPERIMENTAL OBSERVATIONS

It had been thought that the relation between LVEDP and LVEDV, the so-called diastolic compliance,[5] is practically invariant. This assumption was the basis for the Sarnoff ventricular function curve analysis in which LV filling pressure was used to reflect LVEDV, or LV preload.[6] However, diastolic compliance can be changed rapidly, for example, by giving nitroglycerin for heart failure.[7] It was suggested that this was due to unappreciated decreases in pericardial pressure,[8] but many thought this was unlikely because pericardial pressure had been shown to be negative and unchanging, even as RVEDP was increased to high values.[9] It was later shown that pericardial pressure is more accurately measured[10,11] with a flat, liquid-containing balloon transducer; an open

catheter seriously underestimates pericardial pressure unless there is sufficient fluid in the pericardial space. It is important to note that pericardial pressure is similar to mean right atrial (RA) pressure, and both increase (during volume loading) in parallel.[12] Thus, pericardial pressure is changeable acutely and is approximately equal to RVEDP in most circumstances.[13] Without an excess of liquid, pericardial pressure is fundamentally a compressive contact stress.[11]

An excellent demonstration of the importance of these concepts consists of the hemodynamic effects of acute pulmonary embolism and subsequent volume loading.[14–16] As shown in Figs. 28-1 and 28-2, with the pericardium intact, the relations between LVEDP and LVEDV and between LV stroke work and LVEDP suggest that pulmonary embolism and subsequent volume loading decrease LV compliance and contractility.[14] However, when diastolic compliance and contractility are evaluated with transmural LVEDP instead of intracavitary pressure, it is clear that LV compliance and contractility are unaffected by embolism.[17] Most importantly, despite increased LVEDP during volume loading after embolism, *transmural LVEDP and LVEDV may decrease* and result in decreased stroke work and worsening hypotension. In those circumstances, volume removal may *increase transmural LVEDP, LVEDV, and stroke work*, despite the decreased LVEDP. In the absence of constraint, this apparent paradoxical response to volume manipulation is not observed.[16]

The complementary change in RV and LV volumes occurs largely by septal shift, which is controlled by the transseptal gradient; therefore, changes in the trans-septal gradient are a convenient indicator of ventricular interaction. Mirsky and Rankin observed that the left ventricle is surrounded by the pericardium over approximately two-thirds of its surface and by the right ventricle over the remaining third.[18] Therefore, when changes in RV and pericardial pressures are not similar, it is best to modify the definition of transmural pressure to better account for those differences.[19]

VENTRICULAR INTERACTION DURING MECHANICAL VENTILATION

As intrathoracic pressure increases during positive-pressure inspiration, there are complex interactions between the heart and lung that are beyond the scope of this chapter. However, constraint to ventricular filling and ventricular interaction deserve consideration here. Positive end-expiratory pressure increases constraint to filling and thus decreases cardiac output. Therefore, if pericardial pressure is increased by an effusion or especially if tamponade is present, mechanical ventilation will increase constraint further and should be avoided. Some studies have suggested that leftward septal shift (perhaps due to increased pulmonary vascular resistance at larger lung volumes) may decrease LV filling more than that caused by constraint alone.[20] In addition, positive-pressure inspiration decreases venous return and RV output, with the reverse occurring during expiration.[21,22] The consequences of these complex changes on LV function appear to differ. In some circumstances, LVEDV and output decrease during positive-pressure inspiration; in others, both increase. A synthesis of available data suggests that, during mechanical ventilation, pulmonary vascular resistance increases more at lower LVEDPs (zone 2 conditions) and causes leftward septal shift during inspiration and that pulmonary vascular resistance increases little during inspiration at higher LVEDPs (zone 3 conditions) with little or no leftward septal shift; the decreased RVEDV that occurs during inspiration then allows for increased filling of the left ventricle (despite a decreased total volume of the ventricles) and, hence, output. The reverse occurs during expiration.

Clinical Manifestations of Pericardial Disease

Pericardial disease is most often manifested clinically as the pain syndrome caused by pericarditis or by the hemodynamic compromise caused by increased pericardial fluid (tamponade) or by a thickened or calcified pericardium (constrictive pericarditis). Other clinically important diseases of the pericardium are much less common (e.g., purulent or tubercular pericarditis) but also must always be considered, as discussed below.

PERICARDITIS

Pericarditis commonly presents with a characteristic syndrome that includes central, pleuritic chest pain that is worse when lying down and less severe when standing upright or leaning forward. Frequently, there is no pericardial friction

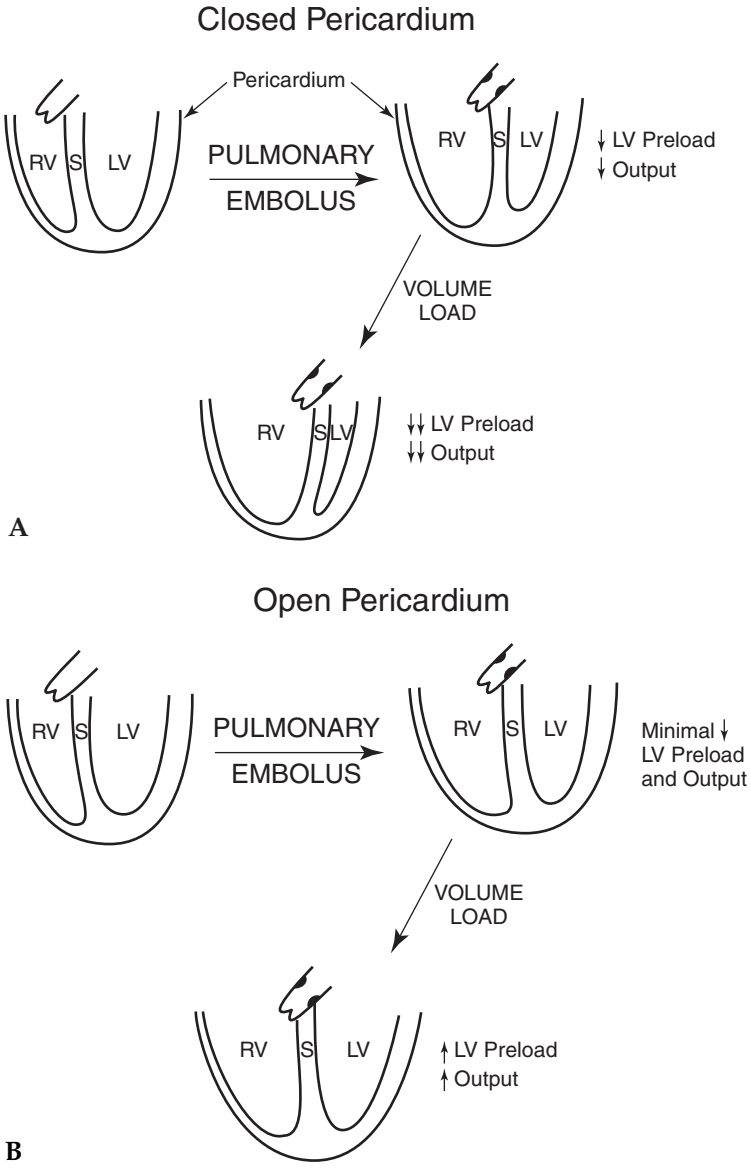

FIGURE 28-2 ***A*****. This panel illustrates how pulmonary hypertension, such as after pulmonary embolism, may cause a substantial reduction in LV preload by direct ventricular interaction and how subsequent volume loading may aggravate the hemodynamic problem. There is decreased RV output with a consequent LV output decrease (series interaction). In addition, the increased RVEDP and the decreased LVEDP result in a decreased transseptal pressure gradient, which causes a leftward septal shift (decreased LVEDV) by direct interaction. Thus, decreased RV output and decreased LV filling because of septal shift contribute to the hemodynamic consequences of acute pulmonary hypertension. Subsequent volume loading increases the RVEDP more than the LVEDP; this decreases the transseptal pressure gradient further and shifts the septum even farther to the left. Thus, LVEDV is reduced even further despite the increased intracavitary LVEDP. Constraint by the pericardium prevents the free wall from distending, so RVEDV increases only at the expense of LVEDV (and therefore stroke volume).** ***B*****. This panel illustrates the importance of external constraint in modulating direct ventricular interaction. Pulmonary embolism increases RVEDV, there is leftward septal shift, but the absence of external constraint allows the LV free wall to distend so that the hemodynamic effects of the embolism are less severe. The animal tolerated much greater amounts of infused clot than when the pericardium was intact. Furthermore, subsequent volume loading increases RV and LV preloads and outputs. rub; however, the presence of a friction rub or an abnormal electrocardiogram or echocardiogram may suggest pericarditis in patients without symptoms of pericarditis who are being assessed for other conditions such as cancer, myocardial infarction, uremia, or a collagen vascular disease. The pain associated with pericarditis may be atypical and difficult to differentiate from pain caused by myocardial ischemia. The electrocardiogram is often normal or not diagnostic; the characteristic type of diffuse ST elevation (concave upward), not restricted to leads reflecting a region supplied by one coronary artery, when present, may be difficult to distinguish from early repolarization (normal). PR-segment depression is very suggestive of pericarditis. Repolarization changes may evolve over hours to days; in contrast to changes due to ischemia or infarction, the ST segment returns to baseline before the T wave inverts. No Q waves develop, and cardiac enzymes usually are normal but may increase in some patients.

In general, it is not difficult to discriminate between myocardial ischemia and pericarditis. However, occasionally, this can be very difficult and the two may coexist. The classic symptoms of pericarditis, unassociated with symptoms, signs, or electrocardiographic changes (Fig. 28-3) suggesting ischemia or infarction, can be confidently attributed to acute pericarditis. This may be confirmed by the presence of classic ST changes on the electrocardiogram (frequently absent) and/or a pericardial friction rub (also frequently absent). If the patient has known or suspected chronic or acute coronary artery disease, the disease may coexist with pericarditis so that the potential for pericarditis after infarction should be considered. Other characteristics may be helpful in discerning the cause of the pain, such as its duration, the response to anti-ischemic or anti-inflammatory medications, or the results of laboratory tests. Minor elevations in cardiac enzymes including troponin T or I may not be indicative unless serial changes indicate either diagnosis. It is not rare for the dilemma to be resolved in the cardiac catheterization laboratory. The association of myocarditis with pericardial pain may make the diagnosis even more difficult to resolve.

Benign idiopathic pericarditis is appropriately named except for occasional cardiac tamponade[23] or refractory chest pain. Progression from clinically apparent idiopathic pericarditis to constrictive pericarditis is very uncommon.

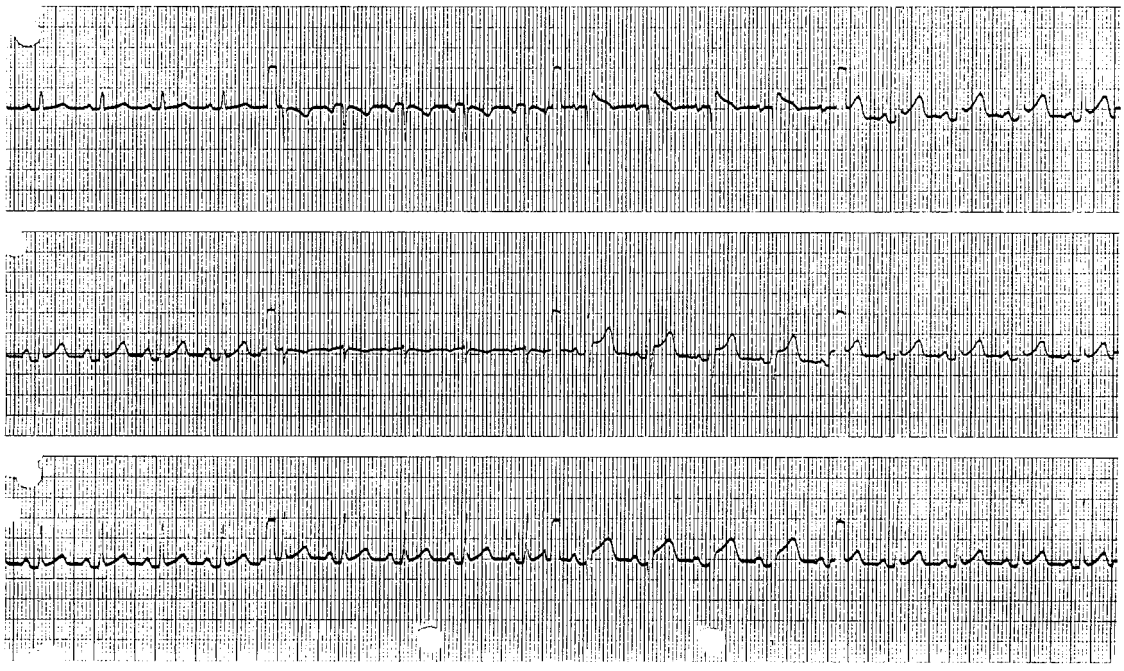

FIGURE 28-3 Twelve-lead electrocardiogram of a patient with acute pericarditis. Note PR segment depression prominent leads 2, 3, and aVF. ST-segment elevation is present globally (except in lead aVR) and is concave upward.

TREATMENT

Unless the clinical characteristics suggest a condition other than benign idiopathic pericarditis or there is a hemodynamically significant effusion, a conservative approach is generally appropriate and diagnostic pericardiocentesis is usually not indicated. Treatment is usually with nonsteroidal anti-inflammatory drugs or colchicine; steroids should be reserved for only the most refractory symptoms, and pericardiectomy is only rarely indicated.[23] If the cause of the pericarditis is known, specific treatment for that disease is indicated.

CARDIAC TAMPONADE

Small pericardial effusions are relatively common in patients with heart disease or in critically ill patients. The presence or absence of a pericardial friction rub correlates poorly with the volume of fluid. Tamponade is caused by accumulated fluid usually distributed throughout the pericardial space over the ventricles and the right atrium and, to a lesser extent, behind the left atrium. Localized collections of fluid, particularly early after open heart surgery, may compress individual chambers with similar consequences. The rate of fluid accumulation is very important; if slow, the pericardium stretches over time and large volumes (up to several liters) may collect before causing hemodynamic difficulty. However, if the fluid accumulates quickly, the noncompliant pericardium does not stretch and tamponade can be caused by as little as 150 to 200 mL. As pericardial pressure increases, transmural ventricular pressures decrease despite increased intracavitary pressures.

Cardiac tamponade develops when constraint is sufficient to substantially reduce cardiac filling and, hence, output. When this happens, diastolic pressures equilibrate in all chambers so that RA and left atrial pressures, RVEDP, LVEDP and pulmonary artery diastolic pressures become equal or nearly equal (<3- to 5-mm Hg difference).[24] Commonly, cardiac tamponade is apparent at pericardial pressures of 15 to 20 mm Hg and with a jugular venous pressure usually greater than 10 cm of water above the sternal angle. It is characteristically associated with tachycardia, decreased cardiac output, and hypotension, although hypertension occasionally is present. The normal inspiratory decrease in arterial blood pressure (<10 mm Hg) is exaggerated (pulsus paradoxicus); this is not specific for tamponade and can occur in other circumstances, particularly when there is increased inspiratory effort. However, it is almost always present in cardiac tamponade (in the absence of aortic regurgitation, atrial septal defect, or severe LV dysfunction).[24] The normal inspiratory increase in venous return persists in tamponade; the resultant increase in RVEDV causes a decrease in LVEDV and output because the pericardium cannot expand to accommodate the increased RVEDV. The decrease in LVEDV causes blood to accumulate in the lungs during inspiration. Persistent constraint to filling throughout diastole is responsible for the decreased *y* descent (early diastole) in the jugular venous pulse and RA pressure tracing and the slowly rising RV early diastolic pressure (Figs. 28-4 and 28-5). The Kussmaul sign and the square root (dip-plateau) sign in the jugular venous pulse are not seen in tamponade.

Once considered, the diagnosis of cardiac tamponade is generally straightforward. In a critically ill patient, a pericardial infusion sufficiently large to cause hemodynamic problems may be discovered fortuitously when echocardiography is performed for various reasons. Increased right-sided filling pressures or pulsus paradoxicus should initiate a systematic hemodynamic assessment that will ultimately lead to the correct diagnosis. Physical examination may show an obvious cause for the increased right-sided filling pressure. However, causes of increased filling pressures are often best evaluated initially by transthoracic or transesophageal

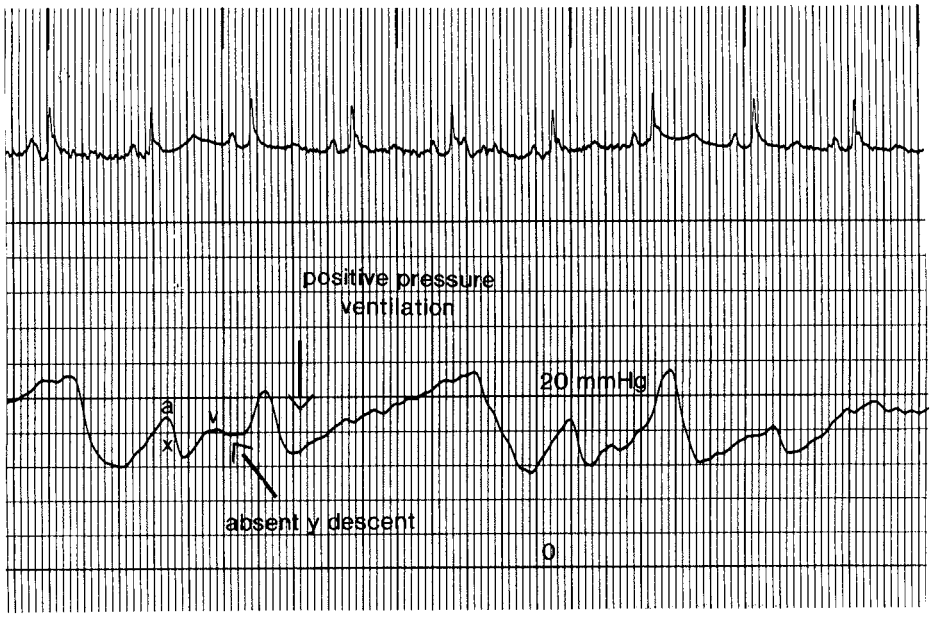

FIGURE 28-4 Right atrial pressure in a patient with cardiac tamponade during mechanical ventilation. Note the absent *y* descent and the blunting of the waveforms, especially during positive-pressure ventilation.

echocardiography. Either modality helps to detect valvular or myocardial disease and pericardial causes of increased RA pressure. The assessment may be complicated by the presence of other conditions. One may also be faced with the management of tamponade and the need to deal with the specific cause of the effusion, for example, tuberculosis or neoplasm.

The characteristic hemodynamic features of tamponade (equilibration of diastolic pressures) may be readily apparent in hemodynamically monitored patients. Electrocardiographic features of tamponade include low voltage and electrical alternans, but these findings need not be present. Electrical alternans suggests the presence of tamponade (Fig. 28-6); it is generally associated with swinging of the heart within the pericardium. Hemodynamically significant effusions are characterized echocardiographically[25–30] by the presence of moderate or large effusions (unless accumulated rapidly), early diastolic RV collapse, right atrial collapse (Fig. 28-7), the presence of fluid behind the left atrium, a dilated inferior vena cava, and increased respiratory variation in tricuspid and mitral Doppler flow velocities. However, the diagnosis of tamponade remains a clinical diagnosis.[31] Differentiation from constrictive pericarditis is not an issue, although hemodynamic comparisons are interesting (see below). The chest x-ray can be useful in identifying patients with cardiac tamponade, especially when associated with a quiet precordium (Fig. 28-8). There may be a characteristic "water-bottle" appearance, with rapid tapering of the bulging pericardial silhouette. Pulmonary edema is almost never seen in uncomplicated tamponade. Decreased QRS voltage associated with an enlarged cardiac silhouette on radiography or electrical alternans may suggest the presence of a large effusion. Other radiographic signs are not relevant because of the greater sensitivities of other imaging modalities. Computed

tomography and magnetic resonance imaging are useful to diagnose effusions and may indicate the nature of the effusion.[32]

The contribution of a small effusion to a patient's condition may be difficult to ascertain and is based on the principles described above. Even a small effusion may be significant if it accumulated rapidly; examples include trauma, recent invasive cardiac procedures, and other conditions that may cause bleeding into the pericardium, such as aortic dissection.

FIGURE 28-8 Chest radiogram (anterior) of a patient with rapidly increasing pericardial effusion and hemodynamic evidence of cardiac tamponade. Note how the cardiac silhouette is rounded in its lower portion and tapers at the base of the heart, resembling a plastic bag filled with water sitting on a table.

TREATMENT

In the absence of tamponade, even large effusions may not need to be drained.[33] If the effusion is believed to be benign, a careful conservative approach may be sufficient. The fundamental problem in cardiac tamponade is constrained ventricular filling, so removal of the fluid is central to effective treatment. Unless the patient's volume has been depleted, there is no potential benefit from volume loading because filling cannot be increased. There is also limited potential benefit from inotropic agents because there is already substantial neurohumoral stimulation in these patients. The method of pericardial drainage is not standardized.[34–38] Unless the etiology of the effusion indicates otherwise, needle drainage should be performed with echocardiographic guidance. Large effusions are usually safely drained, whereas small effusions are inherently associated with greater risk. Electrocardiographic monitoring with a lead connected to the needle (using ST-segment elevation on the electrocardiogram to indicate contact with the myocardium) is not as safe as echocardiographic monitoring. Drainage of the first 50 to 100 mL of fluid usually relieves much of the hemodynamic compromise. A catheter is usually left in place under suction to drain the pericardial space for at least 2 to 3 days. Clotting of the catheter may be prevented with a slow infusion of heparinized saline.[39] The drained fluid should be sent for appropriate diagnostic assessment even if the underlining etiology is known or suspected, despite a low diagnostic yield.[40] The presence of blood in the effusion is not helpful in establishing the cause of the effusion.[41] Recurrent effusions are not uncommon, particularly if the original effusion was large. Other different techniques are used initially or subsequently. These include balloon pericardiotomy,[42] thoracoscopic drainage (which improves diagnostic accuracy),[43,44] and a pericardial window.[35] Surgical drainage should be considered initially in patients with smaller effusions because of the higher risk when drained by needle. Long-term survival rate is dependent on the underlying disease rather than on the method of drainage.[34,35,45,46] Large effusions due to metastatic disease may be best treated surgically, whereas benign effusions may be adequately treated with a single-needle drainage procedure. Chemotherapeutic or sclerosing agents or steroids may be installed in the pericardium after drainage.[47]

ANTICOAGULATION

Whereas substantial pericardial effusions have been associated with anticoagulation, the presence of a friction rub or a very small amount of pericardial fluid detected by echocardiography should not deter the clinician from continuing anticoagulation when there is a clear indication for it. Examples include myocardial infarction and the presence of a prosthetic heart valve. Patients can be safely monitored clinically and echocardiographically for the unlikely development of tamponade. Anticoagulants should be discontinued in Dressler syndrome (which is increasingly rare after myocardial infarction).

RENAL FAILURE

Up to 40% of patients with chronic renal failure develop pericardial effusions during the course of their disease. Effusions may occur before dialysis and during maintenance dialysis.[48] There is some question as to whether heparin contributes to the development of effusion, but patients on dialysis using heparin-free solutions still develop effusions. Because preload is reduced during hemodialysis, the risk of rendering an asymptomatic effusion hemodynamically significant is real. The probability that dialysis will cause an effusion to clear is highest when the effusion predates the start of intensive hemodialysis or develops early in its course (within weeks).[49] The size of the effusion is the single most important determinant of need for surgical therapy. Hemodialysis is more effective than peritoneal dialysis for reducing effusions and should be initiated early if there is evidence of enlargement. Indomethacin and steroids are of uncertain value. Failure to resolve or progression of an effusion during the course of intense hemodialysis may dictate the need for drainage.

CARDIAC SURGERY

Pericardial abnormalities are common after cardiac surgery. Early after surgery, hemopericardium and hemomediastinum can cause tamponade, even though the pericardium is commonly left open. When there is postoperative hemodynamic compromise, it is necessary to consider the possibility of tamponade. Although echocardiography is often very helpful in this regard, tamponade is sometimes caused by a localized collection of fluid or blood that may be difficult to identify, even by transesophageal echocardiography. A careful synthesis of hemodynamic and echo data may require reoperation without a clear diagnosis beforehand. The presence of unexplained hemodynamic deterioration (e.g., with good ventricular function) suggests the possibility of localized tamponade, even if it is difficult to demonstrate echocardiographically.

The postpericardiotomy syndrome occurs several weeks postoperatively in 10% to 20% of patients and is characterized by fever, chest pain, and the presence of a friction rub.[50] In many ways, it is analogous to the Dressler syndrome, which occurs weeks after myocardial infarction. Good evidence supports an autoimmune pathogenesis, with antiheart antibodies and circulating immune complexes present in many patients.[51] Electrocardiographic changes identical to those seen in acute pericarditis may or may not be present. Aspirin is the treatment of choice. Corticosteroids may be considered in patients who do not respond to aspirin or colchicine.

PURULENT PERICARDITIS

Pericardial effusions are much more likely to be sterile than infected. Purulent pericarditis is most often the result of local spread from empyema, mediastinitis, endocarditis, prior pericardiotomy, or burn injury.[52] It is rare, tends to occur in immunocompromised patients, and may be difficult to treat. Although drainage is necessary, it is not clear what the best approach is. It is commonly first discovered when pericardiocentesis is performed by needle; continuous catheter drainage should be initiated then, but surgery likely will be necessary. Patients with the human immunodeficiency virus may present with tamponade, and an infectious cause is frequent; this is associated with a very high mortality rate.[53]

Purulent pericarditis may develop in the setting of severe infectious disease with a wide variety of causative organisms. When pericardial fluid is evident on echocardiography in a

patient who is at risk for purulent pericarditis, a definitive diagnostic procedure should be considered because its mortality rate is high. The best approach is removal of the fluid. Some centers perform a subxiphoid procedure and proceed to pericardiectomy, if infection is present. Thoracoscopic pericardiectomy also may be useful in such cases.

It is clearly important to discriminate between purulent and sterile effusions. Electrocardiography and echocardiography are not useful. Gallium 67 (^{67}Ga) uptake, when used with single-photon emission computed tomography, has been reported to have a resolution that can distinguish pericardial from myocardial inflammation and that may be able to detect inflammation associated with secondary infection of the pericardial space. There are several reports of tuberculous pericarditis diagnosed by planar ^{67}Ga imaging. In patients with complex disease who may have multiple areas of ^{67}Ga uptake in the region, simultaneous use of technetium 99 and ^{67}Ga with subtraction imaging may increase the specificity of the test.

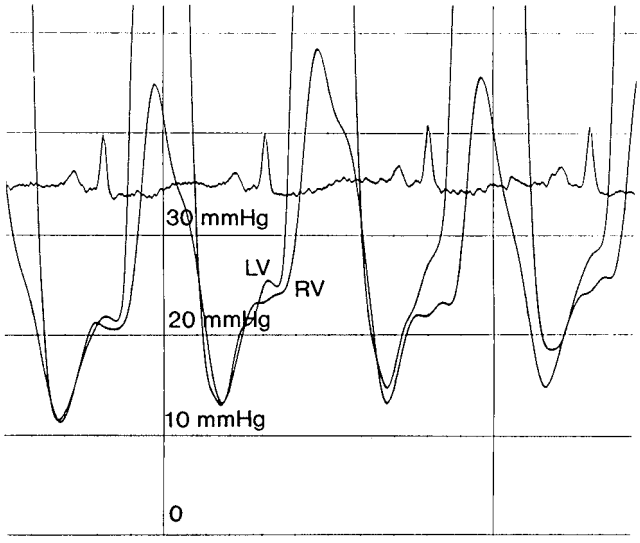

FIGURE 28-9 Simultaneous right ventricular and left ventricular pressures in a patient with constrictive pericarditis. The pressures are elevated and nearly equal, with little rise in right ventricular pressure during the last two-thirds of diastole. LV, left ventricle; RV, right ventricle.

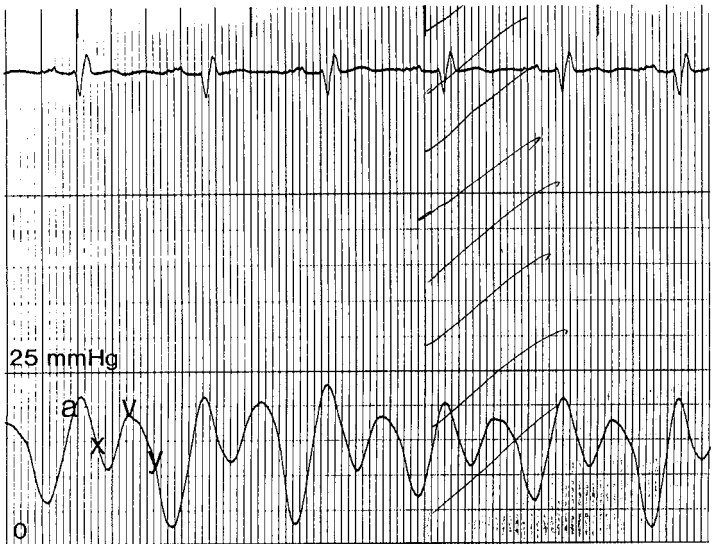
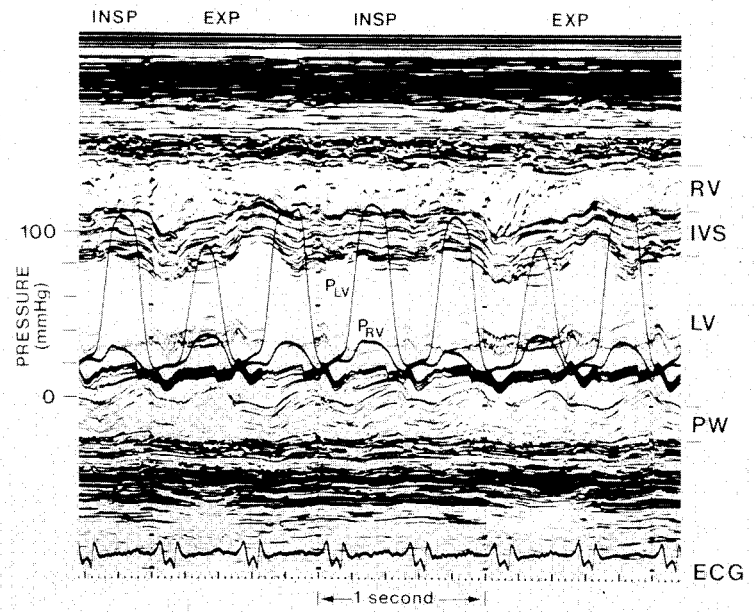
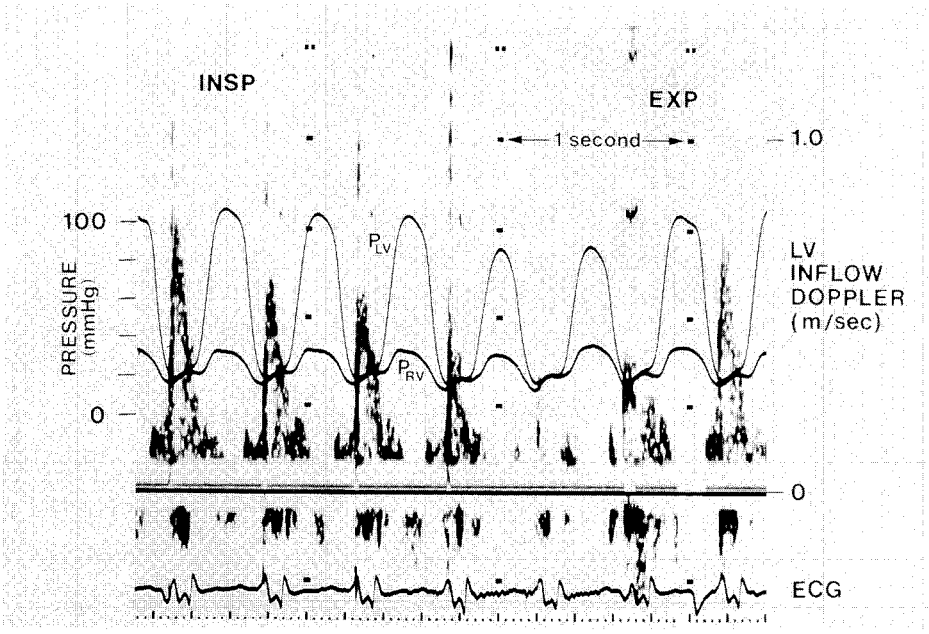
CONSTRICTIVE PERICARDITIS

In constrictive pericarditis, the pericardium becomes thickened, may be calcified, and prevents normal ventricular filling. Signs of constriction may become evident as effusive pericarditis resolves, and normal hemodynamics may return spontaneously or with conservative treatment.[54,55] Forward output is compromised and the increased diastolic pressures cause edema. Early diastolic ventricular filling is rapid in constriction and is responsible for the classic dip-plateau configuration of atrial and ventricular pressure tracings; there is a rapid *y* descent with an early nadir and a sharp rise in pressure as the chamber reaches its limits of expansion (Fig. 28-9). After atrial systole, there is a rapid *x* descent so that an M-shaped jugular venous pulsation may be observed (Fig. 28-10). The fixed maximum volume of the pericardium results in equalization of end-diastolic pressures, similar to that in cardiac tamponade. If the central volume has been decreased, as might result from excessive diuresis, equalization of pressures may not be observed; volume expansion, however, will cause this to occur.

The Kussmaul sign (inspiratory increase in the jugular venous pressure) is common[56] but not specific for constriction; it is seen most often in RV infarction and other conditions affecting the right ventricle. There are several echocardiographic findings associated with constrictive pericarditis (Fig. 28-11), none of which is pathognomonic.[29] The pericardium may appear thickened, but this usually cannot be discerned with confidence; transesophageal studies may be more accurate in defining pericardial thickness. Because rapid ventricular filling occurs early and stops abruptly, M-mode evidence of absent LV filling in the last half of diastole is common (flat posterior wall tracing); continued expansion of the left ventricle throughout diastole suggests that constriction is absent. During early rapid filling, there is a "septal bounce," and there may be premature opening of the pulmonary valve (Fig. 28-12). During inspiration, there is substantial leftward







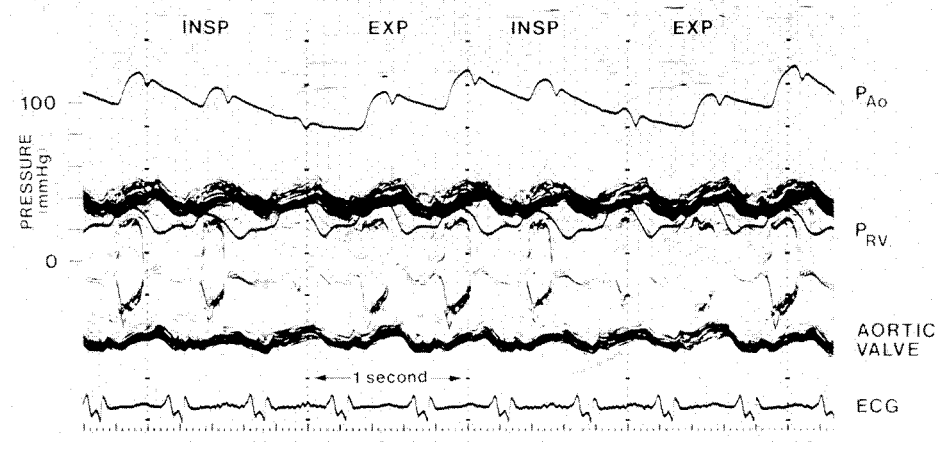


FIGURE 28-10 Right atrial pressure in a patient with constrictive pericarditis. Note the prominent *x* and *y* descents and the M shape. The *a* and *v* waves and the *x* and *y* descents are as described in text.

FIGURE 28-11 ***A.*** **Simultaneous left and right ventricular pressures superimposed on an M-mode echocardiogram in a patient with constrictive pericarditis. At end inspiration, the interventricular septum shifts leftward, thereby enlarging the right ventricle and shrinking the left ventricle. Associated with this shift are increased right ventricular systolic pressure and decreased left ventricular systolic pressure.** ***B.*** **Simultaneous left and right ventricular pressures superimposed on the left ventricular inflow Doppler signal. Left ventricular inflow velocity decreases during inspiration, corresponding to the decrease in left ventricular filling noted in the top panel. This change is associated with a decrease in generated left ventricular pressure and an increase in right ventricular pressure.** ***C.*** **Aortic pressure superimposed on an M-mode echocardiogram through the aortic valve. At end inspiration, opening of the aortic valve is markedly reduced, as is aortic pressure. Ao, aorta; EXP, expiration; INSP, inspiration; IVS, interventricular septum; LV, left ventricle; PW, posterior wall; RV, right ventricle.**

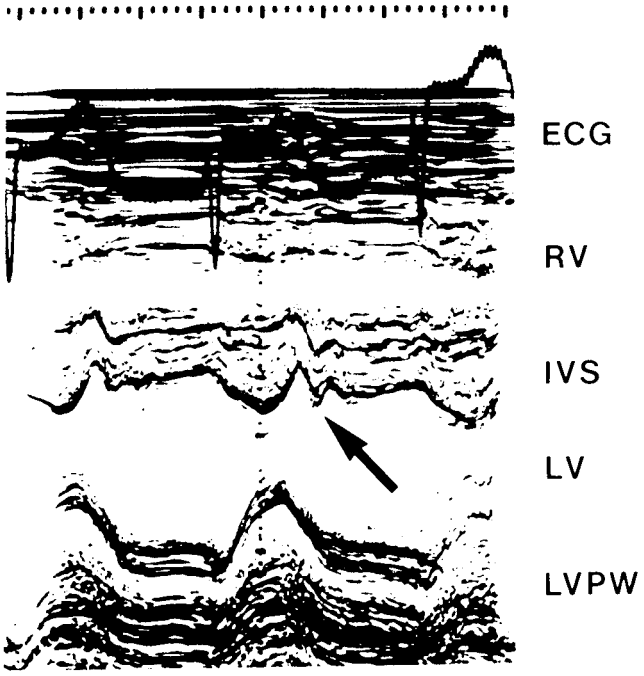

FIGURE 28-12 M-mode echocardiogram in a patient with constrictive pericarditis. Note the flattened posterior wall of the left ventricle during diastole, consistent with little ventricular filling. The early rush of blood into the ventricle results in a shuttering motion of the interventricular septum and creates a notch (*arrow*). ECG, electrocardiogram; IVS, interventricular septum; LV, left ventricle; LVPW, left ventricular posterior wall; RV, right ventricle.

septal shift in keeping with the unchanged or increased RVEDP and decreased LVEDP. Doppler echocardiography adds diagnostic accuracy but is not widely accepted as definitive.[57,58] Chest radiography is often helpful; the absence of signs of left heart failure in the presence of right heart failure helps to narrow the focus. The cardiac silhouette can be small or large, depending on antecedent heart disease. Egg shell–like calcification may be apparent, usually more easily seen in the lateral projection; the absence or presence of calcification is not useful to rule in or out constriction.[59] Nonspecific ST-T-wave abnormalities are often present on the electrocardiogram, but this is of little value.

Pericardial thickening is detected readily and with high sensitivity by computed tomography and magnetic resonance imaging;[32] however, in a large series, it was not present in almost one in five patients with constriction.[60] Because fast computed tomography and magnetic resonance imaging are capable of visualizing dynamic chamber processes and patterns of filling, they can also provide physiologic information.

The characteristic presentation of constrictive pericarditis is that of right heart failure, often severe, without another apparent cause. The diagnosis may be difficult to prove in the presence of other forms of heart disease; this is increasingly problematic because constriction after cardiac surgery is not rare. Hepatosplenomegaly sometimes incorrectly suggests the presence of metastases. The jugular venous pulse may suggest constriction; there may be a Kussmaul sign and the characteristic M-shaped pulsation highlighted by the rapid *y* descent. A pericardial knock (an early diastolic, sometimes loud, sound) may be heard.

In some instances, it is difficult to distinguish constrictive pericardial disease from restrictive cardiomyopathy.[28,29,58] Cardiac catheterization is required for simultaneous measurement of right and left filling pressures; when low, these pressures may differ but will converge if fluid is administered (<5-mm Hg difference). In restrictive cardiomyopathy, diastolic pressures are generally different and pulmonary artery pressure is often higher than in constriction. Volume loading is suggested if the diagnosis is not evident from the initial hemodynamics.[61] Similar measurements can be obtained with a flow-directed pulmonary artery catheter. Doppler echocardiography also may be helpful but remains sufficiently unreliable to preclude it as the only diagnostic test.[62] Myocardial biopsy can be helpful.

Constrictive pericarditis may be a complication of cardiac surgery, occurring in fewer than 1% of patients.[63] The time to onset can be as short as 6 weeks or as long as years after surgery. In one series, almost 65% of patients with postoperative constriction were thought to have developed the postpericardiotomy syndrome earlier in their course.[64] Pericardiectomy is made more difficult by the presence of bypass grafts.

In constrictive pericarditis, pericardiectomy is the only effective treatment. This is often very difficult and sometimes results are poor. As a result, some patients will have persistently increased venous pressure, and others, after initial improvement, may have recurrent constriction.[65]

EFFUSIVE-CONSTRICTIVE PERICARDITIS

Effusive-constrictive pericarditis is a combination of a thickened, potentially constricting pericardium with a variable amount of pericardial fluid. It occurs most often in patients with malignancies.[66] The hemodynamic characteristics are similar to those of tamponade and may evolve into those due to constriction as the volume of fluid is decreased.

Chapter 29

VALVULAR HEART DISEASE

MATTHEW J. SORRENTINO

KEY POINTS

- *Valvular heart disease may remain asymptomatic until an underlying serious illness causes rapid deterioration of health.*
- *Patients with valvular heart disease are at increased risk of bacterial endocarditis following invasive procedures.*
- *Aortic stenosis significantly increases the mortality of patients requiring noncardiac surgery.*
- *Aortic stenosis is a common comorbidity in elderly patients.*
- *Heart failure in a patient with hypertrophic cardiomyopathy should be treated with rate-slowing and negative inotropic agents.*
- *Acute regurgitant lesions are frequently medical emergencies and are not as well tolerated as chronic regurgitant lesions.*
- *Once left ventricular dysfunction occurs in a patient with mitral regurgitation, the lesion is severe and unlikely to improve with surgical correction; in fact, surgery may worsen left ventricular function.*

Valvular heart disease is a common cause of morbidity and mortality in the U.S. Although the incidence of rheumatic fever has declined, many patients that acquired the disease years ago are now presenting with valvular abnormalities. In addition, degenerative diseases of the valves are becoming increasingly common as the population ages. Recognition of valvular diseases is important for proper management of seriously ill patients.

The cardiac physical examination is the essential first step in making the diagnosis of valvular heart disease. Patients presenting with signs and symptoms of cardiac illness, such as shortness of breath, pulmonary edema, angina pectoris, or syncope, should have a detailed examination of the cardiovascular system to ascertain the presence of valvular lesions. Assessment of patients prior to noncardiac surgery should include an evaluation for valvular lesions. Once valvular heart disease is suspected, a diagnostic work-up can be completed to determine the severity of the abnormality and quantitate the risk to the patient.

Many patients with valvular abnormalities remain asymptomatic until the onset of an underlying medical illness precipitates heart failure. Tachycardia due to arrhythmias, pain, blood loss, or hypoxia can suddenly precipitate pulmonary edema or low-output states in patients with previously compensated valvular disease. In these instances, prompt treatment of the critical illness is essential to avoid complications of the valvular lesion.

The lesions of valvular heart disease can be broadly categorized as stenotic and regurgitant. The impact of these abnormalities on left or right ventricular function will determine the clinical presentation and risk to the patient at times of critical illness. Traditionally, cardiac catheterization has been used to diagnose and quantify valvular stenosis or regurgitation. Advances in echocardiography have made this imaging modality highly accurate in assessing valvular structure and function.

The degree of stenosis of a valve can be measured by the Gorlin formula.[1] The Gorlin formula uses the principle that flow equals area times velocity. The formula for calculating aortic valve stenosis can be stated as $A = F/(C \times V)$, where A is the valve area, F is aortic valve flow (calculated as cardiac output divided by the systolic ejection period in seconds multiplied by the heart rate), C is an empiric constant accounting for valvular energy loss and orifice contraction, and V is velocity. Velocity can be expressed as $V = \sqrt{2gh}$, where g is gravitational acceleration (980 cm/s^2), and h is the measured pressure gradient. The Gorlin equation for aortic valve area can then be written as $A = F/(C \times 44h)$.

Considering the empirical nature of the Gorlin formula, the calculated valve areas have been useful in predicting prognosis and risk. Recently formulas calculating valve resistance have been devised. Resistance is less flow dependent and therefore less variable than aortic valve areas.[2] Echocardiographic methods of calculating valve areas have shown good correlation with invasive methods.

Determination of the degree of valvular leakage by cardiac catheterization has depended on visualization of contrast opacifying the receiving chamber. Important determinants of the severity of regurgitation are the size and function of the receiving chamber, both of which can be estimated either by invasive or noninvasive means. Acute and chronic regurgitant lesions have markedly different presentations, in part owing to the inability of a receiving chamber to accommodate a sudden volume overload.

This chapter will review the etiology, pathophysiology, clinical presentation, diagnostic evaluation, and management of the major valvular lesions and hypertrophic cardiomyopathy. The physical examination will be highlighted, as it yields the first crucial clues to the presence of valvular disease. Management of prosthetic valve abnormalities will be covered as well.

Aortic Stenosis

ETIOLOGY AND PATHOPHYSIOLOGY

Over the past few decades, there has been a dramatic shift in the presentation of valvular aortic stenosis. The prevalence of rheumatic fever and rheumatic heart disease has decreased substantially in developed countries, and the advancing age of the population has increased the incidence of degenerative valvular lesions. At present, there are three major etiologies of valvular aortic stenosis: congenital malformations of the valve, which are usually suspected in younger patients; rheumatic aortic disease, which is usually accompanied by mitral valve disease; and calcific or degenerative changes of normal aortic valves, which are seen later in life.

Congenital aortic stenosis may present early in life when fusion of the valvular commissures is present at birth, or later in life after calcification of a congenitally bicuspid valve occurs. It is estimated that 1% to 2% of aortic valves are bicuspid, making this one of the most common congenital heart malformations.[3] A bicuspid valve functions normally in younger people, but the leaflets are prone to earlier calcific

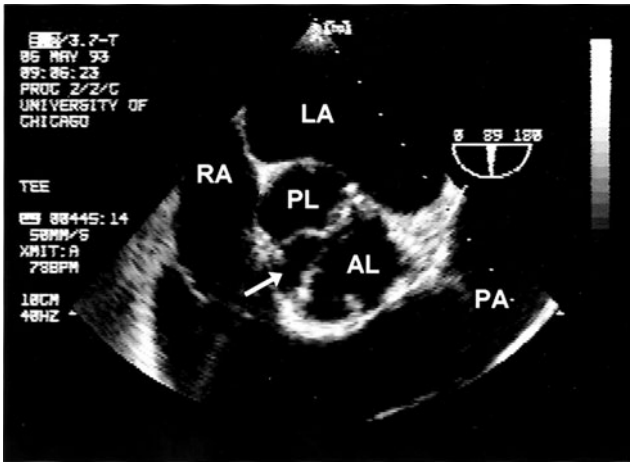

FIGURE 29-1 Bicuspid aortic valve with aortic stenosis. Cross-section transesophageal echocardiogram of a bicuspid aortic valve showing two leaflets. PL, posterior leaflet; AL, anterior leaflet. The valve leaflets are thickened and calcified, with decreased leaflet mobility. The *arrow* indicates the full extent of the opening of the stenotic valve. RA, right atrium; LA, left atrium; PA, pulmonary artery.

and degenerative changes because of increased stress on the valve compared to a normal tricuspid valve. Calcific aortic stenosis of a bicuspid valve usually develops in middle or late adult life (Fig. 29-1).

Senile calcification of normal three-leaflet valves is an increasingly common cause of aortic stenosis in the elderly. Surgical series have reported the incidence of degenerative aortic stenosis at 10% to 30% of surgical cases,[4] but this finding significantly underestimates the true prevalence of the condition in the elderly, since many patients are not referred for surgical correction. Because of its high prevalence, this disease represents a significant morbidity in patients presenting with life-threatening diseases.

As aortic stenosis progresses, the reduced orifice offers increased resistance to blood flow, represented by the transvalvular pressure gradient. The relationship between blood flow or cardiac output and the pressure gradient is not linear, but instead is related to the square root of the pressure gradient. Therefore small changes in cardiac output may have significant effects on the pressure gradient. Critical aortic stenosis is usually considered to exist when the mean pressure gradient exceeds 50 mm Hg or when the calculated orifice area is 0.75 cm^2 or less.

Left ventricular outflow is initially maintained by hypertrophy of the left ventricle. Left ventricular volumes remain normal until late in the disease. In calcific aortic stenosis in which not all of the commissures are fused, the increase in left ventricular systolic pressure may maintain or even augment cardiac output. A fall in cardiac output, however, may make aortic stenosis more severe by preventing adequate opening of the valve. In patients with a relatively fixed aortic orifice, any sudden reduction in blood pressure or systemic vascular resistance, such as that seen in sepsis or with the use of vasodilating drugs, can lead to a precipitous fall in cardiac output and cardiac arrest.

The early symptoms of aortic stenosis are usually related to the left ventricular outflow obstruction. Symptoms of angina or syncope may develop during the early stages. Angina may be due to epicardial coronary artery disease or subendocardial ischemia. About 50% of patients with aortic stenosis and typical angina pectoris have normal coronary arteries. Syncope may be secondary to a vasodepressor response when an abrupt rise in left ventricular pressure with exertion is not accompanied by a corresponding rise in aortic pressure.[5]

Dyspnea is a late symptom of aortic stenosis and is frequently related to changes in left ventricular systolic or diastolic function. With the onset of left ventricular failure, cardiac output decreases, leading to a corresponding fall in the transvalvular pressure gradient. Left atrial, pulmonary, and right heart pressures all increase, presenting as pulmonary edema and heart failure. The left ventricle will then dilate to compensate for the falling output.

Correction of aortic stenosis brings about significant improvement in cardiac function and lowers elevated right heart pressures and left ventricular filling pressures. Left ventricular hypertrophy regresses early, sometimes eventually to a normal mass.[6]

CLINICAL PRESENTATION

Patients with aortic stenosis may present with angina, syncope, or dyspnea on exertion. Some patients complain of nonspecific symptoms such as fatigue, dizziness, or palpitations. Many elderly and sedentary patients remain asymptomatic despite having critical aortic stenosis; the stenosis only becomes life threatening when they develop other critical illnesses or require elective or emergent surgery.

The physical examination can suggest hemodynamically significant aortic stenosis that will likely cause complications in patients who have critical illnesses or require surgery. A loud systolic murmur heard throughout the precordium with radiation to the neck is characteristic. This murmur usually has a crescendo/decrescendo pattern, although in critical aortic stenosis in which there is a significant delay in outflow, the murmur may be late-peaking or holosystolic. The murmur may be loud at the apex of the heart, mimicking mitral regurgitation. Severe aortic stenosis murmurs may be palpable. The aortic component of the second heart sound is typically soft or absent. An absent aortic closing sound may be the most sensitive finding for critical aortic stenosis, but it is not a common auscultatory sign.[7] The carotid impulse is generally diminished in volume and has a delayed, slow-rising peak. The cardiac impulse is usually strong and is not significantly displaced unless the ventricle has dilated.

DIAGNOSTIC EVALUATION

The electrocardiogram (ECG) usually shows left ventricular hypertrophy with a repolarization abnormality or strain pattern. A normal ECG virtually rules out the presence of critical aortic stenosis. The chest x-ray can show calcification of the valve, although cardiac enlargement is present only in the most severe cases, when left ventricular dilation is present.

Echocardiography can reliably diagnose aortic stenosis. There is a high correlation between transvalvular gradients and calculated aortic valve areas derived from Doppler echocardiography and those derived from angiography.[8–10] Doppler methods permit direct noninvasive measurement of the pressure gradient across the aortic valve. The peak gradient is estimated by the modified Bernoulli equation, which states that the pressure drop in mm Hg is equal to four times the square of the velocity (Fig. 29-2). The aortic valve area can

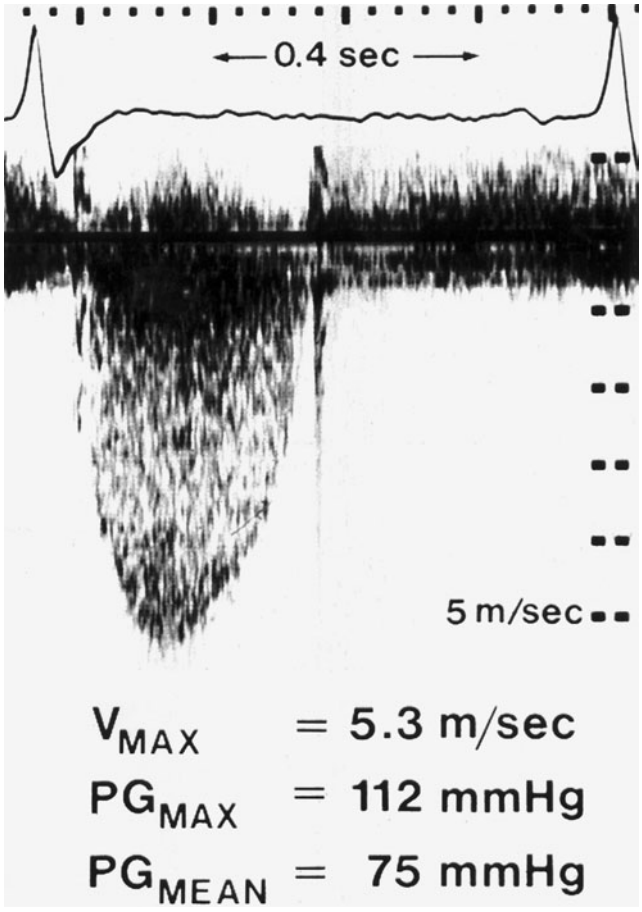

FIGURE 29-2 Doppler echocardiographic signal across a stenotic aortic valve. The peak instantaneous velocity (V_{max}) across the valve is 5.3 m/s. By the modified Bernoulli equation ($4v^2$), the peak instantaneous gradient (PG_{max}) is calculated to be 112 mm Hg. The mean velocity is determined as the mean of the squares of the instantaneous velocities. The mean pressure gradient (PG_{mean}) can then be calculated and is the value used for assessing the severity of aortic stenosis.

be calculated by the continuity equation, which is based on the law of conservation of mass, which states that for a fluid in a closed system, flow at all points must be equal. To calculate aortic valve area, flow is measured proximal to the aortic valve by calculating the area of the left ventricular outflow tract just below the valve, and the velocity at the same level. Velocity is also measured across the valve (Fig. 29-3). The continuity equation can be written as $A_1v_1 = A_2v_2$, where A_1 is the area of the outflow tract, v_1 is the velocity in the outflow tract, A_2 is the aortic valve area, and v_2 is the velocity at the aortic valve. A_2 is the unknown and is solved for from the known measurements.

Cardiac catheterization can confirm the severity of aortic stenosis. Most patients presenting with early symptoms of aortic stenosis will have a normal cardiac output, normal right heart and pulmonary capillary wedge pressures, and a normal ejection fraction. The left ventricular end-diastolic pressure will be increased, with a prominent A wave reflecting a stiff left ventricular chamber. In advanced states, the cardiac output and ejection fraction will be depressed, with a corresponding increase in left atrial and pulmonary pressures. In patients anticipating surgery, the coronary arteries should

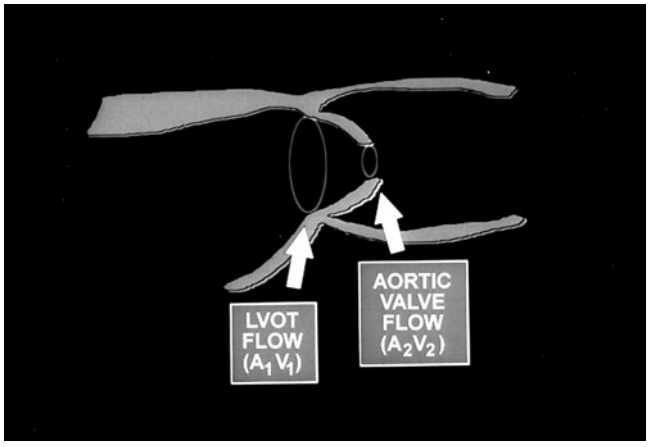

FIGURE 29-3 Continuity equation. The area of the left ventricular outflow tract (A_1) and the Doppler-measured velocities in the outflow tract (V_1) and across the stenotic aortic valve (V_2) can be determined. The aortic valve area (A_2) can then be calculated.

be visualized, because of the high incidence of concomitant coronary artery disease in elderly patients.

MANAGEMENT

Aortic stenosis is a mechanical problem, so the only effective long-term treatment is correction of the obstruction to outflow with surgery. The onset of symptoms is an indication for surgery. The development of heart failure with aortic stenosis is associated with a high mortality, especially if the left ventricular ejection fraction is reduced. Patients with severe aortic stenosis and left ventricular dysfunction have a mean survival of only one year.[11] Patients that present in heart failure must first have their symptoms stabilized and will then need an evaluation of the severity of the stenotic lesion and the degree of left ventricular dysfunction before proceeding with definitive aortic valve replacement surgery.

The left ventricular ejection fraction can be depressed in patients with aortic stenosis due to excessive systolic wall stress (afterload) seen in "true" aortic stenosis, or due to an intrinsic abnormality of myocardial contractility or cardiomyopathy referred to as "pseudo" or "relative" aortic stenosis.[12] Aortic valve replacement in true aortic stenosis can lead to a significant improvement in the ejection fraction once the afterload excess is relieved. Aortic valve replacement may have minimal benefit in pseudo aortic stenosis since the depressed ejection fraction is a muscle contractile abnormality that may not improve with valve replacement.

Patients with severe aortic stenosis and low cardiac output may present with only a modest increase in the transvalvular pressure gradient, referred to as "low-gradient" aortic stenosis. It can be difficult to distinguish true aortic stenosis causing low cardiac output from a low cardiac output state due to a cardiomyopathy in association with only mild or moderate aortic stenosis. In patients with abnormal myocardial contractility, the low-flow state and low pressure gradient can lead to a calculated aortic valve area in the severe range. The standard valve area formula is less accurate and will underestimate the valve area in low flow states.[13]

One method to determine whether a patient is presenting with true fixed aortic stenosis or pseudo aortic stenosis due to left ventricular dysfunction is to calculate the aortic valve

area at two different flow conditions by using dobutamine stress. Patients with true aortic stenosis will increase cardiac output and the transvalvular gradient with dobutamine, but the aortic valve area will remain unchanged.[14] Patients with pseudo aortic stenosis will have an increase in valve area that is frequently outside of the severe range (>1.0 cm^2) with dobutamine infusion. One protocol that has been used is intravenous dobutamine 5 μg/kg per minute and increased by 5 μg/kg per minute every 3 minutes until a maximal dose of 20 μg/kg per minute is obtained.[14] The presence of contractile reserve with dobutamine (increased stroke volume and ejection fraction) is associated with a low operative risk and a good long-term prognosis, whereas operative mortality is high in the absence of contractile reserve.[15]

The development of heart failure in patients with aortic stenosis is an indication for surgery, which should be performed as soon as possible after medical stabilization. Diuretics are frequently used to relieve pulmonary congestion, but need to be used cautiously so as not to decrease stroke volume. It has been thought that vasodilators are contraindicated in aortic stenosis because they may lead to a precipitous drop in blood pressure, causing cardiac arrest. Recent experience with nitroprusside in patients with true aortic stenosis and depressed ejection fraction has shown that afterload reduction with this agent can lead to a significant increase in cardiac output and can be used as a therapeutic bridge to surgery.[16] Therefore, current medical management of severe aortic stenosis with decreased cardiac function consists of the careful use of diuretics, with either positive inotropes (dobutamine) and/or afterload reduction (nitroprusside), being careful not to cause hypotension. Digitalis and angiotensin-converting enzyme inhibitors, as used in heart failure, can be carefully used as well.

The patient that presents with critical noncardiac disease and severe aortic stenosis is a challenging medical problem. The augmentation in cardiac output required for perfusion of tissues in disease states such as sepsis or profound anemia may not be adequate in patients with true fixed aortic stenosis. The need for urgent noncardiac surgery in patients with severe aortic stenosis puts a patient at a very high risk for cardiac complications, including myocardial infarction, congestive heart failure, and death.[17]

Percutaneous balloon aortic valvuloplasty is a procedure in which a balloon is placed across the stenotic valve and inflated, leading to stretching of the valve annulus and separation of the calcified and fused valve commissures. This can lead to an improvement in left ventricular function, a decrease in the transvalvular gradient, and an increase in the aortic valve area.[18] Because of a high complication rate and a high rate of restenosis within 6 months, this procedure is not recommended as definitive therapy. This procedure can be used as a temporizing solution in patients with cardiogenic shock,[19] or in the management of patients requiring major noncardiac surgery.[20] After recovery, definitive aortic valve replacement surgery can be performed at a later date.

Recently a percutaneous implantable prosthetic heart valve made of three bovine pericardial leaflets mounted in a balloon-expandable stent was developed and implanted in a critically ill patient with aortic stenosis and cardiogenic shock, and it led to immediate hemodynamic improvement.[21] Further studies are now in development for this promising new technology.

Hypertrophic Cardiomyopathy

ETIOLOGY

Hypertrophic cardiomyopathy (HCM) is a genetic disorder of cardiac muscle characterized by myocardial hypertrophy out of proportion to the hemodynamic stress. Patients classically present with dynamic obstruction to left ventricular outflow. Valvular aortic stenosis and hypertension are usually absent. Left ventricular diastolic dysfunction is invariably present. The disease is uncommon, estimated to be present in about 2 of 1000 young adults.[22] Because this condition can mimic valvular aortic stenosis, it will be considered in this section.

PATHOPHYSIOLOGY

The pattern and extent of left ventricular hypertrophy differs among patients with hypertrophic cardiomyopathy. In most patients, hypertrophy involves the septum and portions of the anterolateral free wall of the left ventricle. Rare morphologic forms include isolated apical hypertrophy, which is seen predominantly in patients of Japanese descent. Histologic features include cardiac muscle cell disarray and fibrous tissue formation.

In a subset of patients with the severe form of HCM, left ventricular outflow tract obstruction occurs at rest and worsens with exertion. The left ventricle is hyperdynamic, usually with an increased ejection fraction. A pressure gradient can be demonstrated in the left ventricular outflow tract below the aortic valve that at times may exceed 100 mm Hg. The gradient is augmented by factors that increase contractility (such as exercise or premature ventricular contractions) or by factors that decrease ventricular volume. The gradient may represent true obstruction to left ventricular ejection, resulting from portions of the mitral valve apparatus moving across the outflow tract and contacting the hypertrophied septum in midsystole. The displacement of the mitral valve occurs because of Venturi effects generated by the increased ejection velocities in the narrowed outflow tract. As the anterior mitral valve leaflet is drawn toward the septum by these Venturi effects, concomitant mitral regurgitation is produced.

Most patients with HCM have diastolic function abnormalities whether or not they are symptomatic.[23] Diastolic dysfunction is manifested by increased left ventricular filling pressures despite a normal ejection fraction. Isovolumic relaxation is prolonged, early diastolic filling is impaired, and atrial filling becomes an important component of cardiac output. Because of the importance of the atrial contribution to left ventricular filling, the acute onset of atrial fibrillation may cause clinical deterioration of patients with HCM.[24]

CLINICAL PRESENTATION

Classic symptoms of HCM include exertional chest pain, dyspnea, fatigue, and syncope.[24a,24b] Most patients with HCM, however, are asymptomatic until an unrelated illness causes deterioration. Tachycardia, sudden blood loss, or atrial or ventricular arrhythmias can suddenly precipitate pulmonary edema and hemodynamic collapse. As the outflow obstruction worsens, mitral regurgitation increases, leading to high left atrial and pulmonary venous pressures. Blood pressure may fall as cardiac output is impaired.

TABLE 29-1 Physical Examination Differences between Aortic Stenosis and Hypertrophic Cardiomyopathy

Feature	Aortic Stenosis	Hypertrophic Cardiomyopathy
Murmur location	Sternal border to neck	Sternal border to apex
Murmur with Valsalva maneuver	No change or decrease	Increase
Ejection click	Frequent in congenital stenosis	Rare
Regurgitant diastolic murmur	Common	Rare
Carotid pulse	Delayed upstroke	Brisk upstroke
A_2	Soft or absent	Normal

The diagnosis of HCM can be made definitively by careful cardiac physical examination. The carotid pulse has a characteristic brisk upstroke followed by sudden cutoff as obstruction occurs. The left ventricular impulse is vigorous and sustained. A large palpable A wave is present (easily felt in the left lateral decubitus position). A systolic thrill is commonly palpated. The first and second heart sounds are typically normal. The systolic murmur of outflow obstruction is harsh and has a crescendo/decrescendo configuration. The murmur radiates throughout the precordium, but not to the neck. A second murmur of mitral regurgitation can be heard at the apex, with radiation to the axilla. The murmur of HCM increases significantly in intensity with the Valsalva maneuver, a response that can be used to differentiate the murmur reliably from valvular aortic stenosis (Table 29-1).

DIAGNOSTIC EVALUATION

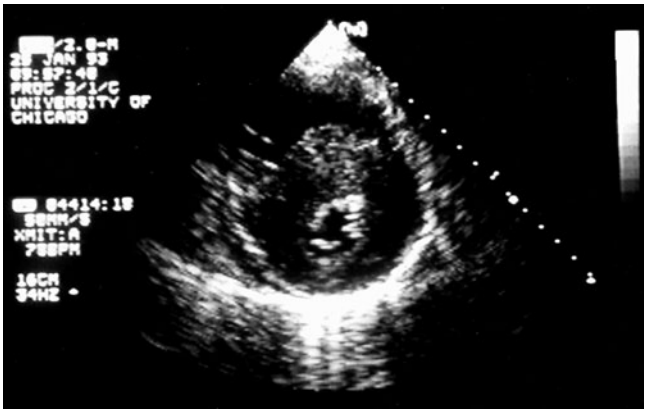
The electrocardiogram is almost always abnormal, with ST- and T-wave abnormalities, left ventricular hypertrophy, and predominant Q waves in the inferior or lateral leads. Giant negative T waves are characteristic of apical HCM of the Japanese type. The chest x-ray generally shows an enlarged cardiac silhouette. Echocardiography can make the diagnosis of HCM definitively and can quantitate the severity of the outflow tract obstruction. Classic features include a markedly hypertrophied interventricular septum, at times more than 20 mm thick (Fig. 29-4), systolic anterior motion of the mitral valve into the left ventricular outflow tract, premature closure of the aortic valve at the time of obstruction, and mitral regurgitation. Doppler echocardiography can accurately measure the magnitude of the outflow tract gradient. The modified Bernoulli equation is used to calculate the gradient in millimeters of mercury by the equation $4v^2$, where v is the maximum velocity measured in the outflow tract.

Cardiac catheterization can demonstrate the systolic pressure gradient in the left ventricle. The arterial pressure tracing may show a "spike and dome" configuration, representing the brisk outflow and sudden obstruction (Fig. 29-5). The pulmonary capillary wedge pressure is usually elevated, with a prominent A wave indicative of diastolic noncompliance. A large V wave may be present if mitral regurgitation is significant. A pressure gradient may be present in the right ventricular outflow tract as well.

MANAGEMENT

It is important to recognize HCM in patients presenting with pulmonary congestion, because management is substantially different than for other forms of heart failure. Pulmonary edema should be treated initially with diuretics to relieve congestion, but excessive preload reduction may aggravate the situation by accentuating the left ventricular outflow tract gradient. β agonists are contraindicated, because they may worsen outflow tract gradients, cause ischemia, and

FIGURE 29-4 Hypertrophic cardiomyopathy. Short-axis two-dimensional echocardiographic view showing the left ventricle in cross-section. Note the thick (>20 mm) left ventricular septum (*top*) compared with the normal-thickness posterior wall (*bottom*).



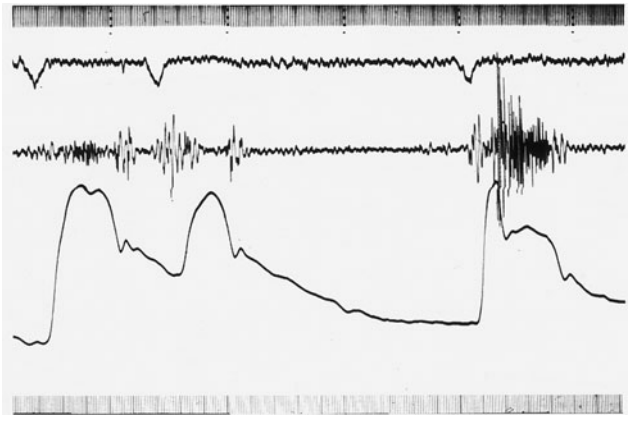


FIGURE 29-5 Carotid artery pulse tracing showing "spike and dome" configuration in the pressure tracing following the premature ventricular contraction, representing sudden obstruction to flow. In the figure, the first line is the surface ECG, the second line is a phonocardiogram, and the third line is the carotid artery pulse tracing.

precipitate arrhythmias. Likewise, digitalis should be avoided unless used to treat atrial fibrillation.

The mainstay of treatment is use of β-adrenergic blockers and calcium channel blockers. β-receptor blockade slows the heart rate and blunts the chronotropic response to exercise or stress, thus preventing the increase in outflow tract obstruction. Patients presenting in pulmonary edema should be started on intravenous β blockers such as esmolol, which has the advantage of a short half-life. The heart rate should be slowed to the slowest tolerated rate that decreases the outflow tract gradient. Large doses of β blockers may be required. If the heart rate cannot adequately be slowed with β blockers, then calcium channel blockers such as verapamil may be added. Verapamil doses of 360 to 480 mg and higher are frequently used. Other negative inotropic agents such as disopyramide can also be used to limit the outflow tract gradient.[25] The antiarrhythmic drug amiodarone has β-blocking activity and may improve survival in some patients with HCM.[26]

Atrial fibrillation may cause sudden deterioration of patients with HCM, as a result of both the increased heart rate and the loss of the atrial contribution to ventricular filling. Electrical cardioversion may be necessary acutely. Pharmacologic treatment may then be started to prevent recurrence. Agents that block the atrioventricular (AV) node, such as β blockers and calcium channel blockers, may be used prophylactically to prevent the sudden increase in heart rate should atrial fibrillation recur.

Surgical techniques for HCM have been developed that are aimed at eliminating the outflow tract gradient and reducing the amount of mitral regurgitation. Septal myotomy-myomectomy performed through the ascending aorta removes a portion of the hypertrophied interventricular septum, and has been associated with a significant reduction in outflow tract gradients and with symptomatic relief.[27] Mitral valve replacement has also been found to reduce or eliminate the outflow tract gradient and to improve symptoms.[28] Valve replacement may be especially helpful in patients with severe mitral regurgitation. There has been interest in pacemaker therapy with dual-chamber pacing of the right heart to decrease outflow tract gradients by changing the timing of depolarization of the interventricular septum to improve symptoms in patients with refractory disease.[29] This therapy may be beneficial acutely with use of temporary pacing wires. Some studies have not shown any clinical benefit with pacing, and possible detrimental effects on ventricular filling and cardiac output.[30] A new procedure using percutaneous septal ablation by infusing ethanol into the septal perforator branches of the left anterior descending artery has been studied.[31–33] This technique causes infarction and thinning of the thickened proximal septum, reducing the outflow obstruction with improvement in symptoms. Long-term results of this procedure are under study. None of these techniques have been shown to reduce the incidence of sudden death associated with this disease.

Aortic Insufficiency

ETIOLOGY

Aortic insufficiency (AI) may be secondary to diseases of the valve leaflets or to abnormalities of the aortic root (Table 29-2).

TABLE 29-2 Etiologies of Aortic Insufficiency

Valvular
Rheumatic fever
Infective endocarditis
Trauma
Bicuspid aortic valve
Myxomatous/prolapsing aortic valve
Fenestrated valve
Aortic root dilation
Aortic dissection
Systemic hypertension
Annuloaortic ectasia
Connective tissue diseases (Marfan syndrome, Ehlers Danlos syndrome, and related disorders)
Seronegative arthritides (ankylosing spondylitis, Reiter syndrome, and related disorders)
Rheumatoid arthritis
Syphilitic aortitis
Discrete subaortic stenosis

AI can be classified as chronic or acute.[34] Chronic AI may remain indolent for years and not require treatment until left ventricular dysfunction becomes evident. Acute severe AI, however, is a medical emergency with a high mortality and frequently requires early operative intervention. The three most common causes of acute AI are (1) infective endocarditis, (2) aortic dissection, and (3) rupture or prolapse of an aortic valve leaflet.[35] The aortic valve is the valve most commonly involved after blunt chest trauma.[36]

PATHOPHYSIOLOGY

The cardiac performance of patients with aortic insufficiency depends on the ability of the left ventricle to adapt to the volume overload. In chronic AI, the left ventricle gradually dilates with a shift in the pressure-volume relationship, so that any change in volume is accommodated at a lower pressure. In acute AI, the left ventricle is suddenly subjected to a large regurgitant volume for which it is not prepared. Left ventricular dilation is limited by the compliance of the ventricle and by the constraining pericardium. Therefore in acute AI, a small rise in volume may lead to a dramatic increase in left ventricular diastolic pressure. As a consequence, patients with acute AI usually present with signs and symptoms of pulmonary congestion.

If the patient survives the acute insult, the left ventricle and pericardium may adapt to the volume overload by dilating. Left ventricular wall stress is diminished by left ventricular hypertrophy. The increase in chamber size and diastolic volume leads to an augmentation of forward stroke volume despite high regurgitant volumes. Afterload is reduced because of the rapid runoff of blood from the aorta into the ventricle. Cardiac performance can be maintained in the normal range for many years despite the presence of severe AI. However, decompensation can occur at any time, owing to ischemia or other factors for which the heart cannot accommodate. Once left ventricular dysfunction develops, the disease tends to progress rapidly. Left ventricular volumes (left ventricular end-systolic dimension >50 mm, left ventricular end-diastolic dimension >70 mm) can be used to predict which patients are more likely to have progressive disease and the development of left ventricular failure.[37]

TABLE 29-3 Clinical Features of Acute versus Chronic Aortic Insufficiency

Feature	Acute	Chronic
Presentation	Pulmonary edema	Gradual congestive heart failure
Systolic blood pressure	Normal to low	Increased
Pulse pressure	Normal	Wide
Heart rate	Tachycardia	Normal
Left ventricular impulse	Normal size	Dilated
S_1	Soft	Usually normal
S_2	P_2 loud	Normal
S_3 gallop	Usually present	May be present
AI murmur	Short	Long
Peripheral signs	Absent	Present

CLINICAL PRESENTATION

Patients that present with acute AI are usually critically ill, with signs of pulmonary edema, diaphoresis, cyanosis, and peripheral vasoconstriction. The left ventricular end-diastolic pressure is markedly increased, at times equaling the aortic diastolic pressure, shortening the aortic regurgitant murmur. Patients are typically tachycardic without a wide pulse pressure or prominent peripheral signs of aortic insufficiency. Systolic pressure may be normal or low. The heart is not enlarged. The first heart sound may be soft, owing to premature closure of the mitral valve caused by the aortic regurgitant jet. The pulmonic component of the second heart sound may be loud, reflecting pulmonary hypertension. A gallop rhythm is usually present. Table 29-3 compares the features of acute versus chronic aortic regurgitation.

DIAGNOSTIC EVALUATION

In acute AI, the electrocardiogram is usually normal, showing only sinus tachycardia. Left ventricular hypertrophy may be present in patients with chronic AI, and usually signifies severe regurgitation. The chest x-ray in acute AI usually shows pulmonary edema with a normal heart size. A widened mediastinum should raise the suspicion of acute aortic dissection as the cause of the aortic insufficiency. In chronic AI, the chest x-ray is likely to show cardiomegaly with a prominent left ventricle. The ascending aorta may be dilated.

Echocardiography is useful for detecting aortic insufficiency and determining its severity and for evaluating left ventricular performance. Aortic insufficiency may be suspected from the appearance of the valve leaflets on two-dimensional echocardiography, but Doppler techniques are the most sensitive for diagnosing AI and determining the severity of the leakage.[38] The presence of AI is confirmed by Doppler echocardiography when an abnormal, high-velocity turbulent jet is detected just below the aortic valve during diastole. Color flow mapping is used to depict the origin and size of the regurgitant jet. The severity of the regurgitation can be estimated from the size of the regurgitant jet, from the size of the regurgitant orifice, or by calculation of the regurgitant volume or fraction. In patients with severe AI, the consequences of a significant increase in left ventricular pressure can be noted by premature closure of the mitral valve, diastolic mitral regurgitation, and premature closure of the aortic valve if left ventricular pressure transiently exceeds aortic pressure.

Transesophageal echocardiography (TEE) should be considered when endocarditis or an acute aortic dissection is suspected as the cause of aortic insufficiency. TEE can better evaluate valvular structure and is more sensitive for the diagnosis of endocarditic lesions than transthoracic echocardiography (Fig. 29-6 and Color Plate 29-6). TEE has been shown to have a sensitivity comparable to that of magnetic resonance imaging (MRI) or computed tomography (CT) for detecting an acute aortic dissection,[39] and it is more easily performed in an intensive care unit on an unstable critically ill patient.

Cardiac catheterization can provide definitive information about the degree of regurgitation, and it can be used to evaluate the aortic root and the status of the coronary arteries if surgery is indicated. Pulmonary artery catheterization is indicated in acute AI to help with management. The pulmonary artery wedge pressure is usually elevated, and pulmonary hypertension may be present. Stroke volume may be normal or increased.

MANAGEMENT

Acute aortic insufficiency is a medical emergency. Fulminant pulmonary edema is a common presentation, because the left ventricle cannot handle the sudden large increase in volume. It is important to determine the cause of the lesion, especially if endocarditis or an acute aortic dissection is suspected. Aortic valve replacement is indicated when the regurgitation is severe. Early aortic valve replacement has been shown to decrease mortality in patients with endocarditis.[40] If heart failure can be medically managed, aortic valve replacement may be delayed until after completion of an antibiotic regimen.[41]

Patients presenting with acute pulmonary edema should be treated promptly with loop diuretics to relieve congestion. Inotropic agents are of limited value, because left ventricular function is usually hyperdynamic. Pressor agents are relatively contraindicated, because an increase in systemic vascular resistance will worsen the amount of regurgitation. Likewise, an intra-aortic balloon pump is absolutely contraindicated.[42] Vasodilators can improve forward stroke volume by inducing dilation of the arterial vessels. An agent such as nitroprusside is ideal, because it can be rapidly titrated to effect. This drug should be administered with pulmonary artery catheter guidance so that the response to therapy can be followed closely. Nitroprusside has been shown to improve cardiac performance, enhance forward stroke volume, reduce the amount of regurgitation, and lower left ventricular filling pressures.[43,44]

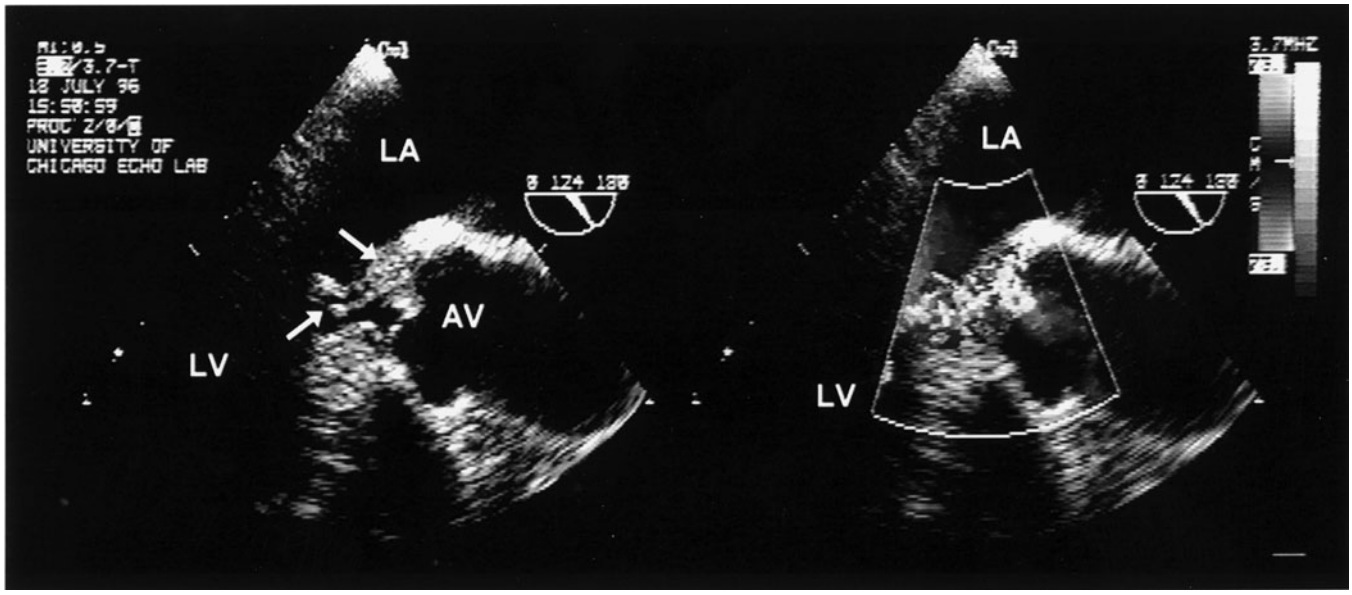

FIGURE 29-6 Acute aortic insufficiency secondary to endocarditis. Transesophageal echocardiogram showing a large mobile vegetation (*arrows*) extending from the aortic valve (AV) into the left ventricle (LV). Doppler echocardiography reveals significant regurgitation from the aorta into the LV. LA, left atrium. (See Color Plate 29-6.)

Patients that can be stabilized should be treated with long-term vasodilator therapy. Vasodilator agents such as hydralazine, angiotensin-converting enzyme inhibitors (ACEIs), β blockers, and calcium channel blockers have been used.[45] Recently, nifedipine has been shown to delay the need for aortic valve replacement in patients with asymptomatic chronic severe aortic insufficiency.[46] Aortic valve replacement should be performed before irreversible changes occur in the left ventricle. The end-systolic dimensions and shortening characteristics of the left ventricle can be used to determine the optimal time for operative intervention.[47] Aortic valve replacement for severe aortic insufficiency with a low left ventricular ejection fraction has a high perioperative mortality and an increased incidence of congestive heart failure after surgery, but many patients will sustain improvement in their cardiac function and a prolonged survival.[48]

Mitral Stenosis

ETIOLOGY

Rheumatic fever is the main cause of mitral stenosis, and in underdeveloped countries is a significant cause of morbidity and mortality in young people. Recent outbreaks of rheumatic fever and an influx of immigrants from countries where rheumatic fever is prevalent will ensure that this disease remains an important valvular condition in the United States as well.[49] Other forms of mitral stenosis may be encountered, such as calcification of the mitral annulus so extensive as to involve the submitral apparatus and the valvular leaflets. This rare cause of mitral stenosis is seen in elderly patients and patients with long-standing renal failure.

PATHOPHYSIOLOGY

Rheumatic mitral stenosis results from an inflammatory process that leads to fusion of the mitral commissures, chordae tendineae, or both. The disease tends to cause a slowly progressive degeneration of the valve, and many patients remain asymptomatic for decades after the initial infection. The normal mitral valve has an area of 4 to 6 cm^2. When the valve has narrowed to 2 cm^2, mild mitral stenosis is present. A valve area of 1 cm^2 is thought to represent critical mitral stenosis. At this orifice size, a transvalvular gradient of approximately 20 mm Hg is required to maintain a normal cardiac output. As a consequence, left atrial pressure rises, leading eventually to pulmonary hypertension.

Any increase in heart rate will shorten diastolic filling time and diminish the time for blood to flow across the stenosed mitral valve. Tachycardia will augment the transvalvular pressure gradient and further increase left atrial pressure. That is why patients may suddenly present with pulmonary edema and the onset of atrial fibrillation.[50] Patients with mild to moderate mitral stenosis may be asymptomatic at rest, but exercise may cause a dramatic rise in the transmitral gradient and left atrial pressure, leading to exertional dyspnea.[51] In addition, the atrial contribution to left ventricular filling may account for 20% or more of total cardiac output. Loss of the atrial filling component can significantly worsen symptoms in patients with mitral stenosis.

As mitral stenosis becomes more severe, resting pulmonary artery pressures begin to increase. In critical mitral stenosis, pulmonary pressures may exceed systemic pressures. Pulmonary pressures greater than 70 mm Hg lead to elevated right ventricular and right atrial pressures, eventually causing right ventricular dilation and failure.

CLINICAL PRESENTATION

Patients with rheumatic mitral stenosis may be asymptomatic for many years despite progressive narrowing of the valve. Symptoms initially occur with exercise. Patients may suddenly decompensate and present in pulmonary edema during an episode of respiratory infection, atrial fibrillation, or another condition associated with tachycardia.

Sudden, profuse hemorrhage may occur from disruption of bronchial veins. Thromboembolism can be a serious complication, occurring most often in patients with chronic atrial fibrillation.

The physical examination in critically ill patients with mitral stenosis can be difficult. The left ventricle is usually normal in size, although it may be displaced leftward owing to right ventricular enlargement. The first heart sound is usually accentuated if the mitral leaflets remain pliable. As pulmonary hypertension develops, the pulmonic closing sound (P_2) becomes accentuated. Other signs of pulmonary hypertension include a right ventricular heave, tricuspid regurgitation (a holosystolic murmur at the right or left sternal border with respiratory variation), and the Graham Steell murmur of pulmonic insufficiency. At the left ventricular apex, an opening snap may be heard, followed by the low-pitched rumbling murmur of mitral stenosis. In severe mitral stenosis, the murmur is heard throughout diastole, with presystolic accentuation of the murmur in patients who remain in sinus rhythm.

DIAGNOSTIC EVALUATION

The electrocardiogram will typically show left atrial enlargement and signs of right ventricular hypertrophy in severe mitral stenosis. Atrial fibrillation is a common rhythm disturbance. The chest x-ray can show left atrial enlargement with upward displacement of the left mainstem bronchus by the enlarged atrium. The left atrial appendage may appear as a bulge between the aortic knob and the left ventricular silhouette. With pulmonary hypertension, the pulmonary arteries will be prominent, and the right ventricle may be enlarged. Calcification of the mitral annulus can frequently be detected.

Echocardiography and Doppler techniques have been used to assess and quantify the severity of mitral stenosis noninvasively. Two-dimensional echocardiography can delineate the anatomy of the mitral valve (Fig. 29-7). As the valve leaflets begin to open during diastole, the leaflet tips appear to remain tethered while the body of the leaflet continues to show mobility (doming), producing a characteristic deformity that is classic for rheumatic mitral stenosis. Planimetry of the cross-sectional valve area from the short axis view has correlated well with valve areas calculated invasively by the Gorlin formula.[52] Doppler echocardiographic methods have also been used to quantify mitral valve areas by using a pressure half-time method (Fig. 29-8). The time required for the diastolic gradient to drop to half its initial peak reflects the severity of mitral stenosis.[53] The noninvasively determined pressure half-time is defined as the time required for the early maximal inflow velocity to fall to a value equal to the maximum velocity divided by the square root of 2.[54] The mitral valve area is then calculated by dividing the empirically derived number 220 by the pressure half-time.

Cardiac catheterization is used to verify the severity of the valve lesion and to measure right heart pressures. Left atrial puncture via a transseptal approach can directly measure left atrial pressure. Pulmonary capillary wedge pressures may be used as well, but at times they exaggerate the left atrial pressure and overestimate the severity of the mitral stenosis.[55]

FIGURE 29-7 Mitral stenosis. Cross-section echocardiogram of the mitral valve showing the severely stenotic mitral valve leaflets with a fish-mouth appearance. Planimetry of the fully opened valve yielded a valve area of less than 1 cm^2.

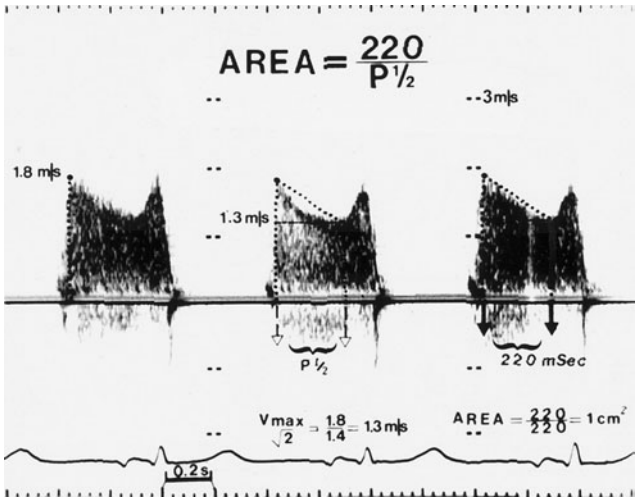

FIGURE 29-8 Pressure half-time method for calculating mitral valve area. Doppler echocardiography depicts an increased velocity across the stenotic mitral valve. The pressure half-time ($P^1/_2$) is the time required for the maximal velocity (Vmax) to fall to a value equal to the maximal velocity divided by the square root of 2. The mitral valve area is then 220 divided by the pressure half-time; in this example it is 1 cm^2.

MANAGEMENT

Patients presenting with pulmonary edema should undergo initial diuretic treatment to decrease lung congestion and improve oxygenation. For patients presenting in atrial fibrillation, control of heart rate is crucial. A combination of digoxin, β blockers, and/or calcium channel blockers may be required to achieve rate control. Use of intravenous esmolol or diltiazem can quickly bring about rate control and is preferred over intravenous digoxin. Patients in sinus rhythm may also benefit from β blockers to slow the heart rate and allow more time for diastolic filling of the left ventricle. Anticoagulation should be started in patients with atrial fibrillation to prevent thromboembolism (IV heparin and warfarin with a goal International Normalized Ratio [INR] of 2 to 3).

Once symptoms develop, mitral stenosis requires definitive management. That can be achieved by surgical mitral commissurotomy, mitral valve replacement, or catheter balloon commissurotomy. For patients with pure rheumatic mitral stenosis, catheter balloon commissurotomy has become the procedure of choice for relieving the stenosis and improving symptoms.[56] The procedure is performed via a transseptal approach, and a balloon is passed across the mitral valve from the left atrium into the left ventricle. A small atrial septal defect remains following the procedure, but in most patients it closes or becomes smaller. Contraindications to catheter balloon commissurotomy include significant mitral regurgitation, a thrombus in the left atrium, unfavorable valve morphology, or only mild mitral stenosis. The procedure is highly successful with low mortality rates and greater than 60% of patients improving to New York Heart Association functional class I.[57] If there are contraindications to catheter balloon commissurotomy, then surgical valvular repair would be necessary.

Mitral Regurgitation

ETIOLOGY

There are multiple conditions that can cause acute or chronic mitral regurgitation (MR) involving the mitral valve leaflets, mitral annulus, chordae tendineae, or papillary muscles (Table 29-4). Involvement of the leaflets is usually due to rheumatic disease leading to shortening or retraction of one or both leaflets. Infective endocarditis, trauma, or systemic lupus erythematosus with Libman-Sacks endocarditis can lead to significant MR (Fig. 29-9 and Color Plate 29-9). Finally, mitral valve prolapse can present with severe MR due to myxomatous change of the valve leaflets.

Abnormalities of the mitral annulus involve dilation and calcification. Severe dilation of the left ventricle, as seen in dilated cardiomyopathies, is associated with mitral regurgitation, although the amount of leakage tends to be less than that seen in primary valvular disorders. Calcification of the mitral annulus is a common degenerative change that when severe, may cause significant MR.

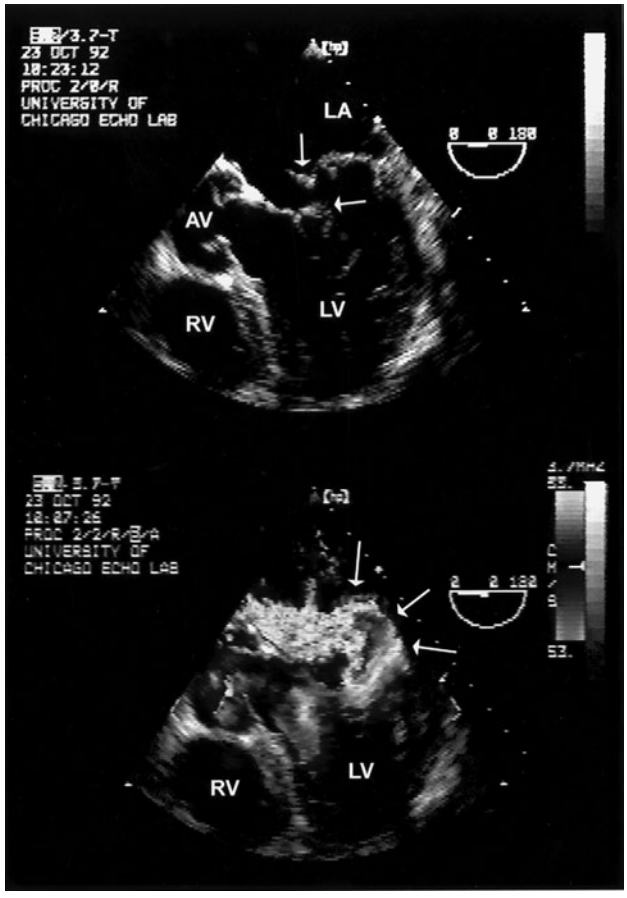

FIGURE 29-9 Mitral regurgitation secondary to endocarditis and a flail posterior mitral valve leaflet. Transesophageal echocardiogram showing thickened mitral valve leaflets with vegetations (*arrows*). The posterior leaflet has prolapsed from the left ventricle (LV) into the left atrium (LA). The second panel depicts severe mitral regurgitation by Doppler echocardiography (*arrows*). AV, aortic valve; RV, right ventricle. (See Color Plate 29-9.)

TABLE 29-4 Causes of Mitral Regurgitation

Disorders of the mitral leaflets
Rheumatic heart disease
Infective endocarditis
Trauma
Systemic lupus erythematosus
Myxomatous mitral valve prolapse
Congenital mitral valve clefts/fenestrations
Parachute mitral valve
Disorders of the mitral annulus
Left ventricular dilation
Mitral annular calcification
Disorders of the chordae tendineae
Myxomatous involvement in mitral valve prolapse
Infective endocarditis
Trauma
Spontaneous rupture
Disorders of the papillary muscles
Dysfunction (myocardial ischemia/infarction/infiltrative diseases)
Rupture (infarction/trauma)

The chordae tendineae and papillary muscles may be involved in patients with ischemic heart disease. Myocardial ischemia or infarction may lead to papillary muscle dysfunction or frank rupture of the muscle head, causing acute severe MR. Ischemia of the papillary muscles may be transient, with improvement in the MR occurring after relief of the ischemia or revascularization therapy. On the other hand, patients with moderately severe to severe MR complicating an acute myocardial infarction have a high risk of mortality.[58] Chordae tendineae may rupture in patients with infective endocarditis and in patients with myxomatous mitral valve prolapse. Mitral valve prolapse is becoming the most common etiology for patients requiring valvular surgery for mitral regurgitation.

PATHOPHYSIOLOGY

In patients who develop acute MR, the left ventricle is initially unloaded, with the regurgitant volume ejected into the left atrium. The left ventricular wall tension is reduced, since

TABLE 29-5 Differential Diagnosis of Systolic Murmurs

Feature	Mitral Regurgitation	Tricuspid Regurgitation	Ventricular Septal Defect
Murmur	Holosystolic	Holosystolic	Holosystolic
Location	Apex	Left sternal border	Left sternal border
Radiation	Axilla	None	Left precordium
Thrill	At apex	Rare	Left sternal border
P_2	Normal	Increased	Normal, usually delayed
Murmur with inspiration	No change	Increased	No change
Apical impulse	Hyperkinetic	Normal	Hyperkinetic
Jugular venous pulse	Normal	Elevated, prominent V wave	Elevated, prominent A and V waves
Pulsatile liver	No	Yes	No

acute MR reduces systolic ventricular pressure and volume. Early diastolic filling of the left ventricle is enhanced, causing small elevations in myocardial contractility and ejection fraction. Following initial compensation, the left ventricle dilates rapidly. The increase in left ventricular end-diastolic volume increases wall tension. Ejection indices will eventually decline to normal, reflecting impairment of myocardial function. Ejection fractions of 40% to 50% already reflect severe impairment of myocardial contractility. Ejection fractions less than 40% represent advanced cardiac dysfunction and indicate a patient who has a high operative risk and is unlikely to experience any improvement in function following correction of the problem.[59]

The compliance of the left atrium and the pulmonary venous system will determine the hemodynamic and clinical manifestations of mitral regurgitation. In patients in whom MR occurs suddenly, as with rupture of a chorda tendineae, left atrial compliance is normal. Left atrial size remains normal, but there is a marked elevation of left atrial pressure (large V wave), and pulmonary congestion is predominant. In contrast, in patients with long-standing chronic MR, massive enlargement of the left atrium occurs with normal or only slightly elevated left atrial pressures. Pulmonary artery pressures and pulmonary vascular resistance are normal or only slightly elevated. Atrial fibrillation is almost invariably present.[60]

CLINICAL PRESENTATION

The symptoms of patients with mitral regurgitation depend on the acuity and severity of the disease. In patients with chronic MR, symptoms usually do not develop until the left ventricle begins to fail. By the time low-output symptoms, pulmonary congestion, or atrial fibrillation develops, permanent myocardial dysfunction may already be present. The onset of a critical illness may cause rapid deterioration in a previously stable patient if increased systemic vascular resistance augments the regurgitant fraction. Patients with acute MR may present with florid pulmonary edema and low cardiac output. Ischemic symptoms may also be present, since myocardial infarction with papillary muscle dysfunction and rupture is an important cause of acute MR.

On physical examination, the left ventricular impulse is usually dynamic and displaced, with a palpable early diastolic filling impulse (S_3). The systolic murmur of mitral regurgitation begins at the first heart sound (frequently obscuring it) and extends throughout systole and beyond the second heart sound to mitral valve opening. The murmur is constant in intensity, is high-pitched, is loudest at the apex, and radiates to the axilla. The intensity of the murmur does not correlate with severity. Patients with acute MR may have barely audible brief murmurs. Murmurs of mitral valve prolapse may begin in mid or late systole and vary in position and intensity depending on left ventricular volume.[61]

Mitral regurgitation murmurs need to be differentiated from other systolic murmurs (Table 29-5). Tricuspid regurgitation frequently exhibits respiratory variation and does not radiate to the axilla. Ventricular septal defect murmurs tend to be harsher, to be located at the sternal border, and to be heard less well in the axilla. Aortic stenosis murmurs may radiate to the apex, but they are usually accompanied by a delayed carotid upstroke and a decreased intensity of the aortic component of the second heart sound.

DIAGNOSTIC EVALUATION

The electrocardiogram in acute mitral regurgitation is usually normal, although it may show signs of acute myocardial infarction. Patients with chronic MR may have signs of left atrial enlargement, right ventricular hypertrophy, or atrial fibrillation. Chest x-ray shows cardiomegaly with left ventricular prominence, left atrial enlargement, and at times evidence of mitral annular calcification.

Two-dimensional echocardiography can help determine the etiology and severity of mitral regurgitation. The underlying cause of the regurgitation, such as rupture of a chorda tendineae, mitral valve prolapse with a flail leaflet, or valvular endocarditis, can readily be determined. Transesophageal echocardiography has improved the diagnostic acumen of echocardiographic studies, especially in determining the presence of valvular vegetations. Doppler echocardiography makes it possible to estimate the severity of MR from the distance the jet travels into the left atrium, the width of the jet at the mitral annulus, and the area of the color Doppler envelope in the left atrium.

Cardiac catheterization is useful in diagnosis and management. Left ventriculography showing opacification of the left atrium is used to quantify severity of the leakage. Effective or forward cardiac output is depressed in severe MR. The pulmonary wedge pressure will show a characteristically tall V wave, reflecting the filling of the left atrium by both pulmonary venous and regurgitant blood during ventricular systole. This tall V wave is frequently seen in the pulmonary artery tracing, and at times little difference between the pulmonary artery tracing and the wedge pressure tracing is

evident. Successful treatment of MR will bring about a significant decline in the V wave.

MANAGEMENT

Patients presenting with acute mitral regurgitation should be treated with the same modalities used in patients who present with acute heart failure. Afterload reduction with vasodilators or noninvasive positive pressure ventilation[62] will reduce the impedance to ejection into the aorta, diminish the amount of mitral regurgitation, increase forward output, and reduce pulmonary congestion.[63] In acute presentations, nitroprusside can achieve these clinical goals and has the advantage of easy titration to blood pressure. If hypotension is present, positive inotropic agents such as dobutamine may need to be combined with the nitroprusside. Diuretics are used to relieve congestion. Digoxin may be useful if left ventricular dysfunction or atrial fibrillation is present. Chronic afterload reduction can then be initiated with ACEIs or other vasodilators.

Unless patients with acute severe MR are treated aggressively, death is almost certain. Emergency surgery should be considered in patients with acute pulmonary edema caused by acute MR due to myocardial infarction and papillary muscle rupture, rupture of a chorda tendineae with a flail mitral leaflet in the mitral valve prolapse syndrome, traumatic MR, or severe MR associated with valvular endocarditis.

Patients with chronic MR should be considered for surgery when they become symptomatic. Exercise testing can precipitate symptoms in patients that are asymptomatic at rest. Asymptomatic patients should be considered for surgical intervention when the ejection fraction falls below 50%, the end-systolic volume index exceeds 50 mL/m^2, or pulmonary hypertension develops.[64]

The decision of whether to replace the mitral valve or to perform valvular reconstruction will depend on the degree of deformity of the valve leaflets and support structures. Mitral valve repair appears to be associated with a lower surgical mortality than is mitral valve replacement, although the patient populations differ.[65] Mitral valve repair is most often used in patients with myxomatous mitral valve prolapse and a flail mitral leaflet or with papillary muscle rupture after an acute myocardial infarction. Repair procedures consist of annuloplasty with the use of a prosthetic ring or resection and repair of the valve. Replacement, reimplantation, or shortening of chordae tendineae is performed in selected patients. Patients who are not candidates for repair receive either a mechanical or bioprosthetic valve. Surgeons frequently leave the submitral apparatus in place, as doing so favors a return to a more normal cardiac function after surgery.[66]

PROSTHETIC VALVES

There are two major types of prosthetic heart valve: mechanical valves, which are made of synthetic material, and tissue valves, which are composed at least in part of biologic tissue. The first mechanical valves were ball valves, such as the Starr-Edwards prosthesis. These valves have largely been replaced by the tilting disk valves, which offer a greater orifice area and less resistance to blood flow. Common examples of the disk valves are the Bjork-Shiley and St. Jude Medical valves. The two major types of tissue valves are stented porcine aortic valves (the Carpentier-Edwards and Hancock valves) and a trileaflet valve made with bovine pericardium (Ionescu-Shiley valve). Other tissue valves are under development, including ones that use cryopreserved aortic homografts.

The advantage of tissue valves is a lower risk of thromboembolism than with mechanical valves. Anticoagulation is frequently used during the first few months after implantation, until the sewing ring becomes endothelialized. Anticoagulation is not required after this time; the thromboembolism rate is estimated to be 1 to 2 episodes per 100 patient-years.[67]

The main problem with the tissue valves concerns durability. The tissue valves are prone to calcification, fibrosis, degeneration, fibrin deposition, and cuspal tears. Valve dysfunction is more common in younger patients and in patients with disordered calcium metabolism. Evidence of degeneration can usually be detected by 5 years after replacement.[68] By 15 years, over 50% of tissue valves will have failed.[69] Fortunately, valve failure is rarely sudden, and a second operation can frequently be done on an elective basis. Sudden cuspal tears can present as an acute regurgitant lesion.

Mechanical valves have the advantage of durability but require anticoagulation to prevent thromboembolism. Without anticoagulation, major systemic embolisms occur at a rate of about 2% to 3% per year.[70] The incidence is higher for valves in the mitral than in the aortic position. With adequate anticoagulation, however, the incidence of thromboembolism is similar to that for tissue valves. The use of a small dose of aspirin plus warfarin anticoagulation may decrease the risk of thromboembolism further, but increases the risk of a bleeding complication.[71]

For patients who require noncardiac surgery and have a mechanical prosthetic valve, the anticoagulation regimen may be stopped for a few days with minimal risk. Minimizing the time off anticoagulants is essential to avoid thromboembolism. Heparin or low-molecular-weight dextran is frequently administered up to the time of surgery, to protect the patient. Heparin should then be restarted after surgery until warfarin treatment increases the International Normalized Ratio (INR) to the target level of 2.5 to 3.5.

Mechanical valve thrombosis is a serious complication and is associated with a high mortality.[72] The tilting disk valves are particularly susceptible to this complication. Thrombosis of mechanical valves is especially common for valves in the tricuspid position, so tissue valves are usually used in this location.[73] Inadequate anticoagulation or withdrawal of anticoagulation for surgical procedures accounts for most instances of thrombotic obstruction.[74] Thrombosis of the valve may lead to leaflet entrapment with acute regurgitation and circulatory collapse. Some patients, however, may remain asymptomatic or develop gradually worsening symptoms.

Obstruction of a mechanical valve usually necessitates reoperation, although that may be associated with a high risk of operative mortality. Thrombolytic therapy has been used successfully for prosthetic valve obstruction, with a success rate of 73% reported for one series.[75] Recurrence rates, however, have averaged 18% regardless of valve position.[76]

Prosthetic valve obstruction may be difficult to detect. Abnormal auscultatory findings, such as muffled opening or closing sounds or the presence of a new murmur, may indicate thrombosis. Doppler echocardiography can diagnose obstruction by detecting an increased transvalvular gradient. Transesophageal echocardiography can frequently visualize thrombosed mechanical valves that are not well seen with

transthoracic approaches owing to signal scatter from the valve structures.

Prosthetic valve endocarditis is a serious complication that occurs in 1% to 9% of patients.[77] Early prosthetic valve endocarditis occurs within 60 days of implantation and results from contamination during the perioperative period. Most contamination probably occurs intraoperatively from direct wound inoculation or via the cardiopulmonary bypass machine. Postoperative sources include intravenous lines, pacing wires, and chest tubes. *Staphylococcus epidermidis* and *Staphylococcus aureus* are the most common organisms. A preoperative diagnosis of native valve endocarditis represents an increased risk of prosthetic valve involvement following surgery. Mortality is high, with one survey reporting a 64% mortality.[77]

Late prosthetic valve endocarditis occurs owing to seeding of the valve by transient bacteremia arising from dental, gastrointestinal, or genitourinary tract procedures. Nosocomial bacteremia has been reported to cause prosthetic valve endocarditis in 11% of patients within 45 days after discovery of the bacteremia.[78] The bacteria responsible are similar to those found in native valve endocarditis, with viridans streptococci the most common isolates. The prognosis of late prosthetic valve endocarditis is worse than that of native valve endocarditis, with mortality rates between 36% and 53%.[79] Complications of prosthetic valve endocarditis include myocardial abscesses, dehiscence of the valve with perivalvular leakage, and embolization (Fig. 29-10 and Color Plate 29-10). Immediate surgery is indicated in patients who are unstable or have significant prosthetic valve dysfunction.[80]

Antibiotic prophylaxis for medical and dental procedures is recommended for all patients with prosthetic valves. Procedures in which prophylaxis is recommended include bronchoscopy, sclerotherapy for esophageal varices, urethral catheterization if a urinary tract infection is present, incision and drainage of infected tissue, and vaginal delivery in the presence of infection.[81] Antibiotic schedules are listed in Table 29-6.

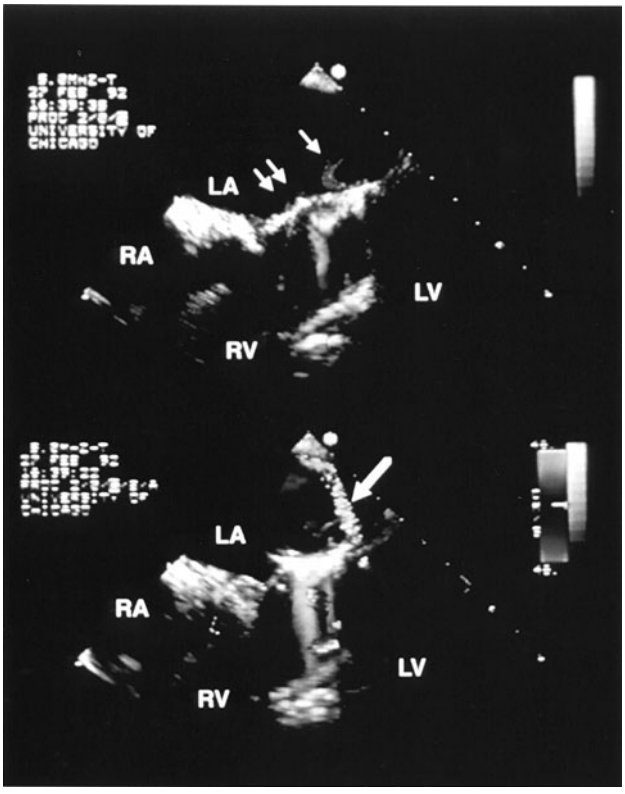

FIGURE 29-10 Endocarditis involving a St. Jude Medical mechanical valve in the mitral position. Transesophageal echocardiogram showing vegetations on the left atrial (LA) side of the mechanical valve (*small arrows*). Doppler echocardiography reveals perivalvular mitral regurgitation (*large arrow*). LV, left ventricle; RV, right ventricle; RA, right atrium. (See Color Plate 29-10.)

TABLE 29-6 Antibiotic Prophylaxis for Medical and Dental Procedures

Regimens for dental, oral, respiratory tract or esophageal procedures:	
Standard regimen:	
Amoxicillin	2 g orally 1 h before procedure
Regimen for amoxicillin/ampicillin/penicillin-allergic patients:	
Clindamycin	600 mg given orally 1 h before procedure, or
Cepahalexin or cefadroxil	2 g orally 1 h before procedure, or
azithromycin or clarithromycin	500 mg orally 1 h before procedure
Regimens for genitourinary/gastrointestinal procedures:	
Standard regimen: high-risk patients	
Ampicillin, gentamicin, and amoxicillin	2 g ampicillin plus 1.5 mg/kg gentamicin (120 mg maximum) IV or IM 30 min before procedure; amoxicillin, 1 g orally 6 h after first dose
For ampicillin/amoxicillin-allergic patients:	
Vancomycin and gentamicin	Vancomycin, 1 g IV over 1–2 h, plus gentamicin, 1.5 mg/kg (120 mg maximum) IV or IM; complete infusion 30 minutes before procedure
Moderate risk-patients	
Amoxicillin	Amoxicillin 2 g orally 1 h before procedure or ampicillin 2 g IV or IM within 30 min of starting procedure
Ampicillin/amoxicillin-allergic	Vancomycin 1 g over 1–2 h

Chapter 30

AORTIC DISSECTION

JOSEPH J. AUSTIN

KEY POINTS

- *Acute aortic dissection occurs more commonly than ruptured abdominal aortic aneurysm.*
- *The typical pain, poor peripheral perfusion, and evidence of aortic branch occlusion suggest the diagnosis.*
- *Early pharmacologic control of systolic blood pressure and the pulse wave (dP/dT) is imperative.*
- *Investigations must be undertaken urgently to confirm the diagnosis and direct definitive treatment.*
- *Emergency surgical repair is indicated for type A dissections.*
- *Control of hypertension is important to minimize complications and maximize survival both in the postoperative period and in the long term.*
- *Type B dissections may have a more ominous prognosis than previously thought and require very close long-term follow-up.*

Aortic dissection is the most common catastrophe affecting the aorta, occurring two to three times more commonly than acute abdominal aortic aneurysm rupture.[1] The reported incidence is approximately 10 to 20 per 1 million per year.[2] Rarely is the outcome of a cardiovascular disease so dependent on the skills and cooperation of the emergency room physician, the cardiac surgeon, and the intensivist as it is with acute dissections of the aorta. Maximal survival depends on a high index of suspicion of the diagnosis despite a myriad of different presentations, early pharmacologic intervention for control of hypertension, rapid diagnosis with definitive imaging, and then appropriate relegation to medical or surgical management depending on the dissection type. Without treatment, the 3-month mortality is 85% to 90%, but with the appropriate treatment, survival rates of over 80% can be expected.

Pathogenesis

Previously, aortic dissections were referred to as *dissecting aneurysms,* as originally coined by Laënnec. This is a misnomer in that the pathology is a dissecting hematoma that separates the intima and inner layers of the media from the outer medial and adventitial layers (Fig. 30-1). The intima is therefore not aneurysmal, and is if anything, narrowed. Blood invades the media through a tear in the intima and proceeds ante- or retrogradely through the aortic wall, forming a false lumen. The hematoma spirals around the right and posterior aspects of the ascending aorta, supraposteriorly along the arch, and then down the left and posterior aspects of the descending aorta.[3] The hematoma may then have several serious sequelae. It may rupture into the pericardial space causing tamponade, or into the pleural space with exsanguinating hemorrhage. This occurs less frequently than expected because the adventitial layer represents 66% of the overall strength of the aortic wall. It may also cause occlusion of aortic branch arteries or prolapse of one or more of the aortic valve cusps, resulting in acute aortic insufficiency.

Generally the tear is due to either a weakening of the wall of the aorta, an increase in luminal shear stress, or both.[3] Weakening of the aortic wall occurs as the result of medial degeneration or iatrogenic injury. Medial degeneration (cystic medial degeneration or necrosis) is manifested by the loss of smooth muscle cells and accumulation of basophilic amorphous material with or without associated "cysts" in the aortic media. This is believed to be due to inborn errors of metabolism (Marfan's or Ehlers-Danlos syndrome). There is a reduction in the cohesiveness of the layers of the aortic wall as a result. Other causes of reduced wall strength causing aortic dissection include annuloaortic ectasia, bicuspid aortic valve, coarctation, and pregnancy (especially in the third trimester.)

Iatrogenic injuries occur during open heart surgical procedures at any point where the aorta is invaded, such as the aortotomy for an aortic valve replacement or the proximal anastomosis of an aortocoronary bypass graft.

Stresses applied to the aortic wall increase wall tension and lead to dissections. Most important are intraluminal shear stresses, which are related both to the level of the systolic blood pressure and to the steepness of the aortic pulse wave.[2] This is referred to as dP/dT_{max} and represents the speed with which the maximal systolic pressure is attained in the aortic root. As this increases, so too does the shear stress on the ascending aorta.

Classification

Dissections are classified by timing and location to identify the morbidity and mortality for the specific lesions.

TIMING

- Acute: <2 weeks
- Chronic: >2 weeks

Acute dissections are very high-risk lesions, with an estimated mortality of 50% for the first 48 hours (or 1% per hour).

LOCATION

- Type A: The ascending aorta is involved independent of the site of the intimal tear (since 15% of transverse arch and 5% of descending aortic tears will involve the ascending aorta), and may include the aortic arch and part of or all of the descending thoracic and abdominal aorta.
- Type B: Descending aorta (beyond the left subclavian artery).

This classification system, proposed by Daily and colleagues and popularized by the Stanford group, replaces the original system proposed by DeBakey (Fig. 30-2). Using this classification, 60% of all dissections are type A, and 40% are type B. The classification system is based on the risk of sudden death from the dissection, which is highest in type A. Here the dissection may cause tamponade or severe aortic insufficiency with congestive heart failure, as well as coronary thrombosis, especially involving the right coronary artery with acute myocardial infarction. Type B dissections do not have these risks and generally can be approached and managed

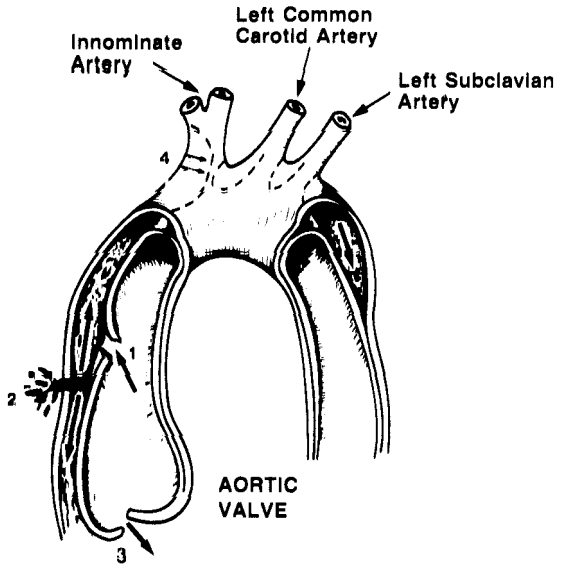
CAL ILLNESS



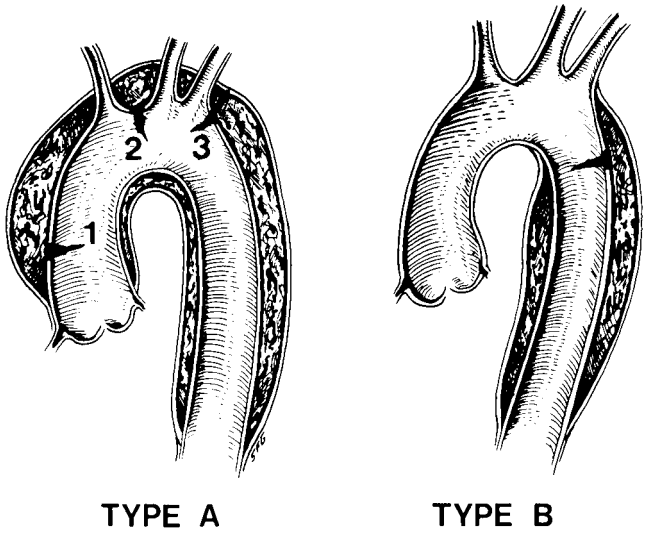


FIGURE 30-1 Aortic dissection begins with an intimal tear (*1*) leading to a hematoma that separates the layers of the aortic wall. The sequelae are rupture through the adventitia into the pericardium (*2*), prolapse of the aortic valve cusps leading to aortic insufficiency (*3*), compression of the aortic branch vessels (*4*), and aneurysmal dilation of the ascending arch and descending aorta.

FIGURE 30-2 Classification of aortic dissection based on the presence or absence of ascending aortic involvement. Type A dissections involve the ascending aorta, and type B dissections do not. The intimal tear in type A dissections may be in the ascending aorta (*1*), the arch (*2*), or the descending aorta (*3*). Type A includes DeBakey types I and II. In type B dissection the intimal tear is distal to the left subclavian artery origin. Type B dissections correspond to DeBakey's type III. *(Reprinted with permission from McGoon C: Cardiac Surgery, 2nd ed. Philadelphia, FA Davis, 1987, p 42.)*

conservatively. As a result, therapeutic interventions are dependent on location, with almost all type A dissections requiring urgent operative intervention, whereas type B dissections are managed primarily pharmacologically, with surgery only for specific complications. However, recent evidence suggests that up to 40% of type B dissections can lead to late death, and there is great interest in endovascular stenting to improve long-term survival.[4–6]

Aortic Intramural Hematoma

Aortic intramural hematoma (IMH) results from hemorrhage within the aortic wall without disruption of the intima. It is likely due to rupture of the vasa vasorum and may progress to rupture through the intima to form a classic dissection in up to 33% of cases.[7] It is an entity that is frequently confused with aortic dissection whose diagnosis, management, and prognosis remain debatable. Most authors believe the clinical course is similar enough to warrant treatment of IMH the same as a classical dissection.[8–10] A high percentage (up to 80%) may completely resolve within 1 year, but up to 60% of the remaining patients can go on to develop saccular aneurysms within 45 days with a significant annular growth rate.[8,10] The diameter of the aorta is important in that if the aortic diameter is <45 mm at 1 month follow-up, then most will resolve. Complications appear to occur mainly in patients with an aortic diameter over 45mm.[9]

Clinical Picture

Men, particularly black men, are at two to three times the risk of developing an aortic dissection as women. More than 90% will have a history of hypertension requiring treatment. The presentation of an acute dissection can be subtle, demanding great attention to detail to make the diagnosis, or classic and obvious. A new murmur of aortic insufficiency is present in 50% to 66% of type A dissections[11] due to the loss of support of the valve at the commissures as the inner layer of the aorta collapses inward. A continuous murmur suggests rupture of the dissection into the right ventricle or atrium.[12] The signs and symptoms are related to the location of the tear and the extent of the hematoma dissection. These are manifested mainly by pain, poor peripheral perfusion despite an increased blood pressure, and signs and symptoms of aortic branch occlusion.

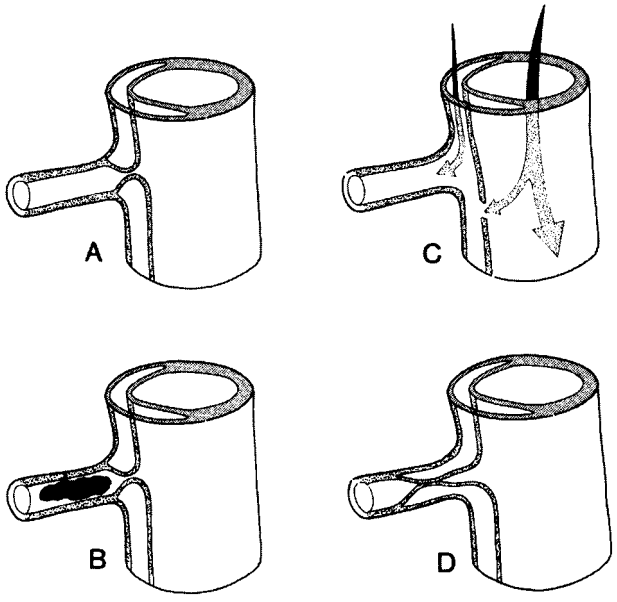
PAIN

Typically, the pain is either retrosternal, or central interscapular back pain, but it may be epigastric. Classically, it begins in the chest, moves to the back, and then moves down to the abdomen or lower extremities as the dissection progresses, but this pattern is rarely seen. Patients describe the pain as "sharp," "tearing," or "knife-like," and it is most often excruciating in intensity. To differentiate it from angina, the pain is maximal immediately upon onset, and it is difficult to obtain complete relief with opiates alone. Clinical diagnostic accuracy may approach 90% if three basic questions are asked regarding the pain's quality (tearing or ripping), radiation (beginning between the scapulae and radiating down the back), and the intensity at onset (abrupt onset of 10/10 pain).[13]

POOR PERFUSION

Patients frequently present with evidence of shock, with a cool, clammy periphery, ashen coloring, and depressed level of consciousness, and yet markedly elevated systolic blood pressure frequently exceeding 200 mm Hg. Most often this is due to reflex sympathetic discharge from the intense pain. It can occur, however, with myocardial infarction due to coronary artery occlusion by the dissection, or from severe aortic insufficiency with congestive heart failure, which is present in 30% to 60% of patients with type A dissections. If the blood pressure is depressed, the dissection may have ruptured into the pericardium with tamponade (as occurs in 30% of type A dissections) or into the pleural space (left more often than right) in type B dissections, with resulting hypovolemia.

SIGNS AND SYMPTOMS OF AORTIC BRANCH OCCLUSION



Approximately one third of all patients will present with compromised flow to a major branch of the aorta as part of their presentation.[14] The vessel may be sheared off or compressed, resulting in occlusion and/or thrombosis, or be perfused through the false channel (Fig. 30-3). Table 30-1 lists the vessels affected and the manifestations. The dissection usually travels in a spiral motion down the thoracic aorta such that the celiac axis, superior mesenteric artery, and right renal artery remain intact. In type A dissections the innominate artery (and thus blood flow to the right carotid artery to the brain, causing cerebrovascular insufficiency, and the right subclavian artery to the right upper extremity, causing a pulse deficit) are the most frequently affected. A measured brachial pressure differential of greater than 20 mm Hg is an independent predictor of the presence of a dissection.[15] The dissection usually stops at the level of the iliac arteries, with the left iliac more often affected, leading to compromised blood flow to the left leg. Rarely is there only one tear in the aorta, and more commonly, the dissection has multiple re-entry sites along its path down the aorta. The common femoral arteries are seldom dissected, an important issue at surgery, since cannulation of the femoral artery is necessary for placing the patient on cardiopulmonary bypass.[16] Fortunately, the visceral and renal vessels are affected in less than 3% of patients, since their involvement denotes a much increased mortality rate of 41% versus 27%.[17]

TABLE 30-1 Aortic Branch Occlusion

Site	Manifestation
Iliofemoral (35%)	Lower extremity ischemia
Carotid (21%)	Cerebrovascular accident (CVA)
Subclavian (14%)	Upper extremity ischemia
Renal (14%)	Renal failure or hypertension
Mesenteric (8%)	Intestinal ischemia
Abdominal aorta (7%)	Aortic aneurysm

NOTE: Peripheral vascular complications are listed in decreasing frequency. Overall 8% to 56% of patients sustain aortic branch complications. Extensive dissections are at higher risk (49% to 56%) than if isolated to either the ascending or proximal descending aorta (8% to 13%).

FIGURE 30-3 Aortic branch occlusion mechanisms. ***A.*** **Compression of the true lumen by the false lumen with a patent true lumen.** ***B.*** **Complete occlusion of the true lumen by the false lumen with thrombosis.** ***C.*** **Complete avulsion of the intima from the origin of the branch vessel with blood flow provided both from the false lumen and the true lumen via distal re-entry.** ***D.*** **Complete occlusion of the true lumen by the false lumen beyond the branch orifice.** ***(Reprinted with permission from Cambria et al.[14])***

Neurologic sequelae are of particular concern. Some neurologic dysfunction, such as depressed level of consciousness or dizziness, is said to occur in 30% to 50% of patients.[3] However, concrete focal neurologic deficits occur much less frequently (<10% overall), and may affect the central nervous system (CNS), spinal cord, or peripheral nerves. CNS deficits range from minor transient ischemic attacks to deep coma. Cerebrovascular accidents (CVAs) causing hemiparesis affect 5.5% to 6.7% of patients with type A dissections. They are primarily due to innominate–carotid artery occlusion, with the right side affected in two thirds of cases. They also can be caused by emboli or low flow with thrombosis due to previous carotid stenosis. Paraparesis and paraplegia fortunately are rare (2% of type A), because they portend a very poor prognosis.

Occasionally patients may present with vascular compromise foremost in their complaints and findings. A patient suffering an acute occlusion of blood flow into their lower extremity, particularly the left, with no definite clot or embolus found at surgery should be strongly suspected of having a dissection and investigated immediately. Unfortunately the physical findings classically associated with dissection are present in less than half of all cases, thereby necessitating a high index of suspicion to save these patients.[18]

Investigations and Diagnosis

LABORATORY

Laboratory data are usually within normal limits in patients with acute dissection. The white blood cell count may be slightly elevated to 12,000 to 20,000/μL, most likely as a stress response. Electrocardiogram (ECG) interpretation may show left ventricular hypertrophy due to chronic hypertension, but other changes are rare. Acute ischemic changes should raise

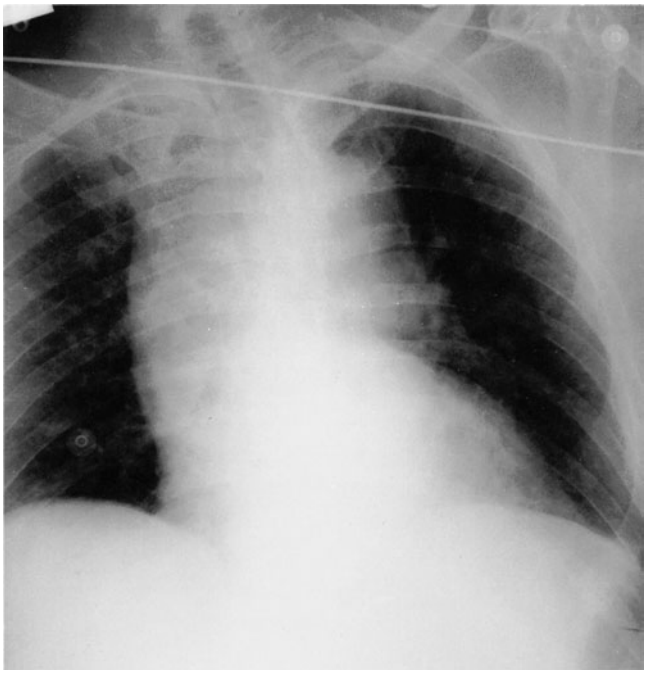


FIGURE 30-4 Chest x-ray illustrating widened mediastinum with blunting of the aortic knob.

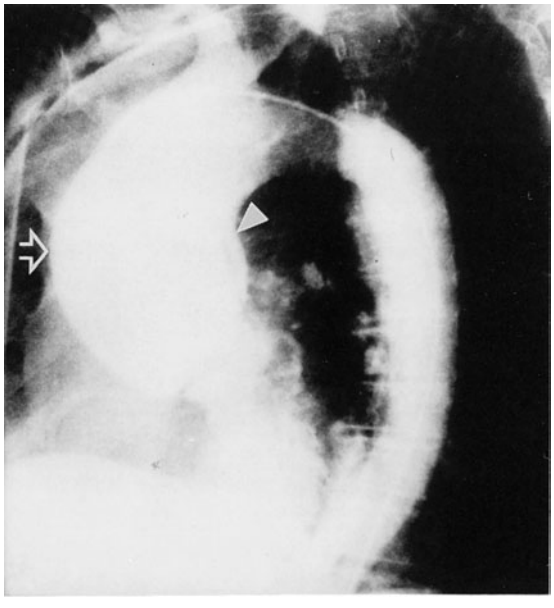
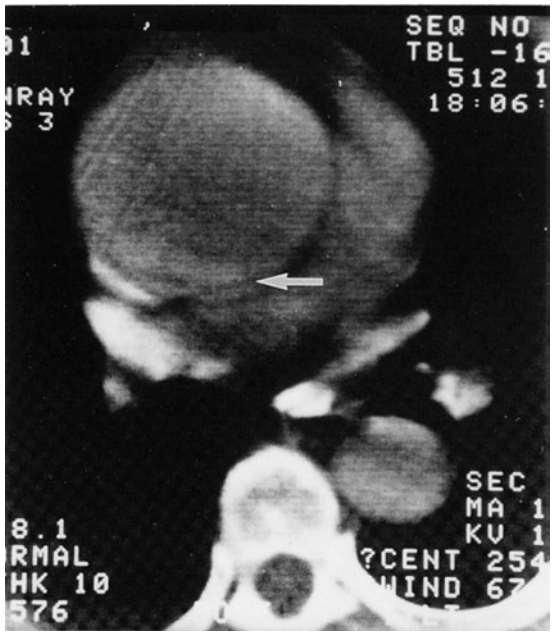


the concern of coronary artery involvement by the dissection in the patient with a typical history. Conversely, to avoid the dire consequences of misdiagnosis, any patient presenting to the ER with ECG changes suggesting myocardial ischemia (especially with evidence of right coronary artery involvement) should have their history considered carefully before immediately moving to anticoagulation, thrombolytics, and urgent cardiac catheterization to treat the more prevalent condition of atherosclerotic coronary artery disease.

DIAGNOSTIC IMAGING



Diagnostic imaging is the most important investigation for the diagnosis and classification of aortic dissections. Standard anteroposterior and upright lateral chest x-rays often reveal a widened mediastinum, although this may be absent in up to 40% of type A dissections (Fig. 30-4). Classically, the aorta bulges to the right with type A and to the left with type B dissections. Occasionally a double rim of calcification may be present in the distal aortic arch or a pleural effusion may be present (left more than right), due mainly to a serous sympathetic reaction rather than to frank blood from a rupture.

Significant debate exists as to the best imaging modality presently available for aortic dissections. The ideal modality would be readily available, easy to interpret, represent no risk to the patient, and provide all the information the surgeon requires. These needs include assessment of the ascending aorta, identifying the site of the intimal tear, the full extent of the dissection, existence of branch vessel involvement, presence of a pericardial effusion, and presence and severity of aortic valve insufficiency.[19] Several imaging techniques including aortography, computed tomographic (CT) scanning, magnetic resonance imaging (MRI), and echocardiography are highly accurate for the diagnosis and classification of dissections.[20] Controversy exists as to which of these is the most accurate.[19,20–24] In the past many authors believed that aortic angiography was the most definitive diagnostic method, with sensitivity and specificity of 88% to 90% and 90% to 95%, respectively.[2,25] In addition to confirming the diagnosis by illustrating the true and false channels, the aortogram could pinpoint the site of the intimal tear (Fig. 30-5),

FIGURE 30-5 ***A.*** **Aortogram (lateral projection). Grossly dilated ascending aorta (*open arrow*) with visible intimal flap (*solid arrow*). establish the extent of the dissection, quantitate the severity of aortic insufficiency if present, and identify the presence and degree of aortic branch occlusions. Some authors, however, have expressed concerns over false-negative reports due to viewing the flap and both lumens en face, with the central beam missing a small localized dissection, and possibly missing the flap due to simultaneous opacification of both true and false lumens.[12] The procedure is also invasive and requires a contrast load, so less invasive investigations are preferred.

CT scanning is a noninvasive technique that yields excellent images of dissections, especially type B. Specific identification of true and false lumens with a flap is possible, as well as detection of pericardial effusions and accurate depiction of the extent of the dissection (Figs. 30-6 and 30-7). The new third-generation helical CT scanners yield excellent images both in two and three dimensions (Fig. 30-8). CT is very specific and accurate (~100%) for the diagnosis of dissection,[18,25] and 96% accurate for the presence of aortic branch involvement.[19] CT scanning does not yield information regarding aortic insufficiency or left ventricular function, and requires both contrast administration and exposure to radiation. CT scanning is also inferior to aortography for identifying the site of the intimal tear. Recently, however, the site of the intimal tear has had debatable bearing on the type of dissection or surgical success. Since CT scanning lacks somewhat in sensitivity, if the CT scan is negative and the suspicion of aortic dissection remains high, other investigations should be done to rule out a dissection. Helical CT scanning is the author's recommended imaging technique for the long-term follow-up of the patient, given its low expense, high reproducibility, and minimal patient discomfort.

Echocardiography is likely the diagnostic modality of choice for acute aortic dissections. Both transthoracic and transesophageal two-dimensional echocardiography can accurately evaluate the most important issues of dissections; involvement of the ascending aorta, presence and severity of aortic insufficiency, the entry sites in the intimal flap, and presence of aortic arch dilation. Two lumens may be seen separated by a flap, or there may be central displacement of intimal calcification. The addition of color-coded Doppler allows better identification of the true and false lumens, even if the false lumen is thrombosed. The presence of a pericardial effusion and any left ventricular wall motion abnormalities also may be assessed accurately. Transesophageal echocardiography (TEE) was previously criticized for being unable to visualize the aortic arch, but current multiplanar TEE transducers have few blind areas. Its main limitation is inability to see the intra-abdominal aorta, but this can be assessed with simple ultrasound.[23]

Transthoracic echocardiography is less accurate than transesophageal echocardiography in the diagnosis of aortic dissections. It is also frequently technically limited due to chest wall abnormalities, chronic obstructive pulmonary disease, and obesity.

TEE[21,23] is the most efficient and accurate diagnostic modality available (Fig. 30-9). Its sensitivity and specificity are

over 98%, so this technique very accurately identifies the presence or absence of a dissection. Notably, it can be performed in less than 30 minutes in an emergency room or intensive care unit. The efficiency and mobility are very important in the management of critically ill patients, who are best cared for in a well-monitored ICU rather than in the radiology suite. Occasional complications (<1%) have included transient arrhythmias (atrioventricular block, bradyarrhythmias, or premature ventricular contractions), reports of rupture of the dissection during the insertion of the probe, and esophageal perforation. Generally the procedure is well tolerated with appropriate control of pain and hypertension.[21,22,24]

MRI is very accurate, sensitive, and specific in dissections, but has been used sparingly as the procedure requires 45 minutes and can be difficult due to limited access to a critically ill patient.[19,23–25] It is, however, the only modality that provides all of the previously mentioned preoperative needs of the surgeon. It is noninvasive and does not require contrast material or ionizing radiation. Excellent contrast can be obtained between extraluminal structures, and it allows the visualization of vascular walls and both clotted and flowing blood. MR technology is advancing rapidly, with accuracy of 100% with phase-contrast cine MR angiography,[1–9] and new MRI sequences (such as the breath-hold gradient-echo) have been able to reduce the procedure time to less than 5 minutes without compromising accuracy.[26]

The author presently recommends TEE as the initial investigation. If this is not immediately available, then a helical CT scan of the thorax is performed. If this is negative and there is still a strong suspicion of dissection, then MR angiography may be performed in a stable patient. Of course, this approach should be modified by availability and the local expertise with these imaging techniques at each institution.

Natural History

Untreated acute type A aortic dissections have a uniformly poor prognosis. Fifty percent of patients die within the first 48 hours, and <10% will survive 1 month. Poor prognostic variables include aortic branch complications (particularly mesenteric and renal arteries), type A dissections, associated coronary artery disease (CAD), and neurologic deficits (CVA and paraplegia).[27]

Hemodynamic instability (systolic BP <90 mm Hg) represents a 32% mortality vs. 8.5% for those with stable hemodynamics.[28]

Treatment

To maximize survival, optimal treatment of acute dissections must include early pharmacologic control of blood pressure and pain, often before the definitive diagnosis is made, combined with appropriate surgical intervention. All patients with aortic dissections must have intensive monitoring in a critical care setting. The patient should be placed on a cardiac monitor, and have an intra-arterial catheter (for ongoing blood pressure control), and central venous pressure and urinary catheters inserted. Blood should be drawn for standard laboratory investigations as well as cross and typing for blood transfusion in case surgery is needed. The patient should be observed closely for any change in hemodynamic parameters or neurologic function and for evidence of organ ischemia.

Pharmacologic Control of Blood Pressure

Intravenous antihypertensive agents are used to reduce the level of systolic blood pressure and the pulse wave (dP/dT_{max}) to halt the progression of the dissecting hematoma. With the hematoma stabilized, pain usually can be controlled with intravenous opiates. Several agents are available for the ICU control of systolic blood pressure and dP/dT_{max}, and these are listed in Table 30-2 along with their suggested mechanism of action and duration of activity.

Labetalol remains the first choice in antihypertensive agents for aortic dissections. It is a selective α_1 nonselective β_1- and β_2-adrenoreceptor blocker, and so reduces dP/dT_{max} and systolic blood pressure by β-blockade and vasodilation. It can be delivered by bolus (as preferred by most authors) or continuous infusion, even in the ER setting. Its peak reduction in systolic blood pressure occurs within 5 minutes,

TABLE 30-2 Antihypertensive Agents in Acute Aortic Dissection

Drug	Mechanism	Administration (Intravenous)
Labetalol hydrochloride	α_1- And β_{1+2}- adrenergic blocker; decreases peripheral resistance without reflex increase in heart rate and myocardial contractility (dP/dT_{max}); action in 5–10 min; half-life 5–8 h	1. Bolus infusion: 0.25 mg/kg over 2 min; may repeat every 10 min 2. Continuous infusion: 1–2 mg/min
Esmolol hydrochloride	β-Blocker with β_1-selective blockade; decrease in heart rate and myocardial contractility (dP/dT_{max}); action in 2 min; half-life 9–10 min.	1. Bolus infusion: 500 μg/kg over 1 min 2. Continuous infusion: 25–200 μg/kg/min
Sodium nitroprusside	Direct vascular smooth muscle relaxant; decreased peripheral resistance and preload, may increase dP/dT_{max} when used alone; action in 1–2 min; half-life 3–4 min	Continuous infusion: 0.5–8.0 μg/kg per min
Propanolol hydrochloride	β-Adrenergic blocker; decreases myocardial contractility and peripheral resistance; action in 1–2 min; half-life 2–3 h	Bolus infusion: 1–3 mg over 2–3 min; may repeat in 2–3 min
Trimethaphan camsylate	Autonomic ganglion blocker; direct vascular smooth muscle relaxant; decreases peripheral resistance.	Continuous infusion: Begin with 3–4 mg/min

and its duration of action is 2 to 12 hours. It is suitable for long-term control of hypertension in oral form.

Esmolol, an ultra-short-acting β-blocker with β_1-selective adrenergic receptor blockade, is extremely useful for the acute control of hypertension in patients with dissections. Its very rapid onset (decrease in heart rate in less than 2 minutes) and short duration of action (half-life of 9 to 10 minutes) allow for tight control of blood pressure, especially in labile patents.

If labetalol and esmolol are not available, then sodium nitroprusside and propranolol hydrochloride may be used. Propranolol must be given because nitroprusside increases dP/dT_{max} through a sympathetic reflex from its peripheral vasodilatory effects when used alone.

Patients who cannot tolerate β-blockade (e.g., those with severe asthma, decompensated congestive heart failure, or bradycardia) may be treated with trimethaphan camsylate. In order to adequately reduce the systolic blood pressure, it may be necessary to elevate the head of the bed or dangle the patient's legs over the side of the bed. Occasionally, trimethaphan may need to be combined with reserpine or guanethidine. It has many sympathoplegic side effects and can drop the blood pressure quite precipitously. Tachyphylaxis occurs quickly.

Systolic blood pressure should be reduced to levels that will halt the progression of the dissection. Most authors agree that a systolic blood pressure of 90 to 100 mm Hg is desirable as long as the patient has adequate organ perfusion, as evidenced by a clear sensorium, good urine output, and the absence of lactic acidosis. If respiratory distress occurs that requires high doses of opiates and benzodiazepines, the patient should be intubated by an experienced cardiac anesthesiologist to minimize changes in heart rate and blood pressure.

Definitive Management

Acute aortic dissections, especially type A, are extremely dangerous lesions that may become complicated with rupture and death at any moment. Investigations should be performed expeditiously to determine the dissection type and the presence of aortic branch complications. Patients with type A dissections should be offered urgent surgical intervention for maximal survival. Relative contraindications to surgery include severe organ dysfunction such as diffuse coronary artery disease, end-stage chronic obstructive pulmonary disease, old age (for those over age 80 the risk rises markedly, perhaps as high as 80%),[29] moribund patient, paraplegia, and CVA. Whether an acute CVA represents a contraindication to surgery is controversial. CVA does represent an independent negative influence on survival. Surgery may make the neurologic deficit worse due to intraoperative bleeding from heparinization, embolization, or reperfusion injury when the occluded carotid is reopened. Without surgery, however, these patients have a near uniformly fatal prognosis. It has been shown that the presence of the CVA does not increase the risk of mortality with surgery. Shumway's group[30] found 85% of survivors to be improved or unchanged neurologically, and suggested that there is no way to predict neurologic outcome from the preoperative neurologic status. A CVA is therefore only a relative contraindication to surgery, and only deeply comatose or moribund patients should be refused definitive surgical repair.

Aortic branch complications in type A dissections are best managed by surgically restoring flow to the true lumen by definitive repair of the dissection and postoperative assessment for persistent ischemia.[14] Less than 10% of patients will require further procedures for persistent ischemia after definitive repair of the dissection. Rarely, organ hypoperfusion may continue, necessitating emergent fenestration (creating communication between the true and false lumina) of the abdominal aorta, ideally by an interventional radiologist with cutting balloons.[4]

Type B dissections are generally best managed by intensive medical treatment of blood pressure, with surgery reserved for complications of the disease. These complications are a result of progression of the dissection despite maximal medical therapy. Intervention is recommended if the aorta increases in size or if evidence of organ ischemia due to aortic branch occlusion (e.g., abdominal pain, renal dysfunction, or lower extremity ischemia) exists. Intractable pain, evidence of a new pleural or pericardial effusion, acute saccular aneurysms, or a rapid increase in size over a period of hours indicates impending or frank rupture, and emergent surgical repair (or endovascular stenting if available) is imperative for survival.

This conservative approach has been challenged.[27] The surgical mortality in acute type B dissections was reported to be reduced from 38% to 13% in a small group of patients. This would be an improvement over medical therapy alone, which incurs a 20% mortality. A larger experience is necessary before this aggressive approach is adopted for all type B dissections. Similarly, stent-grafts have been inserted in the acute setting with good early but unsatisfactory long-term results.[4–6]

Surgical Intervention

Dr. Michael DeBakey is credited with the initial surgical successes in the treatment of acute aortic dissections. The procedures can be considered as being separate for type A and type B dissections.

TYPE A

The surgical procedures for type A dissections are designed to treat the life-threatening complications in the ascending aorta. There are many factors that are important for deciding the appropriate surgical procedure for each patient. Many of these can be identified preoperatively, such as the presence of a preexisting abnormality and/or competency of the aortic valve, patency of the coronary arteries, size of the aortic arch, quality of the aortic tissue (e.g., Marfan's or Ehlers-Danlos syndrome), and presence or absence of associated aortic branch compromise (Figs. 30-10 and 30-11). The surgical options include simple graft interposition, resuspension of the aortic valve and graft interposition, replacement of the aortic valve and supra-sinus graft interposition, and valved-conduit graft insertion (Bentall procedure).

General preparation of the patient for the procedure includes continuous monitoring of arterial and central venous pressures and usually insertion of a pulmonary artery catheter and a transesophageal echocardiography probe. The patient is placed on cardiopulmonary bypass (CPB) by inserting the arterial cannula into either a femoral artery (usually the right) or the right axillary artery[31] to leave the ascending aorta and aortic arch clear for surgical repair. Through a

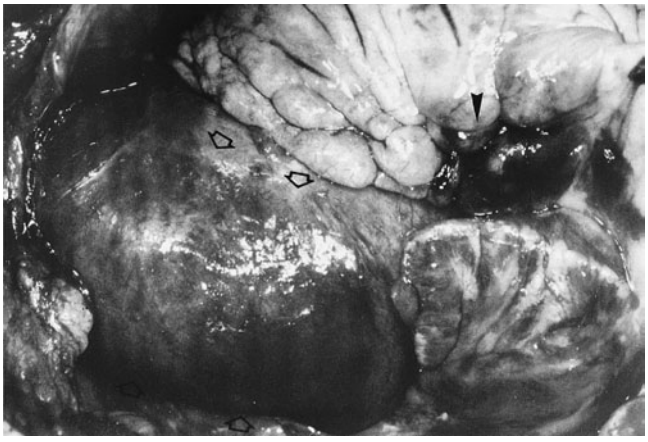

FIGURE 30-10 External appearance of the acutely dissected proximal aorta (*open arrows*). Note the "beefy" appearance as the hematoma spreads down to the origin of the right coronary artery (*solid arrow*), suggesting an ostial injury. *(Reprinted with permission from Borst HG, Heinemann MK, Stone C: Surgical Treatment of Aortic Dissection. New York, Churchill-Livingstone, 1996, p 86.)*

median sternotomy, the patient undergoes continuous CPB and may require hypothermic cardiac arrest or deep hypothermia (15° to 18°C) and total circulatory arrest.[32]

Many surgeons feel it is important to resect the area of the tear in the aorta and thus use total circulatory arrest for all cases, especially for the distal anastomosis when replacing part or all of the aortic arch.[3–1] The time spent with the circulation arrested ideally should be kept to less than 45 minutes to minimize organ dysfunction. The brain is the most sensitive of the body's organs to prolonged circulatory arrest, so several methods have been proposed to improve cerebral protection. Selective antegrade perfusion of the innominate and left carotid arteries, as well as retrograde perfusion by cannulating the superior vena cava are utilized for periods of more prolonged arrest.[33–36]

FIGURE 30-11 Acute proximal aortic dissection opened demonstrating the aortic valve (*Ao*), the inner layer of the aorta (*white arrows*), and the outer layer (*black arrows*). The hematoma (*H*) lies in the false lumen separating them below. *(Reprinted with permission from Borst HG, Heinemann MK, Stone C: Surgical Treatment of Aortic Dissection. New York, Churchill-Livingstone, 1996, p 87.)*

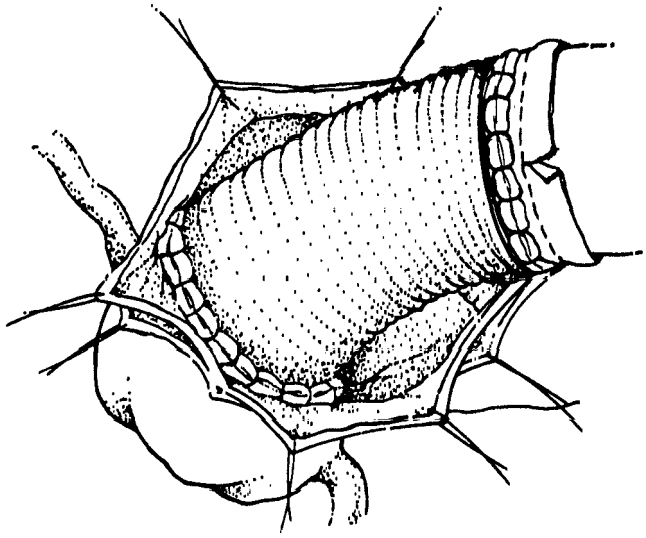

FIGURE 30-12 Suprasinus repair. The ascending aorta is replaced with a Dacron graft. The proximal anastomosis is above the aortic valve, and the suture lines are reinforced with felt strips. The distal anastomosis is proximal to the origin of the innominate artery.

Suprasinus graft interposition is performed for dissections not involving the aortic valve and without gross dilatation of the aortic arch. It involves interposing a woven Dacron tube graft from just above the aortic valve (at the level of the sinotubular junction) to the innominate artery (Fig. 30-12). The aortic wall may be reinforced with fibrin glue and/or felt to increase the strength of these friable tissues.

Resuspension of the aortic valve with suprasinus tube graft replacement of the ascending aorta is indicated for aortic insufficiency in patients without connective tissue abnormalities. The aortic valve commissures are tacked back to the outer wall of the aorta (Fig. 30-13) so as to return the cusps to their normal position and restore competency to the valve. The patient's own aortic valve is preserved and is most often competent.[37] The ascending aorta is then replaced with a tube of Dacron. If the aortic arch is not frankly aneurysmal, the graft is sutured to the distal ascending aorta.

Valved-conduit grafts consist of a prosthetic valve attached to a Dacron tube graft (Fig. 30-14). This procedure was popularized by Bentall and requires replacement of the aortic valve and ascending aorta and insertion of the left and right coronary arteries into the graft. The Bentall procedure is indicated for underlying disease of the aortic wall where there is a high risk of later aneurysmal dilation of the aorta, as in Marfan's or Turner's syndrome and annuloaortic ectasia. It is also indicated for tears arising close to the coronary sinuses or if the native aortic valve is diseased. The prosthetic valve may be either mechanical or bioprosthetic. The most popular mechanical valves are bileaflet such as those made by St. Jude Medical. These are placed primarily in young patients (<60 years old) in whom there are no contraindications to anticoagulation, as they require lifelong warfarin therapy. Older patients or those with contraindications to anticoagulation may have a bioprosthetic-valved conduit inserted, such as the Carpentier-Edwards porcine valve.

Each of these procedures may involve extensive replacement of the aorta to include the aortic arch, in whole or in

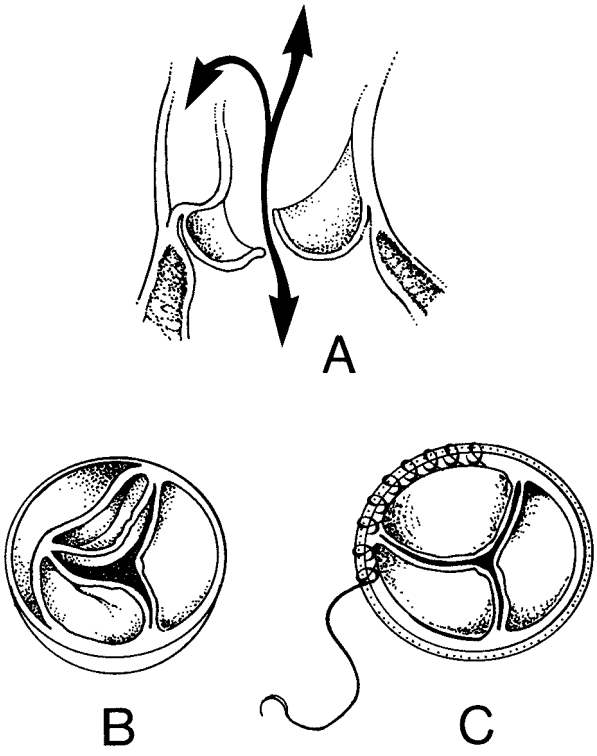

FIGURE 30-13 Resuspension of the aortic valve. *A.* and *B*. The valve cusps are detached from the aortic wall, resulting in aortic insufficiency. *C*. The commissures of the aortic valve are sutured back to the outer wall of the aorta to restore the normal relationships of the valve. The ascending aorta is replaced with a suprasinus graft.

part. This adds to the risk of the operative procedure, but if the arch is grossly aneurysmal, freedom from late operation and overall survival are increased significantly with immediate repair.[38]

Rarely, in cases of extensive aneurysmal dissections involving the ascending aorta, arch, and descending portions of the thoracic aorta, an "elephant trunk" technique must be used.[39] This requires replacement of the ascending aorta and the arch with a graft (Fig. 30-15), with the addition of several inches of telescoping redundant graft beyond the distal anastomosis and down the descending aorta. At a later date the patient has the rest of the descending thoracic aorta replaced through a left thoracotomy utilizing the free end of the redundant, previously placed graft. Dr. Lars Svensson of the Cleveland Clinic has a novel and successful approach to these difficult cases, using stent-grafts to manage the descending thoracic portion of the dissection when aneurysmal. After the patient has recovered from the elephant trunk procedure they return to have a stent-graft placed endovascularly from below and attached to the free end of the "trunk," thereby avoiding the difficult and risky thoracic surgical procedure. Of great interest is that Dr. Svensson has utilized this procedure with excellent results for isolated type B dissections in patients who would not tolerate surgical repair.

The resolution of aortic branch complications should be assessed at the end of the procedure. Pulses should be checked over both carotids and the radial and femoral arteries. If concerns exist for the presence of ongoing ischemia, then immediate surgical revascularization should be undertaken. This usually involves an extra-anatomic reconstruction such as axilloaxillary bypass for upper limb ischemia or femorofemoral bypass for unilateral lower limb ischemia. Aortic fenestration is necessary for bilateral lower extremity or renal ischemia. This can be done either surgically, or perhaps preferably by catheter-based techniques in the radiology department. Surgically this involves opening the abdominal aorta and resecting a portion of the inner wall (consisting of intima and part of the media) so as to allow flow through both the true and false lumens to restore blood flow. With the catheter-based technique, catheters are placed up both lumens and a cutting balloon creates the fenestration between the two.[4]

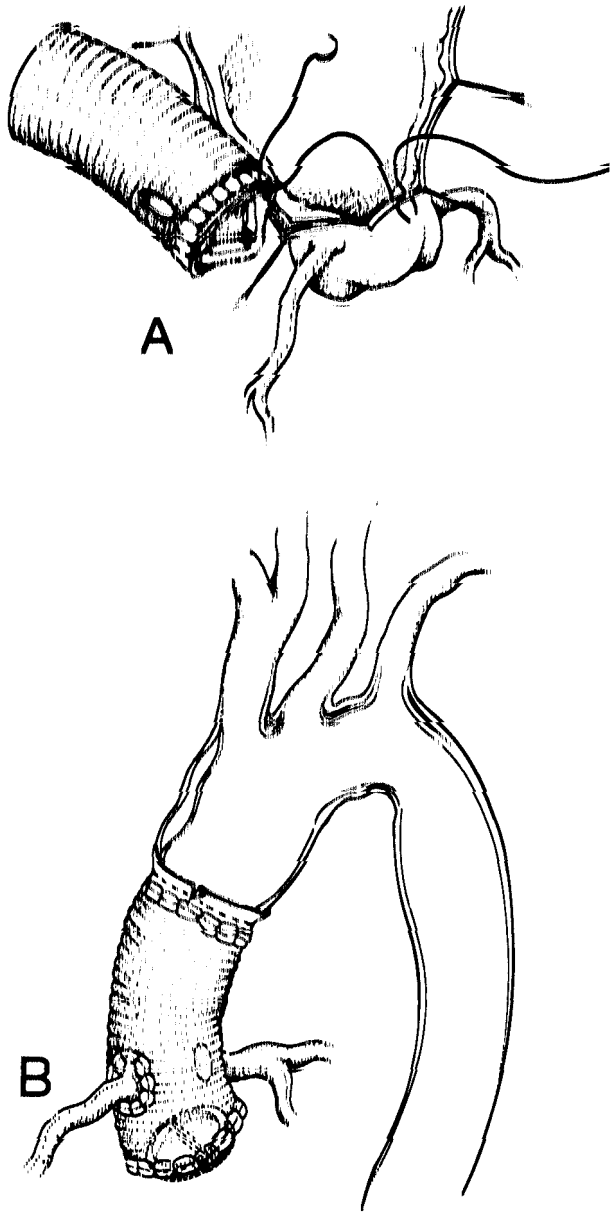

FIGURE 30-14 Composite graft replacement (Bentall). *A.* The aortic valve is removed and replaced with a valved conduit. *B*. The left and right main coronary arteries are reimplanted into the graft.

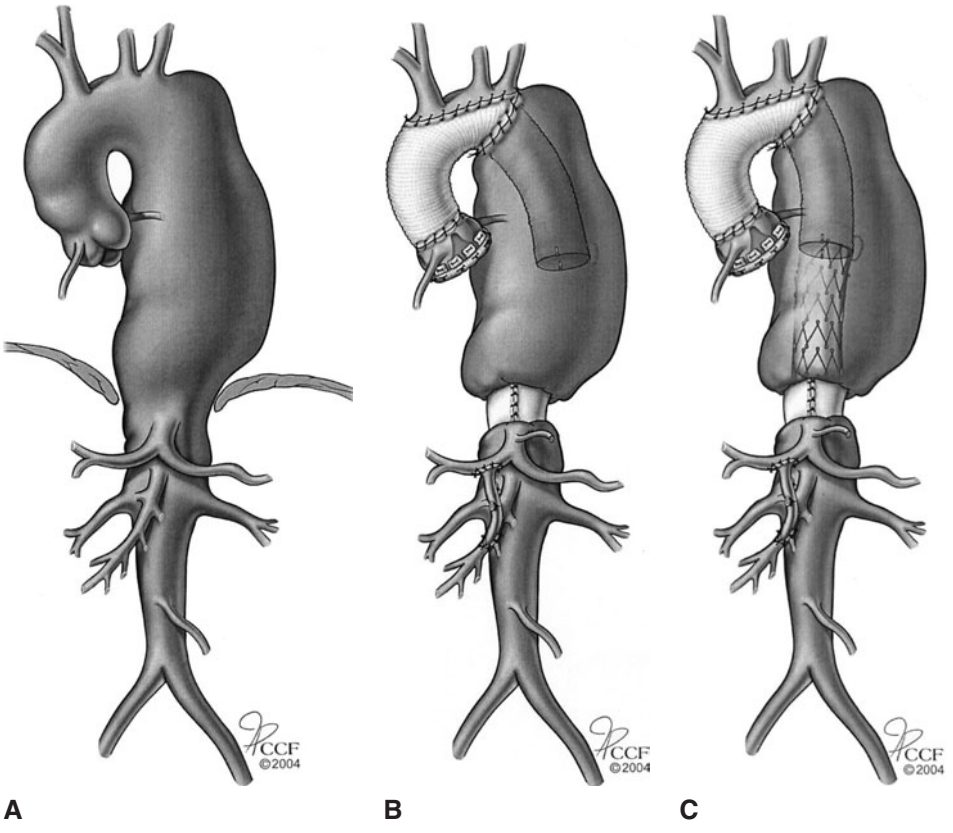

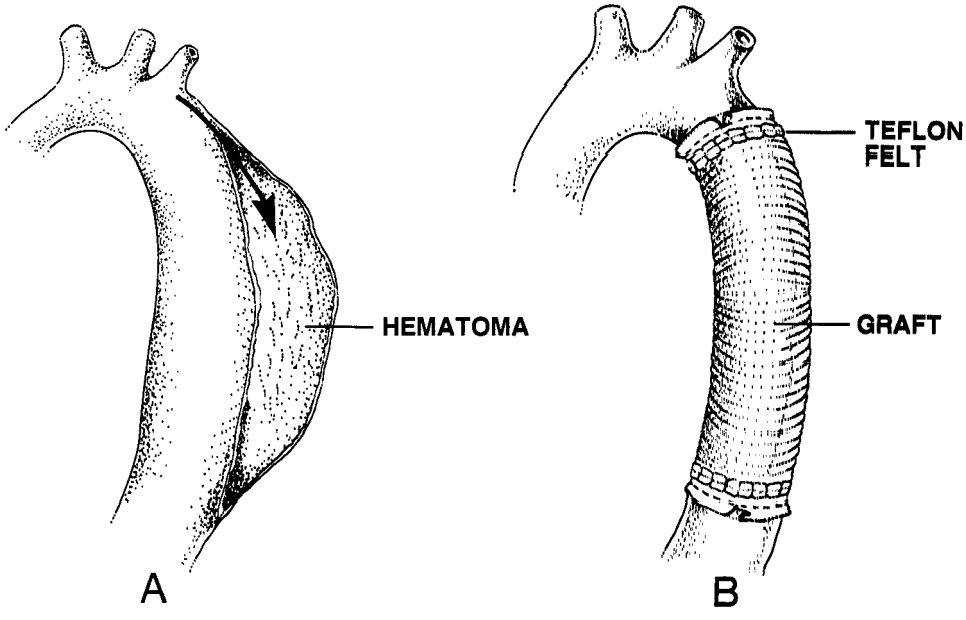

FIGURE 30-15 "Elephant trunk" procedure with stent-grafting of the descending thoracic aorta. ***A.*** **The entire aorta is aneurysmal, but most notably the arch, descending thoracic, and proximal abdominal aorta.** ***B.*** **The aortic valve has been replaced. A suprasinus tube graft replaces the ascending aorta and the entire arch, with the terminal portion of the graft (the "elephant trunk") hanging free in the descending aorta. The abdominal aorta has been narrowed for the stent-graft "landing site." Incidental aortohepatic and aortosuperior mesenteric artery bypasses have been performed.** ***C.*** **The nitinol stent-graft has been placed endovascularly from the terminal portion of the elephant trunk to the landing site in the abdominal aorta.** ***(Reproduced with permission from Dr. Lars Svensson, Cleveland Clinic Foundation, 2004.)***

TYPE B

Repair of dissections involving the descending thoracic aorta is undertaken for failure of medical therapy to control the progress of the dissecting hematoma (i.e., rupture or aneurysm formation) and for aortic branch compromise. Replacement of the descending thoracic aorta is usually necessary from the left subclavian artery down to middle or lower thoracic levels (Fig. 30-16). The entire descending thoracic and abdominal aorta may require replacement if it is involved with the dissection and becomes diffusely aneurysmal. This requires the reimplantation of the arteries supplying

FIGURE 30-16 Repair of type B dissection. ***A.*** **The intimal tear is just distal to the left subclavian artery.** ***B.*** **The descending aorta is replaced with a Dacron graft with felt reinforcement of the suture lines.**

the spinal cord, especially the artery of Adamkiewicz (usually arising between the ninth thoracic and second lumbar segments of the aorta), as well as the neighboring intercostal arteries. Even this does not ensure protection from spinal cord ischemia and resulting paralysis.[40] All renal and visceral vessels must be reimplanted into the graft as well. The surgery is performed through a left thoracotomy or thoracoabdominal incision and requires single-lung anesthesia and cross-clamping of the aorta at the level of the left subclavian artery. The aorta is opened and replaced with a long Dacron tube. Controversy exists as to protection of the spinal cord during aortic cross-clamping. The concern is to maintain blood flow to the distal aorta and so to the collateral vessels to the cord. Although many options exist, the most popular are some form of CPB (using femorofemoral or atriofemoral bypass), intraluminal shunt (Gott), partial drainage of cerebrospinal fluid,[41–43] and the simple clamp-and-sew technique. However, no technique has been shown to be superior to the others in reducing the high risk (~40%) of paraplegia with surgical repair of acute type B dissections.

Stent-grafting of the descending thoracic aorta has been experimented with in both acute and chronic dissections. Between 20% and 40% of patients who survive the acute phase will go on to aneurysm formation within 2 to 5 years, significantly impacting their survival.[44] Aortic stent-graft placement allows for occlusion of the intimal entry tear by implantation of a membrane-covered (Dacron), self-expanding (usually nitinol) stent (see Fig. 30-15C) to initiate progressive thrombus formation within the false lumen and resultant aortic remodeling.[4] Unfortunately, despite good initial procedural success with few complications, long-term results and complications have thus far limited enthusiasm for this approach until marked improvements are made in both the delivery system and the stent-grafts themselves.

Consideration should also be given to the management recommended by Dr. Svensson and illustrated in Fig. 30-15, which combines an elephant trunk procedure with stent-grafting of the descending aorta.

Results

MORBIDITY

Patients undergoing surgical repair of aortic dissections are subject to the same postoperative complications as with any open-heart procedure. Early complications include myocardial infarction, low-output syndrome (systolic BP <90 mm Hg with an elevated pulmonary wedge pressure requiring inotropic support), arrhythmia, bleeding, respiratory complications (prolonged ventilation, atelectasis, and effusion), stroke, and renal failure. Complications specific to repair of type B dissections include paraplegia/paraparesis (up to 40% with rupture), renal and intestinal ischemia, recurrent laryngeal nerve palsy, and chylothorax.[45] Important late complications of both type A and type B dissections include late aneurysm formation and redissection of the aorta. In type B dissections moderate to severe aortic insufficiency is present late in 5% to 20% of patients with insufficiency preoperatively. This is usually well tolerated, with over 80% of these patients not requiring valve replacement at 10 years follow-up.[46]

MORTALITY

Acute type A dissections have an approximate mortality risk of 20% with operation (range = 7% to 35%). The risk is increased with rupture, age >80 years old, and associated illnesses, especially coronary artery diseases and preoperative hemodynamic instability.

Patients with type B dissections survive with medical therapy in 80% of cases. If complications arise requiring surgery, then the mortality increases, reaching 75% if renal and visceral artery occlusion is present.

Follow-Up

Control of the patient's blood pressure and close observation for the development of late aneurysm are the most important variables determining the late complications and survival in type A and B dissections, whether they have undergone surgical repair or not.[2,46,47] The development and rupture of postdissection aneurysms account for 30% of all late deaths. In the postoperative period, the systolic blood pressure is maintained at the lowest level capable of sustaining normal organ function, as indicated by sensorium, urine output, and other parameters. When the patient is transferred to the ward and onto oral antihypertensives, the type and dose must be modified to prevent orthostatic hypotension and syncope. Some form of β-blocker must be used (unless contraindicated) to control dP/dT_{max} as well as systolic pressure. The blood pressure control must be maintained lifelong so as to minimize the risk of late aneurysmal development or redissection.[46] Follow-up must be performed regularly and over the long term, preferably with an easily available and reproducible imaging technique such as CT scanning.[47] New aneurysms form because in 85% of cases the false lumen remains patent, and so the wall of the aorta is permanently weakened. DeBakey's study[48] highlights the importance of long-term hypertension control. Five hundred twenty-seven patients were followed for 20 years after surgical repair of dissections. If hypertension was not controlled, 45.5% developed subsequent aneurysms, compared to 17.4% for those with proper control. Research is ongoing to improve stent-graft delivery and durability to improve long-term survival in these patients.[49,50]

Chapter 31

THE PATHOPHYSIOLOGY AND DIFFERENTIAL DIAGNOSIS OF ACUTE RESPIRATORY FAILURE

LAWRENCE D.H. WOOD

KEY POINTS

- *Type I respiratory failure, characterized by severe, oxygen-refractory hypoxemia, is caused by shunting due to airspace filling.*
- *When blood transport of oxygen is inadequate, treatment includes optimizing cardiac output, hemoglobin concentration, and arterial saturation, and lowering oxygen consumption.*
- *Optimizing does not mean maximizing, and the end point of each therapeutic approach needs to be selected for the individual patient.*
- *Type II respiratory failure is characterized by alveolar hypoventilation and increased P_{CO_2}, caused by loss of CNS drive, impaired neuromuscular competence, excessive dead space, or increased mechanical load.*
- *Type III respiratory failure typically occurs in the perioperative period when factors that reduce functional residual capacity combine with causes of increased closing volume to produce progressive atelectasis.*
- *Type IV respiratory failure ensues when the circulation fails and resolves when shock is corrected, as long as one of the other types of respiratory failure has not supervened.*
- *Liberation from mechanical ventilation is enhanced by identifying and correcting the many factors contributing to increased respiratory load and decreased neuromuscular competence.*

Respiratory failure (RF) is diagnosed when the patient loses the ability to ventilate adequately or to provide sufficient oxygen to the blood and systemic organs. Urgent resuscitation of the patient requires airway control, ventilator management, and stabilization of the circulation, while effective ongoing care for the patient with RF necessitates a differential diagnosis and therapeutic plan derived from an informed clinical and laboratory examination supplemented by the results of special ICU interventions. Recent advances in ICU management and monitoring technology facilitate early detection of the pathophysiology of vital functions, with the potential for prevention and early titration of therapy for the patient's continual improvement. The purpose of this chapter is to provide an informed, practical approach to integrating established concepts of pathophysiology with conventional clinical skills. This chapter does not provide a course in pulmonary physiology nor a comprehensive review of how to treat respiratory failure. Rather, it attempts to provide a conceptual framework of principles useful in approaching the patient with RF, first by discussing an approach to tissue hypoxia, and then by describing the mechanisms causing four types of RF, showing how correcting each derangement allows the patient to resume spontaneous breathing effected by respiratory muscles that are not fatigued.

An Approach to Inadequate Blood Transport of Oxygen

Patients with RF are susceptible to anaerobic metabolism, either because they deliver inadequate O_2 to their systemic organs or because their tissues develop an abnormal inability to extract oxygen from the blood.[1] During air breathing, arterialized blood leaves the normal alveoli with a partial pressure of oxygen (Pa_{O_2}) of about 100 mm Hg. When the hemoglobin concentration is 15 g%, arterial O_2 content (Ca_{O_2}) is about 20 mL per 100 mL blood on the fully saturated hemoglobin and about 0.3 mL in physical solution. Accordingly, a cardiac output ($\dot{Q}_T$) of 5.0L/min transports approximately 1000 mL/min of O_2 to the tissues (transport of oxygen; $\dot{Q}_{O_2}$). There, tissue metabolism (oxygen consumption; $\dot{V}_{O_2}$) extracts 250 mL/min, so 5.0 L/min of mixed venous blood returns to the lungs with 750 mL/min of O_2, or a mixed venous O_2 content ($C\bar{v}_{O_2}$) of 15 mL per 100 mL blood. Accordingly, the normal extraction fraction [$EF = \dot{V}_{O_2}/\dot{Q}_{O_2} = (Ca_{O_2} - C\bar{v}_{O_2})/Ca_{O_2}$] is 0.25. Because this O_2 content corresponds to 75% O_2 saturation (15/20), mixed venous P_{O_2} ($P\bar{v}_{O_2}$) is 40 mm Hg, as determined by the oxyhemoglobin dissociation curve for normal venous pH, partial pressure of carbon dioxide (P_{CO_2}), and temperature. Figure 31-1 plots the relationships between $\dot{V}_{O_2}$ (left ordinate) and EF (right ordinate) with $\dot{Q}_{O_2}$ (abscissa) using these values normalized to a body size of about 65 kg: $\dot{V}_{O_2}$ is 4 mL/kg per minute and $\dot{Q}_{O_2}$ is 16 mL/kg per minute as plotted on the continuous lines.

In many patients with RF, the O_2 transport to the tissues is reduced by abnormally low cardiac output, hemoglobin, or O_2 saturation. Consider the effects of acute myocardial injury or hypovolemia that reduces $\dot{Q}_T$ to 2.5 L/min and $\dot{Q}_{O_2}$ to 8 mL/kg per minute. To maintain the $\dot{V}_{O_2}$ necessary for aerobic metabolism, the tissues must extract 250 mL/min from half the blood flow, so $C\bar{v}_{O_2}$ decreases to 10 mL O_2 per 100 mL blood and EF increases to 0.50. Because this value corresponds to 50% saturation (10/20) of the normal hemoglobin concentration, $P\bar{v}_{O_2}$ is 27 mm Hg. When cardiac output is returned toward normal with vasoactive drug or volume therapy, $P\bar{v}O_2$ rises again. In another patient with normal cardiac output (5 L/min) but severe arterial hypoxemia ($PaO_2 = 40$ mm Hg, O_2 saturation = 75%, $CaO_2 = 15$ mL O_2/100 mL blood), Cv_{O_2} must decrease to 10 mL per 100 mL blood to provide the tissues with 250 mL/min of O_2; again, $P\bar{v}_{O_2}$ decreases to 27 mm Hg. When cardiac output increases in response to hypoxia, $P\bar{v}_{O_2}$ increases again. In a third patient with normal $\dot{Q}_T$ and PaO_2 but with reduced concentration of hemoglobin (7.5 g/100 mL blood), CaO_2 is reduced to 10 mL per 100 mL blood. Accordingly, $C\bar{v}_{O_2}$ and $P\bar{v}_{O_2}$ must decrease to 5 mL per 100 mL blood and 27 mm Hg, respectively, to maintain aerobic metabolism, and these venous values increase again with greater cardiac output or hemoglobin concentration. In

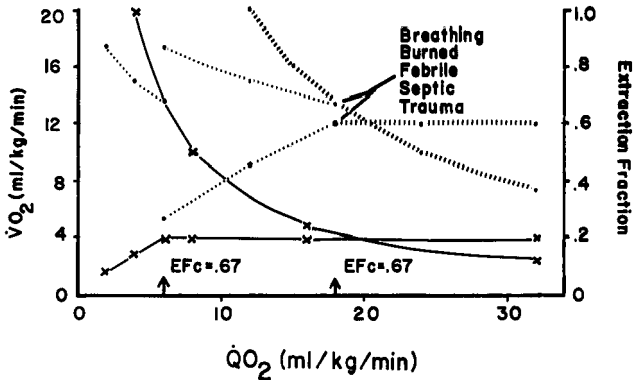

FIGURE 31-1 Oxygen consumption ($\dot{V}_{O_2}$, *left ordinate*) depends on oxygen delivery ($\dot{Q}_{O_2}$, *abscissa*) when low $\dot{Q}_{O_2}$ exceeds the limits of tissue oxygen extraction (EF, *right ordinate*). In patients with normal metabolism ($\dot{V}_{O_2} = 4$ mL/kg per minute), $\dot{V}_{O_2}$ is maintained as $\dot{Q}_{O_2}$ is progressively decreased from 16 to 6 mL/kg per minute (*continuous hyperbolic line drawn through x's*). Below this critical $\dot{Q}_{O_2}$ ($\dot{Q}_{O_2}c$), $\dot{V}_{O_2}$ decreases due to anaerobic metabolism, leading to lactic acidemia because tissue O_2 extraction cannot compensate for the low $\dot{Q}_{O_2}$ indicated by the dotted line departing from continuous hyperbolic EF line at the critical extraction fraction ($EF_c = 0.67$). When $\dot{V}_{O_2}$ is increased threefold (*dotted lines drawn through closed circles*) by several common manifestations of critical illness (e.g., work of breathing, burns, fever, sepsis, and trauma), EF is tripled at each value of $\dot{Q}_{O_2}$, and supply dependence of O_2 consumption begins at a value of $\dot{Q}_{O_2}$ three times greater than for the patient with normal $\dot{V}_{O_2}$ despite normal $EF_c = 0.67$. Accordingly, $\dot{Q}_{O_2}$ must increase with $\dot{V}_{O_2}$ to maintain aerobic metabolism, or $\dot{V}_{O_2}$ must be reduced. See text for discussion.

each case, $\dot{V}_{O_2}$ was maintained as $\dot{Q}_{O_2}$ decreased, creating the horizontal continuous line in Fig. 31-1 indicating that V_{O_2} is independent of O_2 delivery in this range; $\dot{V}_{O_2}$ was constant because EF increased in the hyperbolic manner indicated by the continuous line relating EF to $\dot{Q}_{O_2}$.

These considerations illustrate that one end point of reduced O_2 transport in the blood is reduced $P\bar{v}_{O_2}$. Since $P\bar{v}_{O_2}$ approximates the P_{O_2} adjacent to the exchange vessels in the tissues, it is the driving pressure for O_2 diffusion from the capillaries to the metabolizing cells. When $P\bar{v}_{O_2}$ falls too low, insufficient O_2 diffuses to maintain aerobic metabolism, and the cells begin to produce lactic acid as the end point of anaerobic metabolism.[2] This is illustrated in Fig. 31-1 by the decrease in $\dot{V}_{O_2}$ as $\dot{Q}_{O_2}$ is reduced below 6 mL/kg per minute; this supply dependency of V_{O_2} occurs when EF exceeds 0.67 and tissue O_2 extraction can no longer increase along the hyperbolic continuous line relating EF to $\dot{Q}_{O_2}$. Accordingly, reduced $P\bar{v}_{O_2}$ and increased serum lactate (or falling pH with unchanged partial pressure of arterial carbon dioxide [Pa_{CO2}]) are indications of tissue hypoxia. This improves with therapy increasing Ca_{O_2} (by increasing hemoglobin or O_2 saturation) and increasing cardiac output. In many critically ill patients, two or three of these factors reducing O_2 transport to the tissues coexist, so attention to optimizing all these ($\dot{Q}_T$, hemoglobin concentration, and O_2 saturation) is reasonable in the hypoxic patient. This description of the effects of diminished $\dot{Q}_{O_2}$ on $P\bar{v}_{O_2}$ and hence the utility of $P\bar{v}_{O_2}$ as a monitor of the adequacy of $\dot{Q}_{O_2}$ helps one understand the benefits of early goal-directed therapy guided by this measurement in the treatment of patients with shock[3] (see Chap. 21).

OPTIMIZING $\dot{Q}_{O_2}$

Of course, optimizing does not mean maximizing, and the end point of each therapeutic approach needs to be selected for the individual patient. Patients with low cardiac output due to heart disease may not tolerate infusions of packed erythrocytes even though their tissue hypoxia is made worse by concurrent anemia. Yet thoughtful integration of packed cells within the therapy of plasma volume reduction is often helpful in such patients and may prevent anaerobic metabolism at a time when cardiac output cannot be increased to adequate levels. In other patients with severe arterial hypoxemia and O_2 desaturation due to acute hypoxemic respiratory failure, tissue hypoxia may be relieved by increasing cardiac output and hematocrit. Yet this is often associated with higher central blood volume and pulmonary vascular pressures that increase pulmonary vascular leakage unless vasoactive drugs, diuretics, and fluid restriction are used concurrently. Again, thoughtful integration of the three approaches to therapy of tissue hypoxia provides the optimal level of circulating hemoglobin and cardiac output while reducing rather than aggravating the pulmonary edema. Some patients with chronic severe anemia (e.g., chronic renal failure) become acutely ill with low cardiac output and/or hypoxemic respiratory failure. Their tissue hypoxia is often ameliorated by prompt, transient increases in their hemoglobin concentration without circulatory overload, as by plasmapheresis. Yet the institution of this therapy, like the others mentioned above, has complications that must be weighed against the likely benefit in that patient at that time. Accordingly, this approach to therapy of reduced blood O_2 transport implements early each of the three major interventions ($\dot{Q}_T$, hematocrit, and arterial oxygen saturation [Sa_{O_2}]) in a combination best suited to the condition of each patient.[2,3]

Dissolved O_2 contributes a very small amount to $\dot{Q}_{O_2}$. Yet, in critical hypoxemia, raising the fraction of inspired oxygen (FI_{O_2}) to maximal values may be effective.[2] Consider again the patient with acute myocardial infarction without lung disease in whom low cardiac output has lowered $P\bar{v}_{O_2}$ to 27 mm Hg during air breathing. Even though the hemoglobin is fully saturated, Ca_{O_2} may be increased by 1.7 mL per 100 mL blood when Pa_{O_2} is increased to 650 mm Hg by ventilation with O_2. Then $C\bar{v}_{O_2}$ increases from 10 to 11.7 mL O_2 per 100 mL blood, raising mixed venous saturations to 58% and $P\bar{v}_{O_2}$ to about 34 mm Hg; of course, if anaerobic metabolism existed before oxygen therapy, $C\bar{v}_{O_2}$ may not increase as much as Ca_{O_2} because $\dot{V}_{O_2}$ increases with oxygen. These changes tend to diminish tissue hypoxia and the adverse consequences of anaerobic metabolism by an amount equivalent to that achieved by a 1 g% increase in hemoglobin or a 0.2 L/min increase in cardiac output and so complement a combined approach to hypoxia.[2] Increasing FI_{O_2} may be effected by nasal prongs to deliver O_2 at 1 to 5 L/min (FI_{O2} .21 to 0.4), by rebreathing masks (FI_{O_2} .21 to 0.6), or by head tent (FI_{O_2} .21 to 0.8). The ranges of FI_{O_2} are to indicate that all methods frequently give no O_2 enrichment due to inadequate delivery to the patient (lower limit), and that the amount of O_2 delivered is often

TABLE 31-1 Intratracheal Oxygen Concentrations (%) Attained Using Various Delivery Systems

Oxygen Delivery System	Intended $F_{I_{O_2}}$	TRACHEAL O_2 CONCENTRATION	
		Quiet Breathing	Hyperventilating
Nasal prongs			
3 L/min		22.4	22.7
10 L/min		46.2	30.5
15 L/min		60.9	36.2
Face mask			
10 L/min	60	53.4	41.0
15 L/min	100	68.1	50.2
Venturi mask			
4 L/min	28	24.2	21.4
8 L/min	40	36.4	29.4

less than expected (upper limit), even when the O_2 delivery system is working properly (Table 31-1).

REDUCING $\dot{V}_{O_2}$

With its attendant risks, tracheal intubation ensures delivery of the highest possible $F_{I_{O_2}}$ and allows another approach to therapy of tissue hypoxia, namely to reduce $\dot{V}_{O_2}$ (Table 31-2). Normally, the work of breathing is very low, but in patients with acute hypoxemic respiratory failure and its associated tachypnea and lung stiffness, $\dot{V}_{O_2}$ of the respiratory muscles alone can approach 100mL/min.[4] Increased work of breathing may result in high $\dot{V}_{O_2}$ in other patients with other causes of restriction such as morbid obesity[5] (see Chap. 109). This is illustrated by the interrupted lines in Fig. 31-1 showing that supply dependence of $\dot{V}_{O_2}$ occurs at a high level of $\dot{Q}_{O_2}$ when $\dot{V}_{O_2}$ is tripled (12 mL/kg per minute) by common concomitants of critical illness, even when the tissue ability to extract O_2 is normal. Normally, cardiac output increases with $\dot{V}_{O_2}$, as in exercise, to keep $C\bar{v}_{O_2}$ and $P\bar{v}_{O_2}$ close to their resting values. Yet consider the effects of such work of breathing in the common circumstance of cardiogenic pulmonary edema when cardiac output may not increase much above 5.0 L/min. Then $C\bar{v}_{O_2}$ must fall toward 5 mL O_2 per 100 mL of blood to deliver the total $\dot{V}_{O_2}$ of 750 mL/min so that $P\bar{v}_{O_2}$ approaches 22 mm Hg, a level associated with tissue hypoxia and anaerobic metabolism. Relaxation of the respiratory muscles and positive pressure ventilation reduce $\dot{V}_{O_2}$ to 250 mL/min and raise $P\bar{v}_{O_2}$ to normal with no change in cardiac output.[4]

TABLE 31-2 Oxygen Cost ($\dot{V}_{O_2}$) of Breathing and Fever in 20 Critically Ill Patients

BREATHING (MEAN ± SD; REF. 4)		FEVER (MEAN ± SD, REF. 6)	
Mode	$\dot{V}_{O_2}$	Body Temp.	$\dot{V}_{O_2}$
CPAP	255±92	39.4±0.8°C	359±65
AC/MR	209±79	37.0±0.5°C	295±57
$\dot{V}_{O_2}$ resp	46±21	$\dot{V}_{O_2}$/°C	27.5±8.1

NOTE: $\dot{V}_{O_2}$, oxygen consumption (mL/min) by spirometer (Deltatrac); CPAP, continuous positive airway pressure (spontaneous breathing); AC/MR, assist-control mode with muscle relaxation (full mechanical ventilation); $\dot{V}_{O_2}$ resp, O_2 cost of breathing equals CPAP − AC/MR; °C, body temperature in degrees centigrade; $\dot{V}_{O_2}$/°C, the change in $\dot{V}_{O_2}$ per °C change in body temperature.

Another effect on tissue hypoxia in patients already ventilated is to reduce $\dot{V}_{O_2}$ by cooling the febrile hypoxic patient.[6] Consider the patient with pneumonia causing Pa_{O_2} of 40 mm Hg (Ca_{O_2} = 15 mL%). Then reduction of $\dot{V}_{O_2}$ from 500 to 250 mL/min by sedation, muscle relaxation, and cooling from 40° to 37°C raises $C\bar{v}_{O_2}$ from 5 to 10 mL O_2 per 100 mL of blood. This increase in mixed venous saturation from 25% to 50% would increase $P\bar{v}_{O_2}$ from 22 to 27 mm Hg in normothermic blood. The left shift of the oxyhemoglobin dissociation curve between 40° and 37°C does not limit oxygen extraction in canine studies of the limits of aerobic metabolism,[7] so cooling the febrile patient may be enough to relieve tissue hypoxia in critical situations.

DETECTING ANAEROBIC METABOLISM IN RESPIRATORY FAILURE

To illustrate how several clinical interventions have a beneficial effect on tissue hypoxia, this discussion emphasized how $P\bar{v}_{O_2}$ tracks the changes in $\dot{Q}_{O_2}$. Yet the value of $P\bar{v}_{O_2}$ at the onset of anaerobic metabolism might vary widely as a result of the $\dot{Q}_{O_2}/\dot{V}_{O_2}$ variance among peripheral tissues.[8,9] This is especially true in the septic patient when very high $\dot{Q}_T$ and $\dot{Q}_{O_2}$ are associated with very high values of $P\bar{v}_{O_2}$ and lactic acidosis. To the extent that such lactic acidosis arises from anaerobic metabolism, the rise in $P\bar{v}_{O_2}$ with increased $\dot{Q}_{O_2}$ in the septic patient confounds the utility of $P\bar{v}_{O_2}$ as a marker of tissue hypoxia. Furthermore, lactic acidosis at high levels of oxygen transport does not necessarily signal pathologic supply dependence of oxygen utilization; rather, the high O_2 demands of critical illness may exceed even normal extraction limits from the apparently high but insufficient O_2 transport.[1] An important observation complicating this problem is that lactic acidosis when $\dot{Q}_{O_2}$ is high does not necessarily indicate anaerobic metabolism, but instead accelerated aerobic glycolysis associated with sepsis-related disturbance of important glycolytic enzymes.[10,11] Clinical and experimental studies demonstrate that progressive reduction in $\dot{Q}_{O_2}$ due to hypovolemic or cardiogenic shock is associated with lactic acidemia having a high lactate-to-pyruvate ratio (L/P); yet, in septic shock, the frequently observed lactic acidemia, even at high levels of $\dot{Q}_{O_2}$, is not associated with an increased L/P ratio, for the pyruvate levels have risen in proportion to the lactate levels.[12] These observations raise the possibility that metabolic utilization of tissue protein stores in septic shock produces abundant pyruvate in excess of that required for generation of high-energy adenosine triphosphate (ATP) bonds through aerobic glycolysis; then excess pyruvate circulates in normal equilibrium with excess lactate, and clinicians mistake this lactic acidosis for anaerobic metabolism. To the extent that pathologic supply dependence does not occur in patients,[13,14] and that the lactic acidosis of sepsis is not anaerobic, the critical care practice of maximizing cardiac output and $\dot{Q}_{O_2}$ confers no benefit on oxygen utilization. Even in the apparent absence of sepsis, the value of $P\bar{v}_{O_2}$ at the onset of anaerobic metabolism varies widely, and some organs may be anaerobic when $P\bar{v}_{O_2}$ and $\dot{Q}_{O_2}$ are not worrisome.[15] Accordingly, measuring and following changes in $P\bar{v}_{O_2}$ and venous saturation in conjunction with acid-base status and lactic acid

measurements allow deductions concerning the effects of altered $\dot{Q}_{O_2}$ on $\dot{V}_{O_2}$ and aerobic metabolism, but these are nonspecific and subject to errors and uncertainties. It seems reasonable to ensure sufficient $\dot{Q}_{O_2}$ to provide a normal $P\bar{v}_{O_2}$ in septic patients without maximizing $\dot{Q}_{O_2}$ to treat hypothetical tissue O_2 extraction defects,[13,14] except where measurement of organ acidosis demonstrates improvement with increased $\dot{Q}_{O_2}$.[15]

A Mechanistic Approach to Respiratory Failure

HYPOXEMIC VERSUS VENTILATORY FAILURE

A descriptive survey of patients requiring mechanical ventilation for respiratory failure reveals four patterns of pathophysiology, each having a predominant mechanism[1] (Table 31-3). Intrapulmonary shunt ($\dot{Q}s/\dot{Q}T$) causes hypoxemia refractory to O_2 therapy despite hyperventilation and reduced Pa_{O_2} in type I or acute hypoxemic respiratory failure (AHRF).[2,16] Primary failure of alveolar ventilation ($\dot{V}A$) leads to CO_2 retention and arterial hypercapnia associated with reduced Pa_{O_2}; this hypoxemia corrects easily with O_2 therapy in type II or ventilatory failure.[1,2,17] Figure 31-2 illustrates the different mechanisms for these two common abnormalities in pulmonary O_2 exchange.[2]

ABNORMALITIES IN PULMONARY GAS EXCHANGE

It is helpful to recall that the cause of hypocapnia (inadequate $\dot{V}A$) is often independent of the cause of hypoxemia,[1] so the treatment for hypercapnia (raising $\dot{V}A$) is different from the treatment for hypoxemia (raise $F_{I_{O_2}}$, positive end-expiratory pressure [PEEP]). When CNS depression of the drive to breathe or loss of neuromuscular coupling (see Chap. 66) reduces minute ventilation ($\dot{V}E$), the CO_2 produced at rest each minute ($\dot{V}_{CO2} = 250$ mL/min) is added to the reduced $\dot{V}A$ (normally about 4 L/min), raising the alveolar and arterial partial pressures (P) of CO_2 ($P_{A_{CO2}} = Pa_{CO2} = k \times \dot{V}_{CO2}/\dot{V}A$); recall that the P of a gas in the lungs is the product of the gas fraction (F_g) and the dry barometric pressure ($Pbar2P_{H2O}$), so $P_{A_{CO2}} =$ (250/4000) × 713 × 0.86, or about 40 mm Hg. Mild alveolar hypoxia develops as the required oxygen uptake ($\dot{V}_{O_2}$) is absorbed from the reduced $\dot{V}A$ ($P_{A_{O_2}} = P_{I_{O_2}} - Pa_{CO2}/R$, where $R = \dot{V}_{CO2}/\dot{V}_{O_2}$), so the consequent arterial hypoxemia is corrected with small increments in inspired oxygen fraction ($F_{I_{O_2}}$). In diseases characterized by airflow obstruction[17–19] or lung restriction,[20] $\dot{V}A$ is reduced despite normal or increased $\dot{V}E$ because the dead space:tidal volume ratio [$VDS/VT = (Pa_{CO2} - P_{E_{CO2}})/Pa_{CO2}$] is increased when large numbers of poorly perfused alveoli are excessively ventilated (high $\dot{V}A/\dot{Q}$ units). Accordingly, when a patient requires an abnormally large $\dot{V}E$ to maintain a normal Pa_{CO2}, the causes are an abnormally increased $\dot{V}_{CO2}$, VDS/VT , or both. Hypoxemia develops with airflow obstruction or lung restriction when other alveoli are poorly ventilated in relation to their perfusion (low $\dot{V}A/\dot{Q}$ units), and the hypoxemia is made worse by low mixed venous oxygen content[2,17–20] (see Chap. 39); again, modest increments in $F_{I_{O_2}}$ correct this hypoxemia (see Fig. 31-2, panel A). By contrast, even an $F_{I_{O_2}}$ of 1.0 cannot correct the hypoxemia induced by increased $\dot{Q}s/\dot{Q}T$ (see Fig. 31-2, panel B), and this refractory hypoxemia of AHRF is often associated with increased $\dot{V}E$ and $\dot{V}A$ and so decreased Pa_{CO2}[1] (see Chap. 38).

ABNORMALITIES IN RESPIRATORY MECHANICS

These two classic types of respiratory failure have distinctly different abnormalities in the mechanics of breathing (Fig. 31-3), while they share mechanisms leading to respiratory muscle dysfunction and fatigue.[1] The schematic illustration of the normal respiratory system (see Fig. 31-3*A*) indicates that spontaneous respiration is effected by the pressure (ΔP) generated by inspiratory muscles to expand the lung and chest wall (ΔV) against their elastance and to cause inspiratory flow ($\dot{V}I$) past the airways resistance (R). When R is increased in acute-on-chronic respiratory failure (ACRF) or in status asthmaticus,[1,22] the ΔP required to breathe often exceeds the strength of the respiratory muscles, resulting in fatigue of the muscles. When such a patient is mechanically ventilated, the peak pressure (Ppeak) generated at the airway opening increases well above the normal value (about 20 cm H_2O in Fig. 31-3*B*, upper left) to 60 cm H_2O (Fig. 31-3*B*, lower

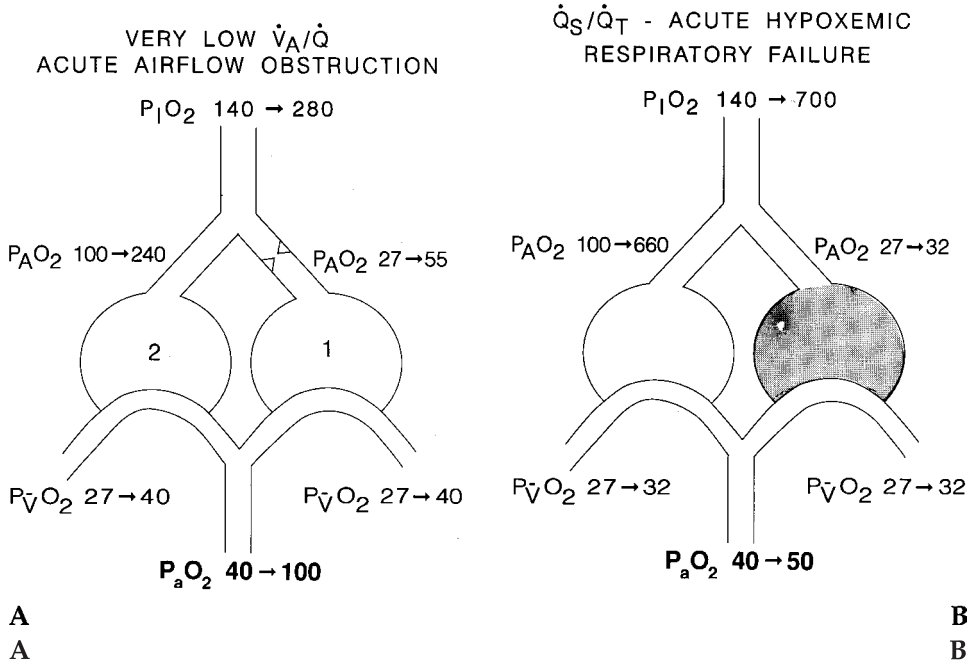

FIGURE 31-2 Schematic illustration showing the effects of oxygen therapy on arterial P_{O_2} (Pa_{O_2}) in two conditions: (*A*) acute airflow obstruction and (*B*) airspace flooding with acute hypoxemic respiratory failure (AHRF). Each panel depicts a two-compartment lung in which each airspace is perfused by half the mixed venous blood with a P_{O_2} ($P\bar{v}_{O_2}$) of 27 mm Hg while breathing room air, which has a fractional concentration of oxygen in the inspired gas (F_{IO_2}) of 0.21. Acute airflow obstruction causes severe hypoxemia that is relatively easily corrected by breathing supplementary oxygen, but hypoxemia in AHRF is much more refractory to oxygen administration and so requires adjunctive therapies. *A.* Because the airspace distal to the obstruction is so poorly ventilated, all its inspired oxygen is absorbed and alveolar P_{O_2} values ($P_{A_{O_2}}$) approach mixed venous P_{O_2} values (27 mm Hg). By contrast, because alveolar P_{O_2} in the well-ventilated alveolus is considerably higher (100 mm Hg), its effluent blood becomes fully saturated (oxygen saturation [S_{O_2}] = 100%); when this blood mixes with an equal amount of effluent blood from the obstructed unit (S_{O_2} = 50%), the resulting arterial blood (Sa_{O_2} = 75%) has a very low P_{O_2} (40 mm Hg). Raising F_{IO_2} to 0.4 (P_{O_2} = 280 mm Hg) increases both the amount of oxygen ventilating the obstructed unit and the alveolar P_{O_2} (55 mm Hg). Accordingly, effluent blood from the obstructed airspace (S_{O_2} = 90%) mixes with fully saturated blood from the well-ventilated alveolus, which also contains more dissolved oxygen, causing arterial S_{O_2} to approach 100% and arterial P_{O_2} to approach 100 mm Hg. Note that this increased arterial oxygen transport is associated with increased mixed venous P_{O_2} (27 to 40 mm Hg). *B.* During room air breathing, the oxygen exchange is as described in *A*, because half the mixed venous blood traverses the flooded airspace from which no oxygen can be absorbed; accordingly, arterial P_{O_2} is 40 mm Hg and mixed venous P_{O_2} is 27 mm Hg. Raising F_{IO_2} to 1.0 increases the dissolved oxygen content in the fully saturated blood exiting the well-ventilated alveolus by about 2 mL/dL (because alveolar P_{O_2} increases from 100 to 660 mm Hg), but oxygen is still not absorbed from the flooded airspace. Accordingly, arterial P_{O_2} increases slightly (40 to 50 mm Hg), and the increased O_2 delivery allows mixed venous P_{O_2} to increase slightly (27 to 32 mm Hg).

right); yet end-inspiratory occlusion allows the airway pressure to return to the normal elastic pressure (Pel = 10 cm H_2O in these same panels), confirming that the resistive pressure (Pr = Ppeak − Pel) has increased fivefold from the normal Pr value of 10 cm H_2O. By contrast, when airspaces become flooded with edema, pus, or blood in AHRF, the tidal volume is delivered to a smaller number of aerated alveoli, overdistending them to increase Pel and Ppeak.[1,23,24] In the lower left panel of Fig. 31-3B, Ppeak is increased to 60 cm H_2O because end-inspiratory occlusion pressure has increased to 50 cm H_2O; in this instance of increased elastance, Pr (Ppeak − Pel) is normal. This large increase in the ventilator pressure mirrors the increased load on the respiratory muscles during spontaneous breathing; combined with the tachypnea, O_2 desaturation, and acidosis in AHRF, this leads to respiratory muscle fatigue.[1,21,23,24]

CLINICAL PRESENTATION AND TREATMENT GOALS

These mechanical and lung gas-exchange distinctions between AHRF and ventilatory failure are paralleled by substantial differences in the clinical description and presentation of patients with type I and type II respiratory failure (Table 31-3). In the second type, decreased $\dot{V}_A$ is caused by reduced drive to breathe (e.g., drug overdoses or head injuries), or by reduced coupling of the adequate or increased drive to breathe to the respiratory muscles (e.g., myasthenia gravis, Guillain-Barré syndrome, amyotrophic lateral sclerosis, botulism, or muscle-relaxing drugs); often the clinical and radiologic examinations of the chest are normal in these patients (see Chap. 66). Alveolar hypoventilation also occurs commonly in respiratory diseases characterized by airflow obstruction and wasted ventilation; Pa_{CO2} increases despite increased CNS drive to breathe, adequate neuromuscular coupling, and increased total ventilation (e.g., status asthmaticus, ACRF, or restrictive pulmonary disease). Wheezing, accessory muscle use, and hyperinflated lungs are common clinical and radiologic features in ACRF and asthma[17,18,25,26] (see Chaps. 39 and 40), while crackles and typical interstitial shadows without consolidated airspaces are observed in patients with RF due to pulmonary fibrosis.[20] The clinical

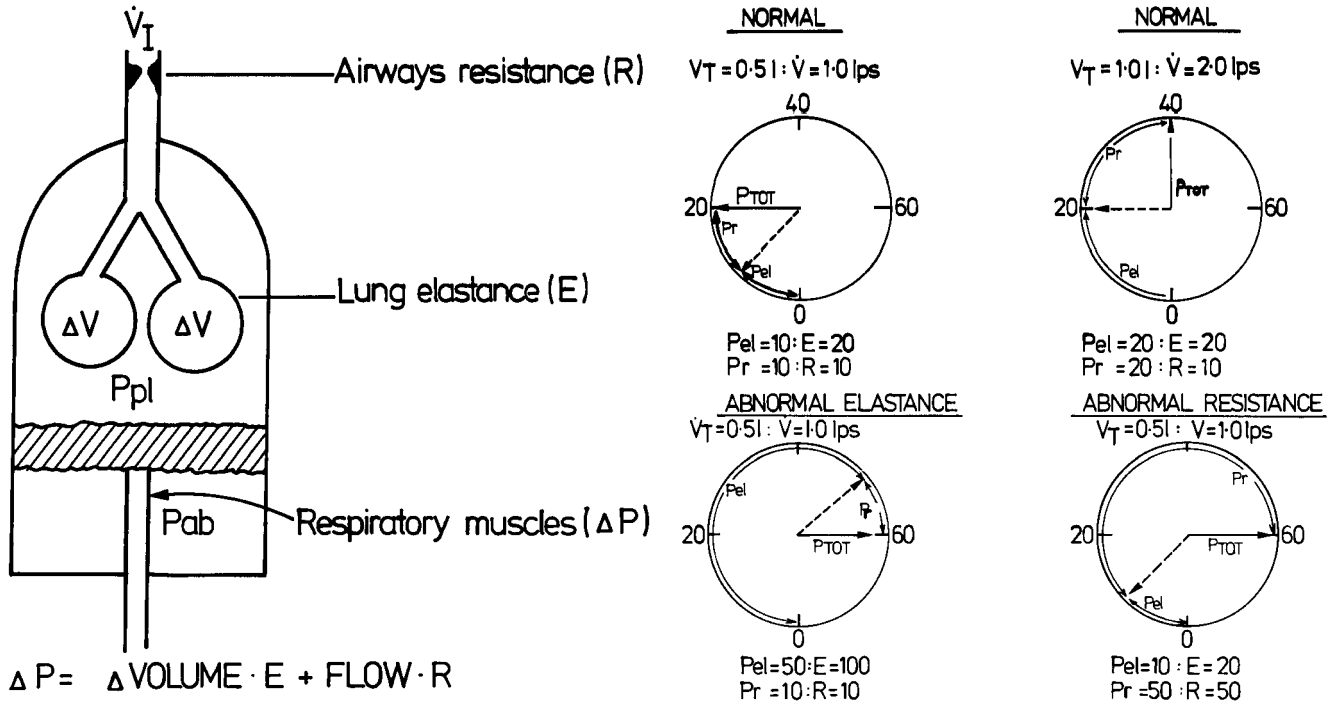

FIGURE 31-3 *A.* **Schematic depicts the mechanical characteristics of the respiratory system. Inspiratory flow ($\dot{V}_I$) is delivered through an airway with resistance (R) to a two-compartment lung model, the units of which have elastance (E) and are distended by the delivered volume (V). During positive pressure ventilation, lung distention raises the pressure between the lungs and chest wall (pleural pressure; Ppl) to increase the volume of the chest wall, in part by pushing the diaphragm downward (see piston at the floor of the thorax) to raise the abdominal pressure (Pab); during a spontaneous breath, the respiratory muscles (P) pull the piston down to lower Ppl and inspire V across R. In either case, ΔP = the elastic pressure (Pel = V x E) plus the resistive pressure (Pr = $\dot{V}_I$ x R).** *B.* **Schematic of the pressure dial on a mechanical ventilator illustrating the measurement of respiratory elastic pressure (Pel) and resistive pressures (Pr) and a calculation of E and R. The upper panels illustrate normal respiratory mechanics for a normal tidal volume and flow rate (*left*) and for a large tidal volume and flow rate (*right*). The lower panels illustrate abnormal elastance (*left*) and abnormal resistance (*right*). See text for discussion.**

presentation of each of these categories of hypoventilating patients contrasts markedly with that of patients presenting with type I AHRF, where cyanosis, tachypnea, and refractory hypoxemia lead to early identification of airspace flooding by physical and radiologic examinations[3] (see Chap. 38). The differential diagnosis of the airspace flooding leading to $\dot{Q}s/\dot{Q}T$ includes cardiogenic or permeability pulmonary edema,[27] pneumonia, and lung hemorrhage,[28] each having specific etiologies and therapy.

While specific diagnostic and treatment plans are being implemented, goals of supportive therapy for types I and II RF are quite different. Therapy for patients with AHRF includes four objectives: (1) stabilization of the patient on the ventilator with minimal respiratory work, (2) ventilation with the least tidal volume providing adequate CO_2 elimination, (3) addition of the least amount of PEEP effecting 90% saturation of an adequate circulating hemoglobin on a nontoxic $F_{I_{O_2}}$, and (4) cardiovascular management to reduce airspace edema by seeking the lowest pulmonary vascular pressures compatible with an adequate cardiac output and oxygen transport to the peripheral tissues (see Chap. 38 for further discussion). Each of these goals of management of type I AHRF differs from the goals of management of type II ventilatory failure, where the patients with depressed CNS drive or reduced neuromuscular coupling receive adequate ventilation and require minimal oxygen supplementation with careful attention to preventing atelectasis and correcting hypoperfusion until the abnormal neurologic condition resolves; the patients requiring ventilation for airflow obstruction are supported with bronchodilator therapy and ventilator settings that minimize intrinsic PEEP until the airways resistance is reduced sufficiently for the respiratory muscles to achieve adequate ventilation independent from the ventilator (see Chaps. 39 and 40 for further discussion). One reason for identifying the causes of increased respiratory load is to view liberation from mechanical ventilation for patients with type I or type II RF as the mirror image of the cause of RF (i.e., a systematic approach to reverse factors increasing the respiratory load and decreasing the respiratory muscle strength) (Table 31-4).

PERIOPERATIVE RESPIRATORY FAILURE

The physician frequently encounters patients in the perioperative period who are unusually susceptible to atelectasis as a primary mechanism causing type III or perioperative respiratory failure.[29,30] In general, abnormal abdominal mechanics reduce the end-expired lung volume (↓FRC)[31–33] below the increased closing volume (↑CV) in these patients,[31,34,35] leading to progressive collapse of dependent lung units (see Table 31-3). The end result can be type I AHRF, or type II ventilatory RF, or both. Yet identification of atelectasis as a distinct

TABLE 31-4 Liberation of the Patient from Mechanical Ventilation

Type I: AHRF
Reduce edema production
Enhance edema clearance
Treat pneumonia
Drain pleural effusions
Stabilize chest wall
Least PEEP
Minimize dead space
Type II; Airflow obstruction
Hypoxemia—give O_2
Reverse sedation
Bronchodilation
Clear bronchial secretions
Treat bronchial infection
Pneumothorax—chest tube
Fractured ribs—nerve block
Decrease intrinsic PEEP
Allow bicarbonate accumulation
Reduce CO_2 production
Type III: Perioperative respiratory failure
Posturize and pummel
Ventilate 45° upright
Treat incisional/abdominal pain
Drain ascites
Re-expand atelectasis early
Stop smoking 6 weeks preoperatively
Avoid overhydration
Type IV: Shock
Hypoperfusion
Hypotension
Anemia
Hypoxia
Sepsis
Fever
Acidosis
Electrolytes (K^+, Ca^{2+}, Mg^{2+}, PO_4^{2-})
Protein-calorie nutrition
Aminophylline
Common confounding conditions
Neuromuscular disease
Muscle-relaxing drugs
Coma, sedation
Cerebrovascular accident
Subclinical status epilepticus
Hypothyroidism
Phrenic nerve paralysis
Respiratory muscle fatigue
Respiratory muscle exercise program
Tone
Power
Coordination

ABBREVIATIONS: AHRF, acute hypoxemic respiratory failure; PEEP, positive end-expiratory pressure.

mechanism leading to this third type of respiratory failure can be harnessed to prevent lung collapse by reducing the adverse effects of common clinical circumstances promoting reduction in FRC, and of those conditions promoting abnormal airways closure at increased lung volume. Because many of these mechanisms are shared by patients with type I or type II respiratory failure, implementation of approaches to minimize atelectasis should be a part of the management of all patients with respiratory failure.

The principles of preventing or reversing type III perioperative respiratory failure are listed in Table 31-4. Bedside nurses in the ICU turn the patient every 1 to 2 hours from the supine position to the left or right lateral decubitus position; during this time, they provide vigorous chest physiotherapy with pummeling, chest vibration, and endotracheal suction. In patients vulnerable to atelectasis, a fourth position 30° to 45° upright is helpful by reducing the load imposed by the abdomen; also, the addition of sighs, continuous positive airway pressure (CPAP), or PEEP returns the end-expired lung volume to a position above the patient's closing volume.[34] Special attention to the treatment of incisional or abdominal pain (e.g., epidural anesthesia or transcutaneous electrical nerve stimulation) and to minimization of the intra-abdominal pressure of ascites or tight bandages helps to prevent atelectasis.[32,36] When lobe or lung collapse is detected by physical or radiologic examination, an early, aggressive approach to re-expansion includes placing the patient in the lateral decubitus position with the collapsed lobe uppermost for vigorous pummeling and suctioning, and then increasing the tidal volume progressively to a pressure limit of 40 cm H_2O with end inspiratory pauses. Re-expansion often occurs within 10 minutes and is signaled by a fall in the ΔPel associated with the normal tidal volume at the end of the re-expansion maneuver; if this re-expansion is not confirmed radiologically, repeating these maneuvers after bronchoscopy to clear endobronchial obstructions is indicated. Once re-expansion has occurred, the implementation of increased levels of PEEP and/or sighs often prevents further episodes of atelectasis. Discontinuation of smoking at least 6 weeks prior to elective operations reduces bronchorrhea and atelectasis,[37] and avoiding overhydration in perioperative patients especially vulnerable to atelectasis reduces this problem.

HYPOPERFUSION STATES CAUSE TYPE IV RESPIRATORY FAILURE

A significant number of ventilated patients fall outside the categories of type I, II, or III respiratory failure. These are the patients who have been intubated and stabilized with ventilatory support during resuscitation from a hypoperfusion state, so type IV RF is most commonly due to cardiogenic, hypovolemic, or septic shock without associated pulmonary problems (see Chaps. 21 and 46). The appropriate rationale for ventilator therapy in these patients who are frequently tachypneic with erratic respiratory patterns is to stabilize gas exchange and minimize the steal of a limited cardiac output by the working respiratory muscles until the mechanism for the hypoperfusion state is identified and corrected.[21,38,39] Note that liberation from the ventilator of the patient with type IV RF is simple: when shock is corrected, the patient resumes spontaneous breathing and is extubated. Note further that when patients with type I, II, or III RF suffer a concurrent hypoperfusion state, the causes of reduced blood flow, hypotension, anemia, acidosis, and sepsis need identification and correction as part of the liberation process (see Table 31-4). Accordingly, the physician managing RF frequently employs the principles of diagnosis and management of hypoperfusion states, as discussed in the next section.

Respiratory Muscle Exercise and Fatigue in Respiratory Failure

The respiratory muscles share with other major muscle groups of the body the characteristic that excessive work leads to fatigue.[21,40,41] This concept seems to explain why patients with severe airflow obstruction or airspace flooding ultimately stop breathing, and why patients requiring mechanical ventilation for these and other causes of respiratory failure are unable to breathe independent from the ventilator until the load on their respiratory muscles is reduced, the respiratory muscles become stronger, or both. Note, however, that while this is a useful paradigm with which to manage patients with RF, it is exceedingly difficult to identify fatigue under clinical conditions. Nonetheless, as a rough guide, spontaneous ventilation can be sustained indefinitely when the effort of each spontaneous breath is less than one third the maximal respiratory effort achievable.[40,41] In normal patients, the

maximum negative inspiratory pressure (MIP) measured at FRC exceeds 100 cm H_2O, whereas the work of spontaneous breathing is less than 10 cm H_2O, providing considerable respiratory muscle reserve before the conditions of fatigue are approached. In contrast, patients with acute respiratory failure frequently have values of MIP <30 cm H_2O, while the load on the respiratory muscles, as measured by the pressure generated by the ventilator during each breath, exceeds 30 cm H_2O.[22–24] Such values predict that the patient's respiratory muscles will fatigue quickly if spontaneous ventilation were required, a hypothesis easily confirmed in such patients who breathe rapidly and insufficiently when taken off the ventilator.[42] Another measure of maximum respiratory effort in the conscious patient is vital capacity (VC). As a rough guideline, when VC is three times the tidal volume (V_T) required to maintain eucapnia and normal pH, respiratory muscle fatigue is unlikely. A corresponding alternate measure of respiratory load is the minute ventilation required to maintain normal Pa_{CO_2} and pH. Factors that increase CO_2 production, dead space, or metabolic acidosis necessarily increase this ventilation and so promote respiratory muscle fatigue. Such fatigue is often signaled by increased respiratory rate (RR >35 breaths per minute), by paradoxical respiratory motion (the abdomen moves in with inspiration as the fatigued diaphragm is pulled craniad by the negative pleural pressure), and by the patient's unexplained somnolence or decreased responsiveness.[21,41] Accordingly, evaluation of the patient's ability to resume spontaneous ventilation includes measurements of MIP, VC, V_T, RR, and $\dot{V}_E$, as well as direct observation of the respiratory motions during a period of spontaneous breathing[43,44] (see Chap. 44).

RESTING FATIGUED RESPIRATORY MUSCLES

Current evidence and common sense suggest that the treatment for respiratory muscle fatigue is respiratory muscle rest, a strategy that must be balanced in nearly all patients against a thoughtful respiratory exercise program. The timing of the move from respiratory muscle rest to an exercise program is not currently guided by objective criteria identifying fatigue. Accordingly, many physicians confronted with this problem develop empirical guidelines as to the likely presence of respiratory muscle fatigue integrated with the type of early ventilator management necessary for the patient's overall condition. For example, the cardiovascular stability and optimal ventilator management of patients with type I AHRF are frequently enhanced by respiratory muscle rest during the first 6 hours after elective intubation for severe hypoxemia. During this time, the acutely depleted glycogen stores of the resting respiratory muscle are repleted, and the accumulated lactic acid or other metabolites associated with fatigue are washed out;[38,39,45] then the patient is ready to move to a respiratory exercise program. By contrast, the patient with ACRF who has developed respiratory muscle fatigue over a longer period of time may require up to 72 hours of respiratory muscle rest before resuming an exercise program free from fatigue. Note that many patients being managed for respiratory muscle rest by mechanical ventilation are actually working as hard or harder than during spontaneous ventilation by breathing actively against the ventilator.[46] This is easily detected by clinical examination coupled with observation of the airway pressure, which should rise at the start of each ventilated breath. In many patients, the airway pressure stays at or below zero during inspiration, indicating active inspiration by the patient; the amount and duration of inspiratory effort often can be assessed by the fall in central venous or pulmonary artery pressure with each inspiration. When respiratory rest is indicated, it can be achieved in these circumstances by increasing the inspiratory flow rate, by increasing the minute ventilation, or, if these measures of eliminating the patient's respiratory effort are inadequate, by sedating and paralyzing the patient to ensure respiratory rest.[40]

EXERCISING RESTED RESPIRATORY MUSCLES

As soon as the patient with respiratory failure is stabilized on the ventilator, the physician should make a decision whether to rest the fatigued respiratory muscles or to institute a program of respiratory muscle exercise in those patients in whom fatigue is neither evident nor expected. The objective of the respiratory exercise program is to increase the tone, power, and coordination of the respiratory muscles.[21,47] The efficacy of each program in increasing tone and power is evaluated by the daily MIP and vital capacity measurements. Coordination is evaluated by bedside observation confirming that the patient's respiratory efforts interact with the ventilator in a manner that is comfortable for the patient. Here the goal is to adjust the ventilator such that the patient receives a breath on demand at a volume and frequency within the ranges expected for that patient off the ventilator. Several different modes of ventilation seek to achieve these goals of increased tone, power, and coordination during the liberation process, and each is described in detail in Chaps. 32, 36, and 44.[39]

LIBERATING THE PATIENT FROM MECHANICAL VENTILATION

This aggressive approach attempts to liberate the patients as soon as possible from mechanical ventilation by using the mode as an exercise program. Then ventilator mode becomes a thoughtful part of a larger program addressing about 50 correctable factors constraining the patient's freedom to breathe (Table 31-4). This effective approach to liberating patients from the ventilator measures and attempts to increase the values of MIP and VC while simultaneously measuring and reducing the respiratory load.[47] The left column of Table 31-4 lists correctable factors to reduce the respiratory muscle load. As a general rule, these are the abnormal respiratory mechanics associated with the several types of acute respiratory failure. The right column of Table 31-4 lists correctable factors increasing respiratory muscle strength, first in the context of those many disturbances of the circulation or internal environment most common to patients with type IV respiratory failure. Attempting to liberate patients with hypoperfusion states or hypotension is almost never successful. Correction of these hemodynamic variables complements the correction of anemia, hypoxemia, and acidosis to provide dramatic increases in the objectively measured respiratory muscle strength by MIP and VC. Similarly, attempting to liberate patients who are septic or have body temperatures >38.5°C is often unsuccessful. While these systemic abnormalities are being corrected, it is also helpful to initiate adequate daily protein-calorie nutrition utilizing protein (0.8 g/kg) and nonprotein calories (about 30 kcal/g of

protein), of which calories 20% to 50% should be supplied as lipid.[48] Elemental malnutrition is corrected by adjustments of serum potassium, calcium, magnesium, and phosphate levels; severe abnormalities of each of these electrolytes is sufficient to cause respiratory muscle fatigue,[49,50] so modest abnormalities in the patient already weakened by critical illness may converge to make the patient weaker than necessary. When each of these abnormalities has been corrected, there is some evidence that respiratory muscles may be strengthened by the infusion of aminophylline in doses that achieve serum concentrations associated with effective bronchodilation.[51] When all other factors are corrected but the patient remains weak, it is helpful to exclude clinical conditions that occasionally cause reduced respiratory muscle strength. Neuromuscular disease, muscle-relaxing drugs,[52] steroids,[53] sedatives, coma, and intercurrent cerebrovascular accidents cause obscure reductions in respiratory muscle strength. Often overlooked causes of inadequate respiratory muscle function are subclinical status epilepticus, hypothyroidism, and paralysis of the phrenic nerve on one or both sides after cardiac surgery with cold cardioplegia or other thoracic trauma.[47]

Chapter 32

VENTILATOR WAVEFORMS: CLINICAL INTERPRETATION

GREGORY A. SCHMIDT

KEY POINTS

- *Pressure and flow waveforms reveal a wealth of information regarding the patient's physiologic derangement.*
- *Distinguishing the contributions of resistive and elastic pressures allows tailoring and monitoring of therapy.*
- *Auto-PEEP should be sought in all mechanically ventilated patients.*
- *Ventilator waveforms show how adequately the physician has accommodated the ventilator to the patient.*
- *Patient effort confounds interpretation of pressures and flows.*
- *Attention to ventilator waveforms can improve the accuracy of hemodynamic interpretation.*

Intensive care ventilators generate tidal ventilation by applying to the endotracheal tube or mask a pressure higher than the alveolar pressure. This is true whether the mode of ventilation is volume-preset (volume assist-control ventilation [ACV] and synchronized intermittent mandatory ventilation [SIMV]); pressure-preset (pressure-support ventilation [PSV] and pressure-control ventilation [PCV]); or more complex modes (pressure-regulated volume control [PRVC], proportional assist ventilation [PAV], airway pressure release ventilation [APRV], and volume-support ventilation [VSV]). The capability to display waveforms turns modern ventilators into sophisticated probes of patient respiratory mechanics and of patient-ventilator interaction. Respiratory system mechanics and waveform analysis should be integrated into routine ventilator management of the critically ill patient. The fundamental aims are to (1) determine the nature of the mechanical derangement of the respiratory system; (2) assay the response to therapy; (3) reveal intrinsic positive end-expiratory pressure (auto-PEEP); and (4) determine the patient-ventilator interaction to guide adjustment of ventilator settings. In addition, respiratory muscle activity must be considered when measuring hemodynamic pressures such as the pulmonary artery occlusion pressure (pulmonary wedge pressure, Ppw) or the right atrial pressure (Pra), since these pressures are determined at end-expiration. The time point of end-expiration, as well as the presence of inspiratory and expiratory effort (both of which can greatly confound interpretation of hemodynamic pressures) can be readily discerned by analyzing ventilator waveforms.

It is easiest to derive clinically useful information about the patient's respiratory system when volume-preset modes such as ACV or SIMV are used. At least when the patient is passive, the pressure at the airway opening (Pao) and the pressure vs. time waveform reflect the mechanical properties of the respiratory system, yielding valuable clinical information. During pressure-preset modes, such as PSV and PCV, some information can be derived from the flow vs. time waveform, but this information is generally less readily interpreted than that obtained during volume-preset ventilation. Below we review the determinants of the pressure and flow versus time waveforms during volume-preset, then pressure-preset ventilation, including how to recognize and quantitate auto-PEEP as well as a method for using this information to adjust the ventilator. Volume-pressure loops are reviewed in terms of how they may aid management of the patient with acute lung injury (ALI) or acute respiratory distress syndrome (ARDS). The potentially confounding effect of patient effort on the pressure and flow waveforms is discussed. Finally, examples of problems revealed through careful interpretation of waveforms are presented.

Pressure at the Airway Opening

VOLUME-PRESET MODES

Gas is driven to and from the lung by a pressure difference between alveolus and airway opening. The majority of adult patients are ventilated, at least initially, with a volume-preset mode (i.e., ACV or intermittent mandatory ventilation [IMV]),[1] allowing ready determination of the respiratory system mechanics. When a muscle-relaxed patient is mechanically ventilated at constant inspiratory flow, the inspiratory Pao consists of three components: one to drive gas across the inspiratory resistance, the second to expand the alveoli against the elastic recoil of the lungs and chest wall, and the third equal to the alveolar pressure present before inspiratory flow begins (PEEP or auto-PEEP) (Fig. 32-1).

The contributions of each of these three components can be found by inserting a 0.3- to 0.5-second end-inspiratory pause,[2] briefly stopping flow and allowing the pressure to fall from its peak value (Ppeak) to a plateau pressure (Pplat), in order to quantitate the flow-related pressure, Pres (Pres = Ppeak − Pplat). At any point during passive inspiration, Pao reflects the sum of these three components, as follows:

$$\text{Pao} = \text{Pres} + \text{Pel} + \text{Total PEEP or}$$

$$\text{Pao} = \text{Flow}_\text{I} \times \text{Rrs} + \Delta\text{V} \times \text{Ers} + \text{Total PEEP}$$

where Pao is the airway opening pressure, Pres is the resistive pressure component, Pel (Pel = Pplat − Total PEEP) is the elastic pressure, Rrs is inspiratory resistance, ΔV is the increment in lung volume, Ers is elastance of the respiratory system, and total PEEP is applied PEEP or auto-PEEP, whichever is higher. Diagnostic and therapeutic information can be gleaned by distinguishing the individual components of the peak Pao (Ppeak) as follows. First, PEEP is set on the ventilator and this value can be used when auto-PEEP is absent. However, auto-PEEP is present in most ventilated critically ill patients,[3] and methods for quantitating it are described below. The Ppeak can be apportioned between its two remaining components, Pres and Pel, by stopping flow (end-inspiratory pause) and allowing the Pres to fall to 0. When flow is 0, Pao drops to a lower Pplat. Then:

$$\text{Pres} = \text{Ppeak} - \text{Pplat}$$

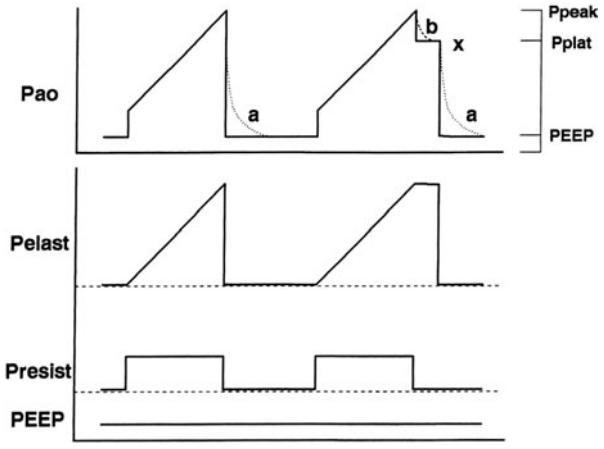

FIGURE 32-1 During constant flow, volume-preset ventilation of a passive patient, Pao is composed of resistive and elastic elements, the latter consisting of the end-expiratory pressure (PEEP or auto-PEEP) and a component proportional to the change in volume and the respiratory system compliance. The second breath includes an inspiratory pause allowing determination of the components of Pao.

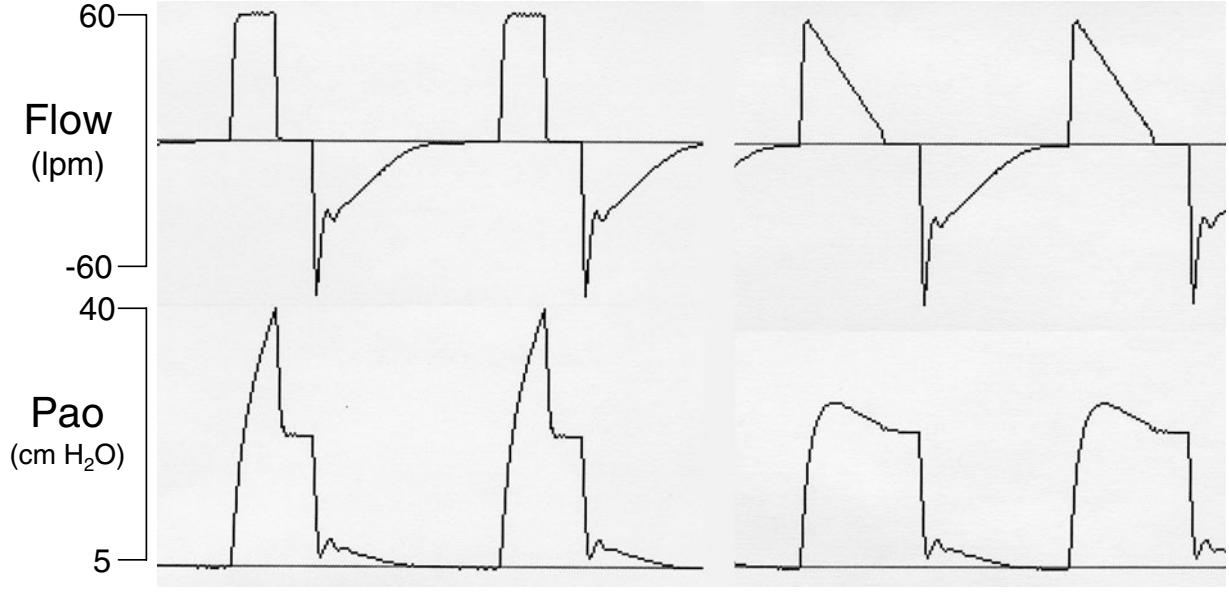
The final component (Pel = Pplat − Total PEEP) is proportional to the elastance of the respiratory system and the tidal volume.

At normal inspiratory flow rates in the range of 1 L/s, Pres is typically between 4 and 10 cm H_2O. Elevated Pres is found with high inspiratory flow or increased inspiratory resistance. At constant flow, a rise in Pres may indicate, for example, increased bronchospasm or endotracheal tube obstruction. Conversely, falling Pres may correspond to a response to bronchodilators. Because the Pres depends on ventilator flow rate as well as inspiratory resistance, when interpreting its value one must be careful to take the set flow rate into consideration. The most dramatic example of potential error in this regard is when the inspiratory flow is set to a decelerating profile (Fig. 32-2).



Since Pel = $\Delta V \times$ Ers, elevated Pel indicates excessive tidal volume or increased elastic recoil of the lungs or chest wall, as in pulmonary fibrosis, acute lung injury, or abdominal distention. Respiratory system static compliance (Crs) is the inverse of Ers:

$$Crs = \Delta V/Pel$$

which is normally about 70 mL/cm H_2O. When the tidal volume is a typical 500 mL, Pel should be only about 7 cm H_2O (500 mL/70 mL per cm H_2O). Thus a ventilated healthy patient should have a Ppeak of roughly 17, consisting of Pres (5 cm H_2O), Pel (7 cm H_2O), and applied PEEP (5 cm H_2O). Often the cause of ventilatory failure has not been determined by the time of endotracheal intubation. If the Ppeak is not increased in a passive ventilated patient, the physician should suspect impaired drive, neuromuscular weakness, or a transient, now resolved, problem (e.g., upper airway obstruction bypassed by the endotracheal tube) as the cause for ventilatory failure. When the Ppeak is high, partitioning its components into the resistive pressure (Pres), the elastic pressure (Pel), and PEEP can aid the physician to narrow the differential diagnosis (Fig. 32-3 and Table 32-1).

In addition, such analysis may allow therapy to be tailored specifically to the cause of ventilatory failure. For example, in a patient with COPD and congestive heart failure who fails extubation following colon resection, bronchodilators will not be helpful if Pres is normal and auto-PEEP is 0. Similarly, if auto-PEEP is greatly elevated, measures to decompress the abdomen are not likely to get the patient off of the ventilator.

FIGURE 32-2 This is a passive patient with modest airflow obstruction ventilated with a volume-preset mode and square wave flow (*panel A*) at 60 liters per minute (lpm) or decelerating flow (*panel B*) beginning at 60 lpm. A 0.4-second end-inspiratory pause is set in order to allow determination of Pplat. Notice that there is a significant difference between Ppeak and Pplat (40 to 22) during square wave ventilation, but not during decelerating flow (27 to 22) because flow is so low during the later parts of the breath.

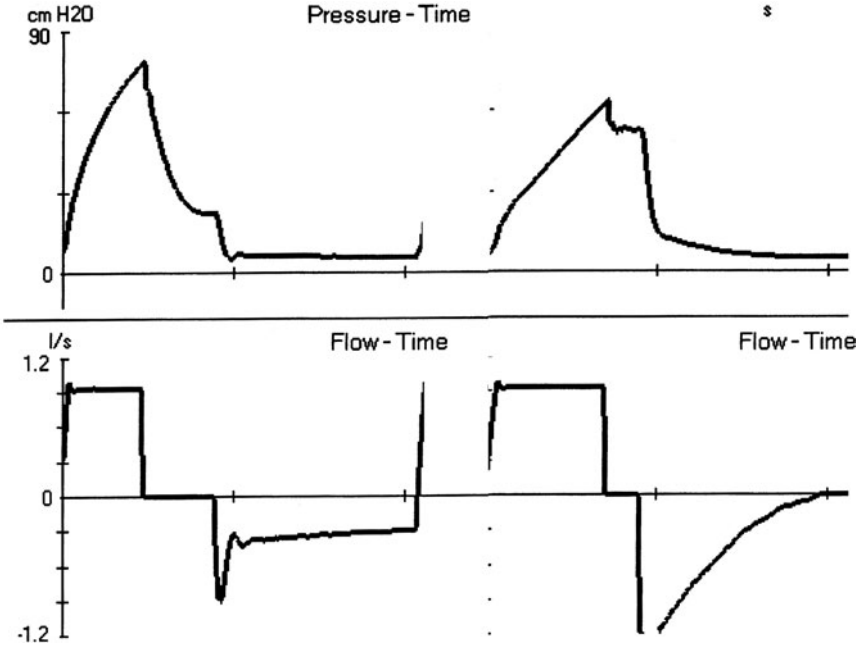


FIGURE 32-3 Both patients have elevated airway pressures. A brief pause inserted at end-inspiration reveals a striking difference between the two records: the left-hand tracing shows that Pao falls dramatically when flow is stopped, indicating elevated Pres (this patient had status asthmaticus); the right-hand tracing shows that Pao falls quite modestly, since Pel is elevated (this patient had a massively distended abdomen and abdominal compartment syndrome). Note also that expiratory flow differs substantially between the two, with low and prolonged expiratory flow in the left-hand tracing.

PRESSURE-PRESET MODES

The inspiratory pressure waveform during pressure-preset modes, such as PSV and PCV, reflects ventilator settings only and reveals nothing about the respiratory system physiology. These waveforms serve mostly to reveal the current ventilator settings as a snapshot (Fig. 32-4) or to demonstrate the impact of certain complex modes on ventilator actions (Fig. 32-5).

EXPIRATORY PRESSURE

During either volume-preset or pressure-preset ventilation, analyzing the expiratory pressure [Paw(ex)] is substantially less useful than the inspiratory pressure, since Paw(ex) is largely determined by characteristics of the mechanical ventilator, not the patient.

$$\text{Paw(ex)} = \text{PEEP} + \text{Flow}_E \times \text{Rexlimb}$$

where PEEP is the applied PEEP (not auto-PEEP), Flow_E is expiratory flow rate, and Rexlimb is the resistance of the expiratory limb of the ventilator. It is important to realize that Paw(ex) does not reflect expiratory alveolar pressure or auto-PEEP, and relates to the patient's respiratory system only indirectly through the expiratory flow. Although some ventilators display inspiratory and expiratory pressure-volume plots, only the inspiratory segment gives useful information about the patient.

TABLE 32-1 Differential Diagnosis of Elevated Peak Airway Pressure

Increased Pres	Increased Pel	Increased Total PEEP
High flow	High tidal volume	High applied Peep
Bronchospasm	Chest wall	Auto-PEEP
COPD	Kyphoscoliosis	Expiratory limb malfunction
Secretions	Rib deformity	
Kinked or obstructed tubing	Pleural disease	
Airway edema	Obesity	
Airway tumor/mass	Abdominal distention	
Airway foreign body	Lung	
	Interstitial lung disease	
	Lung resection	
	Atelectasis	
	Pulmonary edema	
	Pneumonia	

ABBREVIATIONS: Auto-PEEP; COPD, chronic obstructive pulmonary disease; PEEP, positive end-expiratory pressure; Pel, elastic pressure; Pres, flow-related pressure.

Flow Waveforms

EXPIRATORY FLOW

Expiratory flow depends largely on patient features, such as end-inspiratory lung volume, lung elastic recoil, and characteristics of the airways, rather than ventilator settings. For this reason, expiratory waveforms can be analyzed without respect to mode of ventilation. Look again at Fig. 32-3. Notice the striking difference in the expiratory flow between these two patients, the first having airflow obstruction, the second restriction.

The most valuable information to come from the expiratory flow tracing is evidence suggesting airflow obstruction, signaled by low or prolonged expiratory flow, often with flow at end-expiration. In addition, there may be two distinct components to the expiratory flow decay, rather a single exponential one (Fig. 32-6), in patients with airflow obstruction.

INSPIRATORY FLOW

PRESSURE-PRESET MODES

It is more difficult to infer the mechanical properties of the respiratory system during pressure-preset ventilation than when

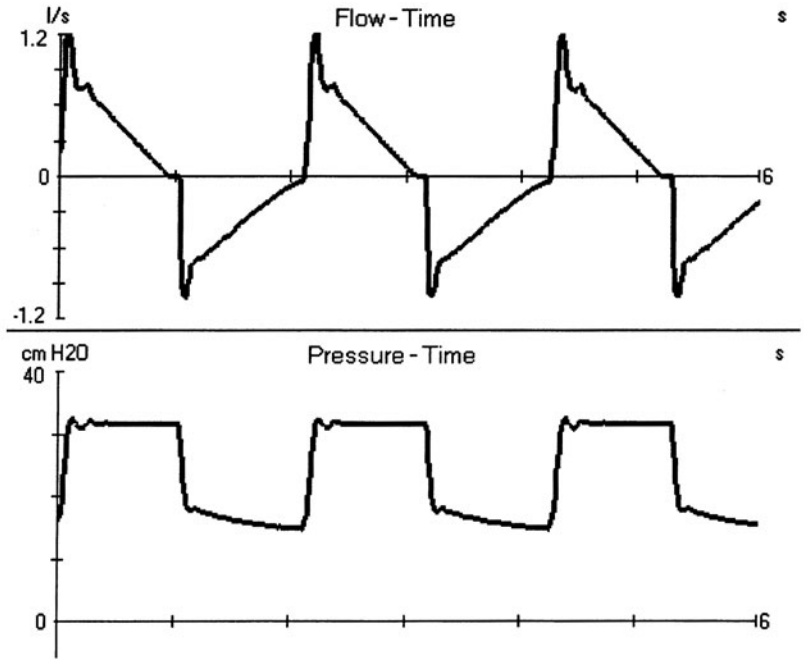

FIGURE 32-4 Flow and pressure waveforms during PCV, showing the typical linear fall in flow through the breath. The pressure tracing merely reflects the ventilator settings as pressure cycles between P_I (32 cm H_2O) and PEEP (14 cm H_2O).

using constant-flow volume-preset ventilation, since the Pao waveform becomes meaningless. Information regarding the combined respiratory resistance and elastance (or time constant) can be gained by examining the slope of the inspiratory flow waveform (Fig. 32-7). Assuming a passive patient, during PCV the flow falls throughout inspiration as the rising alveolar pressure reduces the driving pressure for flow (since the Pao is maintained constant by the ventilator). The rate of fall of the flow is related to how fast Palv rises, itself a function of the mechanical properties of the respiratory system. Because the slope of the flow decay cannot be measured readily at the bedside, and because the information it contains lumps features of elastance and resistance, it may be useful to turn patients from PCV to ACV periodically to determine the respiratory mechanics.

Flow may or may not terminate before end-expiration depending on the inspiratory time (T_I) and the time constant of the respiratory system (Fig. 32-8). If inspiratory flow terminates in a passive patient, the peak alveolar pressure equals the ventilator inspiratory pressure (P_I). Flow waveform displays facilitate adjustments of T_I and respiratory rate as discussed below.

When patients are breathing spontaneously on PSV, thereby determining their own T_I and rate, waveform analysis aids the identification of patient-ventilator asynchrony. This may be especially important during noninvasive ventilation

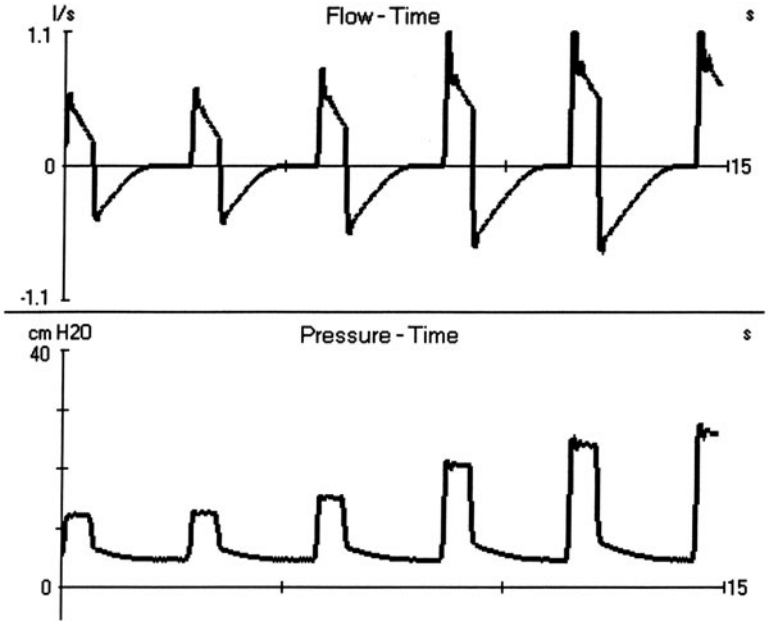

FIGURE 32-5 These waveforms of flow and pressure demonstrate the effect during pressure-regulated volume control mode of increasing the tidal volume. Over the course of several breaths, pressure gradually rises, driving more flow and increasing the tidal volume, until the new target tidal volume is reached.

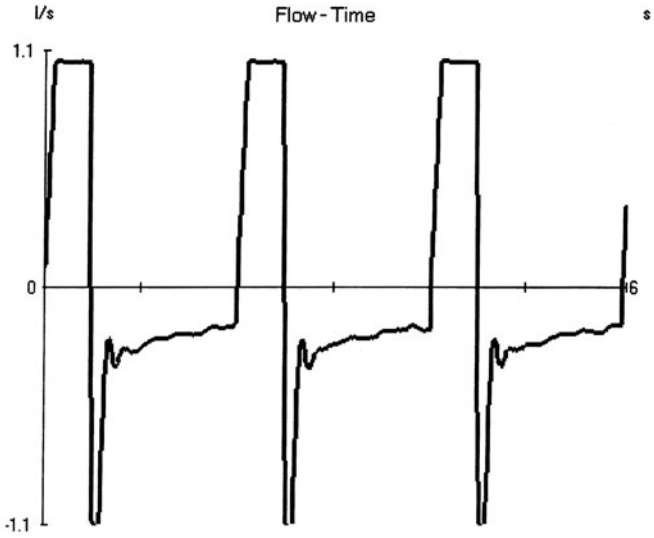

FIGURE 32-6 Flow waveform in a patient with emphysema. The initial expiratory flow is quite high, but quickly falls off to a much lower (and abnormally low) flow rate, persisting until the next breath. These two components reflect initial airway collapse at the onset of expiration (high flow) followed by much lower flow driven by the reduced elastic recoil of the emphysematous lung.

(NIV). Common problems during NIV include failure of the ventilator to recognize the onset of patient inspiration (generally due to auto-PEEP, as described below) and the onset of expiration (most often due to mask leaks).

VOLUME-PRESET MODES

During ACV and SIMV, flow is set by the physician either directly or indirectly through the choice of minute ventilation and rate. Flow may also be altered by changes in rise time, inspiratory plateau, inspiratory:expiratory ratios, and other settings, depending on the particular ventilator in use. Flow waveforms can reveal the effects on flow of other setting changes, as discussed below, and also whether the flow profile (square, decelerating, or sine) has been inadvertently changed.

The Obstructed Patient

CLUES IN THE WAVEFORMS

The waveform indications of increased respiratory resistance are: (1) increased Pres when an end-inspiratory pause has been set; (2) a high shoulder on the early portion of the Pao versus time tracing (Fig. 32-9); (3) low and prolonged expiratory flow, often with persistent flow at end-expiration (see Fig. 32-9); (4) the presence of two components to the expiratory waveform (indicating early airway collapse; see Fig. 32-6); and (5) scooping of the expiratory flow-volume curve (Fig. 32-10).

DETERMINING AUTO-PEEP

The auto-PEEP effect occurs when there is insufficient time for the respiratory system to return to functional residual capacity by end-expiration.[4,5] Short expiratory times, high minute volumes, and increased expiratory resistance contribute to auto-PEEP, but all of these need not be present. Auto-PEEP is present in the majority of ventilated patients with asthma and COPD (and in many during spontaneous breathing[6,7]), but it is also seen in ARDS and other settings with high minute ventilation.[3] In many regards auto-PEEP acts like PEEP to impede venous return, heighten the risk of barotrauma, and improve oxygenation. In addition, auto-PEEP increases the work of breathing and impairs the patient's ability to trigger the ventilator. For these reasons, it is imperative to monitor routinely the presence and amount of auto-PEEP in mechanically ventilated patients.

Auto-PEEP is present when the expiratory flow tracing reveals persistent end-expiratory flow (Fig. 32-11). Additionally, when the Pres is lower than the height of the early step change in the Pao waveform, auto-PEEP is likely to be present.

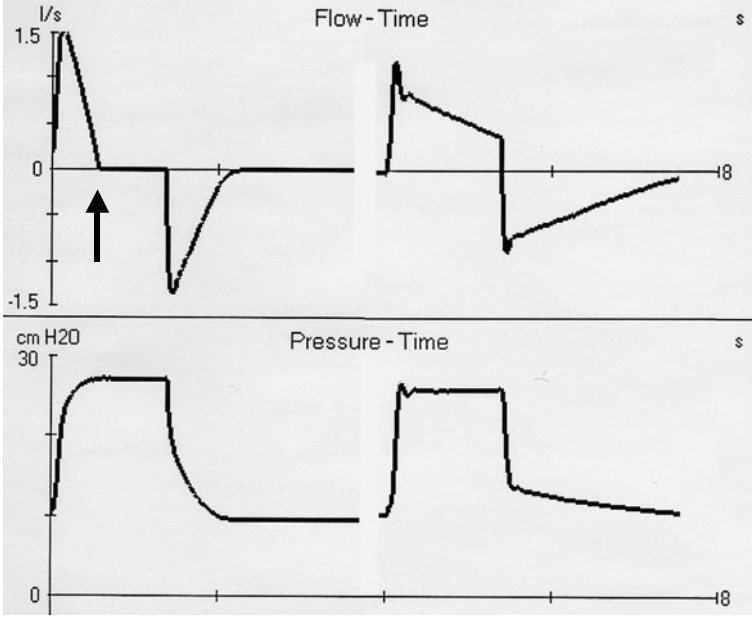

FIGURE 32-7 These two passive patients were ventilated with identical settings on PCV. The patient shown on the left had reduced lung compliance but normal airways, while the patient on the right had normal compliance and increased airways resistance. The slope of the flow waveform reveals these mechanical differences. Note that flow ceases completely in the first patient (*arrow*) well before the ventilator cycles to the expiratory pressure.

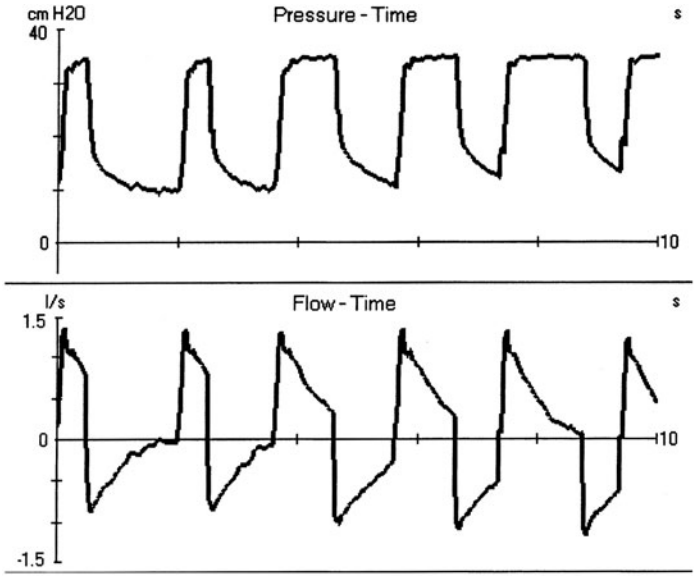

FIGURE 32-8 Pressure-control ventilation as T_I is progressively increased. The first two breaths are characterized by short T_I and cessation of inspiratory flow well before alveolar pressure (Palv) and P_I are equal. Expiratory flow ceases just before the subsequent breaths, showing that the lung has returned to functional residual capacity. Increasing T_I (second pair of breaths) lengthens the time of flow (thereby increasing tidal volume) but shortens exhalation time (T_E) sufficiently that there is now flow at end-expiration (i.e., there is dynamic hyperinflation or auto-PEEP). The final pair of breaths shows end-inspiratory cessation of flow (indicating that $P_I = Palv$), but now T_E is so short that dynamic hyperinflation worsens.

Several methods for quantifying auto-PEEP are available, but the one typically used clinically is the end-expiratory port occlusion method.[4] Several ventilators facilitate this determination by providing an expiratory pause switch. This method will not provide accurate estimation of auto-PEEP if there is a leak in the tubing or around the endotracheal tube cuff, there is gas flow into the circuit during expiration (as during continuous nebulization of bronchodilators), or the patient is not fully passive during the maneuver. In one survey of ventilated patients, quantitation of auto-PEEP was possible by the end-expiratory port occlusion technique in only one-third, because patient effort confounded the airway pressure.[3] Serial measurement of auto-PEEP may give information regarding the obstructed patient's response to bronchodilator therapy (if minute ventilation is constant).[8]

USING PEEP TO EASE TRIGGERING

Auto-PEEP presents an inspiratory threshold load to the spontaneously breathing patient, as discussed in Chap. 36 and Fig. 36-4.[9] The work of breathing due to this inspiratory threshold load is roughly equal in magnitude to the excessive resistive work of breathing in patients with COPD exacerbations,[10] contributing to distress even when on the ventilator. Thus therapy should be directed at reducing auto-PEEP when it is present. Meanwhile, PEEP can be applied externally, greatly easing the effort required to trigger the breath. In intubated patients with acute-on-chronic respiratory failure, continuous positive airway pressure (CPAP) has been demonstrated to reduce the work of breathing by nearly 50%.[11] In patients with COPD and acute respiratory failure, nasal CPAP immediately improves respiratory rate, sensation

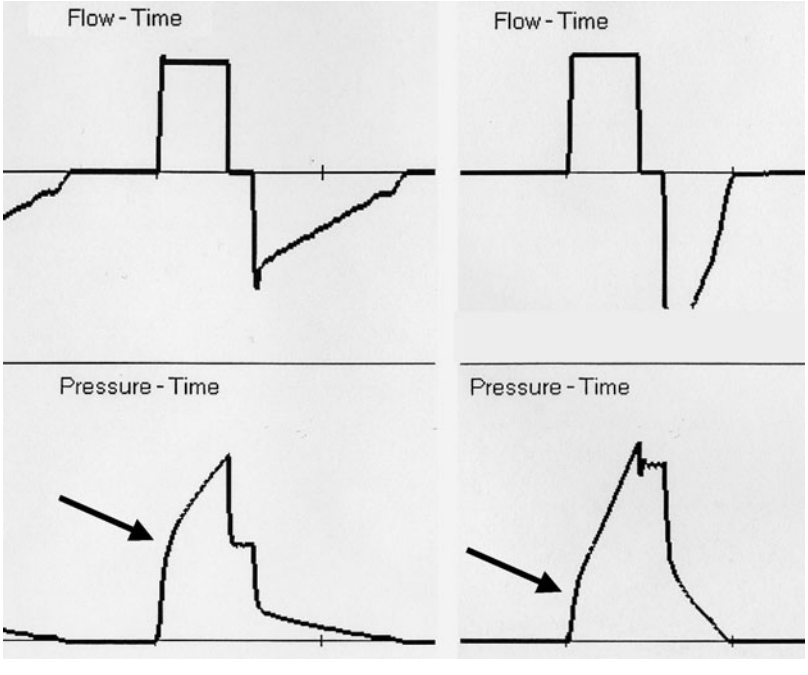

FIGURE 32-9 These two patients had elevated Ppeak to a similar degree but for differing reasons. The left-hand patient had airflow obstruction and an elevated Ppeak – Pplat, whereas the right-hand patient had a normal Ppeak – Pplat but an elevated Pplat (signaling abnormal respiratory system compliance). The Pao vs. time waveform changes slope at different pressures (*arrows*). The difference in pressure between PEEP and this "knee" is roughly equal to the Ppeak-to-Pplat difference.

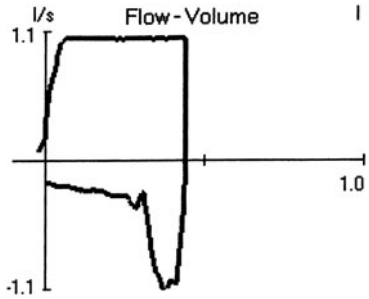

FIGURE 32-10 Flow-volume curve in a patient with airflow obstruction, showing the typical rapid decrement in expiratory flow as lung volume falls. Inspiratory flow is constant since this is set by the ventilator.

of dyspnea, and the partial pressure of carbon dioxide (P_{CO_2}).[12] The amount of auto-PEEP is largely independent of the set PEEP, since the airways of obstructed patients behave more like Starling resistors than like ohmic resistors, much as the rate of flow of water over a waterfall is unrelated to how far the water will fall into the pool below (Fig. 32-12). As long as the set PEEP is not higher than roughly 75% of the auto-PEEP, there is little effect on Palv, expiratory flow, or the magnitude of auto-PEEP,[13] although there are occasional exceptions.[14]

EFFECTS OF THERAPY

A reduction in airways resistance or a response to bronchodilators may be signaled by (1) reduced Pres (and lower Ppeak), (2) reduced auto-PEEP,[8] and (3) a more normal expiratory flow-volume curve. However, expiratory peak flow often does not increase with bronchodilators, because the lowered alveolar pressure (less auto-PEEP) reduces the driving pressure for exhalation.

Effect of Patient Effort

Flow and pressure waveforms are generally easy to analyze when patients are fully passive. On the other hand, an active patient presents numerous challenges and pitfalls. The discussion above always assumed a passive patient, but this is often not the case.

INSPIRATORY EFFORT PRECEDING MACHINE INSPIRATION

The inspiratory threshold load presented by auto-PEEP sometimes leads to a striking delay between the initiation of the patient's inspiratory effort and the onset of machine inspiration, sometimes consisting of several hundred milliseconds (Fig. 32-13). This delay, which signals the presence of auto-PEEP, is often shortened markedly by the addition of externally applied PEEP, a feature that may aid the setting of PEEP in obstructed patients.

EFFORT DURING MACHINE INSPIRATION

It has long been known that patients perform inspiratory work throughout an assist control breath.[15] With modern ventilator management shifted to greater patient effort, lower tidal volumes, less sedation, and only rare use of therapeutic paralysis, most patients exhibit effort on most ventilator breaths, no matter the mode of ventilation. This effort may not be obvious despite careful examination of the patient unless measures of intrathoracic pressure (esophageal, central venous, or wedge pressures) are available. Inspiratory effort may alter Pao (volume-preset breaths), inspiratory flow (pressure-preset breaths), or expiratory flow (any mode). Effort at the end of a volume-preset breath will affect the Ppeak and Pplat, making determination of respiratory system mechanics unreliable. The magnitude of this problem is illustrated in Fig. 32-14, where the degree of patient effort is hidden until therapeutic paralysis reveals it. Some patients have extremely high drive, despite being connected to a ventilator. They may desire inspiratory flow rates much higher than are typically ordered (often in excess of 100 L/min). Since inspiratory flow is set by the physician and ventilator during typical volume-preset ventilation, no amount of patient effort can raise the flow. The effect of this is that Pao may not become positive during the breath or may even become negative (since the Pao reflects the competition between the ventilator,

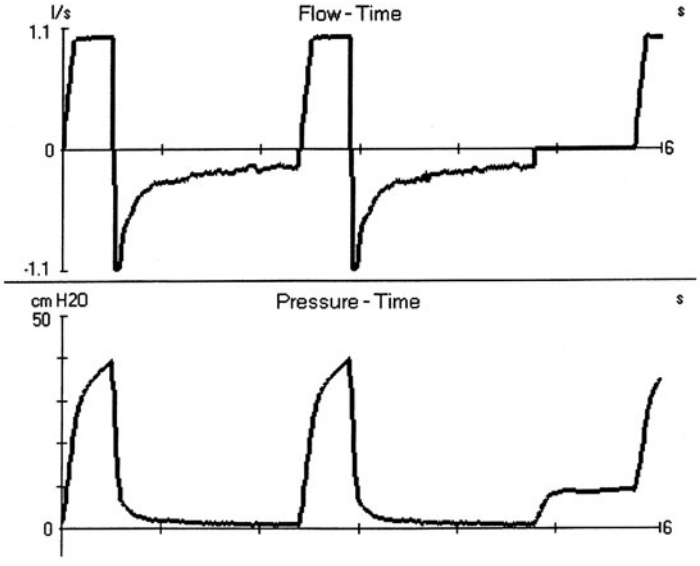

FIGURE 32-11 Auto-PEEP determined by the end-expiratory port occlusion technique. At the time a breath is due, the ventilator closes the inspiratory and expiratory ports and withholds the expected breath. The Pao during expiration of the second breath reflects the set PEEP (here zero) until the third breath is due, when the pressure suddenly rises, reflecting end-expiratory Palv, the auto-PEEP pressure. This patient has 10 cm H_2O auto-PEEP. The presence of auto-PEEP (but not its magnitude) is signaled by the presence of flow at end-expiration.

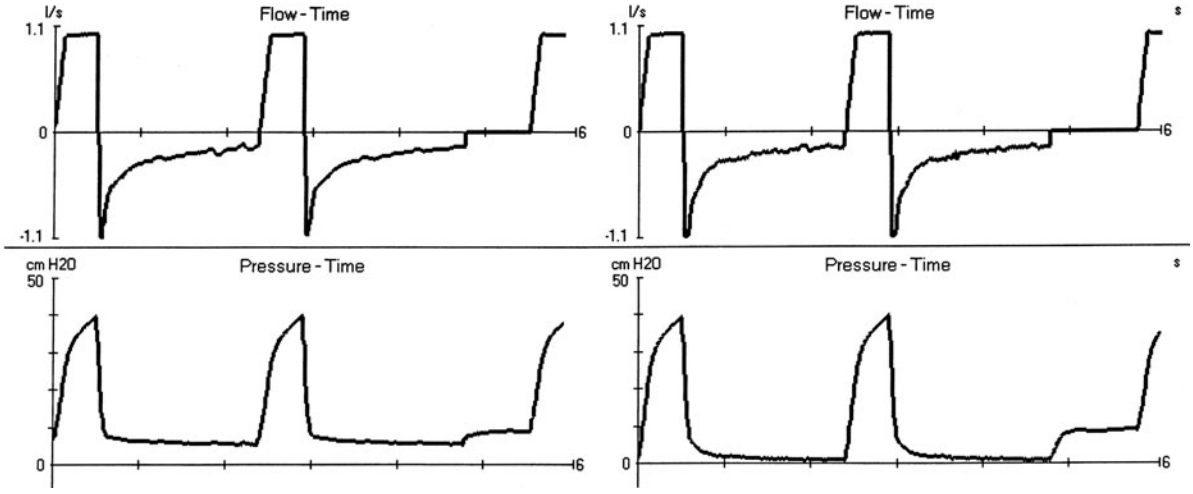

FIGURE 32-12 This is the same patient shown in Fig. 32-11, this time showing the measurement of auto-PEEP while the applied PEEP is 7 cm H_2O (*left panel*) or 0 cm H_2O (*right panel*). The measured auto-PEEP (10 cm H_2O) is identical.

tending to raise Pao, and the patient, tending to lower it). If Pao is not positive during inspiration, the ventilator is not doing work on the patient. That is, the patient's work of breathing would be no lower if the ventilator were disconnected. In extreme circumstances, the ventilator may even impede respiration. This represents a fundamental problem of ACV and SIMV: the greater the patient demand, the lower the Pao. One of the advantages of pressure-preset modes is that Pao is maintained, no matter how high the flow required, and these modes may be more comfortable for the patient with high drive (Fig. 32-15). It would even be sensible to augment pressure when the patient effort is high, and this rationale underlies PAV (see Chap. 36).

Clues to patient effort are often available from the airway pressure tracing when using a volume-preset mode, such as concavity of the rise in Pao, variability of Ppeak, and a dip in Pao before inspiration, indicating a triggering effort (Fig. 32-16). Since every breath of a passive patient should produce identical flow and pressure waveforms, an important clue to effort is simply a lack of uniformity of breaths.

EFFORT PERSISTING AFTER MACHINE INSPIRATION

One of the paradoxes of mechanical ventilation is that the patient's desired inspiratory duration (neural T_I) may bear no relationship to the ventilator inspiratory time (mechanical T_I). Mechanical T_I is set by the physician, either directly (as with PCV) or indirectly (as with ACV and SIMV), whereas neural T_I depends on arterial blood gases, the gas exchange efficiency of the lung, the impact of sedatives, and other central nervous system and patient features. In the usual setting, the patient desires a longer T_I than is set so that the patient's inspiratory effort persists, even while the ventilator has cycled to expiration. When neural and mechanical T_Is are dissimilar, patients may be uncomfortable. Pressure-support ventilation goes far toward solving this problem by switching off when

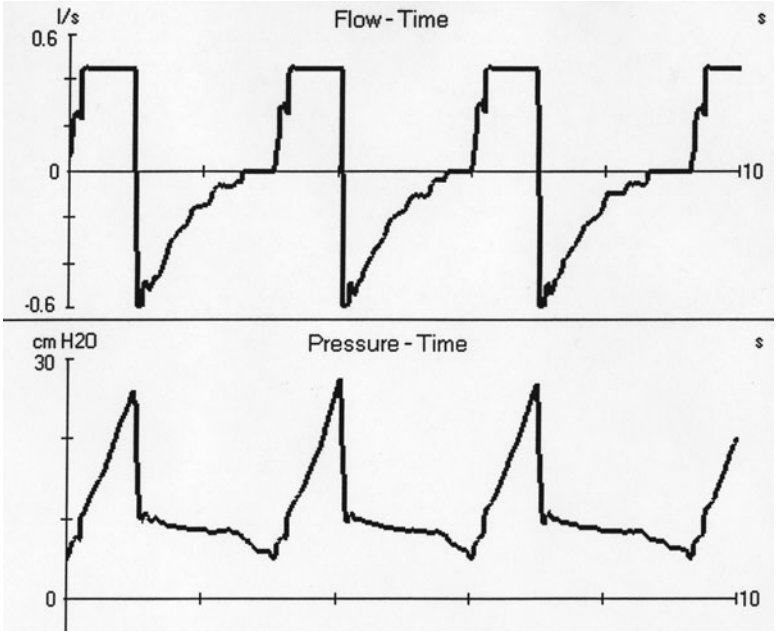

FIGURE 32-13 The pressure waveform in this patient shows a significant fall in Pao preceding each breath by several hundred milliseconds and lasting until the ventilator delivers a breath. This long delay was due to the difficulty experienced by the patient in overcoming a large amount of auto-PEEP. A casual inspection of the flow tracing might lead one to conclude that auto-PEEP was not present (since flow near end-expiration is zero), but flow has ceased only because the patient is making inspiratory effort. On other breaths (not shown) the patient failed to trigger at all, even while lowering Pao and stopping expiratory flow completely.

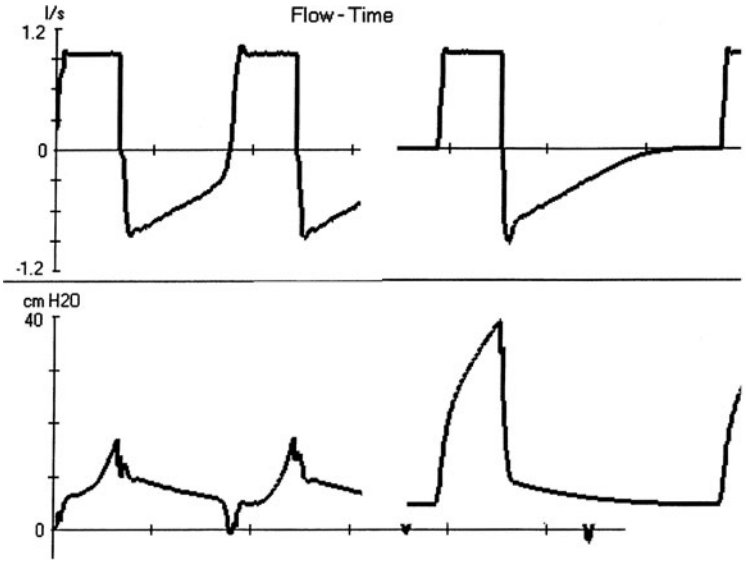

FIGURE 32-14 This patient had respiratory failure due to septic shock. Despite ACV at a high minute ventilation, the patient continued to work hard to breathe, lowering Pao during inspiration below the set PEEP level (*left panel*). Notice that Pao only rises at the termination of inspiration. Following therapeutic paralysis (*right panel*), Ppeak rises to 40 cm H_2O. The difference in Pao before and after paralysis reflects the very high work of breathing of this patient.

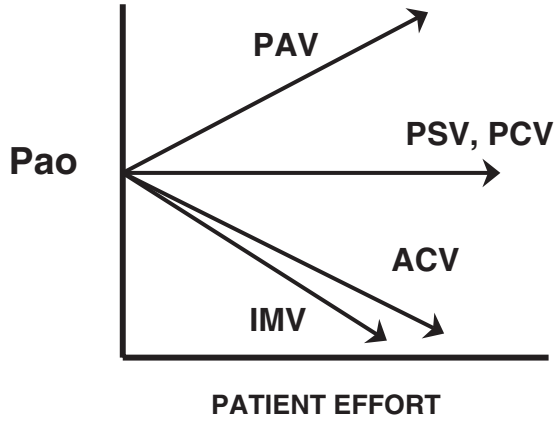
inspiratory flow falls, since reduced flow often correlates with the end of neural inspiration. In contrast, many patients ventilated with PCV or volume-preset modes rely on happenstance or sedatives to accommodate their neural T_I to the machine T_I (Fig. 32-17).

Postinspiratory effort can be recognized as loss of the usually rapid initial expiratory flow, as illustrated in Fig. 32-17, or by double- or triple-triggering. The patient shown in Fig. 32-18 was being ventilated with a lung-protective tidal volume (6 mL/kg ideal body weight [IBW]) for ARDS. Every breath actually consists of a double-triggered breath: exhaled total ventilation (V_T) alternated between 2 mL/kg and 10 mL/kg, showing that this patient was probably not receiving lung-protective ventilation, despite the set tidal volume. Ventilator T_I can be lengthened during volume-preset modes by increasing tidal volume (although this may conflict with lung-protective goals; see Chap. 37) or by reducing inspiratory flow (although this may prompt the patient to exert even more inspiratory effort).

A separate phenomenon is additional attempts to trigger the ventilator during expiration (Fig. 32-19). This is quite common, generally when there is auto-PEEP, and especially during PSV at high levels, and its clinical significance is not known.[16] When ventilator-dependent patients were subjected to increasing degrees of ventilator assistance (and demonstrated reduced inspiratory pressure-time product), the rate of ineffective triggering rose even while the total respiratory rate fell.[17] It is probably valuable to consider the impact of patient-ventilator asynchrony (PVA) in light of the patient's respiratory drive. When drive is high, PVA should be addressed by manipulation of the ventilator to improve the patient-ventilator interaction. If drive is low, however, PVA

FIGURE 32-15 This shows Pao as a function of patient effort during various modes of ventilation. Pressure-preset modes deliver a fixed pressure, whatever the effort, whereas volume-preset (constant flow) modes like ACV and IMV produce ever-decreasing pressure with increasing effort. IMV forces the patient to work even harder, since not all breaths are supported. PAV responds to increasing patient demand by augmenting flow.



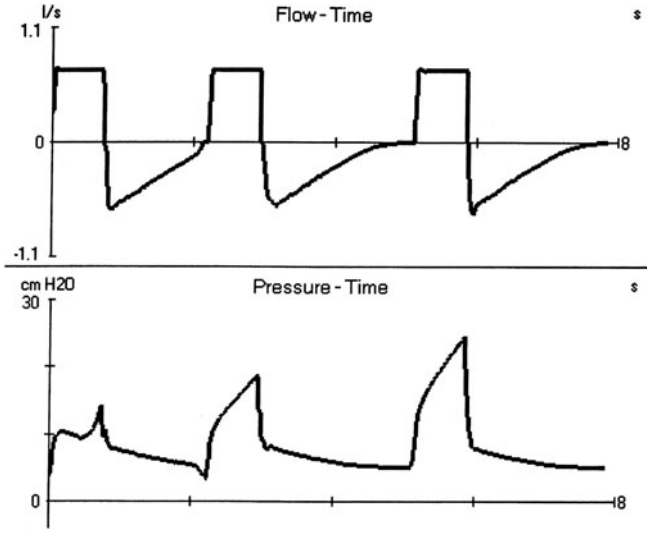


FIGURE 32-16 Signs of patient effort during constant flow, volume-preset ventilation include concavity of the Pao versus time waveform during inspiration; a drop in Pao before the breath indicating triggering; and variability in the height of the Ppeak. Notice the first breath shows marked concavity, the second reveals obvious triggering, and during the third the patient is passive.

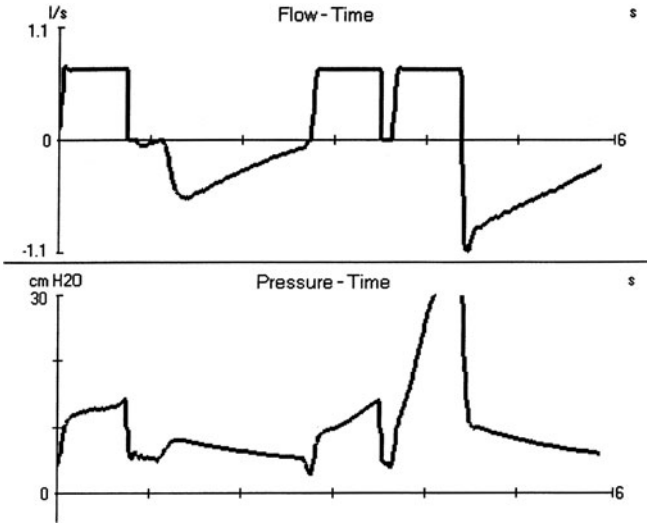

FIGURE 32-17 Volume assist controlled ventilation with a machine T_I of 0.7 second. Notice that expiratory flow does not follow the first breath until after a substantial delay because the patient is still contracting the inspiratory muscles. Only after a total neural T_I of about 1.2 seconds does the patient turn off the inspiratory muscles and begin to exhale. The same phenomenon is seen after the second breath, but this time the patient's continued inspiratory effort is sufficient to double-trigger the ventilator.

may simply indicate unloading of the respiratory system and no changes in ventilator settings are indicated.[18]

EXPIRATORY EFFORT

Patients may recruit expiratory muscles during machine inspiration or expiration. Expiratory effort during machine inspiration may raise Pao during ACV or SIMV, even setting off the pressure alarm, and reduce tidal volume on any mode. Expiratory effort at end-inspiration occasionally raises Pplat artifactually (Fig. 32-20). For this reason, it is prudent to view the waveform whenever measuring plateau pressure in order to confirm that there is a true plateau.

A more common problem is expiratory muscle recruitment throughout expiration, even to end-expiration, as is often seen in patients with severe airflow obstruction. Measured values of auto-PEEP may be artifactually elevated by expiratory effort[19] (as may hemodynamic pressures, as discussed below).

Patient-Ventilator Asynchrony

VENTILATION VIA ENDOTRACHEAL TUBE OR TRACHEOSTOMY

Patients vary greatly in their breathing pattern and desire for flow, tidal volume, rate, and T_I. Any particular initial ventilator settings are unlikely to coincide with the individual patient's needs.[16,17,20] Thus the initial settings should be considered a first approximation. Then, taking into account the patient-ventilator interaction, as judged by subjective patient comfort and waveform displays of flow and pressure, the settings can be tailored to the individual patient. At times, only modest adjustment will improve patient-ventilator synchrony or patient comfort (Fig. 32-21). The beneficial impact of such changes may be evident not just in the flow and pressure waveforms, but in hemodynamic waveforms as well (Fig. 32-22).

A stepwise approach to adjusting the ventilator to the patient during volume-preset ventilation involves changing (1) tidal volume, (2) rate, (3) inspiratory flow rate, (4) T_I, itself a consequence of tidal volume and flow rate, and (5) PEEP to counter auto-PEEP. Rarely, rise time may require consideration, as discussed below. For patients on PCV, the steps are to change (1) P_I, (2) T_I, (3) rate, and (4) PEEP. An example of this process is shown in Figure 32-23. Of course, any of these adjustments can cause problems or create conflict with other goals of ventilation. For example, raising rate (say to match

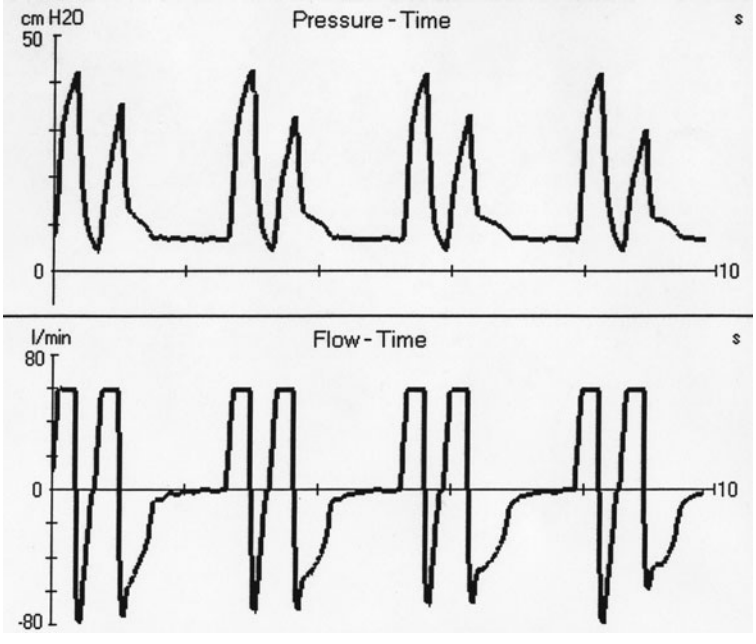

FIGURE 32-18 A patient with ARDS, ventilated with lung-protective settings of tidal volume of 6 mL/kg ideal body weight. Notice that every breath actually consists of two stacked breaths, effectively doubling the tidal volume, since only a trivial amount of each initial breath is exhaled before the next breath is triggered.

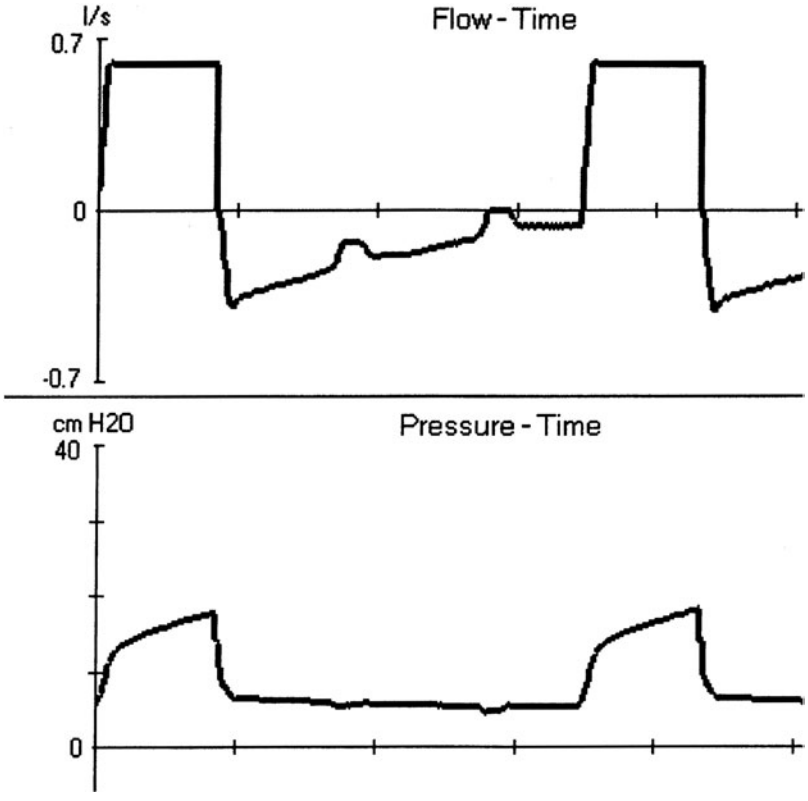

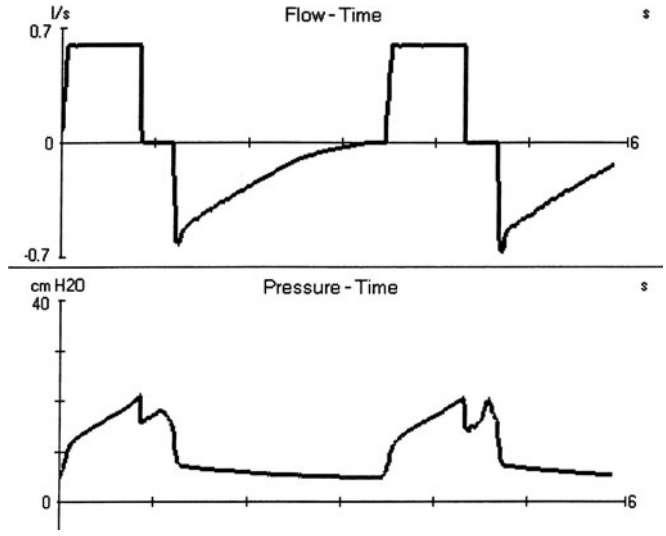

FIGURE 32-19 Patient with airflow obstruction ventilated with ACV. Notice the brief reductions in expiratory flow between the two ventilator breaths, both signaling failed attempts by the patient to trigger the ventilator. The presence of auto-PEEP contributes to the difficulty in triggering.

a patient's high drive) may cause undesired auto-PEEP or hypocapnia, or raising tidal volume to lengthen machine T_I may violate lung-protective goals. Often additional sedation is required to accommodate the patient to the ventilator, but this is appropriate only after steps have been taken to accommodate the ventilator to the patient.

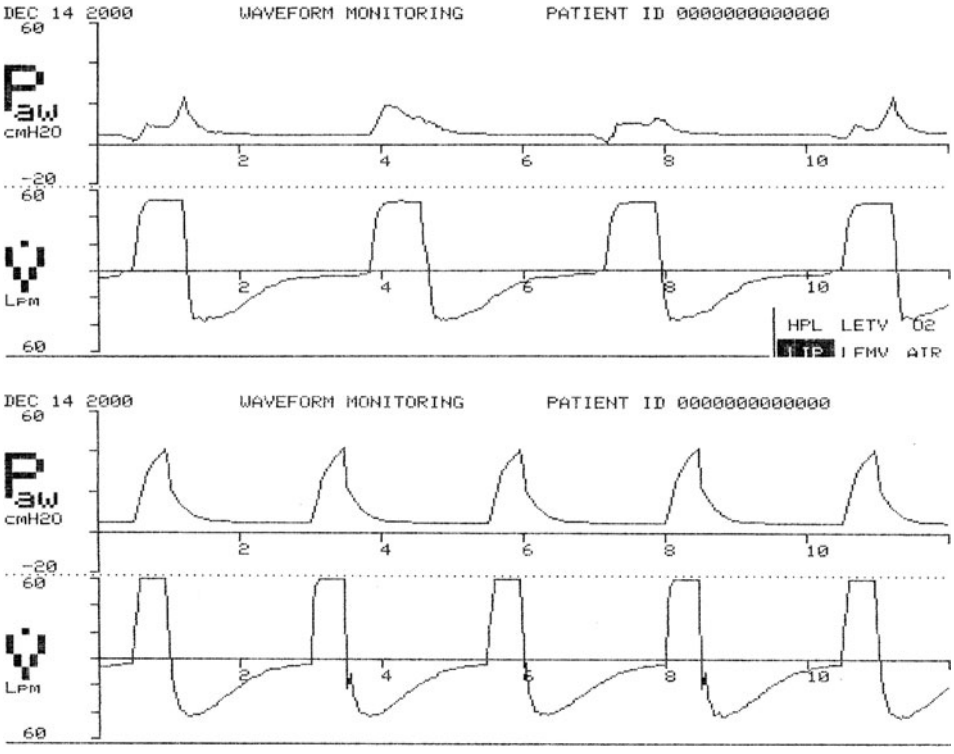
FIGURE 32-20 An end-inspiratory pause is set in order to measure Pplat. Notice that there really is no "plateau," but rather that Pao rises during the pause. This effect is due to expiratory effort, artifactually raising Pao following inspiration.

THE NONINVASIVELY VENTILATED PATIENT

During NIV, the patient and ventilator are coupled less tightly than when an endotracheal tube or tracheostomy is used. That is, the patient and ventilator are more easily asynchronous during NIV and it is even more important to carefully adapt ventilator to patient in order to improve the success of NIV.[18]

Two mechanisms of patient-ventilator asynchrony (PVA) are common. The first is failure of the patient to lower the proximal airway pressure (mask pressure) sufficiently to be able to trigger, due to the presence of auto-PEEP as discussed above. Adding PEEP is helpful to improve synchrony, but it is not generally practical to measure the amount of auto-PEEP in these patients, due to their effort. Rather, the clinician must adjust the machine PEEP upwards while assessing the patient's triggering effort. This modification can be greatly aided by the analysis of flow and pressure waveform displays. We begin routinely with the PEEP set at 2 or 3 cm H_2O and find that maximal benefit is reached between 4 and 10 cm H_2O.

The second common mechanism for PVA is failure of the ventilator to detect end-inspiration because the patient's subsiding effort is cloaked by a mask leak. Most PSV ventilators terminate inspiration when inspiratory flow falls to a preset threshold, often at an arbitrary low value of flow or at a fixed percentage of the peak inspiratory flow. Mask leaks prevent the flow from falling to this threshold, so the ventilator fails to switch off the inspiratory pressure, even while the patient is making active expiratory efforts. This serves to increase patient discomfort and the work of breathing. Using other methods for terminating inspiration, such as time-cycled pressure-support or ACV, can minimize this problem. Six patients with acute lung injury were studied during NIV with both conventional flow-cycled PSV and time-cycled PSV while the



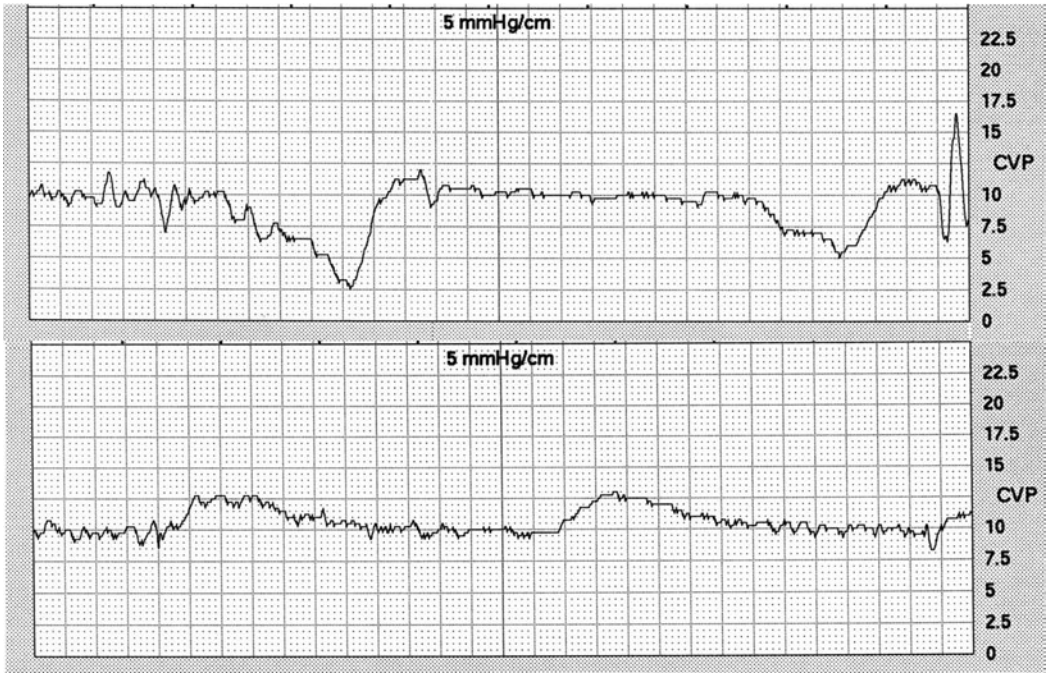


FIGURE 32-21 This patient was being ventilated for severe sepsis, yet Pao (*top panel*) was only slightly and inconsistently above PEEP during inspiration, indicating substantial patient effort. Increasing inspiratory flow rate modestly and raising the rate (at the same tidal volume) changed the pressure waveform greatly (*bottom panel*). Now all breaths are identical, each complex is convex upwards, and there are no signs of triggering (i.e., the patient appears passive).

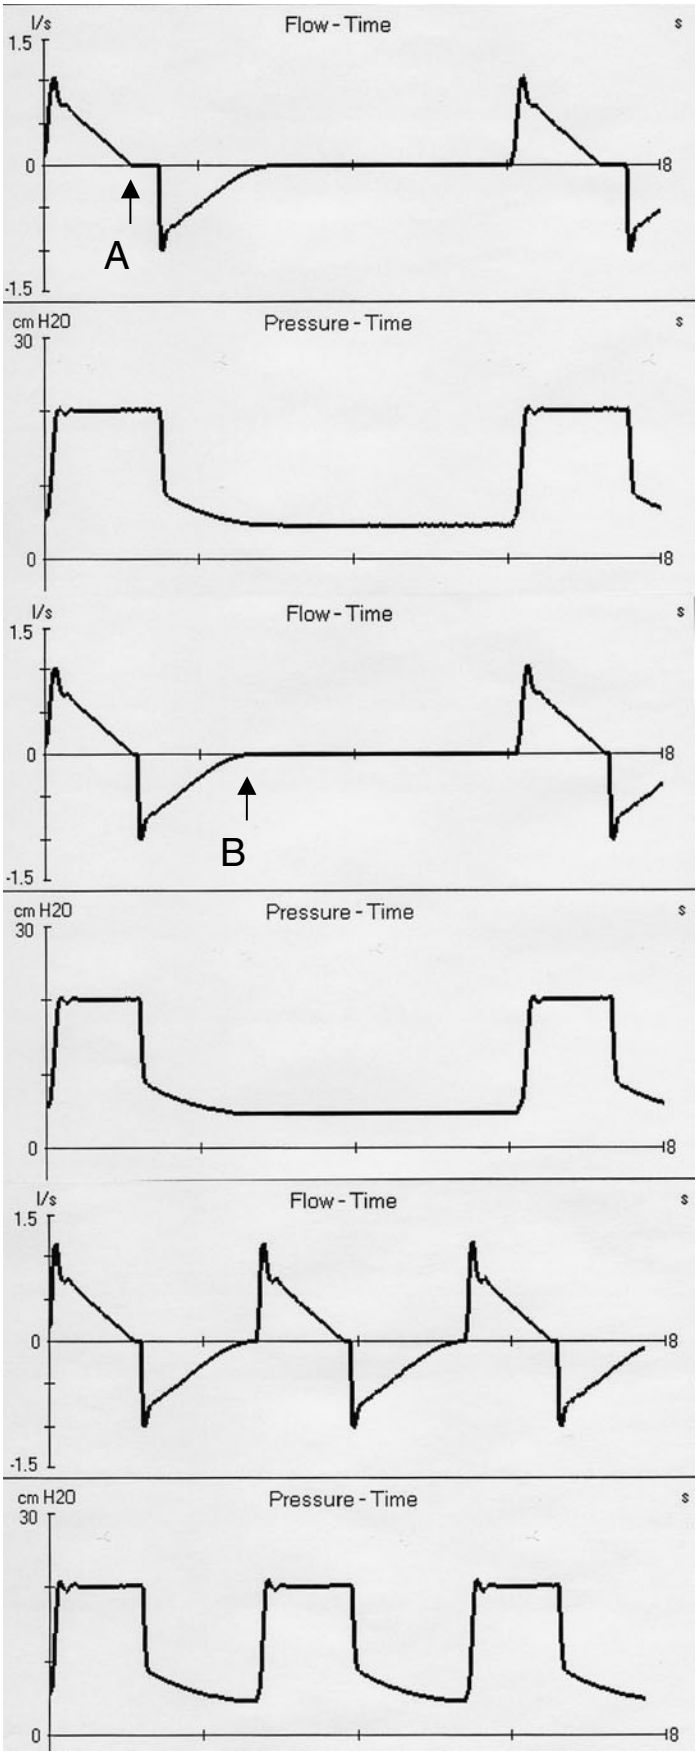
masks were adjusted to facilitate leaks.[21] Time-cycled PSV significantly reduced the work of breathing (as judged by the esophageal pressure tidal swing and pressure-time product) and also more dramatically lowered the respiratory rate.

Displays of inspiratory and expiratory flows can be very valuable in detecting PVA and further assist the intensivist in modifying the mask or ventilator to improve synchrony and comfort. Carefully observing the patient-ventilator interaction and modifying the settings accordingly requires substantial time in the first hour on the part of the physician-respiratory therapist-nurse team.

FIGURE 32-22 Central venous pressure tracings in the patient shown in Fig. 32-21. Notice the periodic falls in pressure (coinciding with inspiration) in the top panel (before ventilator adjustment), which are replaced by positive deflections following ventilator adjustment (showing that pleural pressure is rising during inspiration in this now passive patient).



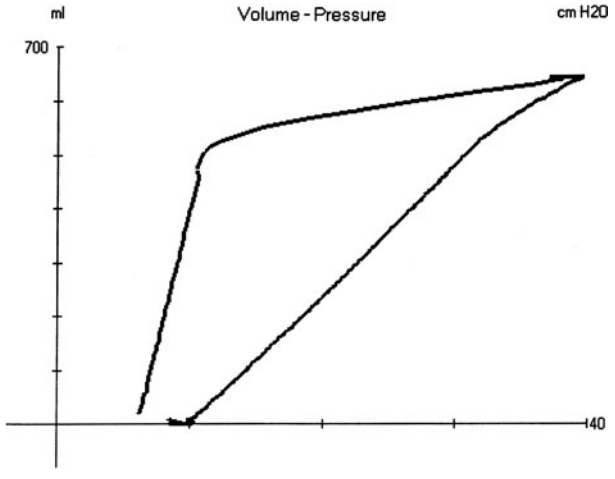


FIGURE 32-23 The settings on PCV are adjusted during ventilation of a passive, hypercapnic patient. The top two waveforms show flow and pressure with initial settings of $P_I = 20$; PEEP = 5; f = 10; $T_I = 1.5$ seconds. Note that flow ceases before the end of the set T_I (*arrow A*), indicating that T_I is set too long for this patient. The next two panels show T_I reduced to 1.2 seconds to match the patient's mechanics. Now expiratory flow ceases (*arrow B*) well before the subsequent breath, indicating that the rate can be raised without causing auto-PEEP. The final two panels show the flow and pressure waveforms after the rate is raised from 10 to 22. Any further increase in rate will create some degree of auto-PEEP.

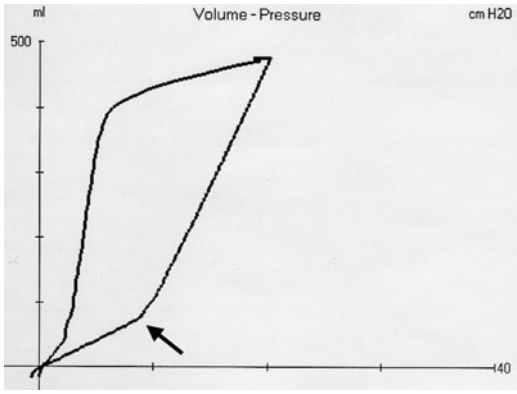
Volume-Pressure Curves in Acute Respiratory Distress Syndrome

Some intensivists have recommended adjusting the ventilator based on the inspiratory volume-pressure (VP) curve.[22] Specifically, the upper end of the curve is examined for an upper inflection point (UIP), thought to signify alveolar overdistention (Fig. 32-24). If a UIP is present the tidal volume should be reduced, according to this view. The bottom part of the curve can be examined in an attempt to identify a lower inflection point (LIP), which may indicate recruitment during inspiration (Fig. 32-25). Such repeated recruitment (and during expiration derecruitment) has been shown in animal models of ARDS to be detrimental.[23] One must take care to reduce the inspiratory flow rate to a low level (e.g., 15 liters per minute or 0.25 liters per second) when displaying the VP curve in order to avoid a flow-related artifact. If the flow rate is not reduced, the VP curve appears to show a LIP regardless of whether there is alveolar recruitment (Fig. 32-26).

There remain multiple problems with using VP curves to guide ventilator management in patients with ALI and ARDS. First, obtaining the VP curve is tedious: it requires physician time; detection of inflection points requires very careful analysis; any inflection points probably change as the lung changes, so repeated measures might be needed to guide ventilator settings; any patient effort makes the curve uninterpretable; the flow rate must be greatly reduced during measurement, which in most patients requires a temporary reduction in breathing rate (in order not to drastically curtail T_E), during which the patient must remain fully passive; lower inflection points may not correlate with recruitment and derecruitment,[24] and most importantly, this method has not been shown to improve outcomes despite its theoretical elegance. A recent study by the ARDS Network failed to show a benefit to a PEEP level higher than "least PEEP" when applied in patients ventilated with tidal volumes of 6 mL/kg IBW.

FIGURE 32-24 During a slow inspiration, the Pao reflects mostly the respiratory system compliance. The falling slope of the inspiratory limb once the volume exceeds about 550 mL indicates alveolar overdistention. There is no lower inflection point in this patient on 10 cm H_2O PEEP.



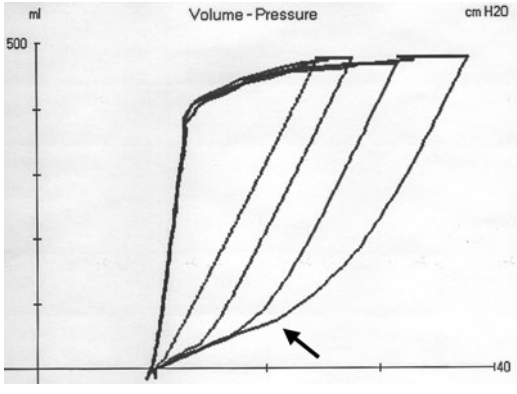


FIGURE 32-25 A pressure-volume loop during ACV, zero PEEP, and very low flow (12 L/min), showing a clear change in slope of the volume-pressure loop (a lower inflection point).

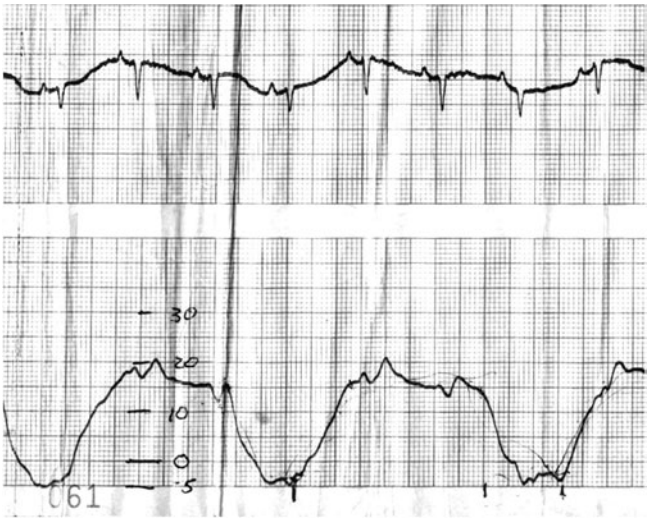
Measuring Hemodynamic Pressures

Respiratory muscle activity greatly affects intrathoracic pressure, which alters measured hemodynamic values. By convention, hemodynamic values such as Pra and Ppw are measured at end-expiration since the respiratory muscles are most likely to be passive at end-expiration. It can be quite difficult to determine the point of end-expiration from a hemodynamic tracing, mostly because of respiratory activity (Fig. 32-27). This can lead to incorrect measurement of important pressures, perhaps prompting incorrect treatments. In the modern era of low tidal volume ventilation, reduced reliance on sedatives, and sparing use of therapeutic paralysis, effort is more the rule than the exception.

End-expiration can often be detected in the hemodynamic waveforms by paying attention to inspiratory-to-expiratory ratios, the nature of the respiratory rise in pressure (which differs between the ventilator-induced rise in the passive patient and the spontaneous expiratory rise in the active patient), and the abruptness of the falls in pressure, as discussed in Fig. 32-27. Additional confidence can be gained at the bedside

FIGURE 32-26 Several volume pressure loops are superimposed while the inspiratory flow rate is reduced from 60 L/min (*largest loop*) to 45 L/min to 30 L/min, and finally to 12 L/min. Notice that what appears to be a LIP moves leftward and becomes progressively less evident as flow is reduced, showing that this is not a LIP but rather an artifact of the changing flow early in the breath.



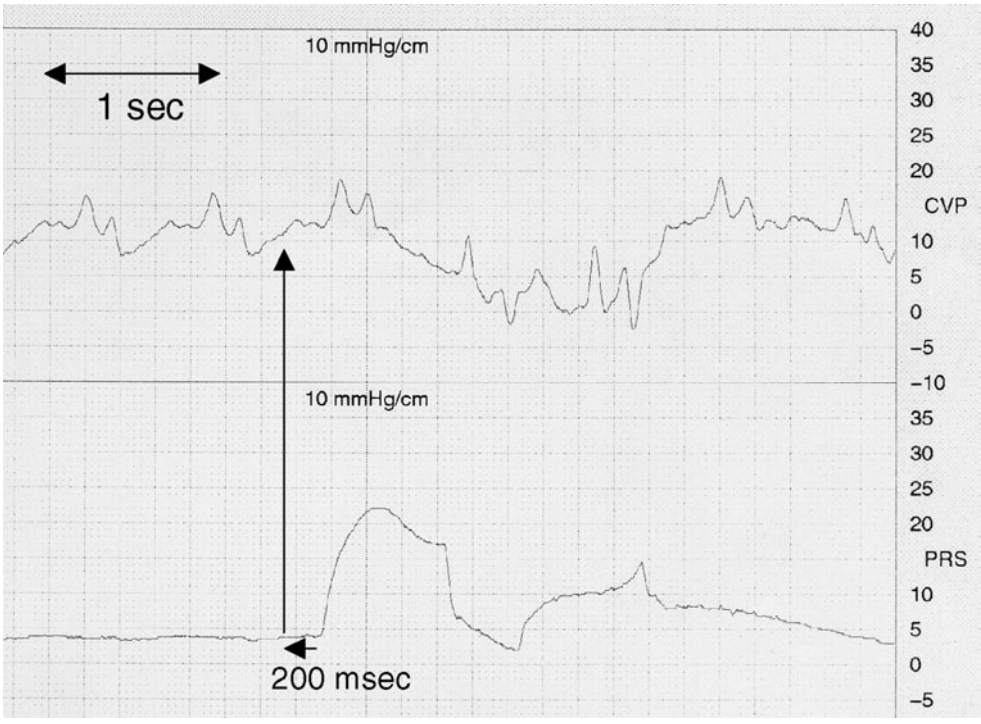


FIGURE 32-27 Wedge pressure (Ppw) tracing in this ventilated patient who was making strong respiratory efforts. Since the Ppw varies from 20 to −5 cm H_2O, reading the tracing properly (at end-expiration) is vitally important. If this patient were passive, one would expect the end-expiratory pressure to be roughly −5 cm H_2O, but then the inspiratory-to-expiratory (I:E) ratio would be 2:1 (inverse ratio ventilation), the fall in pressure during (presumed) expiration too abrupt, and the (presumed) inspiratory pressure would continue to rise (rather than plateauing) throughout the breath. Instead this ventilated patient is quite active and pulls the Ppw down during inspiration. The end-expiratory pressure is 15 cm H_2O.

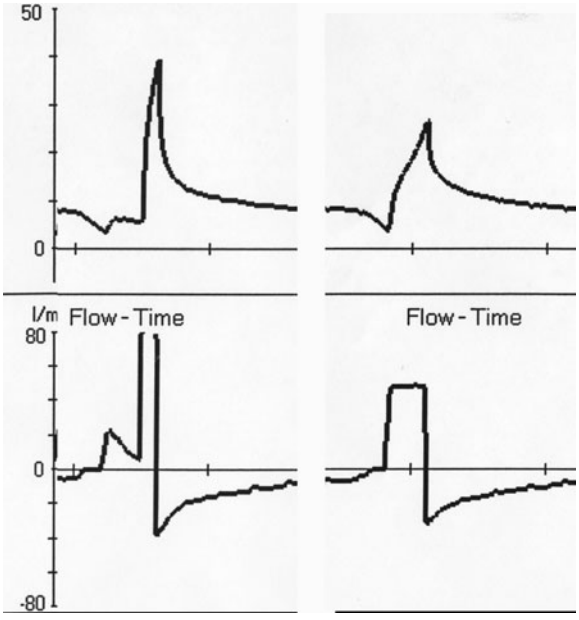
by examining the patient and ventilator while simultaneously displaying the hemodynamic tracing in question. Perhaps the simplest and most accurate approach, however, is to connect the ventilator circuit to a pressure transducer and display this on the same time scale as the hemodynamic waveform. End-expiration is readily identified on the ventilator pressure waveform (Fig. 32-28). One then moves 200 milliseconds earlier on the time scale (since patient effort begins before machine inspiration, especially in the patient with auto-PEEP, as discussed above) and measures the hemodynamic pressure there.

Unusual Problems Revealed by Waveform Analysis

Modern ventilators allow remarkable control over many aspects of ventilation beyond those related to tidal volume, rate, and PEEP. The ability to adjust flow profiles, flow rates, and rise times gives the intensivist tools for improving patient-ventilator synchrony and patient comfort. At the same time, however, changing some of these parameters has unanticipated consequences, many of which are revealed by comparing flow or pressure waveforms before and after the intervention. For example, the first set of pressure and flow tracings shown in Fig. 32-29 were seen in a patient ventilated with ACV and a rise time of 10% (meaning that 10% of the total respiratory cycle is devoted towards raising flow towards its peak value). Pressure does not rise above the PEEP value for the first two-thirds of the breath. The basis for this is readily evident from the flow tracing, which shows that flow is

FIGURE 32-28 The least equivocal method for identifying end-expiration on a vascular waveform is to simultaneously display the vascular pressure (here the CVP; *top waveform*) and the Pao (PRS; *bottom waveform*). A point 200 milliseconds before the Pao rises (signaling inspiration) generally precedes the patient's inspiratory effort and is a good marker for end-expiration. Because the CVP varies during respiration in this patient, selecting end-expiration reproducibly is essential to getting reliable pressures. Here the CVP is 10 cm H_2O.



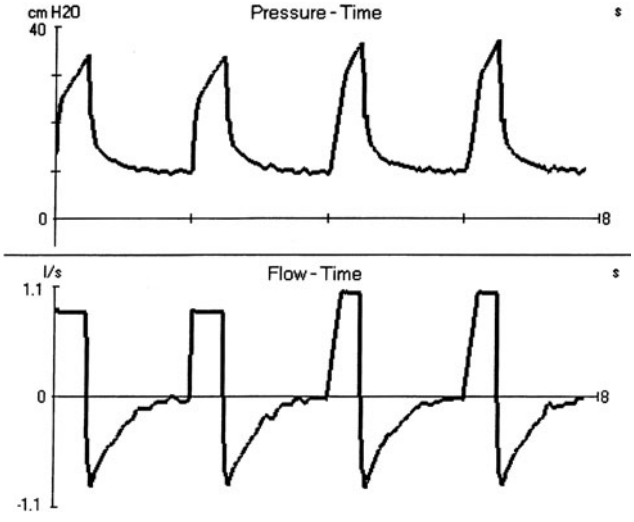


FIGURE 32-29 This patient was ventilated with ACV and a rise time of 10% (*left panel*). Notice that inspiratory flow and pressure are very low for the first two-thirds of the breath, then both rise abruptly. This occurs because the patient had somewhat increased drive and tried to pull inspiratory flow higher than that allowed if the rise time was to remain at 10%. The ventilator resists the patient's effort until finally allowing adequate flow once the 10% time has passed. This same phenomenon was apparent (although less dramatic) when the rise time was set at the default value of 5% (not shown). The right hand panel shows the same patient once the rise time was reduced to 1%. Notice that Pao rises sooner, flow is constant through the breath, and the ventilator is performing more work (although the patient is still not passive).

positive, but excruciatingly slow, for the first two-thirds of the breath. Flow is maintained low because the ventilator is not allowed to give the peak flow until 10% of the respiratory cycle has elapsed. If the patient tries to get more flow before this time, the ventilator simply throttles flow down further. Obviously, this is counterproductive, forcing the patient to work excessively. Yet no alarm will sound; the only clue to this problem is found in the ventilator waveforms. When the rise time was set appropriately (see Fig. 32-29), patient effort was reduced as the ventilator took on more of the burden of the work of breathing.

FIGURE 32-30 During ACV, the rise time was raised from 1% to 10%. Notice that peak airway pressure rises measurably despite no change in the patient's mechanics or tidal volume.

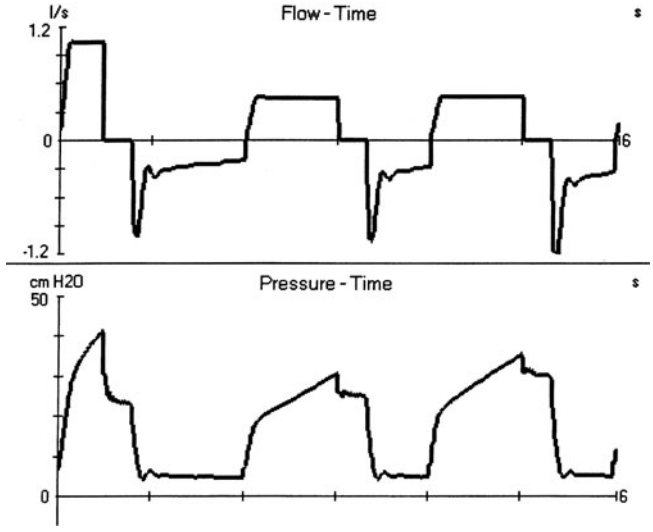

FIGURE 32-31 During ACV, the inspiratory flow was reduced from 1 L/s to 0.5 L/s. Notice that Ppeak falls with the second breath (as does Pres), but then begins to rise again by the third breath. This occurs because the shortened T_E worsens auto-PEEP, raising the Ppeak again. This process will continue to raise the auto-PEEP for several breaths until Palv rises sufficiently to drive the full tidal volume out during the shorter T_E.

Lengthening the rise time also affects peak flow, since as the percentage of time at peak flow is reduced, the amount of flow must be raised in order to keep T_I constant (Fig. 32-30). Therefore changing rise time can alter Ppeak, potentially confounding assessment of the respiratory system mechanics or response to therapy.

Many ventilators are provided with an option during volume-preset modes to give constant flow (the standard approach) or a decelerating (or sine wave) flow profile. Although the decelerating flow profile most closely mimics the flow pattern seen with PSV and PCV, there is no evidence that this pattern is either better or more comfortable than constant flow. The decelerating profile is most often selected when Pao is very high and there is concern for barotrauma. The effect of this is to lower Ppeak since at end-inspiration, when lung recoil is greatest, flow is much reduced. Yet an unavoidable consequence of lowering the flow late in the breath is that T_I is lengthened (and T_E shortened). This almost always serves to cause or exacerbate auto-PEEP (see Fig. 32-2). We strongly discourage the use of any flow profile other than square.

Even when inspiratory flow is kept constant throughout the breath, lowering its value can have a marked impact on auto-PEEP (Fig. 32-31). There are few reasons to ever ventilate a patient with the inspiratory flow set lower than 50 L/min (0.83 L/s).

Chapter 33

NONINVASIVE VENTILATION

LAURENT BROCHARD

KEY POINTS

- *Many patients with ventilatory failure can be successfully managed with noninvasive positive pressure ventilation (NIPPV).*
- *NIPPV improves gas exchange, reduces the work of breathing, and relieves dyspnea.*
- *Patients most likely to benefit include those with acute hypercapnic exacerbations of chronic obstructive pulmonary disease (COPD) or hypercapnic forms of acute cardiogenic pulmonary edema.*
- *In selected patients with acute hypoxemic nonhypercapnic respiratory failure, NIPPV may obviate the need for endotracheal intubation. Selection may require exclusion of patients with hemodynamic instability, central neurologic dysfunction, or an inability to protect the upper airway.*
- *In severely hypoxemic patients, undiscerning use of NIPPV may inappropriately delay intubation. In these patients, the decision to switch to endotracheal intubation should be made early.*
- *The use of NIPPV to treat postextubation respiratory distress has not been found to be superior to conventional management.*
- *The first hour on NIPPV is crucial in predicting the outcome and requires that experienced physicians, nurses, or respiratory therapists spend considerable time at the bedside.*
- *A favorable response to NIPPV is usually apparent within the first hour. Absence of improvements in dyspnea, respiratory rate, and gas exchange within 1 hour strongly suggests a need for endotracheal intubation.*
- *Typical settings in a patient with COPD include pressure support of 10 cm H_2O above a positive end-expiratory pressure (PEEP) of 5 cm H_2O.*
- *In appropriately selected patients, NIPPV produces better outcomes than does endotracheal mechanical ventilation.*

Noninvasive positive pressure ventilation (NIPPV) has emerged as a valuable tool in the treatment of acute respiratory failure (ARF). NIPPV can substantially reduce the need for endotracheal intubation (ETI) and mechanical ventilation (MV). In selected patients, the benefits of NIPPV include decreased rates of adverse events associated with MV, shorter time spent in the ICU and hospital, and lower mortality rates. Patients with hypercapnic forms of ARF are most likely to benefit, but NIPPV may also improve outcomes of carefully selected patients with hypoxemic respiratory failure. This chapter reviews the evidence supporting NIPPV use in patients with ARF.

Rationale and Objective

When MV was first developed for widespread clinical use during the poliomyelitis epidemic, attention focused on replacing the failing respiratory muscles by a perithoracic pump. This led to the development of the "iron lung," the first form of noninvasive ventilation, which saved many lives.[1,2] However, the device was cumbersome and impeded patient care. In addition, the iron lung proved of limited efficacy in the treatment of parenchymal lung disease. Thus delivery of mechanical assistance through an endotracheal tube that provided access to the lower airway was considered a significant advance, and positive pressure ventilation became the standard for MV.

Soon after the introduction of endotracheal MV, many complications of positive pressure ventilation were identified.[3,4] These complications were found to be common and generated concern about the invasiveness of MV. ETI itself has been implicated in a large number of complications. Of these, some are directly related to the procedure, such as cardiac arrest following laryngospasm or difficult tube insertion and laryngeal or tracheal injury leading to long-term sequelae. Others are ascribable to the fact that the endotracheal tube bypasses the barrier of the upper airway: an important example is nosocomial pneumonia, which carries its own risk of mortality. Other complications are indirectly related to ETI, such as the need for sedation, which often prolongs weaning. These major safety considerations prompted efforts to develop noninvasive methods for delivering positive pressure ventilation. Thus, in patients with ARF, the main goal of NIPPV is to provide ventilatory assistance while lowering the risk of adverse events by reducing the need for invasive MV. Convincing evidence that NIPPV diminishes the risk of infectious complications has been obtained not only from pooled analyses of data from randomized controlled trials, but also from multivariate analyses of large cohort studies and from carefully performed case-controlled studies, all of which show large decreases in all categories of nosocomial infection.[5–7] The reason is that NIPPV is associated with a reduction in the overall invasiveness of patient management: sedation is given at lower levels or not at all, and the use of central venous lines, urinary catheters, and other invasive devices is considerably reduced, as compared to patients receiving endotracheal MV.[8]

Another important factor in promoting the use of NIPPV is the growing number of patients who are either unwilling to accept ETI or considered poor candidates for endotracheal MV because of their poor underlying health status.[9,10] In these patients, NIPPV can offer a chance of recovery with a low risk of complications. Further, by postponing ETI, NIPPV may provide a window of opportunity for the physician, family, and patient to make informed decisions about the goals of therapy.

EPIDEMIOLOGY

The use of NIPPV in the acute setting has increased markedly since the first small case-series were published in the last decade of the twentieth century.[11,12] A multicenter international study on MV was reported in 1998 by Esteban and colleagues.[13] In this study, NIPPV was used in about 5% of ICU patients who required MV. However, because only patients who received MV for longer than 12 hours were included, the study may have missed many patients treated with NIPPV. In a similar observational study performed in 42 ICUs in France in 1997, 16% of patients with ARF received NIPPV as the first-line method of ventilatory support.[14]

Copyright © 2005, 1998, 1992 by The McGraw-Hill Companies, Inc. Click here for terms of use.

Importantly, among those patients who were not intubated before ICU admission, 35% received first-line NIPPV. In 2002, the same group did an identical study in 72 ICUs in France, including most of those in the previous study.[15] In the overall population of admitted patients, the percentage of patients who required some form of ventilatory support was the same in the two study periods. In 2002, the rates of NIPPV use among patients requiring ventilatory support had increased to 24% overall and 52% among patients who were not intubated before ICU admission. Although these results cannot be extrapolated to all countries, they indicate a strong trend toward increasing use of NIPPV in ICU patients with a variety of conditions, and they also reflect the current tendency to reduce the invasiveness of ICU management. Although many patients can be expected to benefit from this approach, great care should be taken to identify those patients who require immediate ETI, as delaying this procedure may reduce the chances of recovery in some patients.

EQUIPMENT

Several types of ventilator can be used to deliver NIPPV to patients with ARF. Turbine ventilators specifically designed for NIPPV have been developed, but standard ICU ventilators can be used as well. Turbine ventilators designed for NIPPV deliver two levels of positive airway pressure synchronized on patient trigger or time trigger, and reproducing pressure support ventilation or pressure control plus PEEP.[16] These ventilators are designed to compensate for air leakage, which is an important characteristic of NIPPV.[17] Although the meaning of "leak compensation" varies from one ventilator to the next, leakage compensation usually results in less triggering dysfunction than with standard ventilators. The main adverse effect of leakage on inspiratory triggering is auto-cycling. Auto-cycling is thought to be more common when high levels of PEEP are used. The cycling mechanism at end-inspiration can also be affected by leakage. When leakage is marked, the ventilator may be unable to recognize the end of inspiration based on flow rate deceleration, unless the unit is equipped with a special adaptive mechanism. This mechanism exists in turbine ventilators and in some ICU ventilators offering an NIPPV option. Adequate patient monitoring may be essential to assess patient-ventilator interaction, to detect leaks, and to fine-tune pressure levels. Bench comparisons assessing in vitro ventilator performance suggest that both turbine ventilators specially designed for NIPPV and late-generation standard ICU ventilators are satisfactory for delivering NIPPV to ICU patients with severe dyspnea.[16–19]

The use of an ICU ventilator that works from wall gas supply requires warming and humidification of the gas prior to airway delivery. With endotracheal MV, the gas temperature drops in the endotracheal tube. This does not occur with NIPPV, and in addition warm gas at the mouth may be difficult for the patient to tolerate. Therefore, lower gas temperatures are used for NIPPV than for endotracheal MV. One option is to use a heat and moisture exchanger. Unfortunately, the internal volume of these devices imposes an additional workload on the patient by generating CO_2 rebreathing. In patients with hypercapnic respiratory failure, this diminishes the effectiveness of NIPPV in reducing blood CO_2 levels and correcting respiratory acidosis.[20,21] A similar problem of CO_2 rebreathing occurs when turbine ventilators (using ambient room air) equipped with a one-line circuit are used with low levels of PEEP.[22,23] The expiratory flow generated to create the PEEP level is also used to flush the exhaled CO_2 from the circuit. With low PEEP levels, high minute ventilation, and/or a high respiratory rate, this can have adverse clinical effects that may require addition of a nonrebreathing valve to the circuit.

The interface used to connect the patient to the ventilator is usually a full face mask covering both the nose and the mouth. Although nasal interfaces are available, their use in ICU patients frequently results in major leakage through the mouth that diminishes the effectiveness of NIPPV and promotes patient-ventilator asynchrony and discomfort.[24,25] Full face masks are responsible for unwanted effects including skin breakdown over the nose, conjunctivitis related to leakage of air directed toward the eyes, rebreathing, claustrophobia, and overall discomfort.[12,26] These problems prompted efforts to design improved interfaces. The first improvement consisted in varying the pressure sites on the face to achieve better tolerance during prolonged use, and subsequently much larger masks enclosing the entire face or head were developed.[27,28] Use of a helmet has been suggested, primarily for patients with acute hypoxemic respiratory failure.[29–31] Because helmets may induce more rebreathing than other masks, they may be less suitable for patients with hypercapnic respiratory failure. The helmet probably markedly improves patient comfort and tolerance, at the price, however, of decreased effectiveness in unloading the respiratory muscles. This latter point is of importance since several studies have established that good clinical tolerance is crucial to successful NIPPV. In their large observational survey, Carlucci and colleagues identified two independent predictors of failure: the severity score (as assessed by the Simplified Acute Physiology Score [SAPS] II) and clinical tolerance.[14] Interestingly, recent physiologic studies with integral masks compared to standard full face masks seem to indicate comparable efficacy in terms of respiratory muscle unloading, suggesting that the theoretical risk of rebreathing associated with the large internal volume may be small or nonexistent in clinical practice.[32,33]

ACUTE EXACERBATION OF CHRONIC RESPIRATORY FAILURE

Many of the studies in the field of NIPPV have been performed in patients with obstructive disease, mainly chronic obstructive pulmonary disease (COPD).[12,34–38] All forms of acute or chronic ventilatory failure share several pathophysiologic pathways, but major differences exist as well. A few data suggest that NIPPV may be less effective in patients with chronic restrictive lung disease than in patients with COPD.[39]

PATHOPHYSIOLOGY

Exacerbation of COPD is a common cause of admission to the hospital and ICU. In addition to worsening of dyspnea and bronchitic symptoms and to development of right ventricular failure and encephalopathy, rapid and shallow breathing with hypoxemia and hypercapnia characterizes these exacerbations. The pathophysiologic pathway involves an inability of the respiratory system to maintain adequate alveolar ventilation in the presence of major abnormalities in respiratory mechanics. This can be modified by NIPPV, which allows the patient to take deeper breaths with less effort, thus

reversing the clinical abnormalities resulting from hypoxemia, hypercapnia, and acidosis.[34,40] At baseline, the transdiaphragmatic pressure generated by these patients can be considerably higher than normal and represents a high percentage of their maximal diaphragmatic force, a situation that carries a major risk of respiratory muscle fatigue.[34,41,42] The main role of NIPPV is to offer the patient a way to increase the tidal volume at a lower work level. The use of ventilatory modalities working in synchrony with the patient's efforts allows larger breaths to be taken with less effort. As a result of the increased alveolar ventilation, arterial partial carbon dioxide pressure (Pa_{CO_2}) and pH values improve, and this in turn reduces the patient's ventilatory drive, thereby lowering the respiratory rate and improving the dyspnea.

CLINICAL EVIDENCE

The efficacy of NIPPV in patients admitted for acute exacerbation of COPD has been extensively studied. An international consensus conference recommended that NIPPV be considered a first-line treatment in these patients,[43] and the British Thoracic Society Guidelines indicate that every hospital should be able to deliver NIPPV on a 24-hour-per-day basis for this indication.[44] The first evidence that NIPPV markedly reduced the need for ETI came from case-control series reported in 1990.[34] Subsequently, several prospective randomized trials confirmed that NIPPV reduced the need for ETI and the rate of complications, shortened the length of stay, and improved survival in patients with COPD.[35,37,38,45–48] In a study by Kramer and associates, 74% of patients had COPD, and in this group NIPPV use was associated with a striking decrease in the ETI rate, from 67% to 9%.[38] Two studies conducted in the United Kingdom established that NIPPV was also effective in non-ICU settings.[35,48] Bott and coworkers[35] reported major improvements in dyspnea and gas exchange with a significant decrease in mortality when patients who refused NIPPV were excluded from the analysis. In the largest ICU study reported to date, Brochard and colleagues randomized 85 patients with COPD to treatment with or without face mask pressure-support ventilation.[37] The ETI rate was 74% in the controls given standard treatment and 26% in the NIPPV group. Benefits in the NIPPV group included a decreased rate of complications during the ICU stay, a shorter length of hospital stay, and more importantly, a significant reduction in mortality (from 29% to 9%). The overall decrease in mortality was ascribable to reductions in the need for ETI and in various ICU-related complications. In the United Kingdom, Plant and colleagues conducted a prospective multicenter randomized trial comparing standard therapy alone (control group) to NIPPV in 236 COPD patients admitted to general respiratory wards for ARF.[48] Treatment failure (defined as fulfillment of criteria for ARF) was more common in the control group (27%) than in the NIPPV group (15%), and NIPPV was associated with a lower in-hospital mortality rate. Because of admission policies in the United Kingdom, patients who failed NIPPV were not routinely transferred to the ICU, and consequently the findings may not be relevant to all health care institutions. The authors emphasized that the benefits of NIPPV out of the ICU were marginal in the most severely affected patients (pH <7.30 on admission), in whom the mortality rate was high. Those patients would probably have done better with early ICU admission for early NIPPV delivery in the ICU environment.

These studies indicate that early NIPPV to prevent further deterioration must become an important component of first-line therapy for COPD exacerbation.[49]

A very low pH, marked mental status alterations at NIPPV initiation, presence of comorbidities, and a high severity score are associated with early NIPPV failure[14] or late secondary failure after an initial improvement.[50] Several of these factors seem to indicate that a longer time from onset of the exacerbation to NIPPV initiation may reduce the likelihood of success. Every effort should be made to deliver NIPPV early, and close monitoring is in order when NIPPV is started late. In addition, a randomized controlled trial found that NIPPV was less effective when started late in the course of COPD exacerbation.[51] In this study, Conti and coworkers found a large reduction in the ETI rate, from 100% to 52%, contrasting with limited short-term benefits.[51] The patients stayed in the emergency ward for a mean of 14 hours before being admitted to the ICU because they met criteria for ETI, and NIPPV was initiated only at ICU admission. Interestingly, NIPPV was associated with significant long-term benefits such as a decrease in the readmission rate.

Whether the results of randomized controlled trials apply to everyday ICU practice must be evaluated. This is particularly important with NIPPV, since there is a learning curve, as shown in two studies. In a single-center study by Carlucci and colleagues, the NIPPV success rate remained stable over the study period, but the patients treated with NIPPV during the last few years of the study period had more severe disease with higher Pa_{CO_2} levels and lower pH values.[52] In an 8-year study performed in our institution, we found that NIPPV use increased gradually, in lockstep with a decline in conventional treatment with ETI.[53] In parallel with this gradual increase in NIPPV use, the nosocomial infection and mortality rates diminished. These important results were obtained in the group of patients with acute exacerbation of COPD and hypercapnic pulmonary edema.

LONG-TERM SURVIVAL

Several studies have suggested that NIPPV use may be associated with higher 1-year survival rates, as compared to standard ICU therapy or invasive MV.[51,54–56] Although these studies have a number of methodologic flaws, the consistency of their results suggests a major benefit of NIPPV, the mechanisms of which remain to be elucidated.

NEGATIVE PRESSURE VENTILATION

This technique is available in very few centers in the world. In acute exacerbations of COPD, it seems to provide better outcomes than conventional invasive MV and may be similar to face mask NIPPV.[57–60]

LOCATION

The study by Plant and associates cited above was performed in the respiratory wards, where the staff received 8 hours of training over the 3 months preceding the study.[48] During the study, it was estimated that maintaining the level of expertise provided by the prestudy training required on average 1 hour of additional training per month in each center. Wood and colleagues performed a study in the emergency ward, but the patients had very low severity, and few had COPD.[61] The results suggested that NIPPV use may have inappropriately delayed ETI. However, the small sample sizes, existence of

several baseline differences across groups, and lack of accurate information on NIPPV settings make it difficult to draw conclusions from this study. The feasibility of treating patients with COPD out of the ICU has thus been demonstrated, but when evaluating whether this applies to a specific ward, the need to train the staff must be taken into account.

HELIUM-OXYGEN MIXTURE

The use of a helium-oxygen mixture for NIPPV seems very promising in patients with COPD.[62–64] Several randomized controlled trials are under way to determine whether this gas mixture increases the NIPPV success rate. Disappointingly, the first study found only modest benefits when helium was added to the gas mixture.

CARDIOGENIC PULMONARY EDEMA

PATHOPHYSIOLOGY

Continuous positive airway pressure (CPAP) elevates intrathoracic pressure, decreases shunting, and improves arterial oxygenation and dyspnea in patients with cardiogenic pulmonary edema. Interestingly, CPAP can both substantially lessen the work of breathing and improve cardiovascular function by decreasing the left ventricular afterload in non–preload-dependent patients.[65] Pressure support plus PEEP induces similar pathophysiologic benefits.

Most patients with cardiogenic pulmonary edema improve rapidly under medical therapy. A few, however, develop severe respiratory distress and/or refractory hypoxemia and require ventilatory support until the medical treatment starts to work. This is particularly common in elderly patients, who may also have a mild degree of chronic bronchitis.[66,67] Several NIPPV modalities have been used successfully, the goal being to avoid ETI.

CONTINUOUS POSITIVE AIRWAY PRESSURE OR PRESSURE SUPPORT PLUS POSITIVE END-EXPIRATORY PRESSURE

Randomized trials comparing either CPAP or pressure support plus PEEP to standard therapy found closely similar results with the two techniques in terms of improvement in arterial blood gases and breathing rate. Both CPAP and pressure support plus PEEP significantly reduced the rate of ETI.[67–71] Several studies, however, indicate a need for caution. One compared pressure support plus PEEP to CPAP.[72] Acute myocardial infarction was more common in the pressure support plus PEEP group than in the CPAP group. Although this difference may be ascribable to randomization bias rather than to a deleterious effect of pressure support plus PEEP, it invites caution in patients with coronary heart disease. No increases in the acute myocardial infarction rates were found in the NIPPV arm of a randomized controlled trial of pressure support and PEEP or in any of the observational studies, although the outcome of these patients may be worse than outcome in those with nonischemic causes of heart failure.[71,73,74] Another study compared intravenous bolus therapy with high-dose nitrates to conventional medical therapy (a different medical therapy) plus pressure support plus PEEP.[75] High-dose nitrate bolus therapy was far more effective clinically than NIPPV and resulted in better outcomes. These studies draw attention to the vulnerability of patients with cardiogenic pulmonary edema, particularly those with coronary heart disease.[70,73] They indicate that both appropriate drug therapy and close monitoring are in order when using any form of NIPPV, especially in patients with coronary heart disease. In a randomized controlled trial, L'Her and associates showed that administration of CPAP to elderly patients with acute cardiogenic pulmonary edema in the emergency ward markedly improved physiologic parameters and 48-hour survival.[67] Unfortunately, there was no effect on hospital survival.

It is also important to draw attention to the fact that most of the studies demonstrating benefits of CPAP or pressure support plus PEEP included patients who, on average, had marked hypercapnia and acidosis indicating acute ventilatory failure.[67,70,71,73] A large multicenter study conducted by Nava and colleagues in patients with pulmonary edema found major benefits of NIPPV in the subgroup of hypercapnic patients, but no significant benefits in terms of ETI rate or outcome in the overall population, which included both hypercapnic and nonhypercapnic patients.[76]

In patients with hypercapnic pulmonary edema, ventilatory support with pressure support above PEEP is therefore a useful adjunct to medical treatment that reduces the ETI rate and improves outcomes. However, caution is needed when using NIPPV in patients with coronary heart disease.

HYPOXEMIC RESPIRATORY FAILURE

PATHOPHYSIOLOGY

Applying PEEP to the airway opening has been shown to increase functional residual capacity and to benefit respiratory mechanics and gas exchange.[77] These findings led intensivists to use CPAP as a means of preventing clinical deterioration and reducing the need for ETI.[70,78] Nevertheless, clinical data do not strongly support the use of CPAP in patients with acute lung injury (ALI),[79] and far better clinical outcomes have been reported with the combined use of pressure support ventilation and PEEP.[8,80,81] In patients with severe hypoxemia, ventilatory support should be able to relieve the dyspnea, improve oxygenation, and decrease the patient's effort to breathe. In a physiologic study, L'Her and coworkers confirmed the limited efficacy of CPAP alone in lessening the work of breathing.[82] They showed that addition of pressure support was crucial to reduce patient effort and dyspnea, whereas effects on oxygenation were dependent on the PEEP level.

CLINICAL EVIDENCE

CPAP

A recent investigation evaluated whether face mask CPAP produced physiologic benefits and reduced the need for ETI in patients with ALI.[79] Despite an early favorable physiologic response to CPAP in terms of comfort and oxygenation, no differences were found in the need for ETI, in-hospital mortality, or length of ICU stay. In addition, the use of CPAP was associated with a higher rate of complications including stress ulcer bleeding and cardiac arrest at the time of ETI. Therefore, CPAP alone cannot be recommended as a means of avoiding ETI in patients with ALI. Its use should be limited to a short initial period when no other method is available.

Pressure Support and PEEP

Until the late 1990s, the most convincing successes with NIPPV were obtained in patients with acute respiratory

acidosis in whom hypoxemia was not the main reason for respiratory failure. A randomized controlled trial by Wysocki and colleagues found no benefit of NIPPV in patients with no previous history of chronic lung disease, except in the subgroup of patients who developed acute hypercapnia.[83] However, NIPPV has now been proved beneficial in carefully selected patients with a variety of patterns of hypoxemic respiratory failure.[8,47,80,81,84–87] Recent studies suggest that in selected groups of patients NIPPV may reduce the need for ETI and improve outcomes.[86,88–90] Patient selection generally involves excluding patients who have shock, neurologic disorders with a need for upper airway protection, respiratory arrest, or any other concomitant organ failure. In a randomized controlled study by Antonelli and coworkers, NIPPV using pressure support and PEEP was highly beneficial in hypoxemic patients free from COPD, hemodynamic instability, or neurologic impairment, who were randomized when they reached predefined criteria for ETI.[81] Improvements in oxygenation were similar with the noninvasive and the invasive approach. Despite a 30% failure rate, patients treated with NIPPV had shorter durations of ventilation and ICU stay and experienced fewer complications. This study demonstrated that NIPPV could be effective in selected patients with hypoxemic respiratory failure but no hemodynamic or mental impairment. Other randomized controlled trials confirmed this beneficial effect.[80] The benefits seem greatest in specific subgroups, as discussed below. However, as indicated further on, patients with severe community-acquired pneumonia and profound hypoxemia or patients with acute respiratory distress syndrome (ARDS) may not always benefit from NIPPV, and in inexperienced hands the use of this technique may expose some patients to the risks associated with inappropriately delayed ETI.[15] Nevertheless, a recent study by Ferrer and colleagues indicates that NIPPV is effective in avoiding ETI and improving survival.[87] The study population comprised 105 patients admitted to the ICUs of three hospitals for acute non-hypercapnic hypoxemic respiratory failure due to community-acquired pneumonia, ARDS, cardiogenic pulmonary edema, or other diseases. Compared with oxygen therapy, NIPPV decreased the need for ETI (25% vs. 52%), the incidence of septic shock, and the ICU mortality rate (18% vs. 39%) and increased the cumulative 90-day survival rate.

SUBGROUPS

IMMUNOCOMPROMISED PATIENTS

Because one of the main benefits of NIPPV may be a decreased rate of infectious complications,[6,7,53] patients in whom MV carries a high risk for nosocomial infection may be particularly likely to benefit from NIPPV. Several trials have shown major benefits of NIPPV as a preventive measure during episodes of acute hypoxemic respiratory failure in solid organ-transplant patients or in patients with severe immunosuppression, particularly related to hematologic malignancies and neutropenia.[8,86,88] Significant reductions in ETI use, infectious complications, length of stay, and mortality occurred with NIPPV. Because of the high risk associated with ETI in patients with severe immunosuppression, NIPPV seems of particular interest in this group.[8,86,88,90] Similarly, patients experiencing *Pneumocystis carinii* pneumonia during the course of HIV infection seem to benefit from NIPPV, as shown in a case-control study by Confalonieri and associates.[90]

In the population with immunosuppression, careful patient selection and early initiation of NIPPV are key factors in decreasing the need for ETI and in maximizing benefits to the patients.

LUNG SURGERY

Several studies looked at the use of NIPPV after surgery.[89,91,92] Auriant and associates conducted a randomized controlled trial in patients who experienced respiratory distress after lung resection.[89] Because reintubation shortly after lung surgery carries a very grim prognosis, avoiding ETI in this situation is a major goal. NIPPV was associated with lower ETI rates and higher hospital survival. Furthermore, an uncontrolled study found evidence supporting a beneficial effect of NIPPV in patients with respiratory distress after bilateral lung transplantation.[92] Thus, NIPPV seems useful in preventing reintubation after lung surgery.

COMMUNITY-ACQUIRED PNEUMONIA

A randomized controlled trial reported by Confalonieri and colleagues in patients with community-acquired pneumonia showed major benefits of NIPPV consisting of reductions in ETI rates, complication rates, and length of stay.[47] These favorable effects, however, were almost entirely ascribable to the subgroup of patients with COPD. In a case-control study done by the same group in patients with *Pneumocystis carinii* pneumonia, NIPPV reduced ETI rates, length of stay, and mortality.[90] Other studies found high rates of NIPPV failure in the subgroup of patients characterized by pneumonia with severe hypoxemia.[84,93–95] By contrast, the benefits found in the study by Ferrer and associates were marked in the subgroup of patients with pneumonia.[87] Therefore caution is necessary when using NIPPV in patients with severe community-acquired pneumonia. There is no consensus about recommendations for the use of NIPPV in this situation. The results of NIPPV in patients with severe community-acquired pneumonia may depend on the experience of the user and on the quality of patient monitoring.

POSTEXTUBATION RESPIRATORY FAILURE

The physiologic rationale for this approach in patients with COPD was recently demonstrated by Vitacca and coworkers.[96] A case-control study by Hilbert and associates suggested that NIPPV might prevent reintubation in patients with COPD.[97] A prospective randomized trial by Keenan and colleagues was performed in a population with postextubation respiratory distress that included only a few patients with COPD; no benefit of NIPPV was found.[98] Another prospective randomized trial did not find any evidence that NIPPV decreased reintubation rates.[99] By contrast, the preliminary results of another randomized trial provided indications of strong beneficial effects in COPD.[100] Lastly, a recent multicenter trial by Esteban and associates suggested that NIPPV used for postextubation respiratory distress may delay reintubation and increase mortality.[101]

Thus there is considerable doubt about the effectiveness of NIPPV in obviating the need for reintubation in all patients with postextubation respiratory distress. Using NIPPV in patients with postextubation respiratory distress may increase

morbidity rates, and perhaps also mortality rates, by inappropriately delaying reintubation. The benefits of NIPPV in the treatment of postextubation respiratory distress may be limited to those patients with COPD. When NIPPV is used, the need for ETI should be evaluated early, within the first 2 hours of NIPPV, in order to avoid adverse outcomes related to delayed ETI.

WEANING

A number of patients with COPD require ETI because they fail NIPPV, have a contraindication to NIPPV (such as a need for surgery), or exhibit criteria for immediate ETI. However, when there is a need for prolonged ventilatory assistance, these patients can be switched to NIPPV after a few days of ETI.[102,103] This approach was shown in two randomized controlled trials to reduce the ETI time.[102,103] In a study by Nava and colleagues, complications were reduced and 60-day survival rates were higher with this approach.[102] This benefit was not found in the other study, in which the total length of ventilation was increased in the NIPPV arm.[103] A trial by Ferrer and coworkers suggested major benefits in COPD patients experiencing persistent weaning difficulties.[104] This study included 43 mechanically ventilated patients who had failed a weaning trial for 3 consecutive days. Compared with the conventional-weaning group, the NIPPV group had shorter times on invasive MV and in the ICU and hospital, as well as higher ICU and 90-day survival rates. Multicenter trials are needed to confirm the safety and efficacy of this approach.

PATIENTS WHO SHOULD NOT BE INTUBATED

Several reports have described the effects of NIPPV in patients with acute respiratory failure who were poor candidates for ETI because of advanced age, debilitation, or a "do not resuscitate" order.[9,10] The overall success rate in these reports approximated 60% to 70%. Gas exchange improved rapidly in successfully treated patients. Even when respiratory failure did not resolve, NIPPV provided symptomatic relief from dyspnea.

PATIENTS WITH SEVERE ACUTE ASTHMA

A few studies indicate that NIPPV can be used in asthmatic patients. Two cohort studies found beneficial short-term effects of NIPPV in asthmatic patients whose condition was deteriorating despite medical therapy.[105,106]

NEW MODES OF VENTILATION

Several studies used a new ventilatory mode known as proportional-assist ventilation, which is designed to improve the adjustment of ventilatory support to the patient's needs.[107–110] In several comparative studies with pressure-support ventilation in one of the arms, the efficacy of the two techniques seemed similar, although very few patients required ETI. Studies in patients with greater disease severity are needed. A prospective randomized trial by Fernandez-Vivas and associates in 117 patients with mixed causes of ARF again showed no difference in clinical outcomes between NIPPV delivered with pressure support or with proportional-assist ventilation.[110] Subjective comfort was better with proportional-assist ventilation, however, and intolerance was less common.

FIBEROPTIC BRONCHOSCOPY

Several studies have suggested or demonstrated that fiberoptic bronchoscopy can be performed under NIPPV (CPAP for hypoxemic patients or pressure support plus PEEP),[111–113] and that this approach resulted in better tolerance of the procedure and reduced complication rates and the need for ETI.[113]

Chapter 34

UPPER AIRWAY OBSTRUCTION

BRIAN GEHLBACH
JOHN P. KRESS

KEY POINTS

- *Suspected upper airway obstruction (UAO) constitutes a medical emergency. The immediate bedside consultation of a clinician experienced in the management of this condition is indicated.*
- *The initial evaluation of UAO is focused on determining the severity and suspected site of the obstruction. Arterial desaturation is a late manifestation; better indicators of severity include stridor, poor air movement, accessory muscle use, abnormal mentation or agitation, tachycardia, hypertension, and pulsus paradoxus.*
- *Infections represent important causes of oropharyngeal and hypopharyngeal UAO and include Ludwig angina, peritonsillar abscess, and infections of the retropharyngeal and lateral pharyngeal spaces. Otolaryngology consultation is indicated. Depending on the initial site of infection, spread to other critical sites (e.g., the mediastinum) may occur.*
- *While intubation is not always required in adults with epiglottitis, management in an ICU is mandatory, and intubation equipment and a tracheostomy tray should be at the bedside.*
- *Bacterial infections of the larynx are life-threatening. Causative organisms include* Staphylococcus aureus, Streptococcus pneumoniae, Haemophilus influenzae, *and* Corynebacterium diphtheriae.
- *Laryngospasm and laryngeal edema are important causes of postextubation stridor. Prophylactic corticosteroids have not shown a benefit in preventing postextubation stridor. A short (48 hours) course of corticosteroids is reasonable to treat established cases of laryngeal edema.*
- *Long-term intubation may result in a variety of problems related to the upper airway, including endotracheal tube obstruction from secretions, vocal cord injury, subglottic stenosis, and tracheal stenosis.*
- *Risk factors for foreign body aspiration in adults include diminished level of consciousness; impaired swallowing mechanism or diminished upper airway sensation as a result of neuromuscular disorder, prior cerebrovascular accident, or advanced age; and inability to chew food properly because of poor dentition.*
- *All suspected traumatic laryngeal injuries should be evaluated promptly to reduce the immediate risk of UAO, as well as to prevent long-term sequelae such as subglottic stenosis.*
- *Early laryngoscopic examination of the upper airway is crucial in the evaluation of burn patients with suspected inhalation injury. The risk of UAO increases throughout the first 24 hours.*
- *Functional upper airway obstruction may occur in patients who exhibit abnormal glottic closure during inspiration and/or expiration. There is a high risk of coincident asthma, complicating the evaluation of such patients.*
- *Angioedema may result from allergy, hereditary or acquired disorders of the complement cascade, direct release of histamine from mast cells from nonallergic mechanisms (e.g., opiates), and from angiotensin-converting enzyme inhibitors.*
- *Angioedema from angiotensin-converting enzyme inhibitors may occur at any time during the course of therapy.*
- *Helium-oxygen mixtures reduce the density-dependent pressure required to drive airflow across obstructing upper airway lesions, and may stabilize patients with UAO pending definitive therapy.*
- *Prompt evaluation and management of suspected UAO may prevent subsequent complications including cardiac arrest, anoxic brain injury, and negative pressure pulmonary edema.*

There are few medical conditions that are as rapidly and predictably lethal as the loss of upper airway patency. Because of the relative infrequency with which upper airway obstruction (UAO) is encountered by most physicians, opportunities to acquire significant clinical experience are limited. This, combined with the frequently subtle presentation of upper airway obstruction and the clinician's inability to visualize the upper airway in its entire extent through routine physical examination, may hamper diagnosis of this condition until a crisis results. This chapter describes an approach to diagnosing and treating UAO as it presents in adults. While certain infections of the head, neck, and upper respiratory tract are considered here as they relate to UAO, the specific approach to their management is considered in greater detail in Chap. 54. A high index of suspicion for UAO, combined with early consultation of anesthesia and otolaryngology services, is critical to the successful management of this condition.

Anatomy of the Upper Airway

The upper airway comprises air-conducting passages that begin at the mouth or nose and end at the mainstem carina.[1,2] The thoracic inlet divides the upper airway into the intrathoracic and extrathoracic airways. The extrathoracic airways are further divided into the nasopharynx, oropharynx, hypopharynx, larynx, and extrathoracic trachea. Air inspired through the nose passes through the nasal cavities and enters the nasopharynx after exiting the nose by way of the posterior nares. Airflow proceeds inferiorly through the nasopharynx, passes posterior to the soft palate, and enters the oropharynx. Closure of the soft palate allows inspiration of air through the mouth. Air passes inferiorly through the oropharynx to the hypopharynx, which begins just superior to the hyoid bone, and passes the epiglottis, thereby entering the larynx.

The larynx is constructed of a cartilaginous skeleton consisting of the thyroid, cricoid, and arytenoid cartilages (Fig. 34-1). This skeleton surrounds the vocal cords, the movements of which are controlled by the intrinsic muscles of the larynx, with their innervation arising from the left and right branches of the recurrent laryngeal nerve. An exception to this rule is the innervation of the cricothyroid muscle, which arises from the superior laryngeal nerve. This nerve also supplies sensation to the epiglottis and vestibular folds (false cords), which lie superior to the true vocal cords. The larynx is

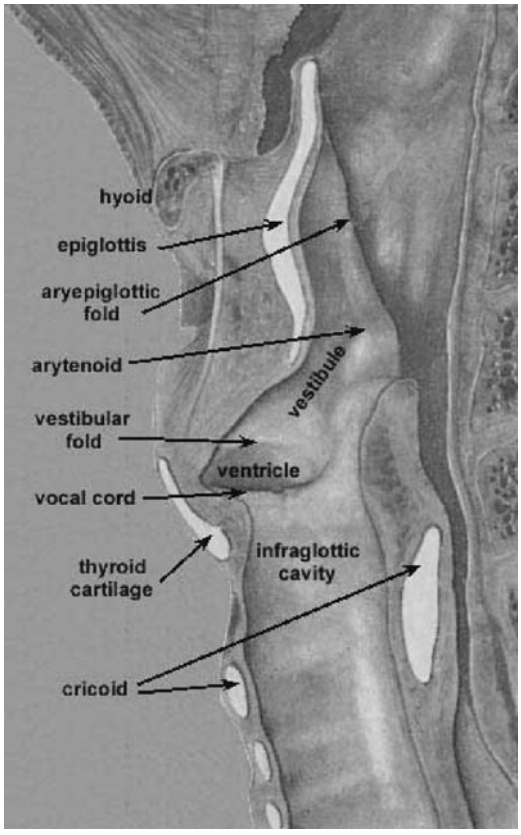

FIGURE 34-1 Laryngeal anatomy. ***(Reproduced with permission from http://mywebpages.comcast.net/wnor/homepage.htm, author Wesley Norman, PhD, DSc.)***

divided into the supraglottic portion, the glottis, and the subglottic portion. The glottis contains the structures within the plane of the true vocal cords and is located at the midpoint of the thyroid cartilage. The supraglottic region extends from the epiglottis to just above the true vocal cords, while the subglottic region lies between the vocal cords and the lower border of the cricoid cartilage.

The trachea lies between the inferior border of the cricoid cartilage and the main carina, and is 10 to 13 cm in length in adults. The extrathoracic trachea is typically 2 to 4 cm long, and comprises the segment that lies between the cricoid cartilage and the thoracic inlet. The normal trachea has roughly the same coronal as sagittal diameter. Normal coronal tracheal diameter is 13 to 25 mm in men and 10 to 21 mm in women.

This chapter will focus on disorders of the extrathoracic upper airway because of this region's greater importance to the topic of UAO.

Pathophysiology of Upper Airway Obstruction

While obstruction may occur at any point in the upper airway, laryngeal obstruction is most problematic because the airway is narrowest at this point. The glottis is the narrowest region in adults, while the subglottic region is the narrowest in infants. The basis for which seemingly minor reductions in the cross-sectional area of the upper airway have important effects on airflow is presented below.

Alveolar ventilation is accomplished through the bulk flow of fresh gas down to the terminal bronchioles, at which point the cross-sectional area of the airways becomes so large that the forward velocity of gas molecules becomes negligible, and diffusive flow occurs.[3] Airflow may be laminar, transitional, or turbulent. Laminar flow consists of orderly streams of gas arranged in lines parallel to the airway. At higher flow rates and at branch points flow may become transitional, with gas eddies that break away from the parallel streams. Turbulent flow is the most disorganized pattern, and occurs at high flow rates. The Reynolds number (Re) is a dimensionless number that derives from the ratio of inertial to viscous forces and allows prediction of whether flow will be laminar or not:

$$\mathrm{Re} = 2\mathrm{rvd}/\mu$$

where r is the radius of the tube, v is the average gas velocity, d is the gas density, and μ is the gas viscosity. Values less than 2000 predict laminar flow, values between 2000 and 4000 predict transitional flow, and values greater than 4000 predict turbulent flow. The driving pressure for laminar flow is proportional to the flow rate and inversely related to the fourth power of the radius, among other factors. Thus a relatively minor decrease in the radius of a tube like the upper airway causes a large increase in the driving pressure necessary to achieve the same flow rate. Turbulent flow as occurs in a rough tube like the larynx and trachea requires greater driving pressure than laminar flow, being proportional to the density of the gas and the *square of the flow rate*. Inhalation of a low-density gas such as helium therefore decreases the driving pressure required for airflow through two mechanisms: reducing the Reynolds number, thereby increasing the proportion of flow that is laminar; and decreasing the density-dependent driving pressure where turbulent flow exists.[4]

The clinical implications of these principles are as follows: (1) Upper airway obstructing lesions, once symptomatic, can progress rapidly to a crisis with relatively small increases in size and consequent reduction in the size of the airway lumen; (2) while awaiting definitive treatment of the upper airway obstruction, inhalation of a low-density gas mixture such as helium-oxygen may stabilize the patient by decreasing the driving pressure required for a given airflow.

Upper airway obstructing lesions may limit inspiratory flow, expiratory flow, or both, depending on the site and nature of the lesion. Flow-volume loops obtained by spirometry are useful for understanding the physiology of different sites of upper airway obstruction.[5]

VARIABLE EXTRATHORACIC OBSTRUCTION

During normal inspiration the intrathoracic airways dilate, while the extrathoracic airways tend to collapse as the increase in gas velocity causes a fall in intraluminal pressure (Bernoulli effect). As gas velocity increases past an obstructing lesion, this effect is increased, causing flow limitation, with a reduction in peak inspiratory flow and a flattening of the inspiratory limb of the flow volume loop. In contrast, during forced expiration the intraluminal pressure is positive relative to the atmosphere, preserving expiratory flow. These lesions occur above the thoracic inlet and include bilateral vocal cord paralysis, paradoxical movement of the vocal cords, and tracheomalacia of the extrathoracic airway.

VARIABLE INTRATHORACIC OBSTRUCTION

During forced expiration the intrathoracic airways have a tendency to narrow as a result of airway compression and the Bernoulli effect. This leads to a reduction in peak expiratory flow and a flattening of the expiratory limb of the flow volume loop. Inspiratory flow, in contrast, is preserved as lung expansion increases the radius of the airway at the site of the obstructing lesion. Common causes of variable intrathoracic obstruction include low tracheal tumors and tracheomalacia of the intrathoracic airway.[6]

FIXED UPPER AIRWAY OBSTRUCTION

Fixed upper airway obstruction occurs when airflow at the site of obstruction is insensitive to the effects of the respiratory cycle because the lesion imparts rigidity to the walls of the affected area. Affected patients have reductions in peak inspiratory and expiratory flow, while the flow volume loop depicts flattening of the inspiratory and expiratory limbs. Examples of this disorder include subglottic stenosis and some tumors.

Clinical Presentation and Initial Evaluation

Patients presenting with upper airway obstruction may complain of a variety of symptoms including hoarseness, stridor, hemoptysis, dysphagia, odynophagia, drooling, and swelling of the neck or face. Dyspnea is typically exacerbated by exercise, and in the case of certain diseases—for example, anterior mediastinal tumors—by the supine position. In many cases prior evaluations have yielded a diagnosis of asthma or chronic obstructive pulmonary disease. While certain disorders such as epiglottitis have very acute presentations, at times symptoms have developed so insidiously that the patient has habituated to the condition, and has few or no complaints.

If time permits, initial evaluation should include a history of the present illness, focusing on the duration of symptoms and any associated oropharyngeal, gastrointestinal, or constitutional symptoms, along with a history of prior upper aerodigestive tract disorders, recent dental problems or procedures, and smoking. Physical examination is directed toward localizing the site of the lesion.[7] Inspiratory stridor generally indicates a lesion at or above the level of the glottis, while biphasic stridor (stridor present during both inspiration and expiration), which is usually higher in pitch, suggests a lesion at the subglottic or tracheal level. The presence of stridor indicates a severe degree of narrowing, typically to $\leq$6 mm. Supraglottic lesions may cause a muffling of the voice, while oral abscesses may cause a "hot potato voice" (i.e., the speech of someone who has a hot potato in his mouth). Hoarseness accompanies unilateral vocal cord paralysis. An oral examination should be performed, unless epiglottitis is suspected and skilled airway personnel are not present. The submental and submandibular regions should be palpated, along with the neck and cervical and supraclavicular lymph nodes.

The first priority in encountering a patient with suspected UAO is to determine the severity of obstruction. When the obstruction is severe and loss of the airway is feared, the airway should be secured by an experienced operator. Arterial desaturation is an extremely late sign of UAO in the patient with normal lungs, and often heralds a catastrophe. This is illustrated by the difficulty normal, untrained individuals have in achieving arterial desaturation during breath holding. Similarly, arterial blood gases provide little information beyond that obtained through the bedside assessment of an experienced clinician. Better indicators of severe airway obstruction include stridor, poor air movement, accessory muscle use, abnormal mentation or agitation, tachycardia, hypertension, and pulsus paradoxus. All patients with newly diagnosed UAO of more than trivial severity should be monitored in an ICU until treatment can be initiated or clinical stability can be determined.

If UAO is suspected but there is no immediate risk of losing the airway, further evaluation may employ a range of techniques, depending on the suspected diagnosis. Spirometry is useful in the elective evaluation of subacute to chronic UAO; however, because the airway must be narrowed to $\leq$8 mm in order to affect the flow volume loop, spirometry is relatively insensitive. Inspection of the flow volume loop for flattening of the inspiratory or expiratory limb is the most reliable spirometric indication of UAO, particularly when done by an experienced reader. Poor effort may mimic UAO. The report of patient effort by the technician and the reproducibility of the loops are useful in distinguishing poor effort from UAO. Spirometry may fail to detect even significant degrees of UAO in patients with severe chronic obstructive pulmonary disease.

Plain chest radiographs may demonstrate tracheal deviation from masses arising in the mediastinum or neck. Lateral neck films may suggest the diagnosis of croup or epiglottitis. Computed tomography (CT) is extremely useful in evaluating suspected tumors of the upper airway, and in characterizing the extent of upper airway soft tissue infections. Three-dimensional reconstruction is useful in identifying fixed anatomic abnormalities of the upper airway, such as tracheal stenosis, and in following the response to therapy.[8] However, dynamically determined disorders such as tracheomalacia require direct visualization.

Endoscopic evaluation may be flexible or rigid. Rigid endoscopy is useful in the management of suspected foreign body aspiration. Flexible endoscopy may be performed via the oropharyngeal or nasopharyngeal route.

Causes of Upper Airway Obstruction

NASAL AND NASOPHARYNGEAL CAUSES

Benign and malignant masses of the nose and nasopharynx constitute important sources of morbidity, and occasionally, mortality. However, because ventilation can usually be maintained via the oropharyngeal route in these cases, they will not be discussed here.

OROPHARYNGEAL CAUSES

INFECTIOUS CAUSES

Infectious etiologies represent relatively common causes of upper airway obstructing lesions. Ludwig angina is an infection of the submandibular space.[9] The source of infection is usually a second or third mandibular molar tooth, with causative organisms representing typical oral flora: streptococci, staphylococci, and anaerobes. Gram-negative

organisms should be considered as potential etiologies in patients with altered oral flora, such as immunocompromised patients and recipients of broad-spectrum antibiotics. Airway obstruction may result from elevation and posterior displacement of the tongue and supraglottic edema. The infection may extend to the lateral and retropharyngeal spaces, and subsequently along the carotid sheath and to the mediastinum.

Affected patients present with dysphagia, neck swelling ("bull neck") and stiffness, trismus, drooling, and brawny induration of the floor of the mouth. Occasionally, crepitus of the submandibular area is present. Tooth pain or a history of recent tooth extraction is usual, but not invariable. While not all patients with Ludwig angina need to undergo endotracheal intubation or tracheostomy, the decision to observe the airway rather than secure it should not be made lightly, and should be made after consultation with an otolaryngologist. If intubation is deemed necessary, placement via a flexible fiberoptic approach may be useful in decreasing the risk of laryngospasm during the procedure. Treatment consists of antibiotic therapy, and in some patients, surgical drainage. Obviously, any infected teeth should be extracted.

Lymphatic drainage from the oropharynx, teeth, maxillary sinuses, and ears passes through the retropharyngeal space, predisposing it to infections from the ear, nose, and throat.[10] While the space itself contains no vital structures, infection may extend into the mediastinum or epidural space, or provoke atlantoaxial dislocation. Whereas this condition usually follows an upper respiratory tract infection, pharyngitis, or otitis media in children, in adults the more common antecedent problems are odontogenic infection or procedures, or oral trauma. Patients present with throat and neck pain, and may have drooling or symptoms of upper airway obstruction. On occasion, infection may spread to the retropharyngeal space from the prevertebral space, such as with tuberculosis of the spine (Pott disease). The diagnosis may be made through a lateral neck radiograph; however, CT is advisable for helping define the boundaries of infection. Importantly, physical examination may fail to reveal any posterior pharyngeal swelling, highlighting the need for a high index of suspicion for this condition and further investigation via endoscopy or imaging. Treatment consists of antibiotics directed at oral flora (streptococci, staphylococci, anaerobes, and in some patients, gram-negative organisms), airway stabilization, and surgical exploration.

Because the lateral pharyngeal space is bounded by the retropharyngeal and submandibular spaces, it serves as a means of transmitting infections from diverse sources, as suggested previously. Again, infections in this space are typically treated with a combination of antibiotics and surgical drainage.

Peritonsillar abscesses are located between the tonsil and the superior constrictor muscle of the pharynx. Affected patients are typically young adults and have a history of prior tonsillitis; not surprisingly, *Streptococcus* species are most commonly isolated, along with other oral organisms. Presenting symptoms include sore throat, trismus, and voice change. Despite the prevalence of this disorder, there are several aspects of management that remain controversial.[11] While steroids are occasionally administered to patients with peritonsillar abscess, there are no studies to support or refute their efficacy. Both needle aspiration and open abscess drainage with tonsillectomy ("quinsy tonsillectomy") have been advocated as initial treatment, and both are effective. Complications include UAO and rarely, thrombophlebitis of the internal jugular vein, a condition known as Lemierre syndrome. This condition is usually associated with *Fusobacterium necrophorum*, but other oral flora may be responsible. Bacteremia and septic emboli may result. The role of anticoagulation in Lemierre syndrome is controversial.

Occasionally, tonsillar enlargement from infectious mononucleosis may be so significant as to obstruct the airway. Management consists of close observation of the airway in a monitored setting, and the administration of corticosteroids.

OTHER CAUSES

Angioedema from a variety of causes can involve the tongue and hypopharynx and threaten airway patency both above and at the level of the larynx. This disorder is discussed below along with other disorders of the larynx. Stevens-Johnson syndrome and toxic epidermal necrolysis are rare vesiculobullous diseases that involve the skin and mucous membranes. Affected patients may develop bullae and edema of the upper airway mucosa, leading to obstruction. Causes typically include medications (with antibiotics, nonsteroidal anti-inflammatory medications, and anticonvulsants frequently being implicated), infections, and malignancies. Depending on their location, facial fractures may lead to UAO through local swelling and a loss of support for the tongue and/or facial skeleton. While oral neoplasms are common, patients typically present for evaluation before the airway can be compromised. Obstructive sleep apnea is a form of chronic UAO that is exhibited only during sleep, and is considered in greater detail in Chap. 109.

LARYNGEAL CAUSES

INFECTIOUS CAUSES

Supraglottitis, or infection of the supraglottic portion of the larynx, may cause life-threatening UAO primarily through involvement of the epiglottis. Vaccination against *Haemophilus influenzae* has successfully decreased the number of cases of epiglottitis in children caused by this organism. As a result, adults comprise a greater proportion of all cases of epiglottitis. In addition to *H. influenzae*, *Streptococcus pneumoniae, Staphylococcus aureus, Haemophilus parainfluenzae,* and anaerobes all have been implicated as causes of epiglottitis. Because most physicians who treat adults will work a lifetime without seeing a single patient with the acute onset of sore throat go on to develop UAO, the diagnosis may be missed. The classic presentation is that of a patient sitting upright and leaning forward, drooling; however, these signs may not be present initially. An additional clue is the rapid onset and severity of odynophagia. Signs of toxicity, such as fever and tachycardia, may be present. Otolaryngology and anesthesiology consultation should be obtained if the diagnosis is suspected, while an oral examination should be performed extremely carefully, if at all. The approach to diagnosis depends on the patient's overall clinical status. While lateral films of the neck may reveal the diagnosis, a negative examination does not exclude epiglottitis. A fiberoptic examination can often be performed carefully via the nasopharyngeal route, but should be performed only by a person experienced in treating this problem, preferably a seasoned otolaryngologist or anesthesiologist. Visualization of a swollen, cherry-red epiglottis confirms the diagnosis. This examination is preferentially performed in the operating room, or at a minimum with all necessary

airway personnel and equipment available. Although many adults with epiglottitis may be managed with antibiotics and observation in the ICU, the potential for acute airway obstruction should always be considered to be extremely high.[12,13] A tracheostomy tray should be at the bedside, and all relevant airway personnel—anesthesia as well as otolaryngology—should be alerted to the patient's condition and location. At no time should the patient be sent unaccompanied to another location in the hospital. While blood cultures may on occasion reveal the etiology, in most cases the specific organism is not identified, and antibiotic treatment is empirical. The response to treatment is typically prompt.

Infections of the larynx may be caused by viruses, bacteria, or fungi. Laryngotracheitis in children (croup) is usually caused by a viral infection, and UAO may result. While viral infections of the larynx are rarely serious in adults, bacterial laryngotracheitis can be life-threatening. Because the causative organisms include *Staphylococcus aureus, Streptococcus pneumoniae,* and *Haemophilus influenzae*, pneumonia may be present as well. *Corynebacterium diphtheriae* should always be considered in the differential diagnosis despite the relative infrequency with which it is currently encountered in the United States. In particular, nonimmunized persons and those individuals who have not received a booster in the past 10 years are at risk. Diphtheria is also more frequently encountered in communities with low immunization rates, as in some Native American communities. Diphtheria commonly presents initially as tonsillitis and pharyngitis. Subsequent spread inferiorly may cause laryngitis, although occasionally the larynx is the only site of involvement. Clinical manifestations include fever, sore throat, malaise, headache, and vomiting. Physical examination may reveal a tenacious gray or black membrane overlying involved sites, and cervical lymphadenopathy may be present. Delays in treatment increase the likelihood of systemic complications from circulating toxin, such as myocarditis, neuritis, and nephritis. Death occurs in 5% to 10% of cases, either from systemic effects of diphtheria toxin or from UAO, the latter occurring more commonly in infants. Treatment includes antibiotics and equine antitoxin, which can be obtained through the Centers for Disease Control and Prevention. Sensitivity to horse serum should be assessed prior to administration of the antitoxin, and desensitization should be performed as necessary. Because infection does not ensure immunity, immunization is indicated after recovery.[14]

Fungal laryngotracheitis may be caused by *Candida albicans*, histoplasmosis, blastomycosis, and coccidioidomycosis. In addition to fever and sore throat, affected patients may develop dyspnea and voice change from vocal cord nodules and/or vocal cord fixation. The diagnostic approach depends on the presentation, as other sites of involvement—for example, pulmonary infiltrates—may be present. Respiratory papillomatosis is caused by human papillomavirus types 6 and 11, and is manifested by multiple—sometimes innumerable—papules in the larynx and trachea.

IATROGENIC AND TRAUMATIC CAUSES

Related to Endotracheal Intubation

A variety of upper airway problems can follow endotracheal intubation and are listed in Table 34-1. Several of these problems merit further discussion here. Laryngospasm consists of uncontrolled glottic closure, and respiratory distress with inability to ventilate the patient may result. It can be provoked by a variety of stimuli, including stimulation of the glottic aperture and/or superior laryngeal nerve during intubation, medications including general anesthetics and opioids, and the presence of secretions or blood in the upper airway. Careful suctioning of the mouth and endotracheal tube prior to extubation may reduce the likelihood of laryngospasm after extubation, in addition to improving pulmonary toilet. When laryngospasm occurs, gentle mask ventilation with 100% oxygen should be performed. If the laryngospasm fails to break and ventilation is not possible, the short-acting paralytic succinylcholine may be administered followed by mask ventilation or endotracheal intubation. It should be emphasized that in the ICU, laryngeal edema is a much more likely cause of postextubation stridor than laryngospasm.

TABLE 34-1 Upper Airway Disorders Related to Endotracheal Intubation

Related to insertion
Epistaxis (with nasotracheal intubation)
Tooth avulsion and aspiration
Hypopharyngeal trauma
Laryngospasm (either from airway manipulation or medications)
Laryngeal trauma
Mucosal trauma
Vocal cord paralysis and/or arytenoid dislocation
Related to long-term intubation
Endotracheal tube obstruction from secretions or kinking
Vocal cord injury: edema, ulceration, granuloma, and paralysis possible
Laryngomalacia from ischemic cuff injury
Subglottic stenosis
Tracheal stenosis
Related to extubation
Excess secretions
Residual sedation
Laryngospasm
Previous undiagnosed laryngeal edema or other upper airway injury or disorder

Long-term endotracheal intubation may cause a variety of injuries to the upper airway. Fortunately, current endotracheal tube cuffs have a higher volume and lower pressure than were used a number of years ago, decreasing problems related to long-term intubation. Whether or not an individual patient will develop subglottic or tracheal stenosis is difficult to predict. While duration of intubation has been shown in some studies to be correlated with laryngeal or tracheal stenosis, the relationship is not strong. Similarly, while increased tube caliber, frequency of insertion, the severity of respiratory failure, female gender, and the presence of diabetes or immunocompromise have all been suggested as exacerbating factors, the data on this topic are inconsistent.[1] The decision to perform a tracheostomy therefore depends on the expected duration of need for an artificial airway, and the extent to which conversion to tracheostomy will facilitate other aspects of care; for example, liberation from mechanical ventilation, or recovery from more proximal upper airway injury or toxic therapy (e.g., surgery or irradiation for neoplasm). In general, the usual recommendation of considering tracheostomy for all patients intubated for 2 to 3 weeks who are not likely to recover soon is a prudent one. As mentioned previously, possibility of subglottic or tracheal stenosis should be considered when encountering breathless patients who have undergone

long-term intubation previously. In such cases, the diagnosis of UAO may easily be overlooked. Voice change and stridor are clues to the diagnosis. CT of the upper airway with three-dimensional reconstruction can be very useful in such cases, if patient stability permits.

Endotracheal tube obstruction from secretions may be an insidious cause of UAO that may progress occasionally to a circumstance in which ventilation becomes impossible. Its occurrence may be prevented through frequent suctioning. The development of obstructed respiratory system mechanics—a high peak to plateau airway pressure gradient—in a patient without a history of obstructive lung disease, or in the absence of wheezing, suggests the diagnosis. While difficulty passing a suction catheter is highly suggestive, we have removed endotracheal tubes that are nearly completely occluded through which a suction catheter was able to be passed. If time permits, bronchoscopic examination quickly establishes the diagnosis. Chap. 36 outlines the approach to high peak airway pressures in further detail; here, we stress that prompt removal of the endotracheal tube, with manual mask ventilation of the patient while awaiting reintubation, can be lifesaving.

Stridor has been reported to occur following 2% to 16% of extubations in the ICU, with laryngeal edema most frequently responsible.[15] Limited investigations in adults do not support the prophylactic administration of corticosteroids in order to reduce the incidence of reintubation.[16] Even if corticosteroids are effective at reducing laryngeal edema, the low incidence of reintubation for this disorder in adults means that an extraordinary number of patients would have to be treated in order to demonstrate a benefit in reducing this occurrence. For this reason, a randomized controlled trial of corticosteroids to treat patients with postextubation stridor is not likely to be performed. Our practice is to administer a short (48 hours) course of parenteral corticosteroids such as dexamethasone in such cases. More important is notification of relevant airway personnel and close observation; aerosolized racemic epinephrine may be useful in decreasing laryngeal edema through local vasoconstriction.

Other Traumatic Injuries

Aspirated foreign bodies lodge in the upper airway much less commonly in adults than in children.[17] Still, asphyxiation may follow foreign body aspiration in adults, while large objects aspirated into the esophagus can occasionally obstruct the upper airway. Risk factors in adults include diminished level of consciousness; impaired swallowing mechanism or diminished upper airway sensation as a result of neuromuscular disorder, prior cerebrovascular accident, or advanced age; and inability to chew food properly because of poor dentition. Food particles and medical or dental appliances are most frequently aspirated. Symptoms include cough and dyspnea, and stridor may be present. Chest radiography or lateral films of the neck may reveal the diagnosis. In the case of impending respiratory arrest, the Heimlich maneuver may be lifesaving. Otherwise, the patient should undergo endoscopy in most cases with a rigid endoscope. Flexible fiberoptic endoscopy is generally inadvisable for foreign body removal because the airway cannot be protected if the object lodges in the glottis during removal; however, experienced operators may elect to attempt removal in carefully selected patients.

Upper airway injury may result from inhalation of toxic chemicals, or more commonly from thermal injury. Upper airway burn injury should be suspected whenever a patient has survived a fire or explosion in an enclosed space, and when chemicals or plastics have burned. Physical examination findings that suggest the presence of upper airway injury include the presence of burns or soot on the face, singed nasal hairs, erythema of the oropharynx, and hoarse voice. Sometimes the external signs are relatively mild despite significant inhalation injury. Thus any patient suspected of incurring inhalation injury should undergo fiberoptic laryngoscopy. Affected patients may experience life-threatening UAO from airway edema and mucosal sloughing anytime from initial presentation to 24 hours later. In addition, upper airway edema may be exacerbated by the considerable amount of fluids required to resuscitate patients with extensive burns.[18] When the airway needs to be secured, endotracheal intubation is preferred over tracheostomy because of the higher incidence of tracheal stenosis associated with the latter therapy when performed in burn patients. Because corticosteroids increase the incidence of infectious complications and may increase mortality when administered to burn patients, we do not recommend their use here.

Traumatic neck injury may directly injure the larynx.[7] Such an injury should be suspected whenever there are ecchymoses or tenderness over the thyroid or cricoid cartilages. In addition to pain, patients may have stridor, hoarseness, and hemoptysis. Cervical spine injury should be excluded, while endotracheal intubation must be done with care to avoid exacerbating any existing injury. Stabilization of the neck and avoidance of neck extension during airway manipulation are mandatory. In a crisis, tracheostomy may be necessary to establish an airway. The evaluation and treatment of laryngeal injury is beyond the scope of this review.

There are a number of iatrogenic causes of UAO. A hematoma in the neck may cause UAO through direct compression, as may rarely occur following surgery. Inadvertent carotid artery puncture during central line placement may cause a rapidly expanding hematoma with airway compromise, particularly if the patient has a bleeding diathesis. Recurrent laryngeal nerve injury may occur during neck dissection or cardiac surgery and cause vocal cord paralysis. While unilateral vocal cord paralysis does not by itself embarrass respiration because the contralateral cord has full mobility, bilateral vocal cord paralysis typically requires surgery.

MISCELLANEOUS CAUSES

Functional UAO may result from abnormal closure of the vocal cords during inspiration, expiration, or both. Affected patients often have a history of frequent treatment for severe "asthma" exacerbations, at times even undergoing intubation. We have witnessed patients with this condition who exhibit significant pulsus paradoxus and respiratory acidosis during attacks mimicking status asthmaticus. Physical examination is revealing in that stridor is heard. If the patient is intubated, the respiratory system mechanics are normal, and wheezing is not heard. Complicating the diagnosis is the fact that a significant portion of patients with this condition also have asthma, which may be severe.[19] Spirometry may show flattening of the inspiratory limb of the flow volume loop, indicating a variable extrathoracic obstruction. The diagnosis is confirmed when laryngoscopy reveals abnormal vocal cord closure, particularly during inspiration. Unfortunately, laryngoscopy may

be normal, particularly between attacks, and frequently the diagnosis must be made on clinical grounds. While psychiatric disorders and a history of abuse have been reported to be present in a number of cases, these findings are not invariable, and a loss of regulation of normal reflexes controlling the laryngeal muscles has been postulated.[20] Treatment involves speech therapy and treatment of any underlying psychiatric disorder.

Neoplasms are important causes of laryngeal obstruction, with squamous cell carcinoma being the most common malignancy of the larynx. Risk factors include tobacco and alcohol use, and patients may present with hoarseness or hemoptysis.[21] The diagnosis is typically established through a combination of direct visualization and CT. The evaluation and management of tumors of the head and neck is beyond the scope of this review.

As mentioned previously, bilateral vocal cord paralysis invariably results in UAO, although the presentation is often delayed.[22] Previous thyroidectomy is often responsible for the condition, although malignancy, neck irradiation, neck trauma, and prior intubation are additional causes.

Several systemic diseases are associated with upper airway obstructing lesions.[23] Airway involvement in Wegener granulomatosis is common, although frequently subclinical. Manifestations include ulcerations, mass lesions from proliferating granulation tissue, and circumferential narrowing, particularly in the subglottic region. Treatment typically involves a combination of immunosuppression—usually prednisone and cyclophosphamide—and surgery. Tracheostomy is frequently necessary when subglottic stenosis is severe.

Rheumatoid arthritis presents several potential problems where the upper airway is concerned. Arthritis of the temporomandibular joint may limit the degree to which the mouth can be opened, frustrating attempts at oral intubation. Cervical spine arthritis, particularly of the atlantoaxial joint, should be considered a serious impediment to manipulation of the cervical spine. In particular, neck extension may lead to catastrophic cervical spinal cord injury when significant atlantoaxial disease is present. When patients with rheumatoid arthritis develop hoarseness, vocal cord nodules or cricoarytenoiditis are frequently responsible. The latter is often associated with significant pain. Over time, the vocal cords may fuse in the midline.[24] While treatment with systemic and intralesional corticosteroids is the rule, surgical removal of the arytenoids or tracheostomy may be necessary. Of note, cricoarytenoiditis occurs infrequently in patients with systemic lupus erythematosus, although in affected patients the presentation is more acute, and the response to steroid therapy is more gratifying.[25]

While pulmonary involvement in sarcoidosis is extremely common, laryngeal disease is relatively rare. When present, it is usually the supraglottic region that is affected, and on occasion upper airway patency may be threatened. Treatment includes a combination of intralesional and systemic steroids. Relapsing polychondritis is manifest as recurrent inflammation of the cartilages of the ears, nose, larynx, trachea, and joints. Half of affected patients have respiratory tract involvement. UAO may result initially from airway edema, subsequently from increased collapsibility from dissolution of cartilage, and later from fibrosis and fixed stenosis. Amyloidosis affecting the larynx and trachea is rare, and presents as firm nodules that may coalesce and cause UAO.

ANGIOEDEMA

Angioedema is a typically intense, painless swelling of a localized body area caused by leakage of plasma into the affected tissues, and preferentially involving the face, tongue, larynx, gastrointestinal tract, and extremities. Except in the case of angiotensin-converting enzyme inhibitor–associated angioedema, this leakage typically derives either from mast cell–stimulated histamine release or from activation of the complement system. Mast cell histamine release may occur following IgE-mediated hypersensitivity reactions such as those due to severe food allergies, as well as in response to certain substances—such as codeine, aspirin, and iodinated contrast media—that directly stimulate histamine release. Treatment of histamine-mediated angioedema includes histamine blockade (both H_1- and H_2-receptor blockers are given), corticosteroids, and if the airway is compromised or hemodynamic instability is present, epinephrine.

There are several diseases of the complement cascade that result in angioedema. They can be generally classified according to whether they are hereditary or acquired. Hereditary angioedema (HAE) is an autosomal dominant disease characterized by recurrent episodes of angioedema of the skin, upper airway, and gastrointestinal tract.[26] Attacks may be provoked by dental surgery or general anesthesia. Type I HAE is the most common form and is caused by decreased production of C1 esterase inhibitor. Patients with type II HAE have functionally impaired C1 esterase inhibitors. Corticosteroids, antihistamines, and epinephrine are generally considered to be ineffective in acute attacks in patients with HAE, but should not be withheld until the diagnosis is secured. Purified C1 esterase inhibitor concentrate seems to be both effective and safe in treating exacerbations of HAE, but is not widely available outside of Europe.[27] Fresh frozen plasma infusion may be considered as a means of administering C1 esterase inhibitor, but carries the potential risk of paradoxical worsening of angioedema through C4-mediated tissue damage. Generally, this treatment is reserved as a means of preventing angioedema in patients undergoing major surgical or dental procedures, when C1 esterase inhibitor is not available. Attenuated androgens and antifibrinolytic agents are used as prophylactic therapy. Although the latter is somewhat less effective, they are useful alternatives to androgens in children.

Acquired angioedema (AAE) is associated with autoimmune disorders, lymphoproliferative diseases, various carcinomas, and a number of chronic infections such as those caused by human immunodeficiency virus and hepatitis B and C viruses. Affected patients have circulating antibodies directed either against specific immunoglobulins expressed on B cells or against C1 esterase inhibitor. There is some evidence that antihistamines, corticosteroids, and epinephrine are somewhat more effective in treating AAE than HAE.

Immunosuppressive therapy may prevent attacks by decreasing autoantibody production. Some patients respond to attenuated androgens, although usually not if antibodies to C1 esterase inhibitor are present. Antifibrinolytic agents may be tried if androgens are ineffective.

Some patients experience recurrent angioedema, yet have no known cause. Most such patients also have urticaria. The evaluation of these patients is beyond the scope of this review.

Angioedema occurs in a small fraction (0.1% to 0.5%) of patients receiving angiotensin-converting enzyme inhibitors

(ACEIs). Still, because of the widespread use of these agents, a significant percentage of all cases of UAO are caused by ACEIs. Attacks typically occur shortly after initiation of therapy, but may occur years later. The angioedema seems to respond poorly if at all to treatment with corticosteroids, antihistamines, and epinephrine; although studies demonstrating the efficacy of these agents are lacking, they are frequently administered anyway. The pathophysiology is unclear; although accumulation of bradykinin has been implicated as the cause, the occurrence of angioedema in some patients who have been switched from ACE inhibitors to angiotensin receptor antagonists, which do not inhibit the catabolism of bradykinin, raises questions about the mechanisms by which each agent causes angioedema.[28] We believe that angiotensin receptor antagonists should be used in patients who have had a prior episode of angioedema attributed to ACEI therapy only when there is no other reasonable alternative.

Treatment of Upper Airway Obstruction

The most important aspect of managing a patient with suspected UAO is to immediately summon to the bedside a clinician experienced in the management of such patients. Once a significant UAO has been diagnosed, early involvement of anesthesia and otolaryngology services is crucial. The approach to management varies considerably depending on the site, severity, and tempo of UAO; while patients with slowly progressive or easily treatable causes of UAO may be managed expectantly, signs of impending respiratory arrest dictate that the airway be secured immediately. The presence of an experienced clinician is also important in ensuring that inappropriately aggressive interventions do not take place, such as attempts at intubation by an inexperienced operator with inadequate equipment and backup. In such cases, attempts to secure the airway may in fact precipitate a catastrophe. Because each patient requires an individual approach to management, explicit recommendations are difficult. Following is a discussion of available techniques for treating patients with UAO.

GENERAL STABILIZING MEASURES

If the patient has normal mentation and is able to speak, attempts can be made at stabilizing a severe UAO with noninvasive means pending definitive treatment. Because the pressure required to drive airflow across the upper airway depends in part on the density of the gas, the inhalation of a low-density inert gas such as helium in combination with oxygen has the effect of reducing the work of breathing. In fact, helium-oxygen mixtures have been shown to decrease the transdiaphragmatic pressure swings and the pressure-time index of the diaphragm, as well as improve comfort, in a group of patients with postextubation stridor.[29] The proportion of inhaled gas that can be administered as helium is obviously limited by the need to maintain an adequate arterial saturation. On the other hand, mixtures comprising less than 70% helium are of little to no benefit.

We have used noninvasive positive pressure ventilation in some patients with UAO, particularly those who have postextubation stridor and significantly increased work of breathing. While no controlled trials exist to support its use, we believe this therapy may have a role in preventing respiratory muscle fatigue, and occasionally reintubation in this setting. Conceivably, inspiratory positive airway pressure reduces the work of breathing by unloading the inspiratory muscles, while expiratory positive airway pressure may help to "splint" any collapsible segment of the upper airway in a manner similar to that seen in its use in obstructive sleep apnea.[30] We caution that this treatment should only be used in carefully selected patients. In particular, the decision to defer intubation in favor of noninvasive ventilation may allow the UAO an opportunity to progress to a point at which intubation becomes more difficult, if not impossible. Similarly, this approach should not take the place of intubation when the UAO is critical and expected to progress (e.g., in the case of an upper airway infection or tumor awaiting definitive therapy, such as surgery or radiation). We believe an additional role for noninvasive ventilation is in the stabilization of the patient with UAO while relevant airway personnel and equipment can be assembled, and a consensus reached among the medical team—anesthesia, otolaryngology, and the critical care service—as to the best approach to securing the airway.

SECURING THE AIRWAY

When time permits, and the UAO is known to be severe, the opportunity to perform awake fiberoptic intubation in a controlled manner is invaluable. The unconscious patient with UAO who is unable to be ventilated should first undergo a head-tilt or jaw thrust maneuver to advance the mandible and relieve any obstruction from the tongue base in the hypopharynx. In patients with suspected cervical spine injury, the jaw thrust may be performed without the head-tilt maneuver. Placement of an oral airway also facilitates ventilation when the UAO is proximal. If these measures are unsuccessful, the obstruction is likely to be more distal. Direct laryngoscopy with an anterior commissure laryngoscope and gum bougie introducer often permits successful passage of a small endotracheal tube over the bougie introducer and through the glottis. In situations in which the glottis cannot be well visualized, placement of a laryngeal mask airway may be useful. Subsequent fiberoptic tube placement can then be performed through this device. Depending on operator experience, the esophagotracheal Combitube, which is a dual-lumen tube with an open tracheal cannula and a blind esophageal end that is designed for emergency resuscitation by personnel lacking advanced airway management skills, may serve a similar purpose. Ventilation is performed between two inflated balloons, one in the oropharynx and one in the esophagus. This device should not be used when there is known hypopharyngeal or esophageal pathology, or when time permits an attempt to secure the airway by an experienced otolaryngologist or anesthesiologist. Depending on the level of obstruction, ventilation may still not be possible despite successful insertion of either the laryngeal mask airway or the esophagotracheal Combitube.[31]

If the airway cannot be effectively secured with an endotracheal tube, a surgical airway is indicated. Emergency cricothyrotomy is performed by first making a 1-cm horizontal incision just above the superior border of the cricoid, which can be found 2 to 3 cm below the thyroid notch.[32] The cricothyroid membrane is then slit in the midline with the blade directed inferiorly so as to avoid damaging the vocal cords. If the blade is passed too deeply, entry into the esophagus is

possible. The hole is then widened with a blunt instrument to allow passage of a small tube or cannula for ventilation. Complications include vocal cord injury, esophageal perforation, and later, subglottic stenosis. While jet ventilation via needle cricothyrotomy utilizing a 14-gauge angiocath may allow adequate ventilation of the patient pending definitive therapy, the frequency of complications is high and operator experience with this technique is typically limited.

The best approach to securing an obstructed upper airway is best determined through a multidisciplinary approach involving the critical care team, anesthesia, and otolaryngology. Available techniques for securing the airway are discussed in greater detail in Chap. 35.

THE DECISION TO EXTUBATE

Deciding when to extubate a patient with an UAO is often difficult. The presence of the endotracheal tube makes an assessment of upper airway patency difficult. Sometimes improvement in the UAO is suggested by the overall clinical course; for example, if a patient was intubated for a borderline indication in the setting of a soft tissue infection, a significant reduction in facial and neck swelling may indicate that the UAO has improved to the point where extubation is safe. Similarly, complete resolution of lip, tongue, and hypopharyngeal swelling from angioedema is often accompanied by resolution of laryngeal edema. However, care must be taken in such circumstances. It is frequently useful to perform a "cuff leak" test. After scrupulous oral and endotracheal suction, the endotracheal tube cuff is deflated. If a patient is unable to pass air around the tube, its removal may not be tolerated, particularly if the tube is small (i.e., 6.0 or 6.5 mm). When the patency of the airway is in question, it is useful to pass a tube changer through the endotracheal tube prior to its removal. The tube changer allows repassage of an endotracheal tube through the glottis and into the trachea if reintubation is required. Careful consultation with anesthesia and otolaryngology services prior to making a decision to extubate is important, and all necessary equipment and personnel should be at the bedside in marginal cases.

Some studies have suggested that quantification of the cuff leak, either by volume or by percentage of total tidal volume, may predict the occurrence of postextubation stridor in patients not intubated for UAO. Because the rate of reintubation in such cases is low and the benefit of steroids uncertain, it is not clear whether this practice should be generally employed, particularly if it results in more patients remaining intubated for longer periods.

Complications of Upper Airway Obstruction

Short of cardiac arrest, the most feared complication of UAO is anoxic brain injury. Negative-pressure pulmonary edema may also occur.[33] This condition typically occurs in patients with severe UAO, in whom several mechanisms act synergistically to promote its development. First, the patient generates extremely negative pleural pressures during inspiration attempting to overcome the UAO. This promotes venous return and a shift of the interventricular septum to the left, decreasing left ventricular preload. At the same time, left ventricular afterload is dramatically increased by the fall in intrathoracic pressure, as well as by catecholamine-induced systemic hypertension. These events cause a transfer of blood volume from the systemic to the pulmonary circulation. Here, pulmonary capillary transmural pressure is elevated because of reduced interstitial pressure and possibly elevated capillary pressure, the latter from increased blood volume and pulmonary vascular tone from hypercapnia and hypoxia. This rise in capillary transmural pressure causes pulmonary edema. On occasion, the edema fluid in such patients has been noted to be pink or blood-tinged, possibly from red blood cell leakage caused by high transmural pressures across disrupted alveolar-capillary membranes.

Chapter 35
AIRWAY MANAGEMENT

MICHAEL F. O'CONNOR
ANDRANIK OVASSAPIAN

KEY POINTS

- *The choice between noninvasive ventilation via mask versus ventilation via translaryngeal tracheal intubation is an increasingly critical branch point in the management of patients with respiratory failure.*
- *Shock, a failed trial of extubation, inability to protect and maintain one's own airway, need for larger minute ventilations or larger transpulmonary pressures, and transport of an unstable patient all remain indications for tracheal intubation.*
- *Assessment and adequate preparation of the patient prior to intubation are crucial to ensuring successful and safe intubation.*
- *Awake tracheal intubation with topical anesthesia remains the preferred technique, although skilled operators can perform rapid sequence induction and intubation with a high degree of success. General anesthesia and paralysis are associated with substantial risks in critically ill, hemodynamically unstable patients.*
- *The appropriate timing of tracheostomy remains poorly defined. Improved endotracheal tubes allow for prolonged intubation with a low risk of associated traumatic injury.*
- *Percutaneous tracheostomy and conventional tracheostomy are increasingly performed at the bedside to minimize the hazards associated with transporting a critically ill patient.*

Tracheal intubation remains one of the most common and important procedures performed in the intensive care unit (ICU). When done well, tracheal intubation can be a lifesaving procedure. When done poorly, it may initiate a cascade of events that can lead directly or indirectly to trauma, severe complications, and death. The widespread adoption of noninvasive ventilation in the management of patients with type II acute-on-chronic respiratory failure (ACRF) and high-pressure pulmonary edema has created a population of patients who have failed moderate levels of ventilatory support and require emergent airway management (see Chap. 33). It is imperative that those who manage the airways in these patients have a high degree of knowledge, skill, and comfort in managing patients with little physiologic reserve. It is imperative that ICU physicians have knowledge and understanding of the indications for tracheal intubation, the assessment of the patient for tracheal intubation, the devices and techniques available for tracheal intubation, and the consequences and complications of tracheal intubation.[1]

Indications for Intubation

The decision about whether to intubate a critically ill patient requires that a practitioner at the bedside synthesize all of the information they have at their disposal about a patient, compare it to their institutional practice patterns and resources, and decide how to proceed. These decisions are rarely clear-cut; reasonable practitioners can arrive at different decisions in identical circumstances. Patients who require intubation as part of the initial management of their respiratory failure include but are not limited to those with cardiopulmonary arrest, respiratory arrest, acute respiratory distress syndrome (ARDS) of almost any cause, and any patient who is unlikely to respond to noninvasive ventilation (Table 35-1). The decision to intubate a patient after noninvasive ventilation is even more difficult to make. Triggers to convert to an invasive airway include progressive hypercapnia in spite of adequate levels of support (such as a patient with sleep apnea who is worsening on biphasic positive airway pressure [BIPAP]), unacceptably high airway pressure, hypoxemia which persists in spite of moderate levels of continuous positive airway pressure (CPAP) and high fraction of inspired oxygen ($F_{I_{O_2}}$), diminishing mental status, patterns of respiration which suggest evolving respiratory muscle fatigue or impending respiratory arrest, and unfavorable anatomy (which is present at the start of treatment, or which evolves) (Table 35-2).

In patients with airway compromise, two decisions need to be made at the time the patient is evaluated: (1) Does this patient require an artificial airway? and (2) Does this patient require a tracheostomy? It may be difficult or impossible to translaryngeally intubate the trachea in patients with an unstable cervical spine, airway tumor, unfavorable anatomy, or significant facial trauma. Preparation for tracheostomy should occur concurrently with preparation for translaryngeal tracheal intubation in such high-risk patients.

The decision to intubate patients in cardiopulmonary arrest is a simple one, as intubation is the safest and most effective way to both ensure adequate ventilation in these patients and to protect their airway. The goal of intubating the trachea in the patient in shock is to decrease the proportion of cardiac

TABLE 35-1 Indications for Tracheal Intubation

Airway support
Diminished mental status or decreased ability to maintain airway and clear secretions
Compromised airway anatomy
Diminished airway reflexes, full stomach, or fluctuating consciousness
Requirement for sedation where airway control may be difficult to establish
Pharyngeal instability
Pulmonary disease
Acute respiratory distress syndrome
High pressure pulmonary edema unlikely to respond to noninvasive ventilation, or which has not responded to a reasonable trial of noninvasive ventilation
Hypoventilation (including central nervous system causes and weakness)
Hypercapneic respiratory failure that has failed noninvasive ventilation
Failed trial of extubation
Forseeable protracted course of respiratory failure
Circulatory
Cardiopulmonary arrest
Shock
Other situations
Elevated intracranial pressure requiring hyperventilation (increasingly rare)
Transport to less monitored situations

TABLE 35-2 Indications for Converting Noninvasive Ventilation to Intubation and Mechanical Ventilation

Patient inability to tolerate noninvasive ventilation
Unfavorable anatomy and poor mask fit or large leak
Progressive hypercapnia in spite of adequate levels of support (typically over 1 hour)
Requirement for unacceptably high airway pressure (typically total delivered pressures >20 cm H_2O)
Hypoxemia in spite of appropriate levels of continuous positive airway pressure and high F_{IO_2}
Diminished mental status and inability to protect the airway
Respiratory pattern consistent with evolving fatigue or impending respiratory arrest

output devoted to perfusing their respiratory muscles, allowing this blood flow to be diverted to other vital organs.

Assessing the Patient Prior to Intubation

All patients being evaluated for tracheal intubation should be treated with the highest F_{IO_2} available. Oxygen saturation, blood pressure, heart rate, electrocardiography (ECG), and the frequency and strength of respiration should be closely monitored. Blood gas analysis may be helpful in facilitating the decision to intubate the patient, but has been largely supplanted by pulse oximetry, which is also essential for monitoring during intubation.

Patients requiring urgent intubation benefit from an expeditious but thorough assessment of their underlying medical conditions and airway anatomy (Tables 35-3 and 35-4). The possibility of increased intracranial pressure (ICP) or increased risk of intracranial hemorrhage is important to ascertain, since the presence of elevated ICP changes the emphasis in airway management from the maintenance of an adequate airway to the avoidance of further increases in ICP. Whereas most airway manipulation in the ICU can be done safely with patients awake, patients with elevated ICP and increased risk of intracranial hemorrhage (from unstable arteriovenous malformations or aneurysms) are best managed with intravenous general anesthesia for intubation. Laryngoscopy and tracheal intubation reliably produce myocardial ischemia in patients with coronary artery disease. Adequate anesthesia—topical and intravenous—can attenuate or prevent the myocardial ischemia associated with laryngoscopy and intubation. Inadequate anesthesia can elicit ischemia and associated arrhythmias. The use of intravenous agents in this setting is fraught with hazard. Too little intravenous agent can be associated with ischemia, while too much can cause hypotension, ischemia, hypoperfusion of vital organs, and a decreased rate of redistribution of the offending agent, prolonging its cardiovascular effects. The use of intravenous agents in these patients is thus best avoided if possible.

Intubation and positive pressure ventilation (PPV) will magnify the shock associated with intravascular hypovolemia. In hypovolemic patients, reflex sympathetic tone usually decreases venous capacitance, increases mean systemic pressure, and maintains venous return. Administration of sedative or anesthetic agents blunts this physiologic compensation. PPV increases intrathoracic pressure and therefore decreases the pressure gradient driving venous return. Singly or in combination, these effects can substantially reduce venous return, blood pressure, and tissue perfusion. In the setting of suspected hypovolemia, intravascular volume expansion may be desirable before intubation. In any case, preparation for rapid volume infusion should be made prior to intubation.

TABLE 35-3 Medical Evaluation for Intubation

Neurologic factors
Elevated intracranial pressure
Presence of intracranial bleeding, arteriovenous malformation, or aneurysm
Cervical spine disease
Cardiovascular factors
Ischemia
Hypovolemia
Myocardial infarction (especially within the past 6 months)
Cardiomyopathy
Dysrhythmias
Drug allergies
Pulmonary factors
Severity of hypoxemia, airway obstruction, or lung restriction
Aspiration risk
Nothing by mouth (NPO) status
Morbid obesity
Impaired gastric emptying or gastroparesis
Ileus
Obstruction
Pregnancy
Coagulation factors
Thrombocytopenia
Anticoagulant therapy
Coagulopathy
Recent or anticipated therapy with thrombolytics
Current therapy with activated protein C for sepsis
Contraindications to succinylcholine
Major burn within the past year
Crush injuries
Stroke or spinal cord injury resulting in denervation of a significant portion of the body
Malignant hyperthermia
Hyperkalemia

TABLE 35-4 Anatomic Evaluation for Intubation

Obesity
Pregnancy
Short neck
Large tongue
Inadequate mouth opening or temporomandibular joint dysfunction
Small or recessed mandible (short thyromental distance)
Limited flexion at the base of the neck or extension at the base of the skull
Cervical instability
Prominent incisors
Dentures
Loose teeth
Tumor (e.g., adenoma, carcinoma, or abscess)
Large epiglottis
Lingual tonsil hyperplasia
Copious secretions or blood
Trauma
History of prior intubations
Mallampati 3 and 4
Lip bite test

Patients with respiratory failure require thoughtful assessment of their shunt, V/Q mismatch, and bronchospasm prior to airway manipulation. The more severe their pathology, the more rapidly they will become hypoxic or hypercarbic during airway manipulation. Patients with acute hypoxemic respiratory failure are usually hypoxemic in spite of a high F_{IO_2}, and frequently desaturate further during airway manipulation. Patients with type II respiratory failure may become hypoxemic, hypercapneic, or both during airway manipulation. The more severe the lung disease, the less likely it is that ventilation with a mask or laryngeal mask airway (LMA) will be successful. Patients with severe pulmonary edema or severe bronchospasm cannot generally be ventilated successfully with a mask or LMA because the pressures and flows required to maintain an acceptable minute ventilation cannot be generated with these systems.

Manipulation of the airway in the ICU is accompanied by a substantial risk of aspiration. Unlike patients undergoing airway manipulation in an elective setting, such as the bronchoscopy suite or operating room, patients in the ICU typically are at high risk of aspiration. Stomach contents may include enteral feedings, blood (from gastrointestinal hemorrhage), acid, and bacteria. Conditions that decrease emptying, such as diabetic gastroparesis, morbid obesity, and perhaps critical illness itself, require management as if the patient has a full stomach, even during elective airway management. Cricoid pressure (the Sellick maneuver) should be performed whenever possible on patients undergoing tracheal intubation in the ICU.[1–4]

The presence of a coagulopathy is a relative contraindication to nasal intubation and techniques that are associated with a risk of bleeding, such as transtracheal injection of anesthesia, superior laryngeal nerve blocks, and retrograde intubation techniques.

Finally, contraindications to the use of succinylcholine (see Table 35-3), the most commonly used muscle relaxant for airway management in the ICU, should be considered prior to any airway manipulation.

A variety of anatomic conditions are associated with increased difficulty of intubation by rigid laryngoscopy (see Table 35-4).[5] A history of difficult intubation is perhaps one of the most important but least available elements of a patient's history. The presence of many anatomic conditions makes attempts at rigid laryngoscopy and intubation in the awake or asleep patient more difficult. This in turn increases the attractiveness of techniques which allow for the patient to be awake and spontaneously breathing, and that do not require direct laryngoscopy, such as fiberoptic intubation, blind nasal intubation, and techniques which utilize an intubating laryngeal airway. Patients with severely compromised airway anatomy may be best managed by either awake fiberoptic intubation or tracheostomy. When a difficult airway is anticipated, it is best to have equipment for performing a tracheostomy immediately available, and physicians skilled at performing the procedure at hand.

Equipment

In spite of the vast array of available equipment, most tracheal intubation can be accomplished using a very small subset of the equipment and a very simple checklist (Table 34-5). A cart that is fully stocked with all of the equipment required to manage a difficult airway should be available to airway managers, but need not be brought to the bedside of every patient in crisis.[6]

Ideally, bags or boxes containing the equipment on the basic list for cardiac arrest are readily available to airway managers and can be brought by them to any situation in which they may be asked to manage an airway. The more complete equipment set for urgent and elective intubation can be kept in a cart stocked specifically for this purpose. Equipment should be checked at least daily and should be stored so that it is readily accessible. It is important that the equipment is checked by the person who will use it. This procedure ensures that the airway manager can focus on the patient during airway

TABLE 35-5 Equipment List for Intubation

Cardiac arrest
Two laryngoscopes with functioning lights (ideally one with a short handle)
Macintosh no. 3 and 4 and Miller no. 3 blades
Small, medium, and large face masks
Laryngeal airways (e.g., laryngeal mask airway [LMA], cuffed oropharyngeal airway [COPA], Proseal, Combitube)
Suction with Yankauer tip
6.5, 7.0, 7.5, 8.0, 8.5, and 9.0 mm endotracheal tubes with cuffs checked
Malleable metal stylet
10-mL syringe for inflation of endotracheal tube cuff
Oxygen supply
Ambubag or other circuit (e.g., Mapleson D) to ventilate patient
Stethoscope
Gloves and eye protection
Portable end-tidal CO_2 monitoring device (e.g., EZ-Cap, capnograph)
Cricothyroidotomy kit
Urgent and elective intubation
Functioning IV line
Monitors: pulse oximeter, blood pressure, electrocardiograph
Resuscitation cart
Drugs
Atropine
IV lidocaine
Ephedrine
Epinephrine
Glycopyrrolate
Succinylcholine
Rocuronium
Topical anesthetics (lidocaine jelly, benzocaine spray)
Topical phenylephrine spray
Controlled substances
Propofol
Thiopental
Etomidate
Midazolam
Fentanyl
Ketamine
Tape
Magill forceps
Size 7, 8, 9, and 10 oral airways
28, 30, 32, and 34 French nasal trumpets
Full variety of endotracheal tubes, including 7.0 and 8.0 mm Endotrol tubes, armored tubes
Fiberoptic bronchoscope
Jet ventilator

manipulation, and is not distracted by equipment failures, equipment checks, or preparation.

PHARMACOLOGIC PREPARATION AND USE

The goals of pharmacologic preparation of the patient include creating conditions that allow safe intubation, providing relief from the discomfort and hemodynamic consequences associated with airway manipulation and tracheal intubation, and decreasing the hormonal and neurologic consequences of the procedure. The spectrum of pharmacologic preparation ranges from topical to intravenous general anesthesia. In the hands of experienced operators, most airway manipulations can be accomplished with topical anesthesia alone. Intravenous general anesthesia is indicated in the setting of elevated ICP and favorable airway anatomy (Table 35-6). There are many institutions where an intravenous general anesthetic is routinely administered for tracheal intubation, but this practice should be strongly discouraged. The majority of the literature suggests that the use of intravenous general anesthesia to facilitate airway management may be associated with a higher rate of failure and need for emergency tracheostomy/cricothyroidotomy.

Patients who require urgent intubation benefit from pharmacologic preparation when circumstances allow. The administration of 0.2 mg IV glycopyrrolate will dry the mouth and facilitate direct laryngoscopy or fiberoptic laryngoscopy. The oropharynx can be anesthetized topically with 4% lidocaine spray, followed by approximately 1 to 2 mL of 2% lidocaine jelly on an oral airway of appropriate size for the patient. The oral airway can also be used to direct topical anesthetic at the vocal cords. The use of lidocaine for topical anesthesia is preferable to benzocaine, as the latter can cause methemoglobinemia. Care should be taken to avoid giving high doses (>6 mg/kg) of lidocaine for topical anesthesia, since lidocaine is readily absorbed by the mucosa of the pharynx. Some practitioners routinely perform transtracheal and superior laryngeal nerve blocks to facilitate awake intubation, but these procedures add little or nothing to topical anesthesia, and can cause significant bleeding in coagulopathic patients. Topical/local anesthesia schemes that avoid anesthetizing the trachea have several advantages in the ICU setting. They allow the patient to retain some ability to protect themselves from aspiration, and they also allow confirmation of tracheal intubation when the patient coughs in response to introduction of the tube into the trachea.

TABLE 35-6 Steps for Tracheal Intubation in the Presence of Elevated Intracranial Pressure and an Anatomically Favorable Airway

1. Administer 1 mg vecuronium or pancuronium (if available)
2. Preoxygenate for 3 minutes
3. Apply cricoid pressure
4. Administer 0.03 mg/kg midazolam (if available)
5. Administer 1–2 μg/kg fentanyl (if available)
6. Administer 100 mg lidocaine (optional, but generally desirable)
7. Administer 3–5 mg/kg thiopental or 2 mg/kg propofol
8. Administer 1.5 mg/kg succinylcholine or 0.2 mg/kg vecuronium or 1 mg/kg rocuronium
9. Hyperventilate for 45 seconds with Ambu bag/mask following succinylcholine administration, or for 2 minutes following vecuronium administration
10. Perform laryngoscopy/intubation
11. Confirm intubation with auscultation or capnography
12. Elevate head of bed and ventilate to goals for patient

The use of intravenous agents to facilitate tracheal intubation in the ICU is hazardous. The degree of hypovolemia, myocardial dysfunction, and shock that often exists in these patients is difficult to ascertain prior to manipulating the airway in an urgent situation. Doses of intravenous agents that are well tolerated or even subtherapeutic in healthy patients can precipitate respiratory arrest or circulatory collapse in critically ill patients, converting a serious situation into a desperate one. Intravenous lidocaine in a dose of 100 mg is frequently sufficient to induce general anesthesia in patients with shock. The use of intravenous agents such as midazolam, fentanyl, thiopental, etomidate, propofol, and ketamine should be restricted to experienced practitioners. When indicated, these agents may be used to either titrate up to an acceptable level of sedation (which will be accompanied by a corresponding decline in both hemodynamics and minute ventilation, with associated worsening of hypoxia and hypercapnia), or to deliberately induce brief general anesthesia.

MUSCLE RELAXANTS AND AIRWAY MANAGEMENT IN THE INTENSIVE CARE UNIT

The use of muscle relaxants to facilitate airway management in the ICU remains controversial. Although these agents are routinely administered to facilitate airway management in the operating room, their use in ICU patients is not essential. The use of intravenous induction agents to initiate general anesthesia is motivated by the desire to produce intubating conditions quickly and to minimize unpleasant recall. Most patients undergoing elective surgery tolerate the hemodynamic consequences of intravenous anesthetic agents well and can be readily oxygenated and ventilated with a bag and mask. When anesthesiologists are confronted with patients who have abnormal airway anatomy or who may be impossible to oxygenate or ventilate with a bag and mask, they tend to opt for awake intubation strategies, as outlined in this chapter. Muscle relaxants, including succinylcholine, vecuronium, mivacurium, rocuronium, and cisatracurium should be used only by those who are experienced in managing the airway with an Ambu bag and mask, and who are thoroughly versed in techniques used to manage the difficult airway. The reason for this stipulation is that once these agents are administered, it is imperative that a definitive airway be obtained within minutes. Attempts at ventilating most patients in respiratory failure with an Ambu bag and mask are often difficult and frequently futile, since the decreased compliance of the lungs and/or increased airway resistance makes it difficult to maintain adequate minute ventilation. Among muscle relaxants available to facilitate airway management, succinylcholine remains the agent of first choice in ICU and ER patients for whom it is not contraindicated.[7]

There is an evolving literature about the use of intravenous anesthetic agents and muscle relaxants to facilitate airway management in both the field and the emergency department.[8–18] This literature suggests that the use of intravenous agents can both improve intubating conditions and cause hypotension, although brain-injured trauma patients have worse outcomes.[19,20] Airway management utilizing muscle relaxants in these reports is associated with a

success rate in the range of 94% to 99%, with 1% of patients requiring a surgical airway of some kind. At first glance, this appears to be conspicuous success, but compared to airway management in the operating room, it is a very high rate of failure, and a very high rate of requirement for a surgical airway. No doubt some of the need for surgical airways in these patients is a consequence of their pathology, their anatomy, and the circumstances surrounding their airway management. Nevertheless, it seems plausible if not certain that the requirement for a surgical airway in some of these patients is a consequence of the use of either intravenous anesthetics or muscle relaxants as part of their airway management.

Procedures for Intubation

Compared to the operating room environment, arterial oxygen desaturation occurs quite rapidly in most patients undergoing intubation in the ICU, even if the patient has been preoxygenated with 100% oxygen. Factors that contribute to desaturation include an increased alveolar-arterial gradient, decreased functional residual capacity (FRC), and increased metabolic rate. Nevertheless, all patients undergoing airway management in the ICU should be preoxygenated.

The presence and help of well-trained assistants increases safety and success of intubation. Assistants might include other physicians, ICU nurses, respiratory therapists, and others trained in airway management and routinely engaged in the bedside care of critically ill patients. Ideally, the person managing the airway in the ICU has several helpers, one to help position the patient and apply cricoid pressure, one to hand off equipment, and one to monitor the patient and administer IV drugs as necessary.

Patients in cardiopulmonary arrest are relatively straightforward to intubate, as they are typically unconscious and flaccid. No drug therapy is necessary to facilitate airway management in these patients. Direct laryngoscopy should be attempted immediately, and the largest possible appropriate-sized endotracheal tube (ETT) should be inserted into the trachea. Many patients will have aspirated oral secretions or gastric contents prior to or after their cardiopulmonary arrest, and the necessity of suctioning using a rigid catheter (Yankauer) to achieve adequate visualization should be anticipated. Patients receiving cardiopulmonary resuscitation (CPR) do not typically deliver much carbon dioxide to their lungs, and attempts to confirm endotracheal intubation with CO_2 monitors may therefore be futile. The ability to detect carbon dioxide in the exhaled gases of such patients is usually a sign of the recovery of a spontaneous circulation. Cervical instability is the only coexisting condition that requires serious consideration during the intubation of a patient receiving CPR. All other medical and anatomic considerations are secondary in this situation.

In the past few years, there have been several clinical studies that have demonstrated an association between nasal intubation and the evolution of sinusitis, and between sinusitis and the development of ventilator-associated pneumonia (VAP) (see Chap. 43). Given this, it is probably the case that the oral route of intubation is preferable in most critically ill patients. Nasal intubation may still be desirable in a select population of patients with normal immunity, normal coagulation status, and relative contraindications to oral intubation.

OROTRACHEAL INTUBATION

Advantages of oral intubation include the requirement for less equipment (a laryngoscope), less trauma and bleeding, a lower incidence of sinusitis and VAP, and a high success rate independent of patient respiratory effort.[21,22] The disadvantages of oral intubation include the substantial stimulus associated with direct laryngoscopy, risk of dental and cervical trauma, difficulty securing the tube, difficulty of maintaining oral hygiene, and the occasional problem of a patient biting the tube. Patients must generally be supine to undergo orotracheal intubation. Orotracheal intubation is far more difficult to accomplish than it appears to the casual observer, especially in the less-than-ideal conditions that are typical of airway management in the ICU.

Most patients can be successfully intubated with topical anesthesia alone. Most patients will benefit from treatment with 0.2 mg of glycopyrrolate as a drying agent, and topical anesthesia using a combination of lidocaine spray (4%) and jelly (2% to 4%). Topical anesthesia usually begins with spraying the oropharynx with lidocaine, obtaining as much coverage of the oro- and hypopharynx as possible to obliterate the gag reflex. An appropriately sized oral airway (9 mm is a good default) is then covered with lidocaine liquid or jelly and inserted into the pharynx. The patient is instructed to suck on the airway. Lidocaine can also be sprayed through the oral airway directly towards the larynx. The importance of the oral airway as a mechanism to administer topical lidocaine requires emphasis, as it is the quality of the hypopharyngeal anesthesia that allows direct laryngoscopy to be performed. An adequately prepared patient will permit placement of a laryngoscope blade or even a more uncomfortable device such as an intubating LMA. Once the operator is assured that the airway has been adequately prepared, laryngoscopy (direct or fiberoptic) is performed, and intubation is attempted. Direct laryngoscopy in adults is usually performed using a Macintosh no. 3 or 4 blade, although straight blade designs (such as the Miller) are popular with some operators. The curved blades are generally easier to use, but the straight blades may be more useful in the event of difficulty obtaining an adequate view. It is desirable for those who manage airways in the ICU to be comfortable with both designs. Although circumstances are frequently less than ideal, the operator should do everything possible to ensure successful laryngoscopy. If possible, the head of the bed should be removed, and the bed moved away from the wall. The patient should be positioned in the sniffing position using pillows and rolled blankets as necessary. Failure to adequately position the patient is a common cause of repeated intubation attempts in the ICU setting. Once the patient has been intubated, it is imperative that the airway manager hold the tube firmly in place until the tube has been secured. Oral ETTs must be secured at least with tape; they may be wired to secure teeth in circumstances in which the use of tape is undesirable or impossible. Importantly, the pressure in the cuff of the tracheal tube should be maintained at 20 to 22 cm H_2O pressure from the time it is inserted to minimize the risk of VAP.[23]

Successful tracheal intubation can be confirmed by a variety of techniques in the spontaneously breathing patient,

including the appearance of humidified gases in the tube, audible breath sounds at the end of the tube, breath sounds synchronous with Ambu bag ventilation, and carbon dioxide detected via capnography or capnometry.

NASOTRACHEAL INTUBATION

The disadvantages of nasal intubation are the increased risk of associated purulent sinusitis, VAP, and bleeding.[24,25] Advantages of nasal intubation include ease of securing the tube, free access to the mouth, greater stability relative to oral intubation, and absence of biting-associated obstruction. Nasal intubation can be accomplished with the head in a neutral position (or in traction) and with the patient sitting upright in bed. Nasally intubated patients are less likely to self-extubate than orally intubated patients.[26,27] Blind nasal and fiberoptic nasal intubation are readily accomplished in patients with air hunger. Other disadvantages include the greater length of the ETT and trauma to the nasal mucosa, septum, and turbinates. Relative contraindications to nasal intubation include coagulopathy, compromised immune function, and suspected or known skull-base trauma.

Nasal intubation can be performed either blindly, with direct laryngoscopy, or fiberoptically. Larger-bore tubes, such as 8.0 mm ETTs, should be used in nasal intubation, as they can be inserted as readily as smaller tubes in most patients, present substantially less resistance to air movement than do smaller tubes, and are large enough to allow fiberoptic bronchoscopy to be performed.[28]

Nasal intubation can be successfully performed without sedation, provided that adequate topical anesthesia is used. Many experienced operators prepare both nares simultaneously, so if an anatomic complication arises in attempts to use the first one, the second one can be used without delay. Those who desire to vasoconstrict the nasal mucosa prior to manipulating it can do so with 0.5% phenylephrine spray.[29] Topical anesthesia such as 4% lidocaine can then be sprayed into both nostrils. Following this step, a nasal trumpet lubricated with 2% lidocaine jelly is introduced into one of the nares. Successful introduction of the trumpet confirms the presence of a passage patent enough to allow an ETT to be passed. If the operator encounters any difficulty in passing the nasal trumpet, the attempt to intubate the trachea through that nostril should be abandoned. Once the trumpet is successfully inserted, lidocaine is then sprayed through the trumpet onto the vocal cords. It is best to use ETTs intended for use in the nose (such as the Endotrol tube) when performing nasal tracheal intubation, as conventional tubes may be too short and too rigid to be used safely for this purpose. The ETT is lubricated with 2% lidocaine jelly and passed into the nasopharynx. If any resistance is encountered as the tube is advanced, the operator should stop immediately. Attempts to advance the tube past substantial resistance are associated with mucosal tears, polypectomies, turbinatectomies, crushed and perforated nasal septa, and tunneling of the ETT underneath the mucosa, all of which can be associated with exuberant bleeding and other major complications. If fiberoptic intubation is planned, the bronchoscope is introduced through the tube into the nasopharynx and is advanced into the trachea. The bronchoscope is used as a stylet to advance the ETT into the trachea. Tracheal intubation can be confirmed by observing the carina and presence of tracheal rings beyond the tip of the ETT. If the plan is to perform nasal intubation under direct laryngeal visualization with a rigid laryngoscope, the oropharynx should be anesthetized concurrently with the nose. Direct laryngoscopy is then performed, and a Magill forceps may be used to guide the tube into the trachea. If blind nasal intubation is planned, then the ETT is advanced slowly, with inspiration, while the operator listens at the end of the tube for breath sounds. As the end of the tube gets close to the glottis, the breath sounds become louder. The tube is advanced into the trachea while the patient is instructed to take a deep breath. The sensation of the tube popping through the cords followed by efforts at a cough by the patient suggest successful introduction of the tube into the trachea. The disappearance of breath sounds suggests that the esophagus has been intubated. If this occurs, the tube should be withdrawn until breath sounds are heard again. The patient's head should then be repositioned and another attempt made to pass the ETT. If an Endotrol tube is being used, tension should be applied to the ring to redirect the tip of the tube more anteriorly before another attempt is made.

FIBEROPTIC INTUBATION

Fiberoptic tracheal intubation is increasingly performed in critical care units.[6] There are a variety of explanations for this, including the proliferation of fiberoptic bronchoscopes, increased familiarity and comfort with their use, and increased recognition of their utility as the technique of first choice in the patient with an anticipated difficult airway. Because the technique can be made difficult or impossible by the presence of blood or secretions, it requires meticulous preparation of the airway with drying agents, suctioning of secretions, and careful avoidance of any trauma which might cause bleeding. The technique is more successfully performed in awake patients, because their airway muscle tone maintains airway patency, which is important for good viewing conditions.[30]

Preparation for performing fiberoptic intubation consists of warming the ETT, if possible, to soften it and make it easier to advance through the vocal cords. The ETT is then placed on the fiberoptic scope in position to be slid forward when the scope is advanced into the trachea. The airway is prepared with topical anesthesia as discussed previously. Specialized oral airways, such as the Ovassapian airway are very useful, as they keep the tube midline, displace the tongue anteriorly, and prevent biting on the bronchoscope (Fig. 35-1). For optimal viewing conditions, it is imperative that a competent assistant either provide a vigorous jaw thrust or pull on the tongue, delivering it anteriorly. The fiberoptic bronchoscope is then passed through the vocal cords, down the trachea to the carina. The tube is then threaded into the trachea, over the scope with a smooth twisting motion. Tracheal intubation is confirmed with the bronchoscope as it is withdrawn from the trachea. The distance from the carina to the tip of the tube is determined by measuring how far the bronchoscope must be withdrawn from the carina before the tip of the tube becomes visible. Difficulty advancing the tube is usually from the tube catching laryngeal structures, and can be corrected by pulling the tube back and advancing with a twisting motion. Rarely, the tube may be too large for the glottic opening, requiring the bronchoscope to be withdrawn and a smaller tube to be placed instead. Of note, cricoid pressure may decrease the time and difficulty of fiberoptic intubation.[30]

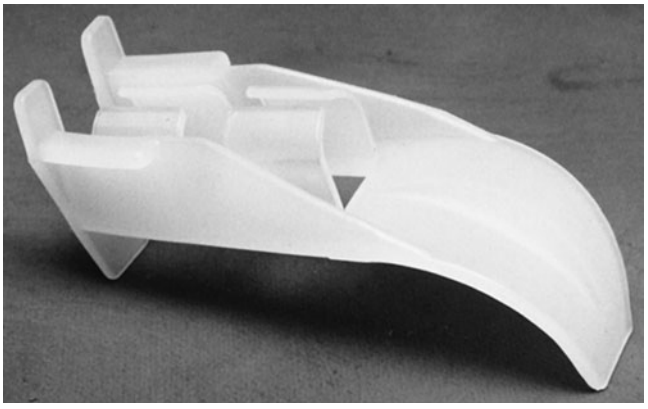

FIGURE 35-1 Ovassapian fiberoptic intubating airway. It keeps the tongue forward and the fiberscope midline, provides open air space in the hypopharynx, protects the fiberscope from the patient's bite, and is removed from the mouth without disconnecting the endotracheal tube adapter.

The technique for nasal fiberoptic intubation is similar in most regards. Most operators will introduce the tube through the nose and into the nasopharynx, thus proving patency of the nose and allowing the tube to be used as a guide through the nose for the bronchoscope. Viewing conditions for the nasal approach are also improved by either the jaw thrust or the tongue-tug, especially in unconscious or sedated patients.

INTUBATING WITH A LARYNGEAL MASK AIRWAY

Laryngeal mask airways in their various forms have become a critical component of airway management, especially in difficult-to-intubate patients (Fig. 35-2).[31] A variety of LMAs (e.g., the classic, Fastrach, and ProSeal) have been designed to facilitate ventilation and intubation under the most difficult conditions. As with most airway management skills, the use of such devices appears to be deceptively easy and unskilled practitioners will have a high rate of failure.[32,33]

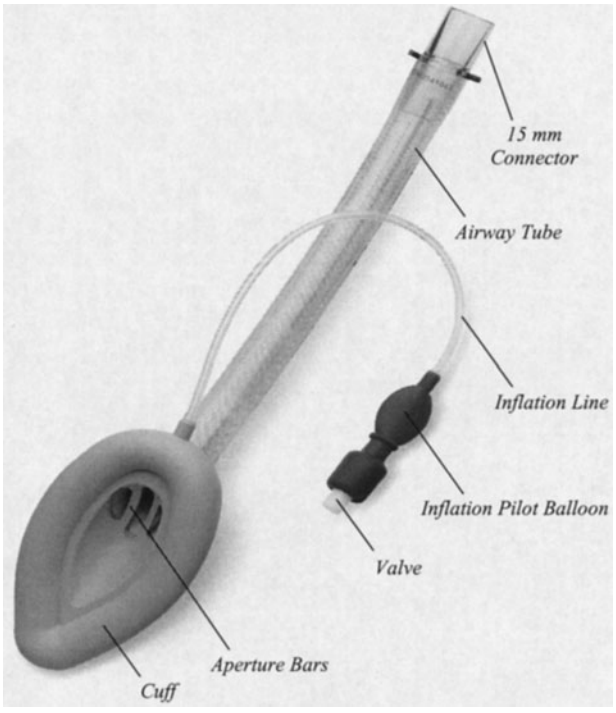
The intubating LMA is designed to facilitate tracheal intubation with a large size ETT. It has a rigid anatomically curved tube made of stainless steel with a standard 15-mm connector, and an epiglottic elevating bar (EEB). The caudal end of the EEB is not fixed, allowing it to elevate the epiglottis when an ETT is passed through the aperture. The tube is large enough to accept a cuffed 8-mm ETT, and is short enough to ensure passage of the ETT cuff beyond the vocal cords. The Fastrach is fitted with a rigid handle to facilitate one-handed insertion, removal, and adjustment of the device's position.

The device permits single-handed insertion from any position without moving the head and neck from a neutral position and without placing fingers in the mouth. Ventilation and oxygenation may be continued during intubation attempts, lessening the likelihood of desaturation. Prior to insertion of the LMA-Fastrach, the cuff should be tightly deflated using a syringe so that it forms a smooth spoon shape without any wrinkles on the distal edge. Lubricant is applied to the posterior surface of the LMA before insertion. The LMA cuff is inflated with 20, 30, and 40 mL of air for size 3, 4, and 5 tubes, respectively.

The application of cricoid pressure reduces the chances of successfully positioning the LMA and intubating the trachea by 30%.[34] For this reason, and because LMAs do not protect against aspiration, the intubating laryngeal mask airway is more properly used as a rescue device than an approach of first choice in any ICU patient who may have a full stomach. In the settings of upper airway bleeding or copious secretions and failed rigid laryngoscopy, it is reasonable to attempt to use an intubating LMA.

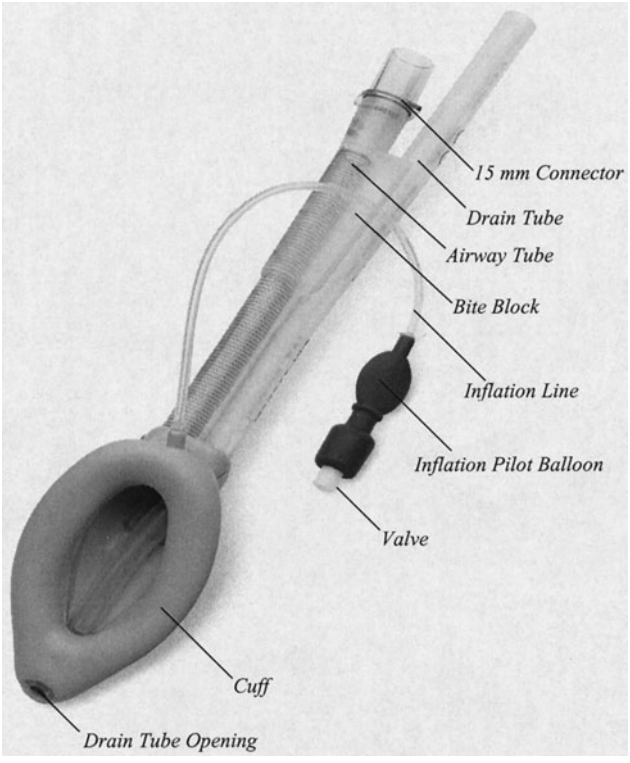
THE DIFFICULT AIRWAY

The difficult airway is far more commonly encountered in the ICU and emergency room than in the operating room. Under these emergent conditions of airway management, multiple attempts at laryngoscopy are common (25% to 35%), and between 0.5% and 2% of patients require a surgical airway. Copious secretions and inadequate positioning are common obstacles encountered in the ICU, but not in the operating room. The American Society of Anesthesiologists' Difficult Airway Algorithm outlines the options available to practitioners faced with a difficult airway (Fig. 35-3).[31] Choices for proceeding include: ventilate with the bag and mask, summon help in the form of another operator, reposition, attempt laryngoscopy with a different blade, and apply other techniques as appropriate. Ideally, a competent operator will ventilate the patient with an Ambu bag as the operator prepares for their next attempt to secure the airway. If the patient can be adequately oxygenated with mask ventilation, then the operator has a variety of options for how to proceed. Changing the operator or laryngoscope blade will sometimes permit successful intubation where previous attempts have failed. Straight blades, such as the Miller blade, are especially useful in patients with prominent maxillary teeth, a small mandible, an anterior larynx, a floppy epiglottis, or trismus.



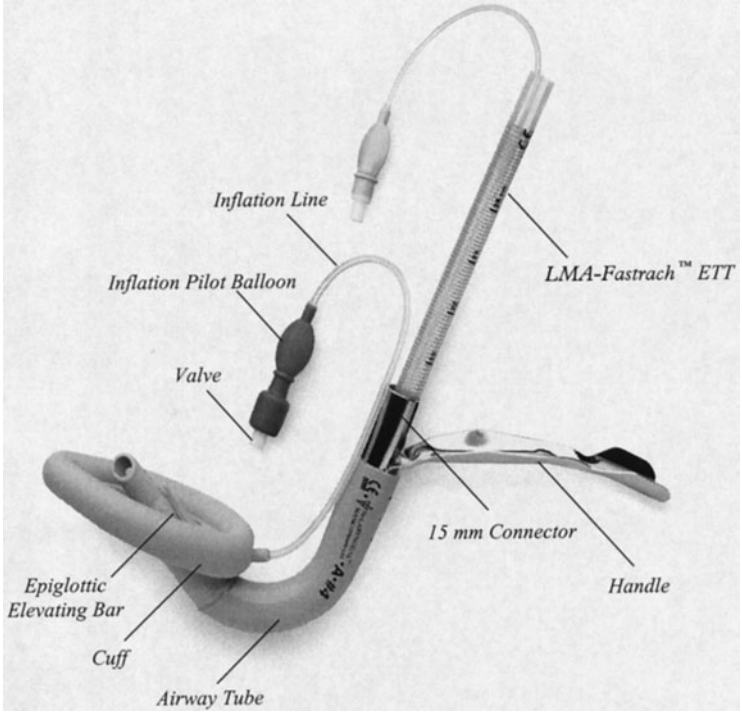
LMAs are useful as a bridge to oxygenate patients who cannot be intubated, but cannot be counted on to do so in the presence of abnormal lung mechanics or very abnormal anatomy.[35]

Care must be taken when using classic LMAs in such situations; a malpositioned LMA can insufflate the esophagus and increase the risk of aspiration. Even when properly inserted, inflation pressures over 20 cm H_2O can cause both leaks and esophageal and gastric insufflation. The LMA-ProSeal is a better option than a classic LMA under these conditions.



The LMA-ProSeal is an advanced form of the classic LMA and has four components: cuff, inflation line with pilot balloon, airway tube, and drain tube (see Fig. 35-2). The drain tube communicates with the upper esophageal sphincter and permits blind insertion of gastric tubes and venting of the stomach. The LMA-ProSeal introducer is provided to aid insertion of the LMA-ProSeal without the need to place fingers in the mouth. The technique of LMA-ProSeal placement with the introducer is similar to LMA-Fastrach placement.

The features of the LMA-ProSeal provide more patient management options. While the classic LMA may be used with low-pressure PPV, the LMA-ProSeal has been designed for use with PPV at higher airway pressures. The drain tube will direct the regurgitated fluid to the outside, avoiding aspiration of gastric contents; however, it is not as effective as an ETT in preventing aspiration.



If the patient cannot be either intubated or oxygenated with less invasive means, then a surgical airway is indicated. This decision cannot be made lightly, as emergency surgical airways (such as tracheostomy) have a complication rate

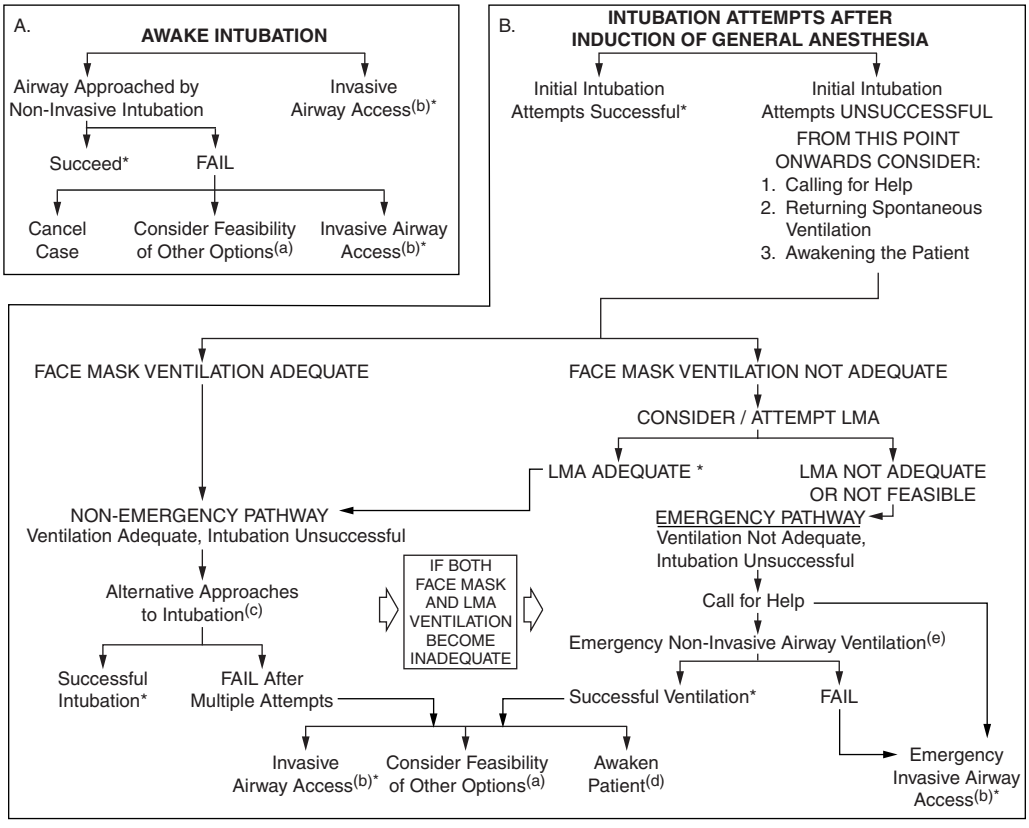

FIGURE 35-2 ***A*****. Classic laryngeal mask airway is available in eight sizes (1, $1^1/_2$, 2, $2^1/_2$, 3, 4, 5, and 6) that can be used in patients ranging from neonates to large adults. Its role in difficult or failed face mask ventilation is well established, and it has multiple applications in the American Society of Anesthesiologists' Practice Guidelines for Management of the Difficult Airway algorithm published in 1993 and revised in 2003.** ***B*****. Intubating LMA (Fastrach) is available in sizes 3, 4, and 5, and is designed to facilitate tracheal intubation with endotracheal tubes up to 8-mm inside diameter. Intubation can be performed blindly or in case of difficulty with the help of flexible bronchoscope. Like the classic LMA, the Fastrach establishes ventilation when face mask ventilation has failed, and permits oxygenation and ventilation during intubation, which is useful when large amounts of secretions and blood are present in the airway following failed intubation attempts.** ***C*****. LMA-ProSeal is an advanced version of the classic LMA with more airway management options. It provides higher seal pressure and therefore is more suitable for positive pressure ventilation. The drain tube communicates with the upper esophagus and permits passage of a nasogastric tube and decompression of the stomach, which is very valuable in patients with failed intubation and a distended stomach. ProSeal will establish ventilation and allow decompression of the stomach.** ***(Courtesy of LMA North America, Inc.)***

of 30%.[36] Tracheostomy is preferable to cricothyroidotomy, but requires the timely availability of both skilled personnel and appropriate equipment. Tracheostomy provides a large-bore cuffed airway that both protects against aspiration and can be used for mechanical ventilation. A wide variety of kits are commercially available for these procedures, and are preferable to ad-hoc kits because they contain all of the necessary equipment and supplies, are sterile, and have a variety of training aids. Individuals who anticipate the possibility of using such kits as part of their airway management practice should obtain training in their use. Needle cricothyroidotomy and jet ventilation is increasingly viewed as the approach

1. Assess the likelihood and clinical impact of basic management problems:
   - A. Difficult Ventilation
   - B. Difficult Intubation
   - C. Difficulty with Patient Cooperation or Consent
   - D. Difficult Tracheostomy
2. Actively pursue opportunities to deliver supplemental oxygen throughout the process of difficult airway management
3. Consider the relative merits and feasibility of basic management choices:

4. Develop primary and alternative strategies:

* Confirm ventilation, tracheal intubation, or LMA placement with exhaled CO_2

FIGURE 35-3 The American Society of Anesthesiologists' Difficult Airway Algorithm provides a simple general guideline for management of an anticipated and unanticipated difficult airway. *Confirm ventilation, tracheal intubation, or LMA placement with exhaled CO2. (a) Other options include (but are not limited to): surgery utilizing face mask or LMA anesthesia, local anesthesia infiltration or regional nerve blockade. Pursuit of these options usually implies that mask ventilation will not be problematic. Therefore, these options may be of limited value if this step in the algorithm has been reached via the Emergency Pathway. (b) Invasive airway access includes surgical or percutaneous tracheostomy or cricothyrotomy. (c) Alternative non-invasive approaches to difficult intubation include (but are not limited to): use of different laryngoscope blades, LMA as an intubation conduit (with or without fiberoptic guidance), fiberoptic intubation, intubating stylet or tube changer, light wand, retrograde intubation, and blind oral or nasal intubation. (d) Consider re-preparation of the patient for awake intubation or canceling surgery. (e) Options for emergency non-invasive airway ventilation include (but are not limited to): rigid bronchoscope, esophageal-tracheal combitube ventilation, or transtracheal jet ventilation.

that is most likely to succeed when attempts to ventilate and secure an airway via laryngoscopy fail.[37]

CHANGING THE ENDOTRACHEAL TUBE

Changing the endotracheal tube is frequently more hazardous than original insertion, because the patient may have evolved significant facial and airway edema, and may require both very high $F_{I_{O_2}}$ and positive end-expiratory pressure (PEEP). The most common indications for changing ETTs include failure of the cuff to retain volume and pressure, occlusion of the tube by inspissated secretions and clots, and the requirement for a different tube than the one originally inserted (e.g., one of a larger diameter, or a different type such as a

single- rather than a double-lumen tube). Tube changes motivated by complete occlusion or cuff rupture in the face of high PEEP may be dire emergencies; most other endotracheal tube changes are not.

Practitioners called on to change an endotracheal tube have the advantage that the patient already has an artificial airway, and hence the ease or difficulty of obtaining an airway has been discovered at least once for the patient. If laryngoscopy was easily accomplished before, and the patient's airway anatomy has not changed appreciably (e.g., as a result of edema), many practitioners elect to perform endotracheal tube changes with direct laryngoscopy under deep sedation and paralysis. This practice is safe when the old tube is withdrawn simultaneously with the introduction of the new tube into the trachea. Many operators prefer to perform endotracheal tube changes with the patient breathing spontaneously, reasoning that attempts at ventilation by the patient will delay the onset of hypoxia and hypercarbia in the event of difficulty in inserting the new airway. Withdrawing the old tube prior to attempting laryngoscopy, or when the view is difficult, can produce a cannot-intubate, cannot-ventilate situation, which can quickly become a crisis.

A variety of semirigid catheters are available for use as tube changers. Although they can be helpful in difficult circumstances, they can become dislodged from the trachea, and in some cases it is impossible to thread the new tube over them. Such tube changers may be best used in combination with direct laryngoscopy when the anatomy is challenging. Tube changers with a central lumen may be used to attempt to jet ventilate patients in the event that a more permanent airway cannot be established immediately. In patients with substantial facial and neck edema or burns, several assistants will be required for successful tube changes. Fiberoptic-guided exchange of tracheal tubes requires both excellent preparation of the airway (including treatment with drying agents such as glycopyrrolate and aggressive suctioning), and a high degree of skill by the operator, but can produce success where most or all other approaches would yield failure.[38]

Physiologic Changes Associated with Intubation and Mechanical Ventilation

Tracheal intubation has a range of important physiologic consequences. These are not complications of the procedure per se, but are consequences of the presence of an artificial airway and mechanical ventilation.

Tracheal intubation and the institution of positive pressure ventilation can cause a variety of changes in circulatory physiology. Laryngoscopy and tracheal intubation are frequently accompanied by hypertension and tachycardia.

Endotracheal tubes may cause an increase in airway resistance. An 8.0-mm endotracheal tube causes a 20% increase in airway resistance in the normal airway, all of it in the central airways and nonresponsive to therapy with inhaled bronchodilators. Smaller tubes have exponentially higher resistances.[39] A 7.0-mm endotracheal tube has twice the resistance of an 8.0-mm tube, whereas a 9.0-mm tube has one-third the resistance of an 8.0-mm tube. The airways resistance associated with a particular tube increases as inspissated secretions accumulate in the tube, decreasing its diameter and increasing the turbulence of flow. Tracheal intubation can also precipitate bronchospasm in susceptible individuals, which can further increase airways resistance.

Hypotension frequently evolves after the establishment of tracheal intubation and mechanical ventilation, and has many contributing factors.[40] First, these usually entail a change in mean intrathoracic pressures from large negative pressures to large positive pressures, with a corresponding fall in venous return and cardiac output. Mechanical ventilation is also frequently associated with a resolution of hypoxia, hypercapnia, and dyspnea, and a proportionate decline in circulating catecholamines.[41] Patients with obstructive lung disease can develop high levels of auto-PEEP very quickly during vigorous ventilation with an Ambu bag, which can be associated with hypotension.[42,43] Finally, high levels of PEEP can increase the pulmonary vascular resistance, with an associated shift of the interventricular septum into the left ventricle.[44,45]

Complications

Airway manipulation in critically ill patients is a necessarily hazardous undertaking (Table 35-7). Death, circulatory collapse, arrhythmias, hypoxia, airway trauma, aspiration, and failed intubation can all occur, even when the airway is managed flawlessly.

Right mainstem intubation is a common consequence of intubation in the ICU. It can be avoided in many cases by

TABLE 35-7 Complications of Intubation

Immediate
Right mainstem intubation
Esophageal intubation
Gastric aspiration
Dental injury, tooth aspiration
Mucosal laceration or tear
Hypertension/tachycardia
Myocardial ischemia
Elevated intracranial pressure
Hypotension
Arrhythmias
Ventricular premature beats
Ventricular tachycardia
Ventricular fibrillation
Atrial fibrillation
Bradycardia (in young patients)
Bronchospasm
Vocal cord trauma
Dislocation of arytenoid cartilage
Pain
Chronic
Serous or purulent otitis
Sinusitis
Mucosal ulceration
Necrosis of lip or nose
Granulomas
Dental damage from biting
Tracheal mucosal injury
Tracheoesophageal fistula, tracheoinnominate fistula
Laryngeal stricture
Vocal cord synechiae/paralysis
Tracheomalacia, cricoarytenoid edema, subluxation and fracture
Tracheal stenosis

taping tubes at 23 cm at the lip in males and 21 cm at the lip in females of average stature (using the average tooth-to-carina distance, which is 28 cm in the average male and 24 cm in the average female).[46] Tooth-to-carina distance varies; a tube taped at 24 cm at the lip might be in perfect position for the average 180-cm male, but might not even be in the trachea of a very tall patient. Correct positioning of the endotracheal tube is difficult to verify clinically and requires fiberoptic bronchoscopy or a chest radiograph for confirmation.[47,48]

In spite of assertions that it should never happen, esophageal intubation remains an inevitable complication of airway management. In theory, it should be quickly recognized and the offending tube removed expeditiously. In practice, it will occur in circumstances in which auscultation of the breath sounds is difficult and where endotracheal intubation cannot be confirmed with capnography, including patients with severe bronchospasm (especially children), and in adults in full cardiopulmonary arrest.[49]

Gastric aspiration that occurs around the time of intubation in the ICU can cause pneumonia and precipitate acute respiratory distress syndrome; it occurs approximately 4% of the time.[10] In less controlled settings, such as in trauma patients, aspiration may occur in up to 30% of patients around the time they are intubated.[50] The application of cricoid pressure and manipulation of the airway with the patient awake are the two most effective strategies to avoid this problem.

A variety of tissue injuries are associated with airway management in the ICU setting.[51–54] These injuries are more likely to occur in uncooperative patients, seizing patients, and patients with anatomically difficult airways.[55] Dental injury and tooth fragment aspiration remain a complication of airway management. Tracheal and esophageal lacerations can also occur. At least some bleeding is likely to occur in coagulopathic patients and in patients with friable tissues. The vocal cords and arytenoid cartilages can also be traumatized during intubation. Prolonged tracheal intubation can also impair swallowing, which increases the risk of aspiration in these patients after extubation.[56] Residual muscle paralysis is an important risk factor for aspiration in perioperative patients, and perhaps in critically ill patients as well.[57]

A variety of cardiac complications may occur around the time of airway manipulation. Myocardial ischemia can be precipitated by the stress response to airway manipulation. The amount of ischemia precipitated can be minimized with adequate topical anesthesia and by matching the sedation given to the degree of stimulation created. Ventricular premature beats are a common consequence of the stress response in the setting of airway manipulation. Ventricular tachycardia and ventricular fibrillation can occur in patients susceptible to these arrhythmias. Bradycardia can also occur, particularly in young patients with high vagal tone.

Death occurs around the time of endotracheal intubation in approximately 3% of critically ill patients.[10] In some patients, issues of airway management will contribute to the sequence of events that result in death; an expeditious intubation averts death in the vast majority of patients.

Tracheostomy

The role of tracheostomy continues to evolve in critically ill patients. The improved design of endotracheal tubes and careful attention to sedation has minimized the traumatic consequences of intubation, making translaryngeal intubation for weeks both safe and tractable. On the other side, the improved techniques for performing tracheostomy, and the increasing ability to perform tracheostomy at the bedside has made tracheostomy safer and more available than it has been previously. Tracheostomy continues to have immediate and long-term complications that intensivists manage.

INDICATIONS FOR TRACHEOSTOMY

The least controversial indication for tracheostomy is upper airway obstruction, especially long-term or permanent airway obstruction. Tracheostomy is also widely accepted as preferable to transglottic intubation for long-term mechanical ventilation. Tracheostomy is also indicated when a patient will be unable to clear their airway secretions for a long period of time. Finally, tracheostomy is frequently used to facilitate liberation from mechanical ventilation.

Tracheostomy has several benefits in patients who will require long-term mechanical ventilation. It allows easier and safer access to the mouth, which allows improved oral hygiene. It is substantially more comfortable than translaryngeal intubation, so the need for both analgesics and sedation may be significantly reduced. Specially designed tracheostomy tubes allow for speech and even normal eating in patients who are either continuously or intermittently ventilated. There was a time when patients underwent tracheostomy after only very brief periods of translaryngeal intubation and mechanical ventilation (e.g., 7 to 10 days). The decision to perform a tracheostomy on a patient in these circumstances should not be motivated as much by the time that has already elapsed on mechanical ventilation, but rather by the amount of time it can be foreseen that they will require mechanical ventilation. If the patient will obviously require ventilation for the coming weeks, then it is quite reasonable to perform a tracheostomy for both their safety and comfort.[58,59] Patients at high risk of the complications of translaryngeal intubation, such as diabetics, may benefit from earlier tracheostomy.

Tracheostomy has the great benefit of reducing the anatomic dead space, resulting in substantially greater alveolar ventilation for any given minute ventilation. This benefit may be of critical importance in patients whose strength is very closely matched to their requirement for minute ventilation, and who might not otherwise be easy to liberate from the ventilator. The ease of reinstituting mechanical ventilation, and the wide bore and short length of tracheostomy tubes are also of benefit in these circumstances.

PERCUTANEOUS VERSUS SURGICAL TRACHEOSTOMY

There is a large and growing literature which clearly demonstrates that percutaneous and surgical tracheostomy are equally successful and safe in competent hands.[60–62] Interestingly, the sum of the patients in all of the prospective studies published thus far is less than 600, limiting the statistical power of inferences about rare complications, such as death, pneumothorax, and posterior tracheal wall perforation, but certainly allowing the conclusion that the success rates and overall complication rates of the two procedures are very similar. Mortality of either procedure is now less than 1%, which

is significantly lower than that reported in older literature. When performed at the bedside in the ICU, both percutaneous and surgical tracheostomy are significantly less expensive and easier to arrange than tracheostomy in the operating room. The difference in cost between the two procedures performed at the bedside is small, and likely to be outweighed by other institutional factors and considerations.

A variety of techniques for percutaneous tracheostomy have been described and are in widespread use. Briefly, after appropriate sedation, the patient's neck is extended to open the tracheal interspaces. The skin over tracheal interspaces below the cricoid cartilage is then anesthetized, prepped with an appropriate cleansing agent, and draped in the usual sterile fashion. A 2-cm horizontal incision is made, and the neck is bluntly dissected down to the trachea. The existing tracheal tube is then withdrawn to a position just below the vocal cords. A needle is then inserted into the trachea (usually under bronchoscopic guidance), and a wire threaded into the tracheal lumen. The tract is then mechanically dilated, and an appropriately sized tube inserted into the trachea. Commercially available kits are now available that replace multiple dilators with a single dilator (e.g., Blue Rhino PDT from Cook Critical Care, Bloomington, IN), which may save time and reduce the risk of the procedure as well. Two of the advantages of the percutaneous technique are the minimal sharp dissection involved, and the use of dilation to create the tract for the tracheostomy tube, both of which limit the bleeding associated with the procedure.

The literature about percutaneous tracheostomy clearly documents that it can be accomplished successfully and safely in the hands of competent practitioners. Some techniques incorporate bronchoscopic guidance, incurring additional expense, time delay, and need for additional operators to provide some increase in the safety of the procedure. Although simultaneous bronchoscopy is advocated by some authorities, many more experienced operators rarely if ever use it to facilitate the procedure. The speed with which percutaneous tracheostomy without the use of a bronchoscope can be accomplished is impressive, making it attractive as a procedure to emergently secure the obstructed airway in institutions with readily available kits and highly skilled operators. Morbid obesity and previous tracheostomy are frequently cited contraindications to percutaneous tracheostomy, but there are case series which suggest that the procedure can be performed safely in select patients with either diagnosis.[63,64] There is no doubt that as with any other procedural skill, there is and will be significant variation across practitioners and institutions, which makes prescriptions about percutaneous tracheostomy inappropriate.

MINITRACHEOSTOMY

Minitracheostomy is a procedure that is sometimes performed in select critically ill patients to facilitate clearance of bronchial secretions.[65] Minitrach allows repeated suctioning of the trachea below the cords without passing a tube through them at the cost of undergoing the procedure (which is generally performed at the bedside) with its attendant complications. The procedure itself is very similar to that described for percutaneous tracheostomy, except that it does not result in an airway. Minitracheostomy has been demonstrated to reduce the incidence of radiographic collapse, but has not otherwise been proven to improve outcomes.[66,67] Minitracheostomy is commonly done at some centers, rarely done at most, and never done at others. This is unlikely to change unless studies demonstrating more dramatic benefit to the procedure are published.

COMPLICATIONS OF TRACHEOSTOMY

The immediate complications of tracheostomy include hemorrhage, malpositioning of the tracheostomy tube, and pneumothorax/pneumomediastinum. Hemorrhage can occur as a consequence of bleeding from subcutaneous vessels, neck veins, and the thyroid gland. Most postoperative bleeding is venous in origin, and it may take hours for a noticeable hematoma to form. A hematoma in the neck can compress the trachea or cause it to deviate, resulting in increased airway pressures, a sensation of dyspnea on the part of the patient, and hypoventilation. Airway obstruction caused by a hematoma is best treated by decompression/evacuation, as all other therapies will fail to interrupt the cascade of events leading to deterioration and will allow the underlying process to progress.

Rarely, tracheostomy tubes may be placed into tissue planes in the neck instead of the trachea. Monitoring end-tidal carbon dioxide concentrations after the tube is inserted will aid in the timely recognition of this problem, allowing it to be quickly corrected. Tracheal positioning of the tracheostomy tube can be verified with auscultation, capnography, and fiberoptic bronchoscopy.

Pneumothorax and pneumomediastinum are consequences of invasion of these tissue planes, which can extend superiorly into the neck in some patients (particularly those with chronic obstructive pulmonary disease or on high amounts of PEEP). These complications are more likely to occur in situations in which the anatomy is difficult, such as patients with morbid obesity, previous neck surgery, or goiter. These complications are usually recognized on the routine chest radiograph taken postoperatively in these patients to confirm adequate positioning of the new tracheostomy tube.

LONG-TERM COMPLICATIONS OF TRACHEOSTOMY

Tracheostomy tubes are frequently left in patients for months and occasionally years. This situation puts the patient at risk of complications due to chronic irritation or erosion of the trachea, including tracheoesophageal fistula, tracheoinnominate fistula, tracheomalacia, and tracheal stenosis.

The absence of a large epidemiologic database, the heterogeneity of patient populations undergoing tracheostomy in the ICU, and the high mortality in some patient populations that undergo the procedure make discussion of the complications of tracheostomy difficult.[68] Tracheal stenosis is diagnosed in 40% to 60% of patients who have undergone tracheostomy, but it is unclear if this is a complication of their tracheostomy or their prior transglottic tracheal intubation.[69,70] The high cuff pressures thought to be the major cause of the tissue injury that drives this process are more likely to be present during the early, acute phase of critical illness, when high airway pressures are present.[71] On the other hand, the disruption of the tracheal cartilages caused by the presence of the tracheostomy tube may lead to instability, which may in turn cause tissue injury, which may be worsened by the immune response to both the tracheostomy tube

and the purulent secretions that contaminate its tract. Given this, it is unsurprising that a majority of the tracheal stenoses attributed to tracheostomy occur at the level of entry into the trachea.

Tracheoinnominate fistula occurs in less than 1% of patients, typically within 1 month of undergoing insertion of a low-lying tracheostomy. Either the tip of the tube or its cuff erodes through the wall of the trachea and into the vessel, causing life-threatening bleeding which requires immediate surgical repair. Tracheoesophageal fistula occurs via the same mechanism, but entails erosion through the posterior wall of the trachea into the esophagus. Tracheoesophageal fistula is frequently difficult to diagnose, as it can present as recurrent pneumonia in a ventilated patient. Other more obvious symptoms include cuff leak refractory to inflation, aspiration of large quantities of tube feeds in spite of an appropriately inflated tracheostomy cuff, and gastric distention with large quantities of air. The diagnosis of a tracheoesophageal fistula can be established with either barium swallow or computed tomography scan. Treatment is usually surgical, although a variety of stents have been employed as an alternative.[72]

Teaching Airway Management Skills

The place to learn basic airway management skills is the operating room, not the ICU. Basic airway management skills, although apparently very simple, in fact take a great deal of time and experience to master. These basics are best learned in an environment in which patients will generally have normal anatomy, circulation, and lung mechanics. Elective procedures in the operating room present ideal opportunities to learn the basics of mask ventilation, laryngoscopy, fiberoptic laryngoscopy, nasal intubation, and insertion of laryngeal mask airways. Outpatient bronchoscopies present excellent opportunities to learn how to adequately topically anesthetize the nasopharynx and oropharynx. Literature from a wide variety of fields supports the contention that most practitioners tasked with managing the airway are either inadequately trained, or will predictably benefit from more training.[73,74] Once the basics of airway management have been mastered in the elective setting, they can be applied in airway management under adequate supervision in the ICU. Attempts to teach the basics of airway management at the bedside in the ICU should be discouraged, as critically ill patients do not tolerate the high rates of failure that typically occur as practitioners learn these skills. Participating in airway management workshops and the practice of various airway management techniques in models and simulators is extremely valuable, especially for procedures such as fiberoptic bronchoscopy, which requires hours of practice to attain facility manipulating the bronchoscope. The wide variety of things that skillful airway managers take into account at the bedside or consider as they proceed are given in Table 35-8.

TABLE 35-8 Some Practical Bedside Rules of Thumb

1. Save the brain
2. Save the circulation
3. A spontaneously breathing patient has at least one vital sign; an apneic patient may soon have none
4. Mask ventilation is better than esophageal intubation
5. The worst time for a patient to aspirate is when it's time to intubate
6. If you don't give any IV anesthetics, the CODE can't be blamed on you
7. The patient who asks for a tube needs one
8. A patient who doesn't mind a tube needs one
9. The best procedure for a patient may be the one that you know how to do best
10. The place to learn basic airway management skills is the operating room, not the ICU

Chapter 36

MANAGEMENT OF THE VENTILATED PATIENT

GREGORY A. SCHMIDT
JESSE B. HALL

KEY POINTS

- *Effective preventive measures in ventilated patients include raising the head of the bed during enteral feeding, using measures to prevent venous thromboembolism, avoiding unnecessary changes of the ventilator circuit, and reducing the amount of sedation.*
- *Ventilator parameters should be determined by the pathophysiology underlying the particular form of respiratory failure; this approach facilitates stabilization and comfort of the patient on the ventilator, prevention of common complications, and early liberation from this supportive therapy.*
- *Although some patients may require sedation and muscle relaxation for initial stabilization on the ventilator, these agents should not be used to routinely adapt the patient to the machine; rather, ventilator adjustments should be used to stabilize and comfort the patient. This latter approach is facilitated by a careful analysis of airway pressure and flow waveforms.*
- *Whenever the adequacy of oxygen exchange is in question, the initial fraction of inspired oxygen ($F_{I_{O_2}}$) should be 1.0; this will be diagnostic and therapeutic because failure to achieve full arterial hemoglobin saturation identifies a significant right-to-left shunt.*
- *Typical ventilator settings for the patient with normal lung mechanics and gas exchange include an $F_{I_{O_2}}$ of 0.5, tidal volume of 8 to 12 mL/kg, and respiratory rate of 8 to 12 breaths/min; if mechanical ventilation has been instituted to rest fatigued respiratory muscles, deep sedation may be necessary to minimize respiratory muscle activity.*
- *The patient with severe airflow obstruction often develops hypoperfusion after institution of positive-pressure ventilation as a result of occult positive end-expiratory pressure (autoPEEP); this responds to temporary cessation of ventilation and vigorous volume resuscitation while measures are used to reduce airflow obstruction.*
- *The goals of ventilator management in severe airflow obstruction include a plateau airway pressure below 30 cm H_2O, an autoPEEP below 10 cm H_2O, or an end-inspired lung volume smaller than 20 mL/kg even if this results in hypercapnia; short expiratory times must be avoided.*
- *The patient with acute hypoxemic respiratory failure resulting from pulmonary edema benefits from lung-protective ventilation (6 mL/kg ideal body weight and rate approximately 30 breaths/min). The initial $F_{I_{O_2}}$ of 1.0 can be lowered to nontoxic levels by raising PEEP, which is guided by pulse oximetry.*

Too often, the management of the patient on a ventilator is guided by (a) a standard protocol applied to diverse patients regardless of the underlying pulmonary derangement or (b) mode-dominated thinking on the part of the physician, by which various microprocessor-controlled machine functions are hoped to have a salutary effect on patient outcome. This chapter offers an alternative approach, in which ventilator parameters are tailored to the patient's mechanical and gas exchange abnormalities. This facilitates early stabilization of the patient on the ventilator in such a way as to optimize carbon dioxide removal and oxygen delivery within the limits of abnormal neuromuscular function, lung mechanics, and gas exchange and limit complications of barotrauma, lung injury, and cardiovascular depression.

Other chapters of this book are complementary to the information presented here. The pathophysiology of respiratory failure is broadly reviewed in Chap. 31; monitoring the respiratory system is delineated in Chap. 32; noninvasive ventilation is covered in Chap. 33; ventilator-induced lung injury is discussed in Chap. 37; and several chapters (e.g., Chap. 38, "Acute Respiratory Distress Syndrome"; Chap. 39, "Acute on Chronic Respiratory Failure"; Chap. 40, "Status Asthmaticus"; Chap. 42, "Restrictive Disease of the Respiratory System") discuss ventilatory support for specific problems.

The fundamental purpose of mechanical ventilation is to assist in elimination of carbon dioxide and inspiration of adequate oxygen when the patient is unable to do so or should not be allowed to do so. Such patients fall into two main groups: those in whom full rest of the respiratory muscles or permissive hypercapnia is indicated (e.g., during shock, severe acute pulmonary derangement, or with deep sedation or anesthesia) and those in whom some degree of respiratory muscle use is desired (e.g., to strengthen or improve the coordination of the respiratory muscles, to assess the ability of the patient to sustain the work of breathing, or to begin spontaneous ventilation). It is important for the intensivist to be explicit about whether the respiratory muscles should be rested or exercised because the details of ventilation (mode and settings) usually follow logically from this fundamental point.

We discuss the various conventional modes of ventilation practiced in most intensive care units (ICUs). If full rest of the respiratory muscles is desired, it is incumbent on the physician to ensure that this is achieved. Although some patients are fully passive while being ventilated (those with deep sedation, some forms of coma, metabolic alkalosis, sleep-disordered breathing), most patients will make active respiratory efforts, even on volume assist-control ventilation (ACV),[1] at times performing extraordinary amounts of work. Unintended patient effort can be difficult to recognize but, aside from obvious patient effort, may be signaled by an inspiratory decrease in intrathoracic pressure (as noted on central venous or pulmonary artery pressure tracings or with an esophageal balloon), by triggering of the ventilator, or by a careful analysis of real-time flow and pressure waveforms, discussed more fully in Chap. 32. When there is evidence of unwanted patient effort, ventilator adjustments, psychological measures, pharmacologic sedation, and therapeutic paralysis can be useful, as discussed later in this chapter. Ventilator strategies to decrease the patient's work of breathing include increasing the minute ventilation to decrease arterial partial pressure of CO_2 (Pa_{CO2}; although this may run counter to other goals of ventilation, especially in patients with acute respiratory distress syndrome [ARDS] or severe obstruction), increasing the inspiratory flow rate, and changing the mode to pressure-preset ventilation, as in pressure-support (PSV) or pressure-control

(PCV) mode. Adjusting the ventilator to the patient's demand is described more fully below.

If some work of breathing on the patient's part is desired, this can be achieved through any of the existing ventilatory modes. The amount of work done may be highly variable, however, and depends on the specific mode, the settings chosen within each mode, and the interaction between the patient and the ventilator. A recurring question during the time when a patient can carry some of the work of breathing is, "Can this patient breathe without ventilatory assistance?" This issue is more fully developed in Chap. 44, "Liberation from Mechanical Ventilation."

Choosing a ventilatory mode and settings appropriate for each patient depends not only on the physician's goals (rest versus exercise) but also on knowledge of the mechanical properties of the patient's respiratory system. Determining respiratory system mechanics is an integral part of ventilator management and a routine part of examination of the critically ill patient, discussed fully in Chap. 32 ("Ventilator Waveforms") and reviewed extensively in the literature.[2,3] The intensivist can combine clinical information, chest radiography, and respiratory system mechanical properties (as described in Chap. 32) to categorize the patient into one of four prototypes: (a) normal gas exchange and mechanics, (b) significant airflow obstruction (as in status asthmaticus or acute exacerbations of chronic obstructive pulmonary disease (COPD), (c) acute lung injury and ARDS, and (d) restriction of the lung or chest wall.

Appropriate initial ventilator settings and subsequent adjustments for each of these four states is discussed later in this chapter. We emphasize the use of pressure and flow waveforms to further adjust the ventilator to meet the physician's goals and maximize the patient's comfort. We discuss the role of sedation of the ventilated patient and describe how to respond to "crises" on the ventilator. This chapter concludes with a brief review of novel modes of ventilation, such as high-frequency ventilation, followed by a summary of preventive measures appropriate to all ventilated patients.

General Preventive Measures

Mechanically ventilated patients are at risk of numerous complications related to the presence of the endotracheal tube, most notably ventilator-associated pneumonia (VAP), and complications of the sedatives and paralytics that are often given. Effective preventive measures are more fully discussed in Chaps. 4, 10, and 14, but are briefly summarized here.

Noninvasive ventilation should be used in appropriate candidates because this decreases the risk of VAP in COPD patients and perhaps those in an immunocompromised state.[2,3] For intubated patients, the head of the bed should be elevated to 30 to 45 degrees during enteral feeding, a simple but effective step for decreasing the risk of VAP.[4] Ventilator tubing should be changed only when the tubing is visibly soiled or malfunctioning, rather than on a time-based schedule.[5] Heat and moisture exchangers should not be changed more than every 48 hours. Sedative use should be limited and patients should be allowed to wake up daily, as discussed below and in Chap. 14. Prophylaxis against venous thromboembolism is indicated in most patients. There is no consensus regarding the effectiveness of selective decontamination of the digestive tract, the use of lateral rotation therapy, or postpyloric placement of feeding tubes, so these measures should not be routinely applied.

Modes of Mechanical Ventilation

Technologic innovations have provided a plethora of different modes by which a patient can be mechanically ventilated. Various modes have been developed with the hope of improving gas exchange, patient comfort, or speed of return to spontaneous ventilation. Aside from minor subtleties, nearly all modes allow full rest of the patient, on the one hand, or substantial exercise, on the other. Thus, in the great majority of patients, choice of mode is merely a matter of patient or physician preference. Noninvasive ventilation should be considered before intubation and ventilation in many patients who are hemodynamically stable and do not require an artificial airway, especially those with acute-on-chronic respiratory failure, postoperative respiratory failure, and cardiogenic pulmonary edema. Management of the patient ventilated noninvasively is discussed thoroughly in Chap. 33.

PRESSURE-PRESET VERSUS VOLUME-PRESET MODES OF VENTILATION

The terminology describing modes of ventilation can be very confusing and may vary from one manufacturer to another. In this chapter, we refer to volume-preset modes as those in which the physician sets a desired tidal volume (V_T) that the ventilator delivers, using whatever pressure required, and pressure-preset modes, in which the physician sets a desired pressure that the ventilator maintains, delivering a volume that depends on the settings, respiratory mechanics, and patient effort. These two fundamental types of mode are compared in Table 36-1. Some modern modes (dual-control modes, see below) attempt to blend pressure and volume presets.

Historically, most adult patients have been ventilated using volume-preset modes (ACV and synchronized intermittent mandatory ventilation [SIMV]), but pressure-preset modes have several theoretical advantages. Few studies have compared these modes except with respect to comfort, a measure generally favoring pressure-preset modes.[6,7] The only mode of ventilation shown to affect mortality rate was the application of ACV to patients with acute lung injury and ARDS when physiologic V_T is used (6 mL/kg ideal body weight [IBW] compared with 12 mL/kg), but pressure-preset modes were not employed in that trial.[8]

The differences between volume-preset and pressure-preset modes are fewer than is often appreciated, because volume and pressure are related through the mechanical properties of the patient's respiratory system, most notably the respiratory system compliance (Crs). For example, a passive patient with a static Crs of 50 mL/cm H_2O ventilated on ACV at a V_T of 500 mL with no positive end-expiratory pressure will have a plateau airway pressure (Pplat; see Chap. 32) of about 10 cm H_2O, whereas the same patient ventilated on PCV at 10 cm H_2O can be expected to have a V_T close to 500 mL. The difference to the patient between these modes may be quite trivial, often amounting to small differences in inspiratory flow profile. Thus, although the physician's comfort level with volume-preset and pressure-preset

TABLE 36-1 Volume-Preset and Pressure-Preset Modes

	Volume-Preset Modes	Pressure-Preset Modes
Examples	ACV, SIMV	PSV, PCV
Set (independent) parameter	Volume	Pressure
Dependent parameter	Pressure	Volume
Potential advantages	1. Greater control over ventilation 2. Evidence-based benefit in ALI, ARDS 3. Easier to measure mechanical properties of the respiratory system	1. Greater patient comfort 2. Greater protection against VILI 3. PSV facilitates weaning compared with SIMV 4. More effective support for some patients

ABBREVIATIONS: ACV, volume assist-control; ALI, acute lung injury; ARDS, acute respiratory distress syndrome; PCV, pressure control ventilation; PSV, pressure support ventilation; SIMV, synchronized intermittent mandatory ventilation; VILI, ventilator-induced lung injury.

modes may be very different, the modes can be similar because they are tied to each other through the patient's Crs.

CONVENTIONAL MODES OF VENTILATION

In the following descriptions, each mode is first illustrated for a passive patient, such as after muscle paralysis, and then for the more common situation in which the patient plays an active role in ventilation. On some ventilators, V_T can be selected by the physician or respiratory therapist; on others, minute ventilation and respiratory rates (f) are chosen, secondarily determining the V_T. Similarly, on some machines, an inspiratory flow rate ($\dot{V}$) is selected, whereas on others $\dot{V}$ depends on the ratio of inspiratory time to total respiratory cycle time (T_I/T_T) and f, on an inspiratory-expiratory (I:E) ratio and f, or on rise time and other parameters.

PRESSURE-PRESET MODES

In pressure-preset modes, a fixed inspiratory pressure (P_I) is applied to the patient, whatever the resulting V_T. Depending on the particular ventilator, the physician may have to specify the actual level of P_I or the increment in pressure over the expiratory pressure (PEEP). Ventilators designed primarily for noninvasive ventilation often require setting P_I and PEEP independently, whereas most ICU ventilators require setting the PEEP and an inspiratory pressure increment. For example, the following settings are identical: $P_I = 20$ cm H_2O and PEEP $= 5$ cm H_2O (noninvasive ventilator) versus pressure increment (e.g., "pressure-support" or "pressure-control") $=$ 15 cm H_2O and PEEP $= 5$ cm H_2O. In this chapter, we specify inspiratory (P_I) and expiratory (PEEP) pressures to avoid confusion.

In pressure-preset modes, the V_T is predictable (for the passive patient) when the Crs is known:

$$V_T = (P_I - \text{PEEP}) \times \text{Crs}$$

assuming time for equilibration between P_I and alveolar pressure (P_A) and the absence of autoPEEP (these assumptions are often not true in patients in the ICU: see below).

Compared with volume-preset modes, a potential advantage of pressure-preset ventilation is greater physician control over the peak airway pressure (Ppk; because Ppk $= P_I$) and the peak P_A , which could lessen the incidence of ventilator-induced lung injury (see Chap. 37). However, this same reduction in volutrauma risk should be attainable during volume-preset ventilation if a V_T appropriate to the lung derangement is chosen, as has been shown in patients with acute lung injury and ARDS.[8] Nevertheless, pressure-preset modes make such a lung protection strategy easier to carry out by obviating repeated determinations of Pplat and periodic adjustment of V_T .

Pressure-preset modes also allow the patient greater control over inspiratory flow rate and therefore potentially increased comfort. A disadvantage of pressure-preset modes is that changes in respiratory system mechanics (e.g., increased airflow resistance or lung stiffness) or patient effort may decrease the minute ventilation, necessitating alarms for adequate ventilation. Further, the mechanics cannot be determined readily and partitioned as described in Chap. 32 without switching modes or inserting an esophageal balloon.

Pressure-Control Ventilation

In the passive patient, ventilation is determined by f, the inspiratory pressure increment ($P_I - \text{PEEP}$), the I:E, and Crs. In patients without severe obstruction given a sufficiently long T_I, there is equilibration between the ventilator-determined P_I and P_A , so that inspiratory flow ceases (Fig. 36-1A). In this situation, V_T is highly predictable, based on $P_I (= P_A)$ and the mechanical properties of the respiratory system (Crs). In the presence of severe obstruction or if T_I is too short to allow equilibration between the ventilator and alveoli, V_T will decrease below the value predicted based on P_I and Crs (see Fig. 36-1A). One of the advantages of PCV is that it may facilitate ventilation with a lung protective strategy. For example, alveolar overdistention can be prevented by ensuring that P_A never exceeds some threshold value (this is often taken to be 30 cm H_2O, but a truly safe level is unknown) by simply setting P_I (alternatively, PEEP + PSV) to the desired upper limit. During PCV, T_I and f are set by the physician and may not approximate the patient's desired T_I and f.

When the patient is active, the V_T reflects patient effort, and the patient may trigger additional breaths. When the patient makes inspiratory efforts synchronized with machine inspiration, the V_T is generally greater than that predicted from the Crs and P_I . However, dyssynchrony or expiratory

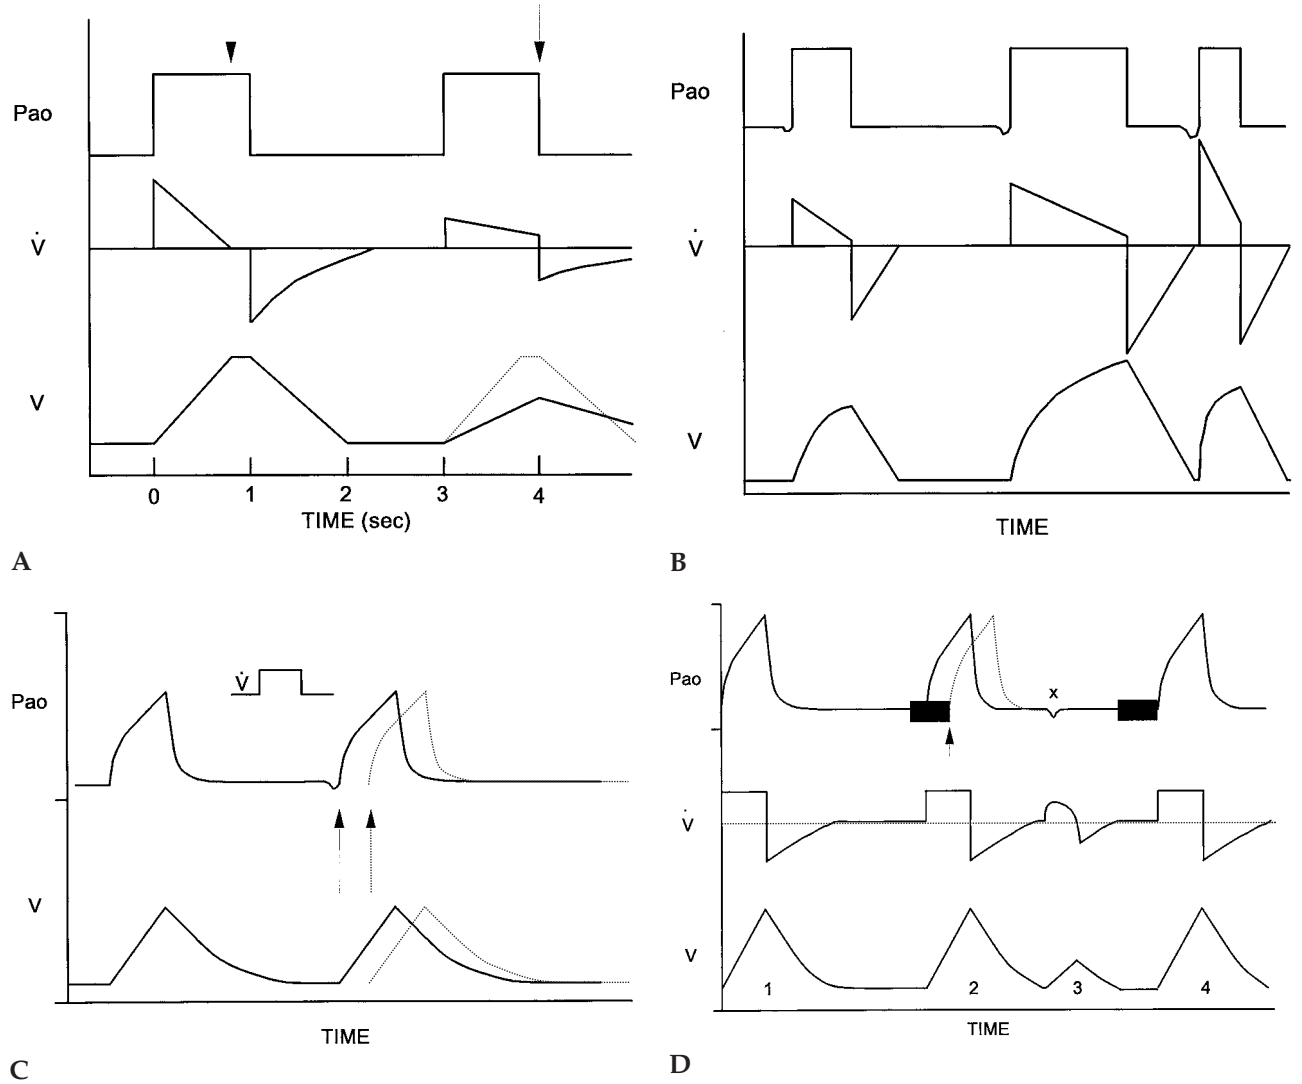

FIGURE 36-1 *A*. **Pressure-control ventilation of a muscle-relaxed patient showing the effects of changed inspiratory resistance. The *left-hand panel* shows a pressure-control breath with normal resistance, during which inspiratory pressure (P_I) equilibrates with alveolar pressure (P_A) before the inspiratory cycle is terminated (*left arrow*), flow ceases, and tidal volume (V_T) can be predicted from the P_I and Cst ($V_T = Cst \times P_I$— positive end-expiratory pressure [PEEP]). In the *right-hand panel,* inspiratory resistance is elevated. At the same P_I, inspiratory flow is reduced, the V_T is not reached until the inspiratory phase is terminated (*right arrow*), and the V_T (*solid line*) falls below that predicted by Cst and P_I minus PEEP (*dotted line*). *B*. Pressure-support ventilation. When a breath is triggered pressure-airway opening (Pao) rises to the set level (P_I) with flow and V_T depending on the P_I minus PEEP, respiratory system mechanics, and patient effort. The first breath shown represents a patient who triggers the ventilator and then remains fully passive (a hypothetical circumstance used here for contrast with the usual patient efforts shown in the next two breaths). As long as there is no significant airflow obstruction, V_T nearly reaches the volume that would be predicted based on the compliance of the respiratory system (Crs; $V_T = Crs \times P_I - PEEP$). During the middle breath shown, the patient makes a moderate but prolonged inspiratory effort. The Pao remains at the set inspiratory level as long as patient effort maintains flow, and a much longer inspiratory time (T_I) and V_T result. In the final breath, a more powerful but briefer inspiratory effort is made, shortening the T_I but generating a larger Vt than during the passive breath. *C*. Pao and lung volume (V) during assist-control ventilation of a patient who is periodically triggering the ventilator. The second breath was set to be delivered at the time marked by the *second arrow*; instead, the patient lowers the Pao, triggering the ventilator at the time marked by the *first arrow*, thereby increasing the respiratory rate above the default value, decreasing the expiratory time (T_E), and increasing the inspiratory-expiratory (I:E) ratio. *D*. Pao, flow (V̇), and V during synchronized intermittent mandatory ventilation. Breath 1 (a mandatory breath) is not triggered by the patient, who remains fully passive. V and V̇ are determined by the ventilator, whereas the Pao reflects the passive mechanical characteristics of the respiratory system. The *shaded rectangle* near the second breath denotes the interval during which the ventilator is programmed to synchronize with the patient's inspiratory effort by delivering the mandatory breath slightly ahead of schedule. At the end of this time interval (*arrow*), a mandatory breath would have been delivered (*dotted tracing*) if the patient had not triggered the ventilator. The synchronized breath (breath 2) has the same volume and flow as a mandatory breath. The Pao may not be the same as during a passive breath because of continued patient effort throughout inspiration. Breath 3 is initiated before the synchronization interval at *x* and is therefore not assisted. Flow and V_T are totally determined by the patient's effort and mechanics. These breaths are typically shorter and smaller (as indicated) than the mandatory breaths. When the patient fails to trigger another breath within the next synchronization window, another mandatory breath (breath 4) is delivered.**

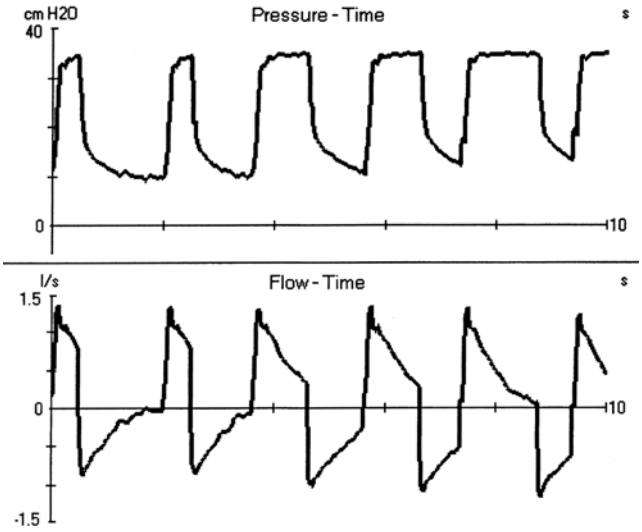

FIGURE 36-2 The effect of changing inspiratory time (TI) on ventilation in the passive patient during pressure-control ventilation. As TI is raised from an initial value of 0.5 second (first two breaths) to 1.0 second (middle breaths) to 1.5 seconds (last breaths), tidal volume increases; expiratory time decreases so much that no positive end-expiratory pressure is created (once TI reaches 1.0 second) and end-inspiratory alveolar pressure increases (signaled by the lower flow at end inspiration, essentially 0 at a TI of 1.5 seconds).

effort during machine inspiration may decrease VT below the value expected. Special care must be taken to adjust TI to the individual patient (Fig. 36-2); otherwise, heavy sedation is typically needed. When unphysiologic settings are intentionally chosen, as when the physician desires an unusually long TI (TI longer than TE results in inverse ratio ventilation [IRV], described later), deep sedation or therapeutic paralysis is often given.

Pressure-Support Ventilation

The patient must trigger the ventilator to activate this mode, so PSV is not applied to passive patients. Ventilation is determined by PI − PEEP, patient-determined f, patient effort, and the patient's mechanics. Once a breath is triggered, the ventilator attempts to maintain PI by using whatever flow is necessary. Eventually, flow begins to decrease due to cessation of the patient's inspiratory effort or to increasing elastic recoil of the respiratory system as lung volume rises. The ventilator maintains PI until inspiratory flow decreases an arbitrary amount (e.g., to 20% of initial flow) or below an absolute flow rate (depending on the ventilator).

It is useful to first consider what happens if the patient were to trigger the ventilator and then remain passive (an artificial situation). VT would be determined by PI and the (largely static) mechanical properties of the respiratory system, as during PCV (see Fig. 36-1B). More typically, the patient makes an effort throughout inspirations, in which case VT is determined in part by the degree of effort (see Fig. 36-1B). At a constant minute ventilation, the patient's work of breathing can be increased by decreasing PI or making the trigger less sensitive (Table 36-2) and can increase inadvertently if respiratory system mechanics change despite no change in ventilator settings. Respiratory system mechanical parameters cannot be determined readily on this mode because the ventilator and patient contributions to VT and $\dot{V}$ are not distinguishable from analysis of the ventilator airway opening pressure (Pao); accordingly, the important measurements of Pplat, Ppk minus Pplat, and autoPEEP are measured during a brief daily switch from PSV to ACV at the corresponding values of VT, $\dot{V}$, and I:E observed during PSV.

T-piece or trach collar trials
CPAP trials
Lower the level of pressure-support ventilation
Change the sensitivity on ACV, PSV, or IMV
Decrease the rate of IMV

ABBREVIATIONS: ACV, assist-control ventilation; CPAP, continuous positive airway pressure; IMV, intermittent mandatory ventilation; PSV, pressure-support mode.

A potential advantage of PSV is improved patient comfort.[6,7] An important caution about PSV is that it can account for a large fraction of total minute ventilation, even when set at rather low levels, as in patients with normal respiratory system mechanics. For example, in a patient with myasthenia gravis, 10 cm H_2O of PSV may represent full mechanical ventilation. A "successful" spontaneous breathing trial with these settings should not be used to judge the patient's readiness for extubation.

VOLUME-PRESET MODES

During volume-preset ventilation, a volume is delivered to the patient at the required pressure (within the limits of the high pressure alarm). The physician generally also sets a $\dot{V}$ (indirectly determining the TI) and f. In volume-preset modes, the Pplat is predictable (in a passive patient) when the Crs is known:

$$\text{Pplat} = \text{VT}/\text{Crs} + \text{PEEP}$$

where PEEP includes autoPEEP.

Compared with pressure-preset modes, a potential advantage of volume-preset ventilation is greater control over the total minute ventilation because VT does not depend on potentially changing patient effort or respiratory system mechanical properties. Another advantage of volume-preset modes was reported by ARDS Network Tidal Volume Trial, which demonstrated an advantage with respect to mortality rate when using ACV. Moreover, it is easy to characterize the

respiratory system mechanics by measuring Ppk and Pplat, thereby simplifying follow-up of the patient's progress or response to therapies.

Assist Control Ventilation

The set parameters of the assist-control mode are the $\dot{V}$, f, and V_T (on some ventilators, one must set the total minute ventilation and rate, thereby determining V_T and indirectly determining $\dot{V}$). In the passive patient, the ventilator delivers f (f = 60 seconds/[T_I+ T_E]) equal breaths per minute, and V_T or $\dot{V}$ setting determine the T_I, T_E, and the I:E. Pplat is related to the V_T and the Crs, whereas Ppk minus Pplat includes contributions from $\dot{V}$ and inspiratory resistance (see Fig. 36-1C).

The active patient can trigger extra breaths by exerting an inspiratory effort exceeding the preset trigger sensitivity at the set V_T and $\dot{V}$ and thereby change T_I, T_E, and I:E and (potentially) create or increase autoPEEP. Typically, each patient will display a preferred rate for a given V_T and will trigger all breaths when the controlled ventilator frequency is set a few breaths per minute slower than the patient's rate; in this way, the control rate serves as an adequate support should the patient stop initiating breaths. When high inspiratory effort continues during the ventilator-delivered breath, the patient may trigger a second, superimposed ("stacked") breath (and, rarely, a third breath). The total V_T of this breath is determined by the point in the first breath at which the second was triggered, so the total V_T can range from the set V_T to twice the V_T.

Typically, the patient performs inspiratory work during an assist-control breath.[1,9] This may not be obvious despite careful examination of the patient unless measures of intrathoracic pressure (esophageal pressure and central venous pressure) are available, or the inspiratory pressure waveform is examined carefully (Chap 32). Effort at the end of the breath will affect the Ppk and Pplat, making determination of respiratory system mechanics unreliable. When the patient is assisting every breath, the work of breathing can be increased by increasing the magnitude of the trigger or by lowering V_T (which increases the rate of assisting; see Table 36-2). Decreasing f at the same V_T generally has no effect on the work of breathing (in contrast to SIMV, discussed below) when the patient is initiating all breaths.

Synchronized Intermittent Mandatory Ventilation

In the passive patient, intermittent mandatory ventilation (IMV) cannot be distinguished from controlled ventilation in the ACV mode. Ventilation is determined by the mandatory f, V_T, and $\dot{V}$ values. However, if the patient is not truly passive, he or she may perform respiratory work during the mandatory breaths. More to the point of the SIMV mode, the patient can trigger additional breaths by decreasing Pao below the trigger threshold (see Fig. 36-1D). If this triggering effort comes in a brief, defined interval before the next mandatory breath is due, the ventilator will deliver the mandatory breath ahead of schedule to synchronize (SIMV) with the patient's inspiratory effort. If a breath is initiated outside the synchronization window, V_T, $\dot{V}$, and I:E are determined by patient effort and respiratory system mechanics (see Fig. 36-1D), not by ventilator settings. The spontaneous breaths tend to be of small volume, as depicted in Fig. 36-1D, and are highly variable from breath to breath. The SIMV mode is often used to gradually augment the patient's work of breathing by lowering the mandatory breath f (or V_T), thereby driving the patient to breathe more rapidly to maintain adequate ventilation, but this approach appears to prolong "weaning"[10,11] (see Table 36-2). Although this mode continues to be used widely, there is little rationale for it and SIMV is falling out of favor.

MIXED MODES

Some ventilators allow combinations of modes, most commonly SIMV plus PSV. There is little reason to use such a hybrid mode, although some physicians use the SIMV mode as a means to add sighs to PSV, an option not otherwise generally available. Because SIMV plus PSV guarantees some backup minute ventilation (which PSV does not), this mode combination may have value in occasional patients at high risk for abrupt deterioration in central drive.

DUAL-CONTROL MODES

The sophisticated microprocessors included with modern ventilators allow remarkably complex modes of ventilation. These modes typically try to meld the best features of volume- and pressure-preset modes. Some cause a switch of modes between breaths (e.g., pressure-regulated volume control [PRVC] and volume support) or within a breath (e.g., volume-assured pressure support). In general, these modes are complex, and their effects may vary greatly depending on the details of the patient's effort. None has been shown to be safer or more useful than more conventional modes. The greatest problem with such newer modes is that they are very complex, the algorithm describing their function is not usually understood by practitioners, and they change during a breath or from breath to breath, depending on patient effort, sometimes in ways that can provoke unanticipated effects.

Pressure-Regulated Volume Control

This is a pressure-preset mode with a set T_I (i.e., it is time cycled) in which the ventilator compares the V_T with a physician-set V_T and automatically and gradually adjusts P_I of subsequent breaths to deliver the desired V_T. A downside of PRVC is that, as patient effort increases, the ventilator decreases support. Proponents argue that this mode provides the benefits of pressure-preset modes and simultaneously guarantees V_T; whether this guarantee makes the mode better or worse for the patient is debated.

Volume Support

Volume support is a pressure-preset mode in which P_I is automatically changed to gradually bring V_T in line with the desired V_T over several breaths, differing from PRVC in that T_I is not set but rather depends on patient effort as in PSV. It is unknown whether this mode speeds or impedes weaning.

Volume-Assured Pressure Support

This mode begins as PSV, but, if a desired V_T is not met, the ventilator switches to ACV within the same breath to guarantee V_T. As with many dual-control modes, the physician delegates decision making to the ventilator. Complex adjustments and their potentially detrimental effects on the patient may come into play at any time of day or night, depending on changes in the mechanical properties of the respiratory system or changes in the patient's level of consciousness, comfort, or neuromuscular competence.

CONTINUOUS POSITIVE AIRWAY PRESSURE

Continuous positive airway pressure (CPAP) is not a mode of ventilation but a means of increasing functional residual capacity and allowing the patient to breathe spontaneously. This approach is frequently used when assessing the patient's ability to breathe without ventilatory assistance. Advantages of CPAP over T-piece breathing is that oxygenation may be increased, ventilator alarms (e.g., low minute ventilation and apnea) remain in place, the patient's spontaneous V_T and rate can be easily read from the ventilator panel, and the work of breathing is decreased if autoPEEP is present.[12,13] Disadvantages include the loss of mobility and independence that comes with being tethered to the ventilator and the sometimes increased work of breathing attributed to triggering ventilator valves and driving flow through excess tubing and flow meters. A potentially misleading feature of some ventilators is that the display may show the mode as "CPAP" when it is "PSV." This could lead health care providers to draw erroneous conclusions about the patient's ability to sustain spontaneous ventilation.

EFFECT OF INSPIRATORY FLOW PROFILE

With most ventilators, the physician can choose one of several inspiratory waveforms, most commonly square or decelerating. The rationale for the use of decelerating flow is the possible improvement in the distribution of ventilation and minimization of Ppk. This rationale works because maximal flow (and therefore flow-related pressure) occurs early in the breath when lung volume (and elastic recoil pressure) is minimal; in addition, near the end of the breath, lung volume is maximal but flow is minimal. However, an inescapable consequence of the overall lower $\dot{V}$ (assuming equal peak inspiratory $\dot{V}$ and a passive patient) is a shorter T_E. Thus, in patients who have obstruction or high minute ventilations (those in whom a decelerating flow pattern will most decrease Ppk), autoPEEP is likely to be caused or increased (Fig. 36-3). Although the relative contributions of Ppk and PEEP (or autoPEEP) to barotrauma risk are not clearly defined, it seems likely that, in most patients, barotrauma risk will be worsened rather than improved with a decelerating profile. A sine waveform similarly lowers Ppk and shortens T_E.

When a square waveform is used, the flow-related pressure near end inspiration is nearly the same as at the beginning of the breath and adds to the elastic recoil pressure to produce a higher Ppk than during sine wave or decelerating flow. However, this higher Ppk is largely borne by the robust proximal airways and not by the alveoli; by contrast, greater autoPEEP means greater P_A and risk of alveolar disruption. Because the peak pressure is visibly decreased by decelerating and sine wave profiles and increased autoPEEP is typically occult, such flow patterns can be insidiously threatening. Accordingly, we believe that there is little reason to use anything other than the conventional square wave inspiratory flow profile, except when IRV is desired (see below). When a decelerating flow profile is used, autoPEEP should be measured diligently and the hidden complexities of this phenomenon made clear to all caring for the patient.

A peak $\dot{V}$ of 1 L/s (60 L/min) is a common initial setting, but this may require adjustment upward (for patient comfort or to lengthen T_E) or downward (to create IRV). Increased

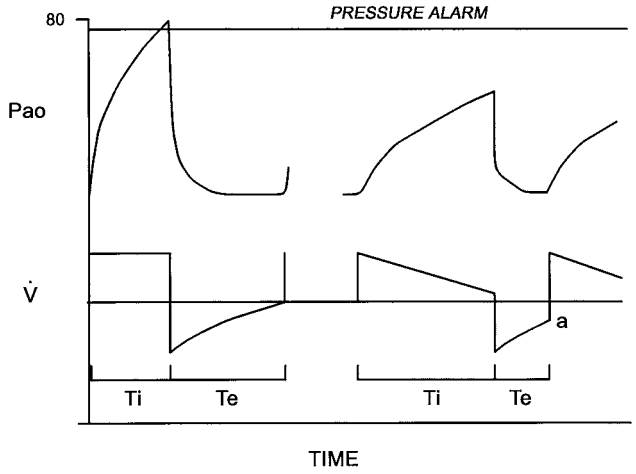

FIGURE 36-3 Effect of flow profile on pressure-airway opening (Pao) and inspiratory-expiratory (I:E) ratio in a patient with status asthmaticus during assist-control or mandatory intermittent mandatory ventilation breaths. The *left-hand tracings* show the typical high peak airway pressure (Ppk) and slow expiratory flow in a patient with severe obstruction ventilated with a square wave inspiratory flow profile. Expiratory flow just reaches zero before the next breath is delivered. The Ppk can be dramatically reduced by changing to a decelerating flow profile (*right-hand tracing*) because much of the high Pao is related to flow. However, to deliver the same tidal volume at the now lower mean inspiratory flow, the inspiratory time (T_I) must increase. At the same respiratory rate, the expiratory time (T_E) decreasing, thereby increasing the I:E ratio. With the now shortened T_E, there is insufficient time for the respiratory system to reach functional residual capacity, expiratory flow is still detected at the onset of inspiratory flow (*a*), and no positive end-eexpiratory pressure (auotPEEP) is present. Therefore, the lower (but not "improved") Pao comes at the cost of new (or higher) autoPEEP and a higher mean alveolar pressure. $\dot{V}$, flow.

$\dot{V}$ may have a stimulatory effect on respiratory rate in active patients,[14] paradoxically shortening T_E, although the impact on respiratory rate and work of breathing after the first few seconds has not been studied. Decreasing the peak $\dot{V}$ will decrease Ppk when there is significant resistance to airflow but, in this setting, will usually worsen autoPEEP, as described above. One often overlooked adverse consequence of setting peak $\dot{V}$ at less than the patient wishes is that the patient will actively inspire against the ventilator, thereby increasing the respiratory work. This occurs frequently when patients having low ventilatory requirements are placed on volume-preset ventilators on which $\dot{V}$ cannot be set directly but rather is determined by V_T and T_I (e.g., the Siemens 900C).

TRIGGERED SENSITIVITY

In the ACV, SIMV, and PSV modes, the patient must decrease the Pao below a preset threshold to "trigger" the ventilator. In most situations this is straightforward because a more negative sensitivity increases the effort demanded of the patient. This can be used intentionally to increase the work of breathing when the goal is to strengthen the inspiratory muscles. In contrast, when autoPEEP is present, the patient must decrease P_A by the autoPEEP amount to have any effect on Pao and then by the trigger amount to initiate a breath. This can dramatically increase the required

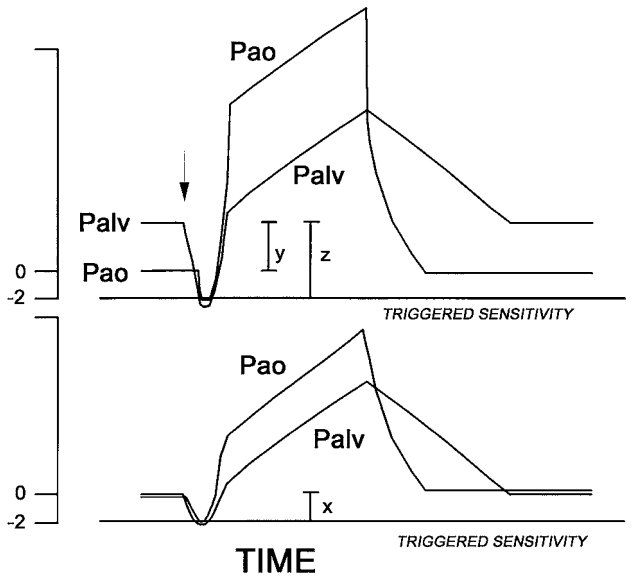

FIGURE 36-4 Effect of occult positive end-expiratory pressure (autoPEEP) on triggering. The *lower tracings* of pressure-airway opening (Pao) and alveolar pressure (P_A) represent a patient who is triggering volume-preset ventilator breaths and who does not have autoPEEP. The *upper tracing* shows a patient similarly ventilated and with the same triggered sensitivity (−2 cm H_2O) but who has 4 cm H_2O of autoPEEP. The patient without autoPEEP must decrease P_A by x (∼2 cm H_2O) to lower the Pao by the same amount, thereby triggering a breath. In contrast, the patient with autoPEEP must lower the P_A by y (∼4 cm H_2O) before there is any impact on Pao and then by another 2 cm H_2O to trigger the ventilator. In the patient with autoPEEP, the total reduction in P_A (z) required to trigger the ventilator rises as autoPEEP rises and is occult. In the extreme, autoPEEP may be so elevated that a weak patient is unable to trigger the ventilator despite great effort.

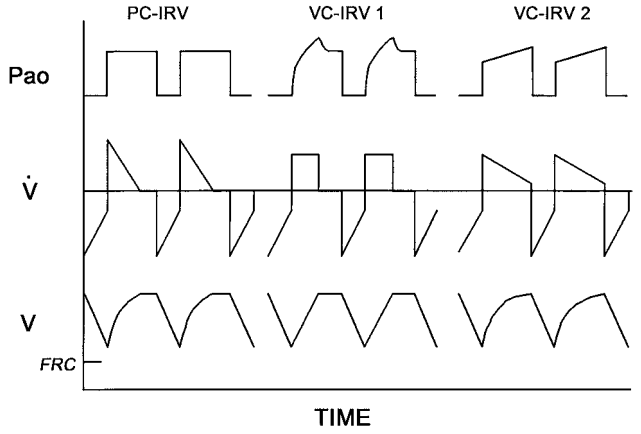

FIGURE 36-5 Inverse ratio ventilation (IRV). The *first panel* shows pressure-controlled IRV (PC-IRV) in which pressure-airway opening (Pao) during inspiration is held constant and expiration time (T_E) is shortened to invert the inspiratory-expiratory (I:E) ratio. Flow and tidal volume (V_T) can be predicted from the passive elastic properties of the respiratory system (assuming inspiration time [T_I] is sufficiently long for equilibration of inspiration pressure [P_I] and alveolar pressure [P_A]). The very short T_E is insufficient for lung volume (V) to return to functional residual capacity (FRC), and there is persistent expiratory flow at end expiration (i.e., no positive end-expiratory pressure [autoPEEP] is present). The *second panel* shows volume-controlled IRV (VC-IRV) with a square wave flow pattern in which an end-inspiratory pause is used to invert the I:E ratio. Peak pressure is higher than during equivalent PC-IRV because flow remains high at end inspiration (when elastic recoil is maximal). AutoPEEP is also present. In the *third panel*, IRV is created by using a decelerating flow profile. The peak airway pressure (Ppk) is midway in between the other two modes because end-inspiratory flow is present but small. The short T_E does not allow expiration to FRC, causing autoPEEP. In all three cases, the mean V and, hence, mean P_A would be increased compared with ventilator modes having normal I:E ratios. V̇, flow.

effort for breath initiation (Fig. 36-4). In several instances, we have seen physicians suspect machine malfunction and even change the ventilator when they are confronted with an obviously struggling patient seemingly unable to get a breath despite a "minimal" trigger threshold. The solution for this problem is to eliminate the cause for autoPEEP, sedate the patient, or use externally applied PEEP to counterbalance the autoPEEP (which only occasionally increases autoPEEP, risking barotrauma and hypotension)[15–17] (see Chap. 39).

Flow-triggering systems ("flow-by") have been used to further decrease the work of triggering the ventilator. In contrast to the usual approach, in which the patient must open a demand valve to receive ventilatory assistance, continuous-flow systems maintain a continuous high flow and then augment flow when the patient initiates a breath. These systems can decrease the work of breathing below that encountered when using conventional demand valves,[18,19] in part by shortening the time to pressurization of the inspiratory circuit,[20] but they do not solve the problem of triggering when autoPEEP is present.

UNCONVENTIONAL VENTILATION MODES

INVERSE RATIO VENTILATION

IRV is defined as a mode in which the I:E is greater than 1. Like PEEP, it was introduced as an empirical variation to salvage lung oxygen exchange in patients with severe acute hypoxemic respiratory failure. There are two general ways to apply IRV: pressure-controlled IRV (PC-IRV), in which a preset airway pressure is delivered for a fixed period at an I:E greater than 1, or volume-controlled IRV (VC-IRV), in which a V_T is delivered at a slow (or decelerating) V̇ (or an end-inspiratory pause is inserted) to yield an I:E greater than 1[21] (Fig. 36-5). For PC-IRV, the physician must specify the inspiratory airway pressure, f, and I:E, and V_T and flow profile are determined by respiratory system impedance as discussed for PCV (see Fig. 36-5). Commonly, the initial P_I is 20 to 40 cm H_2O (or 10 to 30 cm H_2O above the PEEP), f is 20/min, and the I:E is 2:1 to 4:1. For VC-IRV, the operator selects a V_T, f, V̇ (typically a low value), flow profile, and, possibly, an end-inspiratory pause (see Fig. 36-5). The chosen values result in an I:E greater than 1:1 and as high as 5:1.

Compared with conventional modes of ventilation, lung oxygen exchange is often improved on IRV owing to increased mean P_A and volume consequent to the longer time above functional residual capacity (FRC)[22,23] or owing to creation of autoPEEP.[24,25] Conceivably, this decreases shunt as PEEP does by redistributing alveolar edema into the pulmonary interstitium.[26] It is remotely possible that IRV causes better ventilation of lung units with long time constants, but these

are so short in normal lungs[27] (and shorter in ARDS) that such redistribution is unlikely to occur with slower flow and could not reduce shunt even if it did. Because autoPEEP is a common consequence of IRV, serial determination of its magnitude is essential for safe use of this mode. PC-IRV and VC-IRV generally require heavy sedation with or without muscle paralysis.

AIRWAY PRESSURE-RELEASE VENTILATION

Airway pressure-release ventilation (APRV) consists of CPAP that is intermittently released to allow a brief expiratory interval.[28] Conceptually, this mode is pressure-controlled IRV, during which the patient is allowed to initiate spontaneous breaths. It has been applied to patients with acute lung injury[29,30] and has proved effective in maintaining oxygenation and assisting ventilation. A potential advantage of APRV is that mean P_A is lower than it would be during positive-pressure ventilation from the same amount of CPAP, possibly decreasing the risks of barotrauma and hemodynamic compromise. It has been claimed that the most important clinical advantage of APRV is that, compared with conventional ventilation, peak airway pressure can be decreased dramatically.[29] In these studies, however, conventional positive-pressure ventilation was delivered by using excessive V_T (10 to 15 mL/kg).[29,30] Disadvantages of APRV include hypoxemia due to the interruption of CPAP, atelectasis,[30] and patient discomfort that sometimes mandates sedation. Another concern relates to the fact that, because the lung cycles tidally below rather than above the volume determined by CPAP, this mode probably encourages repeated recruitment and de-recruitment of flooded and collapsed alveoli. Although this point is controversial, the weight of evidence suggests that this may amplify ventilator-induced lung injury. Whether this mode provides any benefit over modern low-V_T ventilation remains to be shown.

PROPORTIONAL-ASSIST VENTILATION

Proportional-assist ventilation is intended only for spontaneously breathing patients. The goal of this novel mode is to attempt to normalize the relation between patient effort and the resulting ventilatory consequences.[31,32] The ventilator adjusts P_I in proportion to patient effort throughout any given breath and from breath to breath. This allows the patient to modulate the breathing pattern and total ventilation. This is implemented by monitoring instantaneous $\dot{V}$ and volume (V) of gas from the ventilator to the patient and changing the P_I as follows:

$$P_I = f_1 \times V + f_2 \times \dot{V}$$

where f_1 and f_2 are selectable functions of volume (elastic assist) and flow (resistive assist), respectively, values that can be estimated from the patient's respiratory mechanics. Potential advantages of this method are greater patient comfort, lower Ppk, and enhancement of the patient's reflex and behavioral respiratory control mechanisms. In contrast, proportional-assist ventilation can amplify instabilities in the patient's breathing rhythm, as in the common instance of periodic (Cheyne-Stokes) respiration.

HIGH-FREQUENCY VENTILATION

Several modes of ventilation have in common the use of V_T smaller than the dead space volume.[33] Gas exchange does not occur through convection as during conventional ventilation but through bulk flow, Taylor diffusion, molecular diffusion, non-convective mixing, and possibly other mechanisms. These modes include high-frequency oscillatory ventilation and high-frequency jet ventilation. Theoretical benefits of high-frequency ventilation (HFV) include lower risk of barotrauma due to smaller tidal excursions, improved gas exchange through a more uniform distribution of ventilation, and improved healing of bronchopleural fistulas.[34] Animal studies have suggested that HFV may be superior to lung protective ACV with respect to ventilator-induced lung injury, hemodynamic compromise, and inflammation.[35,36] Delivered V_T is affected mostly by rate but also by I:E and frequency amplitude. In an animal model of severe lung injury, settings of 4 Hz, an I:E of 1:1, and a pressure amplitude of 60 cm H_2O, the V_T was 4.4 mL/kg, a value approaching conventional V_T values.[37] A substantial risk is that dynamic hyperinflation is the rule, and P_A is greatly underestimated by monitoring Pao.[38] A controlled trial of HFV found no clinically relevant benefit, but the approach was shown to be safe, at least in the context of a clinical trial.[39] Nevertheless, HFV is the natural extension of reducing the V_T as a means to prevent volutrauma, and there is renewed interest in this old technique.[39a]

Management of the Patient

INITIAL VENTILATOR SETTINGS

Initial ventilator settings depend on the goals of ventilation (e.g., full respiratory muscle rest versus partial exercise), the patient's respiratory system mechanics, and minute ventilation requirements. Although each critically ill patient presents myriad challenges, it is possible to identify four subsets of ventilated patients: the patient with normal lung mechanics and gas exchange, the patient with predominant airflow obstruction, the patient with acute hypoxemic respiratory failure, and the patient with restrictive lung or chest wall disease. Specific recommendations regarding ventilator settings are detailed more fully in Chaps. 38, 39, 40, and 42 but are reviewed here briefly, in addition to guidelines for ventilating patients with normal respiratory system mechanics.

In all patients, the initial $F_{I_{O_2}}$ should usually be 0.5 to 1.0 to ensure adequate oxygenation, although usually it can be decreased within minutes when guided by pulse oximetry and, in the appropriate setting, applying PEEP. In the first minutes after institution of mechanical ventilation, the physician should remain alert for several common problems, most notably, airway malposition, aspiration, and hypotension. Positive-pressure ventilation may decrease venous return and, hence, cardiac output, especially in patients with a low mean systemic pressure (e.g., hypovolemia, venodilating drugs, decreased sympathetic tone from sedating drugs, or neuromuscular disease) or a very high ventilation-related pleural pressure (e.g., chest wall restriction, large amounts of PEEP, or airway obstruction causing autoPEEP). If hypotension occurs, intravascular volume should be expanded rapidly while steps are taken to decrease the pleural pressure (a smaller V_T and less minute ventilation). Meanwhile, the

F_{IO_2} should be raised to 100%. If these steps do not rapidly restore the circulation, another complicating event (pneumothorax or myocardial ischemia) should be considered while the patient is taken off the ventilator and bagged manually to assess respiratory load and to observe the response of blood pressure to a brief suspension of positive-pressure ventilation.

THE PATIENT WITH NORMAL RESPIRATORY MECHANICS AND GAS EXCHANGE

Patients with normal lung mechanics and gas exchange may require mechanical ventilation because of loss of the central drive to breathe (e.g., drug overdose or structural injury to the brain stem), because of neuromuscular weakness (e.g., high cervical cord injury, acute idiopathic myelitis, or myasthenia gravis), as an adjunctive therapy in the treatment of shock,[40,41] or to achieve hyperventilation (e.g., in the treatment of elevated intracranial pressure after head trauma). After intubation, initial ventilator orders should be an F_{IO2} of 0.5 to 1.0, a V_T of 8 to 12 mL/kg, a respiratory rate of 8 to 12 breaths/min, and a $\dot{V}$ of 50 to 60 L/min (Table 36-3). Alternatively, if the patient has sufficient drive and is not profoundly weak, PSV can be used. The level of pressure support is adjusted (usually to the range of 10 to 20 cm H_2O above PEEP) to bring the respiratory rate down into the low 20s, usually corresponding to a V_T of about 500 mL. It is important to realize that PSV is mechanically supported but entirely spontaneous, with no machine "backup" unless mixed with a mode such as SIMV. Thus, hypoventilation may occur despite the use of PSV, if there is further deterioration of muscle strength or blunting of drive by disease or drugs. If gas exchange is entirely normal, the F_{IO2} likely can be decreased further based on pulse oximetry or arterial blood gas determinations. However, because right mainstem intubation, aspiration, and bronchospasm are relatively common complications of intubation, it is wise to initiate ventilation with the F_{IO_2} at 0.5 or higher. Should hyperventilation be desired, the initial respiratory rate should be increased to the range of 16 to 20 breaths/min. The $\dot{V}$ can be increased if the patient complains of air hunger, but 50 to 60 L/min is often sufficient.[1] Even in most tachypneic patients with underlying lung disease and certainly in those individuals with normal lung mechanics, a $\dot{V}$ greater than 60 L/min is rarely necessary or useful.

Soon after the initiation of ventilation, airway pressure and flow waveforms should be inspected for evidence of dyssynchrony between the patient and the ventilator or undesired patient effort (see Chap. 32). If the goal of ventilation is full rest, the patient's drive often can be suppressed by increasing the $\dot{V}$, f, or V_T.[42,43] The latter two changes may induce respiratory alkalemia. If such adjustments do not diminish breathing effort, despite normal blood gases, to an undetectable level, sedation may be necessary. If this does not abolish inspiratory efforts and full rest is essential (as in shock), muscle paralysis can be considered.

Measures to prevent atelectasis should include sighs (6 to 12 per hour at 1.5 to 2 times the V_T) or small amounts of PEEP (5 to 7.5 cm H_2O). This is particularly important in patients with neuromuscular diseases during protracted ventilation because atelectasis is common. In these patients, we use the upper limit of V_T (12 mL/kg). Three-point turning and chest physiotherapy are desirable in all patients unless other conditions preclude their use. Rotating beds may be effective in some patients for preventing atelectasis and pneumonia.[44]

PATIENTS WITH DOMINANT AIRFLOW OBSTRUCTION

Two general types of patients require mechanical ventilation for significant airflow obstruction; those with status asthmaticus (see Chap. 40) and those with exacerbations of chronic airflow obstruction (see Chap. 39). Rare alternative causes are inhalation injury or central airway lesions, such as tumor or foreign body, not bypassed with the endotracheal tube. In isolated upper airway injuries, assessment of the extent of damage is often possible by bronchoscopy shortly before or at the time of intubation. Bronchoscopy should not be performed routinely in patients with asthma.

STATUS ASTHMATICUS

Because the gas exchange abnormalities of airflow obstruction are largely limited to ventilation-perfusion mismatch, an F_{IO_2} of 0.5 suffices in the vast majority of patients.[45] Requirements for a higher F_{IO2} should prompt a search for an alveolar filling process or for lobar atelectasis. We have had success ventilating these patients with PSV by setting P_I at 25 to 30 cm H_2O. Because these patients are typically anxious, we often give large doses of narcotics to suppress drive, an approach that, when combined with high-level PSV, often leads to an unusual but stable pattern of breathing, with a V_T larger than 900 mL and an f of 3 to 7. This approach appears to minimize autoPEEP by allowing such a long T_E. Alternatively, ventilation can be initiated using the ACV mode with a normal V_T (5 to 7 mL/kg) and respiratory rate of 12 to 15 breaths/min (see Table 36-3). A peak flow of 60 L/min is recommended, and higher flow rates do little to increase

TABLE 36-3 Initial Ventilator Settings

	Mode	F_{IO_2}	PEEP (cm H_2O)	V_T (mL/kg)	RR (min^{21})	Flow (L/min)	Sighs
Normal	ACV[a]	0.5	5	8–12	10	60	Yes
Asthma	ACV	0.5	0[b]	5–7	10–18	60	No
ACRF	ACV[a]	0.5	5	5–7	24	60	Yes
AHRF	ACV	1.0	15[c]	4–6, using IBW	24	60	No
Restriction	ACV	0.5	5	5–7	20	60	Yes

[a] PSV is an alternative.
[b] Assumes that the patient is deeply sedated or therapeutically paralyzed.
[c] Adjust promptly based on pulse oximetry; may not be helpful in focal lung lesions; monitor for hypotension.
ABBREVIATIONS: ACV, assist-control ventilation; ACRF, acute-on-chronic respiratory failure ; AHRF, acute hypoxemic respiratory failure; F_{IO_2}, fraction of inspired oxygen; IBW, ideal body weight; PEEP, positive end-expiratory pressure; RR, respiratory rate; V_T, tidal volume.

T_E . For example, if the V_T is 500 mL, the respiratory rate is 15 breaths/min, and the $\dot{V}$ 60 L/min, the T_E is 3.5 seconds. Raising $\dot{V}$ (dramatically) to 120 L/min increases the T_E to only 3.75 seconds, a trivial improvement. In contrast, a small reduction in respiratory rate to 14 breaths/min increases the T_E to 3.8 seconds. This example emphasizes not only the relative lack of benefit of raising the flow rate but also the importance of minimizing minute ventilation when the goal is to reduce autoPEEP. If the patient is triggering the ventilator, it is essential that some PEEP be added to reduce the work of triggering. This does not generally worsen the hyperinflation as long as PEEP is not higher than about 85% of the autoPEEP.[16,46–48] Ventilatory goals are to minimize alveolar overdistention (keep Pplat<30) and to minimize dynamic hyperinflation (keep autoPEEP<10 cm H_2O or end-inspiratory lung volume <20 mL/kg), a strategy that largely prevents barotrauma.[49] Reducing minute ventilation to achieve these goals generally causes the partial pressure of CO_2 to rise above 40 mm Hg, often to 70 mm Hg or higher. Although this requires sedation, such permissive hypercapnia is quite well tolerated except in patients with increased intracranial pressure and perhaps in those with ventricular dysfunction or pulmonary hypertension.

Patients with status asthmaticus requiring mechanical ventilation are usually extremely anxious and distressed, especially when ventilated using a volume-preset mode. Deep sedation is usually necessary and supplemented in rare patients by therapeutic paralysis. The frequent occurrence of postparalytic myopathy in patients with asthma[50–52] has led us to greatly decrease our use of paralytics, an approach facilitated by the use of high-level PSV.

Sighs are undesirable because they may lead to lung rupture. Because peak proximal airway pressure is so high in this patient group, upper-limit alarms of 75 cm H_2O (and sometimes higher) are often required. Careful attention should be paid to the $\dot{V}$ and flow profile. Changes in flow that have little effect in the patient without airflow obstruction can have a dramatic impact in obstructed patients. Specifically, reducing the inspiratory flow or changing to a decelerating flow profile reduces the airway pressures and the amount of ventilator alarming but, by prolonging inspiration, actually worsens autoPEEP. Although the ventilator looks "better," the patient is worse, but this is only recognized if autoPEEP is regularly sought or if the expiratory flow profile is examined (see Fig. 36-3). Aggressive chest physiotherapy is advised because many patients mobilize mucous plugs during their recovery phase; often these plugs are so large and tenacious that they compromise endotracheal tube patency.

ACUTE-ON-CHRONIC RESPIRATORY FAILURE

Acute-on-chronic respiratory failure is a term used to describe exacerbations of chronic ventilatory failure usually occurring in patients with COPD[53] (see Chap. 39). Many of these patients are successfully (and preferably) ventilated noninvasively (see Chap. 33). When intubated, they are found to have relatively smaller increases in inspiratory resistance (compared with asthma), with their expiratory flow limitation arising largely from loss of elastic recoil.[54] As a consequence, in the patient with COPD, peak airway pressures tend to be only modestly elevated (e.g., 30 cm H_2O), but autoPEEP and its consequences are common.[55] At the time of intubation, hypoperfusion is common, as manifested by tachycardia and relative hypotension, and typically responds to briefly ceasing ventilation combined with fluid loading.

Because most of these patients are ventilated after days to weeks of progressive deterioration, the goal is to rest the patient (and respiratory muscles) completely for 36 to 48 hours, although excessive rest and ventilatory support may contribute to atrophy and weakness of the diaphragm.[56] Also, because the patient typically has an underlying compensated respiratory acidosis, excessive ventilation risks severe respiratory alkalosis and, over time, bicarbonate wasting by the kidney. The goals of rest and appropriate hypoventilation usually can be achieved with initial ventilator settings of a V_T of 5 to 7 mL/kg and a respiratory rate of 16 to 24 breaths/min, with an ACV mode set on minimal sensitivity (see Table 36-3). Because gas exchange abnormalities are primarily those of ventilation-perfusion mismatch, supplemental oxygen in the range of an $F_{I_{O_2}}$ of 0.4 should achieve better than 90% saturation of arterial hemoglobin. Gas exchange abnormalities requiring an $F_{I_{O_2}}$ greater than 0.5 should prompt a search for complicating alveolar filling processes, such as left ventricular failure with pulmonary edema, pneumonia, or lobar collapse. $\dot{V}$ may be adjusted for patient comfort but usually is in the range of 50 to 60 L/min. Measures to prevent atelectasis and its complications (e.g., three-point turning, chest physiotherapy, or sighs) are necessary. PEEP should be used in this phase when the patient is triggering the ventilator because autoPEEP is universally present.

Most patients with COPD appear exhausted at the time when mechanical support is instituted and will sleep with minimal sedation. To the extent that muscle fatigue has played a role in a patient's functional decline, rest and sleep are desirable. Two days of such rest presumably will restore biochemical and functional changes associated with muscle fatigue, but 24 hours is probably not sufficient.[57] Small numbers of patients are difficult to rest on the ventilator and they continue to demonstrate effortful breathing. Examination of airway pressure and flow waveforms can be very helpful in identifying this extra work and in suggesting strategies for improving the ventilator settings (Fig. 36-6). In many patients, this is the result of autoPEEP-induced triggering difficulty, as discussed in Chap. 32 and shown in Fig. 36-4.[58] Frequently, adding extrinsic PEEP to nearly counterbalance the autoPEEP dramatically improves the patient's comfort.[59] An alternative approach is to increase minute ventilation to drive down the partial pressure of CO_2, but this will worsen autoPEEP and waste bicarbonate. This can be a difficult management problem. We advise a careful search for processes that might drive the patient to a respiratory rate higher than is desirable (e.g., hypoperfusion, pleural effusion or pain). If the patient continues to make significant inspiratory efforts—especially if these efforts are ineffective in actually triggering a machine breath or generating a V_T —judicious sedation is in order.

Once the patient improves and the respiratory muscles are rested, the patient should assume some of the work of breathing and be evaluated for liberation. During this phase, some extrinsic PEEP is typically useful to reduce the work of triggering.[59]

PATIENTS WITH ACUTE HYPOXEMIC RESPIRATORY FAILURE

Acute hypoxemic respiratory failure is caused by alveolar filling with blood, pus, or edema, the end results of which are

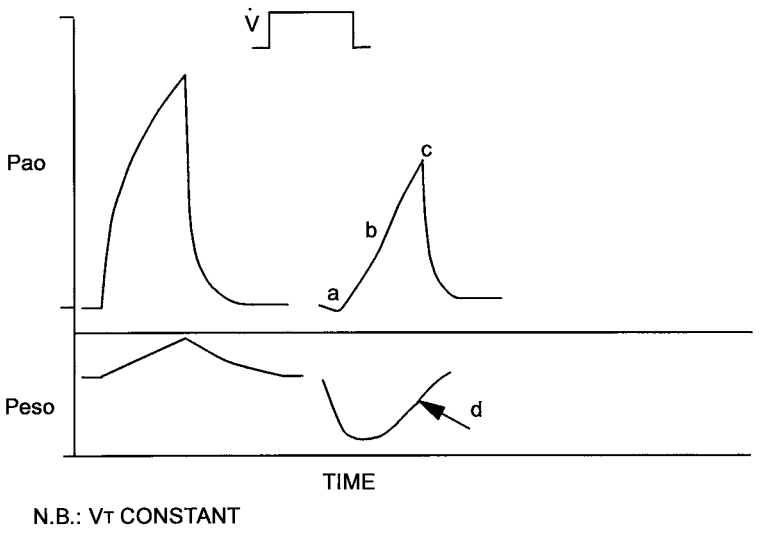

FIGURE 36-6 Signs of patient effort during volume-preset ventilation (assist-control ventilation [ACV] or intermittent mandatory ventilation [IMV] breaths). In these two breaths of equal tidal volume, the *left tracing* represents a muscle-relaxed patient, and the *right tracing* indicates a patient making inspiratory effort. The change in esophageal pressure (Peso) is shown in the *bottom tracings*. Signs of patient effort in the tracing of the pressure-airway opening (Pao) include a decrease in Pao just before the ACV or synchronized IMV breath (triggering; *a*), a concave upward rise in Pao during inspiration (*b*), and a peak airway pressure that is less than it would be if the patient made no effort (*c*). *d*. During the triggered breath, Peso (as an indicator of the pleural pressure) remains more negative than baseline throughout the breath and even after end inspiration (*arrow*).

impaired lung mechanics and gas exchange (see Chap. 31). The gas exchange impairment results from intrapulmonary shunt that is largely refractory to oxygen therapy. In ARDS (see Chap. 38), the significantly reduced FRC due to alveolar flooding and collapse leaves many fewer alveoli to accept the V_T , making the lung appear stiff and dramatically increasing the work of breathing. The ARDS lung should be viewed as a small lung rather than as a stiff lung. In line with this current conception of ARDS, it is clearly established that excessive distention of the ARDS lung compounds lung injury and may induce systemic inflammation.[8,60] Ventilatory strategies have evolved markedly in the past decade and have changed clinical practice and generated tremendous excitement.

The goals of ventilation are to reduce shunt, avoid toxic concentrations of oxygen, and choose ventilator settings that do not amplify lung damage. The initial F_{IO2} should be 1.0 in view of the typically extreme hypoxemia (see Table 36-3). PEEP is indicated in patients with diffuse lung lesions but may not be helpful in patients with focal infiltrates, such as lobar pneumonia. In patients with ARDS, PEEP should be instituted immediately, beginning with 15 cm H_2O, and then rapidly adjusted to the least PEEP necessary to produce an arterial saturation of 88% on an F_{IO2} no higher than 0.6 (the "least PEEP approach"). An alternative approach (the "open-lung approach"[61]) sets the PEEP at a value 2 cm H_2O higher than the lower inflection point of the inflation pressure-volume curve (see Chap. 32), but this has not been shown to confer benefit. The V_T should be 6 mL/kg IBW on ACV because a higher V_T is associated with a higher mortality rate.[8] Some have speculated that unstudied V_T values, such as 9 or 3 mL/kg IBW, might be even more beneficial than 6 mL/kg. It seems likely that there is a dose-response relation, with lower V_T values being superior, and this explains the resurgence in interest in HFV in which V_T can be very small. Nevertheless, because 6 mL/kg IBW has been conclusively shown to be safe and effective, this represents the standard of care to which other (potentially better, potentially worse) ventilator strategies should be compared. There is little doubt that lung protection can be achieved with pressure-preset ventilation, but safe settings are unknown. Some have extrapolated from the 30 cm H_2O plateau pressure limit in the ARDS Network study that a P_I of 30 cm H_2O ought to be safe; however, because the mean Pplat in those ventilated with 6 mL/kg IBW was only 26 cm H_2O, 30 cm H_2O may be too high. Whatever the mode, the respiratory rate should be set at 24 to 36 breaths/min as long as there is no autoPEEP. An occasional consequence of lung protective ventilation is hypercapnia. This approach of preferring hypercapnia to alveolar overdistention ("permissive hypercapnia") is discussed further in Chaps. 37 and 40.[61–63] Alternative modes of ventilation for ARDS, such as IRV, HFV, and tracheal gas insufflation, may have a role as salvage therapies but are of unproven benefit.

Once specimens have been collected from the airway for microbiologic and other studies, PEEP generally should not be disconnected to suction patients or to measure hemodynamic values because alveoli readily re-flood, provoking extreme hypoxemia. This supports multiple observations that PEEP does not reduce lung water but rather redistributes it into the lung interstitium to improve gas exchange.[26] Several modified suction adapters are available to provide a route to the airway and maintain PEEP, although most tend to leak at PEEP levels above 15 cm H_2O.

Sighs and other measures to prevent atelectasis are not necessary during the acute phases of acute hypoxemic respiratory failure, when PEEP levels are typically in excess of 10 cm H_2O. It should be remembered that these patients are at risk of atelectasis as they improve and PEEP levels are lowered. This is probably due in part to surfactant deficiency during the recovery from diffuse alveolar damage and certainly will be aggravated by the use of small V_T.

THE PATIENT WITH RESTRICTION OF THE LUNGS OR CHEST WALL

Several restrictive diseases of the lungs or chest wall can lead to respiratory failure, especially when there is a superimposed ventilatory challenge (e.g., pneumonia). These conditions are fully discussed in Chaps. 42 and 66 and include lung disease (e.g., advanced pulmonary fibrosis or late-stage ARDS), abdominal disease (e.g., massive ascites), and other chest wall abnormalities (e.g., kyphoscoliosis). We describe ventilator management.

Small V_T (5 to 7 mL/kg) and rapid rates (18 to 24 breaths/min) are especially important to minimize the hemodynamic consequences of positive-pressure ventilation and to reduce the likelihood of barotrauma (see Table 36-3). The

$F_{I_{O_2}}$ is usually determined by the degree of alveolar filling or collapse, if any. Rarely, we have encountered patients with enormous restrictive loads from intraabdominal catastrophes (e.g., massive intraperitoneal bleeding) who have a large intrapulmonary shunt but lack signs of alveolar flooding on the chest radiograph. We speculate that, in such patients, large numbers of alveolar units may be subserved by airways forced below their closing volume throughout tidal ventilation, so that these nonventilated alveoli comprise a large intrapulmonary shunt (see Chap. 42). Reversible contributors to restriction (e.g., circumferential burn eschar or tense ascites) should be identified and treated. Sitting the patient up in bed or on a chair may reduce the abdominal pressure, thereby easing the work of breathing.

The high P_A values typically generated in these patients may lead to increased physiologic dead space (when P_A exceeds the pulmonary artery pressure), especially when large V_T values are used. When the restrictive abnormality involves the chest wall (including the abdomen), the large ventilation-induced rise in pleural pressure has the potential to compromise cardiac output. This in turn will lower the mixed venous partial pressure of O_2 and, in the setting of ventilation-perfusion mismatch or shunt, the arterial partial pressure of O_2. If the physician responds to this decreasing arterial partial pressure of O_2 by augmenting PEEP or increasing the minute ventilation, further circulatory compromise ensues. A potentially catastrophic cycle of worsening gas exchange, increasing ventilator settings, and progressive shock is begun. This circumstance must be recognized because treatment is to reduce dead space (e.g., by lowering minute ventilation or correcting hypovolemia).

FACILITATING PATIENT COMFORT AND COMMUNICATION

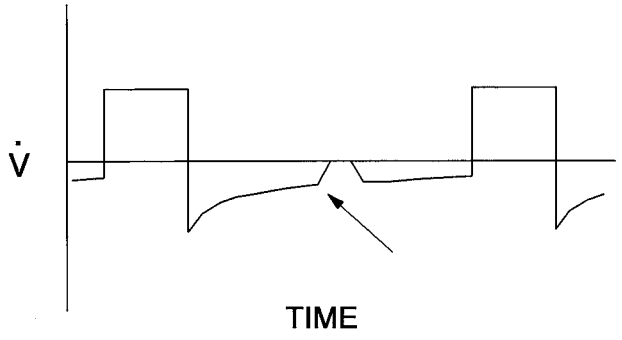
THE ROLE OF SEDATION

Ideally, the mechanically ventilated patient should be alert, comfortable, and capable of communicating with the health care team. These desirable goals must be weighed against the need to heavily sedate and even therapeutically paralyze some patients with cardiovascular instability, severely compromised oxygen delivery to peripheral tissues, or severely deranged respiratory system mechanics.[64]

Much excessive sedation can be avoided by frequent communication, reassurance, and identification of sources of pain, anxiety, and agitation. Often, ventilator adjustment is more effective than drug therapy for calming the patient (see Table 36-1). Patients should be maximally alert during the day, with sedation limited to the evening, if possible. Short-acting benzodiazepines or haloperidol may facilitate sleep, thereby ensuring that the patient is maximally rested for efforts at spontaneous breathing during the day. Many patients must be deeply sedated to ensure comfort or to stabilize them hemodynamically during acute illness. A daily "wake up" during which sedatives are withheld until the patient awakens and is able to follow commands (or becomes agitated) is safe and effective in shortening time on the ventilator and in the ICU.[65] We advocate such a wake up in essentially all patients, even those who are hemodynamically unstable and unlikely to be breathing spontaneously for days.

Whenever neuromuscular blockers are used, the agent should be withdrawn on a daily basis until neuromuscular function returns to prevent excessive drug accumulation.[63] It also may be useful to monitor the degree of neuromuscular blockade with a nerve stimulator (aiming for a train-of-two out of four), although this has not been shown to decrease the incidence of postparalytic myopathy. In patients with impaired renal and hepatic function, continuous infusion of *cis*-atracurium is preferred because pancuronium may accumulate and lead to protracted paralysis. During muscle paralysis, careful assessment of the level of sedation is essential because individuals differ widely in their response to sedatives and narcotics.

When the patient is optimally alert, it is important that the caretakers provide brief, clear explanations of all interventions proposed, especially changes in ventilator settings, to evaluate the patient's perception of beneficial effect. This allows the patient to be a part of the decision making concerning the optimal ventilator settings.



PATIENT-VENTILATOR SYNCHRONY

The initial ventilator settings should be reassessed promptly to assess their appropriateness for the individual patient. Such fine tuning of the ventilator often means the difference between a patient who rests on the ventilator or who continues to perform fatiguing efforts, who is calm yet awake, or who requires deep sedation or therapeutic paralysis. Assessing the patient-ventilator interaction requires substantial skill and experience. In part, the adequacy of ventilator settings is judged by the appearance of the patient (comfortable and resting versus diaphoretic and fighting) and arterial blood gas analysis. Tremendously valuable additional information comes from examination of waveforms, as elaborated in Chap. 32.

The intensivist should ensure that the patient and ventilator are synchronized, that is, that each attempt by the patient to trigger the ventilator generates a breath. The most common situation in which the patient fails to trigger breaths occurs in severe obstruction when autoPEEP is present (see Fig. 36-4). This is recognized at the bedside when the patient makes obvious efforts that fail to produce a breath. Using waveforms, these ineffective efforts cause a temporary slowing of expiratory flow, sometimes halting it completely (Fig. 36-7).

As an example, a patient was newly ventilated for septic shock and ARDS. His physicians found very high Pplat

FIGURE 36-7 Ventilation of an obstructed patient with assist-control or intermittent mandatory ventilation. A failed attempt to trigger can be detected in the expiratory flow waveform, where the expiratory flow briefly ceases (due to the patient's inspiratory effort) but the effort is insufficient to initiate a breath. Often the patient can be seen to make obvious inspiratory efforts between ventilator breaths.$\dot{V}$, flow.

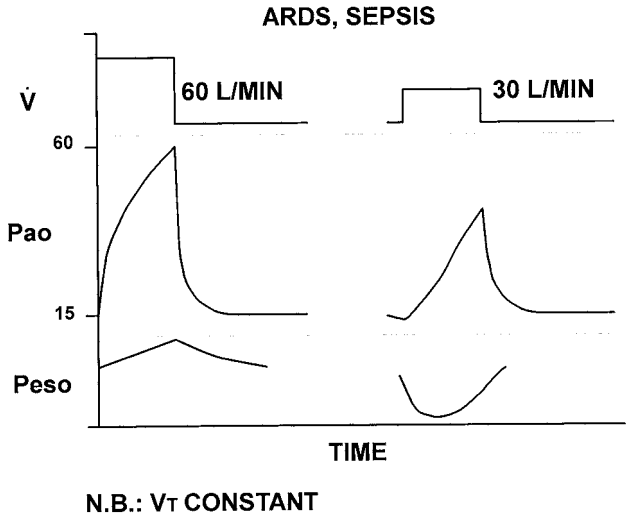


FIGURE 36-8 Ventilated patient with acute respiratory distress syndrome and sepsis. The first breath, at an inspiratory flow rate of 60 L/min, shows no signs of patient effort in the pressure-airway opening (Pao) waveform or the esophageal pressure (Peso) tracing. After the inspiratory flow is reduced to 30 L/min, the Pao decreases, but at the cost of greater patient effort, as reflected in the Pao waveform and the Peso. V̇, flow.

(38 cm H_2O) on the following settings: ACV mode, VT of 480 mL, an f of 28/min, and V̇ of 60 L/min. By reducing the V̇ to 30 L/min, Pplat was newly measured at 28 cm H_2O, which the physicians interpreted as an improvement (Fig. 36-8). However, the airway pressure decreased only at the cost of greatly increased efforts on the patient's part, efforts that can consume a remarkable fraction of the cardiac output (>30% in animal models[40,66,67]). Moreover, the transpulmonary pressure remained excessive because the VT was not reduced.

RESPONSE TO "CRISES" IN THE VENTILATED PATIENT

A vast array of sudden and potentially catastrophic changes in clinical condition can occur in the course of mechanical ventilation (Table 36-4). We focus on high- and low-pressure alarms, worsened oxygenation, and hypercapnia. Whenever the function of the ventilator or the position and patency of the airway are in question, the patient should be removed from the ventilator and hand bagged with 100% oxygen. This point is extremely important because this maneuver immediately circumvents the ventilator (and any malfunction of it), provides the clinician with a direct assessment of respiratory system mechanics, and focuses attention on the patient and not on the machine.

HIGH-PRESSURE ALARM

Aside from alarm or gauge malfunction, increased airway pressure indicates obstruction of the airway, obstruction to gas flow through the ventilator circuit, patient effort against the ventilator, or a change in the mechanics of the respiratory system. If manual bag ventilation is difficult, a suction catheter should be passed immediately through the endotracheal tube. If the catheter cannot be advanced 25 cm or farther, obstruction of the airway is likely. If repositioning of the head does not relieve kinking, and if the patient is not biting the airway, reintubation is necessary. If the patient is biting an endotracheal tube, a bite block should be placed; if this cannot be done, a short-acting neuromuscular blocking drug should be administered.

If the airway is patent but manual ventilation is difficult and the patient is struggling, a sedative should be given. If the patient can be easily ventilated (implicating vigorous respiratory muscle activity), the cause of the patient's distress should be sought. Possibilities include hypoxemia, hypercapnia, shock, or a new central nervous system process.

If ventilation remains difficult after deep sedation or muscle paralysis of a patient with a patent endotracheal tube, a new lower airway, pleural, lung, or chest wall process should be sought. Auscultation, palpation, and percussion often identify pneumothorax, collapse, or consolidation. Early portable chest radiography confirms these diagnoses or identifies an alternative cause of the crisis. Placing the patient back on the ventilator and measuring peak and plateau pressures and autoPEEP will further delineate the problem, as described above.

LOW-PRESSURE ALARM

Low-pressure alarms signal machine malfunction, a leak, or inspiratory effort by the patient (usually obvious). Large persistent leaks can occur within the ventilator itself, in the inspiratory limb, at the connection to the Y adaptor and endotracheal tube, around the endotracheal tube cuff, or through a bronchopleural fistula. If normal resistance to ventilation is noted during manual ventilation, the problem lies

TABLE 36-4 Ventilator Crises

Increased peak airway pressure
Endotracheal tube obstruction, kink, malposition
Airway obstruction (e.g., bronchospasm, mucous plug)
Reduced lung compliance (e.g., pulmonary edema)
Reduced chest wall/abdomen compliance (e.g., pneumothorax, abdominal distention)
Patient effort, agitation (e.g., coughing, biting, fighting)
Reduced oxygen saturation
Ventilator/mixer malfunction
Endotracheal tube malposition, leak
New lung derangement (e.g., atelectasis, aspiration, edema)
New cardiovascular derangement (e.g., shock, pulmonary embolism, fall in hemoglobin concentration)
Increased oxygen consumption
Change in body position, increasing shunt
Rising partial pressure of CO_2
Ventilator malfunction
Endotracheal tube malfunction, leak
New patient mechanical derangement (e.g., bronchospasm, edema)
Increased dead space
Increased CO_2 production
Patient distress
Pain, discomfort unrelated to the ventilator or respiratory system (e.g., myocardial ischemia)
Endotracheal tube malposition
Rising work of breathing
Rising partial pressure of CO_2 (see above)
Oxyhemoglobin desaturation (see above)
Shock, pulmonary embolism
Inadequate sedation
Alcohol or other drug, withdrawl

with the ventilator or tubing. If hand bagging shows minimal resistance, an endotracheal tube cuff leak is likely. This can be confirmed by listening over the neck or by placing a hand over the mouth. A large bronchopleural fistula can be identified by inspection of the chest tube and pleural drainage system.

WORSENED OXYGENATION

When a patient develops hypoxemia, sufficient oxygen should be given immediately to return the saturation to 88%. However, this must be followed by a search for the cause of deterioration. Progression of the primary cause of respiratory failure (ARDS, pneumonia, or lung hemorrhage) will impair gas exchange, but this should not be assumed to be the case. Also possible is a new lesion (e.g., nosocomial pneumonia) that may be identified by physical examination or chest radiograph. However, a systematic approach is useful to identify the myriad (including nonpulmonary) causes of hypoxemia.

From a pathophysiologic perspective, new hypoxemia implies a reduced $F_{I_{O_2}}$ (including ventilator malfunction), hypoventilation, ventilation-perfusion mismatching, shunt, or a decrease in the mixed venous oxygen saturation. Hypoventilation is usually obvious, being signaled by hypercapnia. Ventilation-perfusion mismatch typically causes mild hypoxemia that is easily corrected with supplemental oxygen. Bronchospasm, airway secretions, and airway plugging are common contributors in intubated patients. Inhaled bronchodilators may acutely worsen ventilation-perfusion relations,[68] as will vasodilators.[45] The combination of worsened ventilation-perfusion matching and an increase in dead space should prompt consideration of pulmonary embolism. Most often, when new hypoxemia develops in a mechanically ventilated patient, shunt or a decrease in mixed venous oxygenation can be found. A new shunt (e.g., pulmonary edema, pneumonia, or atelectasis) typically can be found on the chest radiograph, whereas mixed venous desaturation is detected by analyzing a venous blood sample or performing venous oximetry. The causes of venous desaturation include reduced cardiac output or hemoglobin concentration or increased systemic oxygen consumption. These nonpulmonary causes of hypoxemia are particularly common in patients with severe shunt lung disease and may herald life-threatening crises (e.g., pneumothorax).

HYPERCAPNIA

A rising Pa_{CO_2} often elicits a change in the ventilator orders (increased frequency or V_T). However, a pathophysiologic approach is useful in this situation. From the equation for Pa_{CO_2}:

$$Pa_{CO_2} = (V_{CO_2} \times k)/(V_T \times f \times [1 - V_D/V_T])$$

where V_{CO_2} is CO_2 production, k is a constant, and V_D is the dead space, it can be seen that, in addition to a decrease in minute ventilation, rising CO_2 production (e.g., fever, shivering, or agitation) or increasing dead space (e.g., hypovolemia, pulmonary embolism, PEEP) may account for new hypercapnia. Responding to hypercapnia by simply raising the minute ventilation is dangerous because causes of increased CO_2 production and dead space may be important to diagnose in their own right. In addition, augmenting minute ventilation has the potential to (paradoxically) decrease alveolar ventilation if the increase in V_T or f worsens dead space (such as when autoPEEP is present). In this setting, the Pa_{CO_2} may *rise* when minute ventilation is increased and *fall* when minute ventilation is reduced. These issues are further discussed in Chap. 40.

LIBERATION OF THE PATIENT FROM MECHANICAL VENTILATION

We refer to the discontinuation of mechanical ventilation not as *weaning* (which implies the withdrawal of a nurturing life-support system) but as *liberation* (connoting freedom from a confining, noxious, and dangerous circumstance[69]). Because liberation from the ventilator is fully discussed in Chap. 44, we make only a few points relevant to all ventilated patients. Patients recover the ability to breathe spontaneously because central drive is regained, neuromuscular competence is restored, and respiratory system load is reduced. Once these are achieved, the ventilator is no longer needed. Gradual adjustments of IMV rates or pressure-support levels that are too slow for the patient's needs simply serve to prolong the duration of mechanical ventilation, as shown in large trials of weaning strategies,[10,11] and do not facilitate the recognition of evolving ventilatory failure.[70] However, if drive, strength, and load are not repaired, no amount of ventilator technology will allow the patient to breathe on his or her own. Most often, when physicians believe they are "weaning" the patient, they are simply allowing time for their other therapies to treat the respiratory failure; ventilator changes are prescribed coincidentally but are irrelevant. Accordingly, effective liberation of each patient begins with intubation and stabilization on the ventilator, with the measurement of respiratory mechanics to assist in evaluating the reversible features of the patient's abnormally increased load; as soon as is clinically relevant, the respiratory muscle strength is evaluated for reversible causes of weakness.

Before an acceptable balance between neuromuscular competence and load is attained, different methods for exercising the patient may be useful because disuse causes muscles to weaken[56] (see Table 36-3). These include T-piece sprints with which the patient is allowed to breathe without ventilatory assistance for progressively longer periods as ventilatory function improves. Alternatively, the pressure-support mode can be adjusted to allow a reasonably spontaneous V_T (e.g., 300 to 500 mL H_2O) and respiratory rate (<30 breaths/min) but at a level that demands some work from the patient. The physician should be familiar with a number of different modes because patient preference can then dictate which is used in a particular circumstance. SIMV appears to prolong the period of ventilator dependency and should no longer be used for weaning. Aside from this, the method of exercise chosen is not clearly important and certainly secondary to the main goals of restoring drive, improving neuromuscular competence, and reducing load.

Of overriding importance is an approach that asks on a daily basis, "Can this patient breathe on his or her own?" In several studies of methods of weaning, 75% of patients assessed at entry into the trial were extubated successfully.[10,11] The use of interdisciplinary weaning teams or respiratory therapist–driven protocols may expedite successful liberation by actively addressing this question each day.[71,72]

CONVERSION TO A TRACHEOSTOMY

A tracheostomy provides easier tracheobronchial toilet, enhances communication, and is more comfortable for the patient than translaryngeal intubation (TLI). In contrast, endotracheal intubation is less invasive and, in the short run, less likely to cause complications. The timing of tracheostomy involves balancing its complications[73] against the (typically) more delayed complications of TLI. The major complication of TLI is laryngeal damage with resulting postextubation upper airway obstruction or dysphonia.[74] Injuries likely arise from abrasion and compression of laryngeal structures, with sequelae including posterior commissural stenosis, posterior cordal synechiae, arytenoid fixation, and subglottic stenosis. The precise contributions of insertion trauma, duration of TLI, and movement during ICU management to these injuries is not clear, but all are likely important. Some clinicians have suggested that women and patients with diabetes mellitus, rheumatoid arthritis, and ankylosing spondylitis are at increased risk of laryngeal injury during TLI. The incidence of cuff-induced injury to the trachea itself is probably similar between tracheostomy and TLI, at least in the critical care environment.[75]

Our own approach is to begin with TLI in most critically ill patients. Those with an immediate indication for tracheostomy, such as upper airway obstruction or severe sleep apnea, are scheduled for this procedure at the earliest opportunity. Patients who are extremely restless, have copious pulmonary secretions, or are likely to require more than 2 weeks of mechanical ventilation are also considered for early tracheostomy. All other patients are reassessed on a daily basis for these indications for tracheostomy. If extubation seems likely within the first 2 to 3 weeks, TLI is maintained. Occasionally, this approach provides TLI for 3 weeks or longer; however, even with soft cuffs and careful monitoring, the complications of this prolonged TLI begin to outweigh its advantages, and tracheostomy becomes indicated for its greater comfort and potential for enhanced communication. Percutaneous tracheostomy has several advantages in the critically ill patient. Performance of tracheostomy in the ICU provides a safely monitored environment for the procedure and obviates the risks of transporting the patient.

EXTUBATION

Extubation after prolonged (>5 days) intubation should be approached cautiously. In addition to demonstrating freedom from mechanical ventilatory support, as discussed in Chap. 44, the patient must be capable of maintaining airway patency, have sufficient airway reflexes to avoid aspiration, and have adequate cough to mobilize secretions. Laryngeal injury causing postextubation upper airway obstruction should be anticipated.

The most common cause of postextubation stridor is posterior commissure edema, arising from direct mechanical injury to these soft tissues, and impaired vocal cord abduction. Before extubation, the degree of upper airway edema may be assessed by direct laryngoscopy or by deflating the tube cuff, obstructing its lumen, and measuring the amount of airflow around it. Alternatively, the airway can be inspected by fiberoptic laryngoscopy immediately after extubation. Despite these precautions, progressive airway edema with stridor will be encountered in 1% to 5% of patients after prolonged TLI. The initial management should include bag-mask ventilation synchronized to augment the patient's efforts. Noninvasive positive-pressure ventilation is generally considered to be useful, although one clinical trial showed no benefit,[76] and another trial has called into use its general application for respiratory failure emerging shortly after extubation.[76a] Racemic epinephrine by inhalation and intravenous corticosteroids are usually recommended but have not been rigorously studied. A helium-oxygen gas mixture (heliox) also can be useful in this setting.[77] Administration of this low-density gas mixture reduces the large pressure drop associated with turbulent flow across the obstruction, thus reducing the work of breathing. Heliox (21% oxygen and 79% helium) can be delivered by a mask connected to an H tank, supplemented by nasal cannula oxygen, to maintain an arterial hemoglobin saturation of 90%. Heliox and noninvasive positive-pressure ventilation should be used only to temporize while awaiting more definitive therapy of the critical airway narrowing.

If stridor fails to respond to initial measures or reemerges while on therapy, reintubation is usually necessary. The usual approach is to use a small endotracheal tube (6.0 or 6.5 mm) through the nasal route to minimize further injury to the posterior commissure. The managing team should be prepared to perform cricothyrotomy or tracheostomy, if necessary. After reintubation, edema resolves in most patients over 48 to 72 hours. During this time, corticosteroid therapy should be continued (e.g., dexamethasone 4 mg every 6 hours), and the airway should be viewed directly to confirm resolution of edema.

Extubation failure is a marker for prolonged ventilation and ICU stay, increased hospital costs and mortality rate, and greater likelihood of tracheostomy.[78] Risk factors include age, longer duration of ventilation, continuous sedative infusion, and anemia.

AIRWAY DURING SPLIT-LUNG VENTILATION

The lungs may be separated for purposes of differential ventilation by two major means: blocking the bronchus of a lobe or whole lung while ventilating with a standard endotracheal tube or passing a double-lumen tube. Different devices have been used to obstruct a bronchus, but experience is greatest with the Fogarty embolectomy catheter. Double-lumen tubes carry the advantages of allowing each lung to be ventilated, collapsed, reexpanded, or inspected independently.

Split-lung ventilation is only rarely useful in the critical care unit, but occasionally its benefits are dramatic. Large bronchopleural fistulas severely compromise ventilation and may not respond to HFV.[79] A double-lumen tube will maintain ventilation of the healthy lung and facilitate closure of the bronchopleural fistula.[80] During massive hemoptysis, lung separation may be lifesaving by minimizing blood aspiration, maintaining airway patency, and tamponading the bleeding site while awaiting definitive therapy.[81] Patients with focal causes of acute hypoxemic respiratory failure, such as lobar pneumonia or acute total atelectasis, may benefit from differential ventilation and application of PEEP.[82]

Complications with these devices are common because they are difficult to maintain in ideal position during a protracted period of respiratory failure and tend to directly injure the trachea and main bronchi. A clear protocol for airway

assessment and repositioning should exist, and routine input from senior anesthesiology staff is required.

Chapter 37

VENTILATOR-INDUCED LUNG INJURY

JOHN T. GRANTON
ARTHUR S. SLUTSKY

KEY POINTS

- *Ventilator-induced lung injury may occur with both lung volumes that lead to overdistention of lung units (volutrauma) or with low distending pressures that lead to the development of atelectasis (atelectrauma).*
- *Ventilator-induced lung injury may cause injury in previously healthy regions of lung, and may also lead to multiorgan dysfunction.*
- *To reduce the risk of ventilator-induced lung injury, low tidal volumes of 6 mL/kg should be used in treating most patients with acute respiratory distress syndrome.*
- *The appropriate level of positive end-expiratory pressure remains to be determined, but levels of PEEP that minimize atelectrauma may be beneficial.*
- *Permissive hypoventilation (hypercapnia) may be a necessary component of a lung-protective ventilatory strategy.*

There is consistent and convincing experimental evidence that mechanical ventilation, particularly in the setting of lung injury, can contribute to functional and structural alterations in the lung. The experimental evidence has led to the notion that mechanical ventilation not only perpetuates the lung injury, but also contributes to both the morbidity and mortality of the acute respiratory distress syndrome (ARDS). Concern surrounding ventilator-induced lung injury (VILI) culminated in a consensus conference in 1993 that made (based solely on studies in animal models of ARDS) the empirical recommendation to limit tidal volumes to the range of 5 to 7 mL/kg and plateau pressures less than 35 cm H_2O.[1] It would be 8 years until the recommendations of the consensus group were affirmed by a randomized controlled trial demonstrating that a lung-protective strategy designed to limit VILI would lead to an improvement in patient outcome.[2] Unfortunately, it seems that it may take even longer until there is incorporation of these concepts into widespread clinical practice.[3]

The objectives of this chapter are to develop the concept of VILI and provide the rationale for the shift in ventilation philosophy for patients with ARDS. First, the relevant features of ARDS as it pertains to VILI will be reviewed, since most of the studies evaluating VILI have focused on ARDS. Then, the concept of lung-protective ventilation strategies will be discussed, and pertinent studies evaluating these newer strategies in patients with ARDS will be presented. Recommendations based on current clinical evidence, and when this is lacking best experimental evidence, will also be presented (Table 37-1).

Acute Respiratory Distress Syndrome

ARDS is characterized by endothelial and epithelial cellular injury. This loss of integrity of the alveolar-capillary membrane results in a high-permeability pulmonary edema and formation of hyaline membranes. Injury to type II pneumocytes also occurs, and there are alterations in surfactant function. Plain chest radiographs are frequently misleading, in that they suggest that the lung damage is uniformly distributed. However, evaluation of patients with ARDS using computed tomography (CT) of the thorax has demonstrated that the airspace disease is patchy.[4,5] Marked heterogeneity and regional differences in lung injury exist in the lungs of these patients. Regions of lung with airspace disease are contrasted to adjacent areas with normal-appearing alveoli. In addition, an exaggerated vertical gradient of lung inflation has been demonstrated in ARDS, with compression of alveoli and a decrease in aerated lung as one progresses from nondependent to more dependent lung regions.[6] Indeed as emphasized by Mead and coworkers in the early 1970s it is likely this degree of heterogeneity of the lung injury that makes the lung uniquely susceptible to the effects of ventilator-induced injury.[7] The heterogeneity of the lung injury is also responsible for the decrease in lung compliance that characterizes ARDS. It is worth emphasizing that this loss of compliance is due to a functional reduction in alveolar units and not due to the development of "stiff" lungs. Indeed the recognition that ARDS is characterized by a loss of functional lung units with preservation of other alveoli with normal lung compliance (specific lung compliance) is central to the current notion of lung protection strategies.[8] In many respects owing to the reduction in effective lung volume, the 70-kg adult patient with ARDS must be treated from the pulmonary point of view as a 30-kg pediatric patient. Consequently the use of traditional tidal volumes of 10 to 15 mL/kg (700 to 900 mL in our 70-kg patient) would be inappropriate and will simply result in overdistention of lung units with relatively normal compliance. The need to modify the approach to mechanical ventilation in ARDS is further emphasized by three decades of investigations that demonstrate that the overdistention of lung units may in itself lead to lung injury identical to that seen in ARDS. ARDS is also a syndrome characterized by inflammation of the lung with various cytokines and other mediators thought to play a major role. In recent years, there has been a large body of evidence indicating that mechanical ventilation may have an impact on this aspect of the pathophysiology of ARDS, and indeed there is the suggestion that the improvement in mortality with lung-protective strategies may be partly due to a reduction in release of various mediators by these strategies.

Ventilator-Induced Lung Injury

MACROSCOPIC INJURY

Recent evidence suggests that mechanical ventilation may have both regional and systemic effects. VILI may be broadly classified into macroscopic and microscopic injury (Table 37-2). Macroscopic injury consists of what has been classically described as barotrauma. Pneumothorax, pneumomediastinum, pneumoperitoneum, and subcutaneous

TABLE 37-1 Goals of Mechanical Ventilation Modified to Reduce the Risk of Ventilator-Induced Lung Injury

Oxygenation
Maintain saturation >90% (may only require >85%)
Ensure adequate oxygen delivery
Avoid overdistention
Limit tidal volumes to 6 mL/kg PBW
Limit peak inspiratory pressure to <35 cm H_2O
Peak lung inflation less than upper inflection point?
Recruit alveoli
Recruitment maneuver with a sustained inflation?
Pressure-preset ventilation waveform?
Keep alveoli patent
End-expiratory volume greater than lower inflection point?
Titrate end-expiratory volume to best lung compliance?
Keep total positive end-expiratory pressure generally above 15 cm H_2O?
Ventilation
Accept pH to 7.15?

emphysema are recognized complications of mechanical ventilation, and are characterized by the presence of extra-alveolar air.[9] The mechanism of the development of extra-alveolar air was elegantly demonstrated by Macklin and Macklin in 1944.[10] During positive-pressure ventilation (PPV), alveoli rupture at the point where the alveolar base meets the bronchovascular sheath. Air then dissects along the vascular sheaths towards the mediastinum and into the hilum and mediastinal soft tissues. If sufficient gas accumulates, the mediastinal parietal pleura ruptures, and a pneumothorax develops.

Macroscopic barotrauma correlates with a variety of factors. In a retrospective study in 139 intubated patients, barotrauma occurred in 34 patients.[11] Peak airway pressure, level of positive end-expiratory pressure (PEEP), tidal volume, and minute ventilation correlated with the development of barotrauma. However, in a subsequent prospective study of 168 patients over a 1-year period, only the presence of ARDS was associated with the development of barotrauma.[12] Gas trapping has also been associated with the development of extra-alveolar air leakage. In a study in mechanically ventilated asthmatics, an elevation in end-inspiratory lung volume above 1.4 L was associated with macroscopic barotrauma.[13] The relationship of PEEP to the development of extra-alveolar air is inconsistent.[12,14] Patients with severe underlying lung disease often require higher levels of PEEP to maintain oxygenation, and it is possible that it is the underlying lung disease in such patients that explains the correlation between air leaks and PEEP levels. More recently Eisner and colleagues, using data from the ARDS Network trial, reported that higher PEEP was associated with an increased risk of barotrauma (relative risk = 1.5; 95% confidence interval [CI] 0.98 to 2.3).[15] The strength of the association in this trial was the ability to control for other potentially relevant risk factors and uniformity of the ventilation methodology. One will have to see how this observation is born out by clinical trials that are currently underway to evaluate higher PEEP strategies in patients with ARDS. Patients with underlying lung damage are particularly prone to the development of macroscopic barotrauma. Asthma, chronic obstructive pulmonary disease (COPD), and pneumonia have all been identified as risk factors.[11] ARDS has consistently been associated with a very high risk for the development of extra-alveolar air, with an incidence in some series of 40%.[11,12,16] In addition to the immediate hemodynamic consequences, the development of macroscopic barotrauma in patients receiving mechanical ventilation portends a worse prognosis. CT studies of patients with ARDS have expanded the scope of macroscopic injury. Gattinoni and coworkers have described the appearance of bullae and cystic parenchymal lesions located predominantly in the dependent (dorsal) lung regions.[4] These lesions are often occult and are not readily detected on plain chest radiographs. In a histologic study in patients with severe respiratory failure, airspace enlargement with alveolar distention in aerated lungs or intraparenchymal pseudocysts in nonaerated regions were identified in 87% of the lungs examined. Importantly, patients with severe airspace enlargement were ventilated with higher airway pressures and higher levels of inspired oxygen and had a higher rate of pneumothoraces. One reasonable hypothesis is that the cystic changes observed in aerated lungs occur because of the high airway pressures causing overdistention of alveoli. The etiology of the cystic lesions observed in nonaerated, more dependent lung regions remains speculative. Since they occur in dependent regions of the lung, their appearance is not explained by lung overdistention. Possibly they are caused by repetitive opening and closing of nonrecruited alveoli (see below). Alternatively, because perfusion is greater in dependent regions, the cystic lesions may be caused by blood-borne factors such as cytokines and inflammatory cells.

The importance of lung perfusion was emphasized by Broccard and coworkers, who used an isolated rabbit lung preparation and demonstrated that an increase in lung perfusion lead to more severe hemorrhage, an increase in filtration coefficient, and heavier lungs.[17] Injury to conducting airways could also potentially lead to an increase in regional airways resistance, with resultant gas trapping and progressive downstream regional lung distention. Regions of local superinfection and resultant inflammation may intensify the bronchiolar

injury. Goldstein and associates used a piglet model and found cystic lung changes and areas of bronchiolectasis in animals that received intrabronchial inoculation with *Escherichia coli*.[18] The importance of bronchiolectasis in the pathogenesis of VILI is further highlighted by observations that the dead space (a potential prognostic marker in ARDS[19]) correlated with the presence and severity of bronchiolar injury and dilation.[20] In summary, macroscopic lung injury represents a continuum from airspace enlargement through interstitial emphysema and eventually to radiographically apparent extra-alveolar air.

MICROSCOPIC INJURY

More recent investigations have centered on the development of microscopic lung injury related to mechanical ventilation. Shortly after the institution of invasive positive pressure ventilation as a therapeutic modality, the development of lung damage was observed in animals ventilated for prolonged periods. The term "respirator lung" was coined to describe the functional and histologic features.[21] Subsequent investigations have demonstrated that mechanical ventilation, even at modest airway pressures, is capable of producing functional impairment of the lung with loss of integrity of the alveolar-capillary barrier, surfactant dysfunction, and parenchymal damage that mimics the histologic appearance of ARDS. These observations have led some investigators to speculate that mechanical ventilation itself could be contributing to some of the lung injury, morbidity, and mortality in patients with acute respiratory failure.

In 1974, Webb and Tierney graphically illustrated the deleterious effects of mechanical ventilation in rats using varying levels of peak airway pressure and PEEP.[22] Animals ventilated using low peak airway pressures (14 cm H_2O and no PEEP) had no pathologic or physiologic changes. In contrast, rats ventilated with peak pressures of 30 cm H_2O and no PEEP had perivascular edema and no alveolar edema. These findings were magnified in rats ventilated with peak pressures of 45 cm H_2O. Alveolar and perivascular edema developed, along with severe hypoxemia, decreased dynamic compliance, and obvious gross anatomic changes (Fig. 37-1). Interestingly, rats ventilated using 10 cm H_2O of PEEP and peak pressures of 45 cm H_2O had no alveolar edema (see Fig. 37-1, center). This latter finding led to the concept of a protective effect of PEEP, which will be discussed later.

HIGH AIRWAY PRESSURES AND LUNG INJURY

High airway pressures themselves are not responsible for lung injury. As anyone who has seen Dizzy Gillespie play the horn knows, high airway pressures do not produce alveolar disruption. Trumpet players are capable of generating large increases in airway pressure, up to 150 cm H_2O, without pulmonary sequelae.[23] The key factor causing lung injury is an increase in lung stretch that is best assessed in the pressure domain by the transpulmonary pressure (alveolar minus pleural pressure). For Dizzy Gillespie to generate such high airway pressures, he had to generate a high pleural pressure so the transpulmonary pressure was not elevated. Recently the emphasis has shifted away from the concept of pressure-induced injury (barotrauma) to lung overdistention (volutrauma). In this regard, peak inspiratory pressure (PIP) is often used at the bedside as a surrogate marker for the degree of lung inflation.

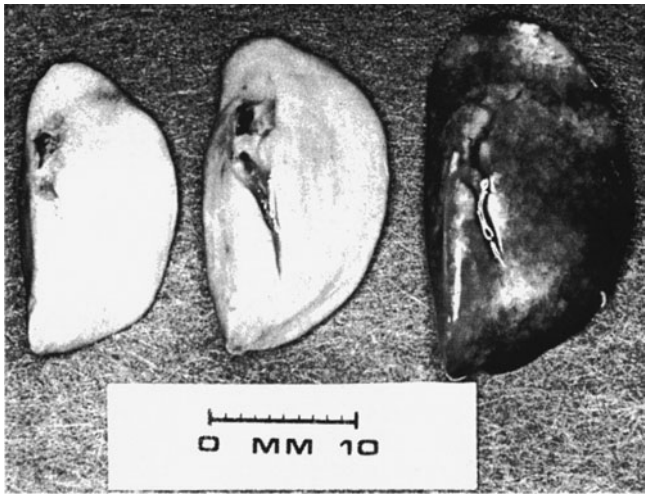

FIGURE 37-1 The effects of high distending pressures in rats and the protective effect of PEEP on the development of VILI. Rats ventilated using low airway pressures (14 cm H_2O and no PEEP) had no pathologic or physiologic changes (*left*). In contrast, rats ventilated with high airway pressures (45 cm H_2O and no PEEP) developed severe perivascular edema, hypoxemia, decreased dynamic compliance, and obvious gross anatomic changes (*right*). Importantly, the use of 10 cm H_2O of PEEP with peak pressures of 45 cm H_2O reduced the amount of lung injury (*center*). ***(Reproduced with permission from Webb and Tierney.[22])***

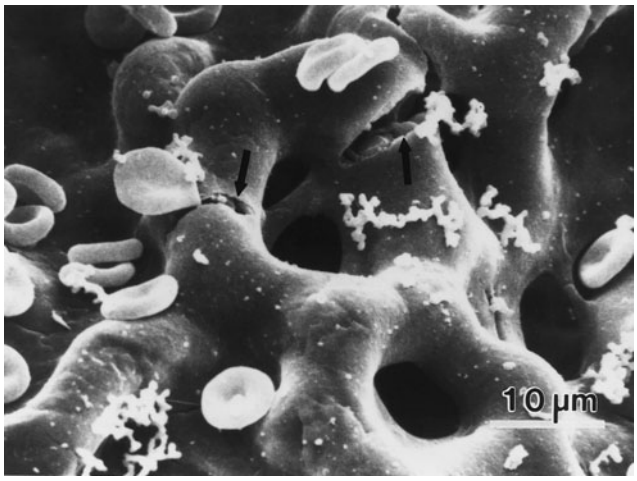
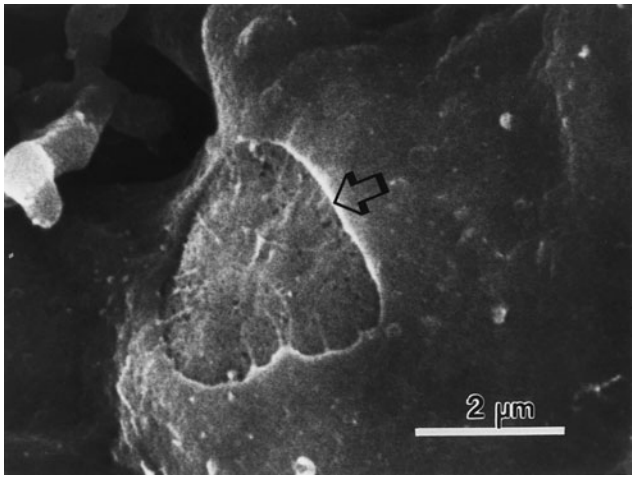
However, PIP is dependent on the resistive pressure drop arising from flow across the endotracheal tube and conducting airways, and is also dependent on the compliance of the respiratory system. Consequently, PIP may not be indicative of the degree of lung inflation; plateau pressure obtained after occlusion of the airway following inspiration more accurately reflects alveolar pressure, but is also hampered by the compliance of the respiratory system, and thus is also an inaccurate surrogate of lung distension. In normal individuals, full inspiration to total lung capacity (TLC) occurs at a transpulmonary pressure of 20 to 25 cm H_2O. Patients with hypoxic respiratory failure, however, are commonly ventilated with very high inspiratory pressures, producing transpulmonary pressures greater than 20 to 25 cm H_2O.[11] Plateau pressures in excess of 30 cm H_2O occur frequently and are often beyond the level expected to produce full inspiration.[24] The development of such high airway pressures in patients with ARDS could in turn lead to high transpulmonary pressures, and consequently to overdistention of lung units and lung injury.

Direct evidence for volutrauma stems from several observations in animals. To separate the effects of pressure and changes in lung volume, excursion of the chest (and hence tidal volume) was limited by binding the thorax during PPV.[25] Open-chest animals whose lungs were ventilated with peak pressures of 15 cm H_2O for 15 minutes had an 850% increase in their filtration coefficient. In contrast, the filtration coefficients of closed-chest animals increased by 31% with a PIP of 30 cm H_2O, and by 450% with a PIP of 45 cm H_2O. Animals in which lung expansion was limited did not develop lung edema during ventilation with peak airway pressures up to 45 cm H_2O. The concept of volutrauma as opposed to a pure pressure-related effect was further supported in a study that compared the development of edema with the use of



negative-pressure ventilation and high tidal volumes, to that with the use of PPV to achieve similar tidal volumes.[26] The amount of edema obtained using negative-pressure ventilation was comparable to that in the animals ventilated with PPV at the same tidal volumes. These studies are important for two reasons. First, they established the importance of lung inflation, and second they demonstrated a dose-response relationship, with larger transpulmonary pressures and tidal volumes producing an incremental increase in lung injury and edema.[27] Theoretically, overdistention of lung units may lead to mechanical disruption of the alveolar-capillary barrier and the development of pulmonary edema.[28] In a very illustrative histologic study using electron microscopy, overdistention of the lung increased the number of endothelial and epithelial breaks and contributed to rupture of the blood-gas barrier and separation of the epithelium from its underlying basement membrane (Fig. 37-2).

Patients with patchy regions of lung injury may be particularly susceptible to the development of VILI. A nonuniform distribution of lung injury with regional differences in lung compliance may lead to regional differences in lung inflation. The importance of regional overdistention of lung units was emphasized in a study in dogs that compared the effect of delivering a PIP of 40 cm H_2O to the entire lung and delivering the same PIP to an isolated lung segment. Inflation of the entire lung did not result in edema.[29] However, distention of a small area for 20 minutes produced a protein-permeable epithelium. Thus inflation limited to a subsection of lung resulted in overdistention as the surrounding lung was compressed and allowed for greater expansion for a given PIP. This observation is particularly germane to the discussion of potential VILI in patients with inhomogeneous lung compliance, such as that described in ARDS. Consequently, the notion of a "safe" level of peak airway pressure in these patients must take into account the heterogeneous nature of the disease.



In addition to a time effect, there appear to be species- and age-specific differences in susceptibility to VILI. Younger and smaller animals seem more susceptible to the injurious effects of high airway pressures.[22,29–31] It has been postulated that this finding is due to immaturity of the alveolar-capillary barrier. Importantly, injured lungs also appear to be especially susceptible to the development of VILI. In rabbits with mild oleic acid–induced lung injury, the effects on lung edema of mechanical ventilation using high airway pressures were greater than those of either lung injury or mechanical ventilation alone.[32] Consequently, patients with underlying acute lung injury secondary to ARDS or pneumonia may be exquisitely sensitive to the adverse effects of mechanical ventilation, and predisposed to the development of VILI.

Gas flow rate may also be important in the development of lung injury. In one study, high flow rates were associated with an increase in filtration coefficient despite similar peak inspiratory pressures, although end-inspiratory lung volume was not accounted for.[33]

In summary, there is persuasive experimental evidence to support the concept of lung overdistention as a major component of VILI. Studies have demonstrated a dose-response relationship, in which both higher inflation pressures and tidal volumes administered over progressively longer periods of time produce a graded severity of lung injury. Second,

VILI has been demonstrated in many animal models, negating the possibility that these observations were due to a species-specific effect.

THE ROLE OF END-EXPIRATORY LUNG VOLUME

In addition to lung overdistention, it is becoming increasingly apparent that ventilation at low lung volumes may also lead to lung injury. Webb and Tierney[22] demonstrated that when animals were ventilated using high airway pressures without PEEP, significant edema and lung injury resulted. These effects were not seen when PEEP of 10 cm H_2O was used, even though the peak airway pressures were identical (see Fig. 37-1). Subsequent studies have confirmed these findings. For example in a canine aspiration model, low levels

of PEEP during mechanical ventilation were associated with an increase in edema compared to ventilation with higher PEEP levels.[34] The precise mechanism of the effect of PEEP on VILI is controversial and potentially multifactorial. The application of PEEP is known to have effects on distribution of lung water, pulmonary hemodynamics, and pulmonary compliance. In patients with ARDS, providing PEEP may have one of three effects on the state of lung inflation. First, lung units that are already aerated may show increased distention, which could contribute to VILI. Second, partially aerated lung units or those that collapse at the end of a tidal breath may be kept patent during the entire respiratory cycle. Third, previously closed alveoli may be recruited, leading to an increase in functional lung and resulting in an increase in total lung compliance. The latter two points deserve further emphasis. In addition to an upper inflection point, a lower inflection point has been described in patients with ARDS. With a progressive increase in end-expiratory pressure, there is a gradual increase in end-expiratory lung volume or functional residual capacity (FRC), until a point is reached at which compliance improves.[35,36] This finding was supported in studies using CT, in which PEEP was found to reduce the vertical gradient of lung density and increase the amount of aerated lung.[6] Consequently, in patients with ARDS, the application of PEEP appears to result in the opening of nonventilated or poorly ventilated alveoli.

In addition to serving as a purely mechanical stent, PEEP may keep alveoli patent by preserving surfactant function (which has been observed to be functionally altered in ARDS), and in so doing may reduce surface tension and reduce the tendency of alveoli to close.[37,38] In a study evaluating the effect of PEEP, eight patients with ARDS initially underwent a lung recruitment procedure involving a period of sustained inflation.[39] When PEEP was decreased below the inflection point, a decay in lung compliance occurred. Interestingly, this study found a decelerating waveform to be more beneficial in producing an improvement in compliance than a constant-flow waveform. It was hypothesized that the decelerating waveform produced an initial high airway pressure that was maintained throughout the respiratory cycle, allowing recruitment of alveoli.[40] This concept is important and raises the possibility that peak airway pressures may in fact lead to alveolar recruitment, and that PEEP maintains the level of recruitment.

The relative importance of maintaining airway patency and using relatively high levels of PEEP is emphasized by recent observations that lung underdistention may be as injurious as lung overdistention and may contribute to the development of VILI. Ventilation without PEEP or at levels of PEEP that did not result in lung recruitment has been shown to cause respiratory and membranous bronchiolar injury, a reduction in lung compliance, and hyaline membrane formation.[41,42] In theory, ventilation at low lung volumes causes repetitive opening and closure of alveoli. This in turn may lead to the development of shear stress along the bronchial and alveolar walls. Repetitive stress is known to disrupt surfactant and is speculated to disrupt epithelial structures and contribute to failure of the alveolar-capillary barrier.

PEEP also improves gas exchange and lung mechanics, potentially by redistributing lung water from the alveolar to the extra-alveolar interstitial space.[43] Finally, PEEP also has significant hemodynamic effects and typically results in a reduction in ventricular preload and a reduction in cardiac output. Dreyfuss and Saumon postulated that the benefits of PEEP in ARDS stem from its effect on pulmonary perfusion, and demonstrated that the reduction of lung edema produced by PEEP was negated when dopamine was administered to keep arterial blood pressure constant.[26] They concluded that it was end-inspiratory volume, and not end-expiratory volume (FRC), that was important in the development of VILI. A recent study by Duggan and coworkers has highlighted the importance of atelectasis.[44] They evaluated the effects of a lung recruitment maneuver on lung and cardiac function. Animals whose lungs were not recruited (and presumably remained atelectatic) had a higher mortality, increased microvascular leak, worse oxygenation, and worse pulmonary vascular resistance. The increase in pulmonary vascular resistance may have led to the decrease in right ventricular function and increase in serum lactate in these animals.

In summary, in patients with ARDS, PEEP may improve lung compliance and oxygenation by recruiting alveoli and maintaining patency throughout the respiratory cycle (Fig. 37-3). Furthermore a ventilation strategy that fails to optimize end-expiratory volume with PEEP may contribute to VILI through the development of shear stress during repetitive opening and closing of lung units. Consequently, the notion of *best* PEEP needs to be extended to include an end-expiratory pressure level that will minimize lung injury.

BIOTRAUMA

It is becoming increasingly clear that mechanical stretch or shear injury leads to inflammatory mediator release and cellular activation. Mechanotransduction—whereby a physical stimulus produces cellular signaling—has been an area of active investigation, and in the setting of mechanical ventilation this effect has been termed *biotrauma*.[45,46] The notion that VILI may be responsible for the production of inflammatory mediators was highlighted in a study by Tremblay and associates in an isolated perfused rat model.[47] They demonstrated that the use of an injurious ventilation strategy (zero PEEP, high tidal volume, or both) had a dramatic influence on lung inflammatory mediators. Since this study, mechanical ventilation has been shown to be capable of causing the regional production of a variety of proinflammatory mediators, including tumor necrosis factor-α (TNF-α), interleukin-1β (IL-1β), interleukin-6 (IL-6), interleukin-10 (IL-10), macrophage inflammatory protein-2 (MIP-2), and interferon-γ (IFN-γ).[48–55] Indeed both overdistention (volutrauma) and underdistention (atelectrauma) may be equally important in inducing inflammatory mediator release.[51,56] However, as emphasized in an excellent review by Uhlig, it is important to differentiate the effects of cellular stretch– or shear stress–induced necrosis from true mechanotransduction, in which intracellular signaling occurs.[46] Cellular necrosis would potentially lead to the release of preformed cellular inflammatory mediators, while stimulation of intact cells would potentially lead to the release of preformed mediators via alterations in the cellular cytoskeleton, and from stimulation of mRNA and production of new proteins. The fact that production and release of inflammatory mediators does occur was illustrated by Tremblay and colleagues in an isolated perfused rat model of VILI, whereby injurious patterns

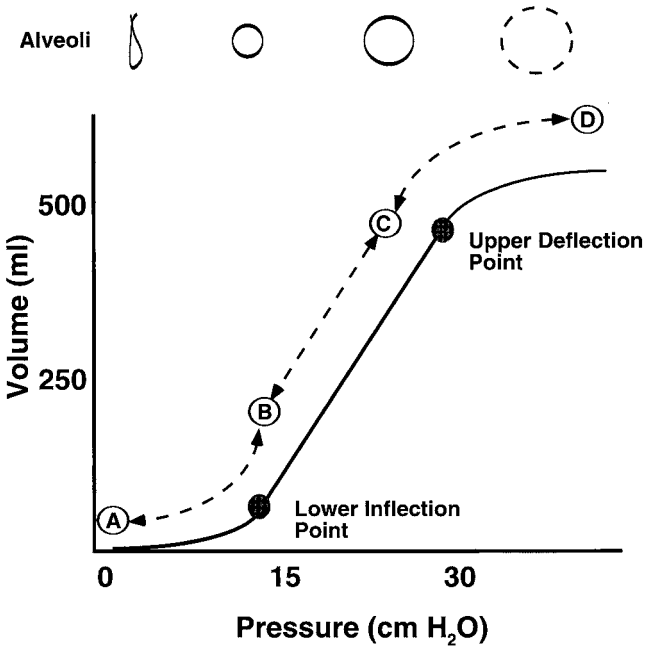

FIGURE 37-3 The sigmoidal shape of the pressure-volume curve of the respiratory system in a patient with ARDS. The outlines across the top of the graph indicate the relative state of inflation of alveoli. At airway pressures above the upper inflection point C (30 cm H_2O), the curve flattens as the limits of lung compliance are reached, and there is progressive overdistention of alveoli. Airway pressures below the lower inflection point B are also associated with lower compliance and result in alveolar collapse. A typical ventilation strategy using 15 cm H_2O of PEEP and a PIP of 40 cm H_2O (points B to D) would lead to repetitive inflation above the upper inflection point, and potentially to disruption of alveoli and the alveolar-capillary barrier (see text). A strategy that attempts to reduce lung distention by reducing PIP (points A to C) would still lead to repetitive opening and closure of alveoli (also associated with lung injury). An optimal ventilation strategy should consider both the lower and upper inflection points of the pressure-volume curve (points B to C). Note also that for the same driving pressure (the segments from A to B, B to C, or C to D), a change in pressure from points B to C is associated with the largest change in lung volume. Thus an optimal ventilation strategy should aim for volume excursions along the steepest portion of the pressure-volume curve (maximal compliance).

of mechanical ventilation led to an increase in production of c-fos mRNA.[50]

The concept of ventilator-induced mechanotransduction and subsequent inflammation is evolving and the cellular source of inflammatory mediators and subsequent lung injury is an area of active research.[57,58] Both inflammatory cells and pulmonary epithelial cells appear to be capable of responding to mechanical stresses. Earlier workers attributed the increase in lung lavage cytokines predominantly to production by neutrophils and macrophages.[59,60] More recent attention has focused on mesenchymal cells. Mechanical stretch of cultured fetal rat lung cells increased the expression of MIP-2, a potent neutrophil chemokine.[58] Interestingly stretch alone did not lead to an increase in MIP-2 mRNA expression while stretch in addition to LPS did. This finding and the rapid increase in MIP-2 following stretch suggested that stretch alone leads to secretion and not synthesis of MIP-2. The same group later demonstrated increased expression of TNF-α and IL-6 mRNA in pulmonary epithelial cells following the application of an injurious ventilatory strategy, in an ex-vivo rat model.[50] Importantly, they demonstrated that the epithelial cells were a major source of TNF-α. These findings are extremely relevant as they support the notion that mechanical stretching or injury to the lung epithelium is sufficient to stimulate an inflammatory response and potentially recruit neutrophils to the lung.[59]

In addition to epithelial cells, endothelial cellular stretch may also lead to the development of a proinflammatory state. Using a novel method of cellular recovery and evaluation of endothelial cells, Bhattacharya and coworkers demonstrated that lung stretch was capable of inducing P-selectin expression on the cell surface through a tyrosine phosphorylation signaling pathway.[61] Indeed the importance of endothelial expression of cell surface receptors may be critical to the development of neutrophil accumulation in the lungs.[62] Bhattacharya and coworkers also observed that lung stretch lead to the development of focal adhesions, suggesting that endothelial cells actively respond to the adverse mechanical milieu, and that the matrix proteins participated in this response. Several investigations have suggested that stretch-induced release of matrix proteins is an important mediator of VILI.[63,64] In particular, the release of matrix metalloproteinases (a group of enzymes that are capable of damaging the extracellular matrix and stimulating fibroblasts) and fibronectin have been reported to be upregulated in models of VILI.[58,65]

The inflammatory effects induced by injurious ventilatory strategies may be attenuated by pretreatment with corticosteroids or heat stress (presumably by induction of heat shock proteins).[48,66,67] Ohta and colleagues demonstrated that 250 mg/kg of methylprednisone suppressed markers of neutrophil activation in rats subjected to high-tidal-volume ventilation.[66] Similarly Held and coworkers[48] demonstrated that administration of dexamethasone blocked the release of nuclear factor-κB (NF-κB), cytokines, and chemokines in an isolated perfused mouse model of endotoxin-mediated acute lung injury and VILI. From a clinical perspective these observations are enticing. They also raise the possibility that the late phase of ARDS, characterized by fever and persistent airspace disease, in some patients may be mediated by ongoing ventilator-induced lung injury.[68–70] Thus the experimental observation that corticosteroids are capable of modifying the inflammatory response from VILI *may* also account for the observed improvement in these patients with persistent ARDS following the administration of glucocorticoids.[71]

In summary mechanotransduction due to lung distention during mechanical ventilation appears to be capable of stimulating signaling pathways with secretion of inflammatory mediators in a variety of cells including neutrophils, macrophages, epithelial and endothelial cells, and the extracellular matrix. However, in the face of these observations, the notion that VILI contributes to mortality in patients with ARDS presents somewhat of a paradox, as most patients with ARDS do not typically succumb to progressive hypoxic respiratory failure from worsening lung injury. Rather, death in these patients is caused by the development of multiple organ dysfunction.[72,73] However, recent experimental and clinical studies suggest that ongoing VILI is capable of causing nonpulmonary organ injury through the translocation of

regional inflammatory mediators and bacteria into the systemic circulation.

DECOMPARTMENTALIZATION

Damage to the alveolar-capillary barrier from mechanical ventilation may be central to several important pathophysiologic mechanisms in the development of VILI. First, loss of membrane integrity is key to the development of the pulmonary edema and hyaline membrane formation—the hallmarks of ARDS. The loss of barrier function may also allow for entry of inflammatory cells into the lung, in turn promoting the perturbation of lung structure and function. More recently, however, the loss of the integrity of the alveolar-capillary membrane has been proposed to be central to the spread of lung inflammation (partially produced by mechanical injury) to nonpulmonary organs, and thus may lead to their subsequent dysfunction.

The development of increased edema fluid during mechanical ventilation is in part due to an increase in filtration of fluid into the interstitial space.[74,75] With progressive lung inflation, a decrease in interstitial pressure occurs.[76] In addition, lung inflation causes dilation of extra-alveolar vessels. The net effect of progressive lung inflation, therefore, is an increase in the hydrostatic gradient for fluid to move from the capillaries into the interstitial space.[76–78] In addition to an increase in filtration, ventilation with high lung volumes may also cause an increase in permeability of the alveolar-capillary barrier to proteins. Several studies have demonstrated an increase in filtration coefficient during mechanical ventilation.[29,79] This effect is thought to be due to a reduction in the integrity of the alveolar-capillary barrier. During mechanical ventilation, injury has been demonstrated to occur to both the epithelial and endothelial membranes. Both edema and injury to the alveolar-capillary barrier can develop rapidly, with transient alterations in filtration coefficient occurring in animals ventilated for only 2 minutes.[80] Subsequent studies have demonstrated that ventilation for more prolonged periods is associated with progressively worse edema, which becomes irreversible. In rats ventilated for 5 to 20 minutes, extravascular fluid accumulation increased with time of ventilation, progressing from perivascular edema to interstitial edema, and eventually to alveolar edema. Damage to type I cells, denudation of the basement membrane, and hyaline membrane formation were seen at 20 minutes. Thus mechanical ventilation appears to have a cumulative effect, with increased exposure to high airway pressures resulting in progressive and eventually sustained lung injury.

It seems logical that the movement of proteins would not be unidirectional from circulation to lung. Indeed recent evidence suggests that translocation of proteins occurs from lung to circulation as well. Using a rat model of VILI, Lesur and associates demonstrated an increase in total protein in lung lavage fluid with lung overdistention.[81] Furthermore they demonstrated that Clara cell protein (found in high concentrations in Clara cells located in terminal bronchioles) decreased in lung lavage fluid with time, but increased in the serum of the rats. These observations are highly relevant and demonstrate that mechanical ventilation can lead to bidirectional translocation of proteins. Promotion of translocation of endotoxin and bacteria from the lungs to the circulation has also been demonstrated to be a feature of VILI.[82–84] This loss of compartmentalization and resultant translocation of proteins, potential inflammatory mediators, and bacteria may be central to the development of more distal organ damage. The concern then is that the lung may become the machinery for multiple-organ dysfunction syndrome (MODS). Indeed Choi and associates recently demonstrated that large tidal volumes produced both pulmonary and renal microvascular leakage of protein and Evans blue dye.[85] Interestingly, endothelial nitric oxide synthase (eNOS) expression was significantly increased in the affected lung and kidney samples. Their observation that inhibition of eNOS attenuated the degree of microvascular leakage supported the notion that eNOS contributed to the loss of the integrity of the membrane barrier. These observations were extended in a recent study by Imai and associates.[86] They demonstrated that serum from rabbits that were ventilated with an injurious ventilation strategy was capable of increasing the rate of apoptosis in cultured epithelial cells from the kidney and villi of the small intestine (Fig. 37-4). Functionally this correlated with biochemical evidence of worsened renal function when intact animals were studied.

That distal organ injury in humans may be mediated by mechanical ventilation is supported by two observations. First, studies in humans have shown that an injurious ventilator strategy leads to an increase in circulating cytokine levels. Ranieri and coworkers randomized 44 patients to receive either mechanical ventilation to maintain normal blood gases ($n = 19$), or a lung-protective strategy attentive to both lung distention and maintenance of an adequate end-expiratory lung volume (above the lower inflection point; see below).[53] Despite similar levels of circulating cytokines at baseline, patients in the control group had an increase in plasma concentrations of TNF-α, IL-6, and TNF-α receptors over a period of 36 hours. Conversely, patients in the lung-protective strategy group had a reduction in plasma concentrations of IL-6, soluble TNF-α receptor 75, and IL-1 receptor antagonist. Additionally they found that the concentration of the inflammatory mediators 36 hours after randomization was significantly lower in the lung-protective strategy group than in the control group. In a subsequent analysis of the serum in 11 of the controls and 9 of the lung-protective strategy group, levels of soluble Fas ligand (shown to induce apoptosis in human epithelial cells in vitro[87,88]) and creatinine were found to be elevated in the controls.[89]

Lung-Protective Strategies: Do No Harm

Traditionally, the goals of mechanical ventilation have been to maintain adequate tissue oxygenation (generally accepted as a saturation greater than 90%, with a reasonable cardiac output) and adequate ventilation to achieve normocarbia and maintain normal blood pH. To achieve these goals, patients with acute respiratory failure were often ventilated using a standard ventilation cocktail consisting of variable levels of PEEP and oxygen, and a tidal volume in the range of 10 to 15 mL/kg. This strategy was often employed with little regard for the underlying cause of respiratory failure. However, based on the forgoing discussion, adopting such a strategy may be deleterious. Consequently clinical trials and experimental endeavors have focused on the development of lung-protective strategies. The principal objectives of a lung-protective strategy are to limit alveolar distention and

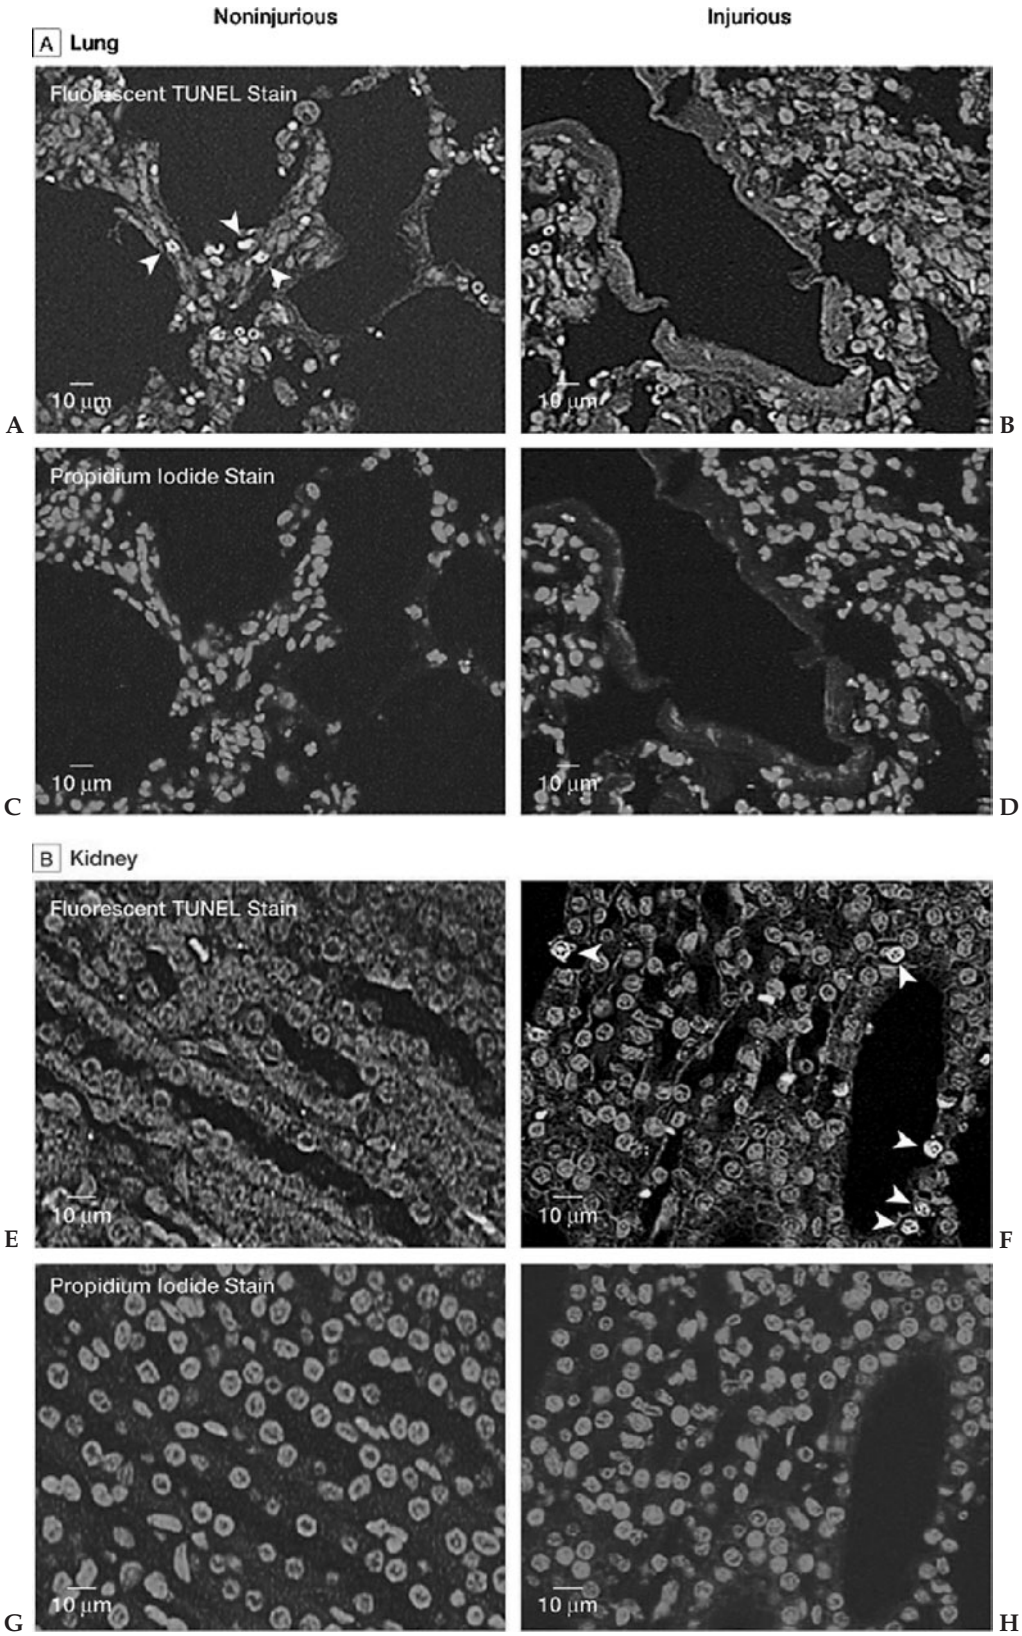

FIGURE 37-4 There was greater apoptosis of renal tubular epithelial cells in the group that received injurious mechanical ventilation compared to the group that received the noninjurious strategy, as evidenced by the greater number of TUNEL-positive cells (*arrowheads*) in the injurious group. Terminal deoxynucleotidyltransferase-mediated dUTP nick end-labeling (TUNEL) staining identifies the apoptotic cell, and propidium iodide staining identifies nuclei and helps ensure that noncellular background staining is not inadvertently identified as a TUNEL-positive cell (original magnification ×400). *(Reproduced with permission from Imai et al.[89])* (See Color Plate 37-4.)

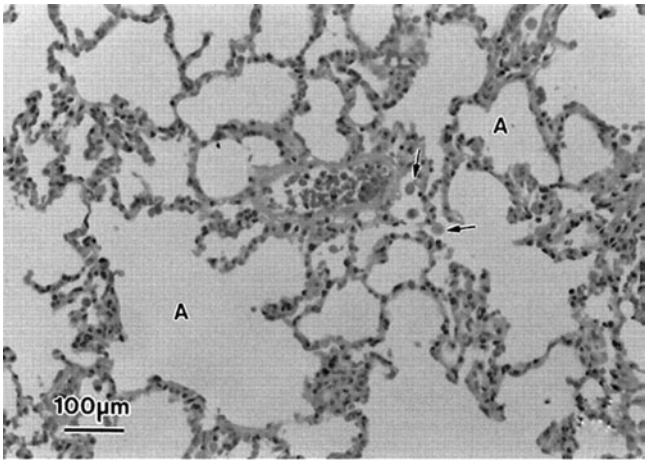
maintain alveolar patency. A lung-protective strategy should be implemented early in the course of respiratory failure to prevent the development of VILI.

There are four potential strategies, none of which are mutually exclusive, to reduce alveolar overdistention. The first strategy is to limit inflation pressure. Current opinion and recommendations from a consensus conference on mechanical ventilation in ARDS recommend that plateau pressure be kept below 35 cm H_2O in patients with ARDS. However, as emphasized in a review by Brower,[90] a strategy that focuses on plateau pressure alone may still produce potentially injurious tidal volumes. Conversely, another limitation of using airway pressure as an indicator of lung inflation is that this method assumes that chest wall (including abdominal) compliance is normal. Patients with ARDS and conditions such as obesity or ascites may have a significantly reduced abdominal compliance. Consequently, high airway pressures may not be a reflection of overdistention. A second strategy to prevent lung overdistention is to limit tidal volume. This strategy is attractive because it is simple and eliminates concerns about changes in thoracic or abdominal compliance. In addition, this method was shown to be effective in decreasing mortality compared to conventional lung volumes.[2] The potential difficulty with limiting volume is that the tidal volume used is still rather arbitrary and does not take into account the severity of lung injury. In fact, the ARDS Network study[2] used a protocol that limited tidal volume to 6 mL/kg predicted body weight (PBW) *and* limited plateau pressures to less than 30 cm H_2O. It is clear based on this study that tidal volumes of 12 mL/kg are excessive. What is not known at present is whether 6 mL/kg PBW volumes are superior to larger volumes (8 to 10 mL/kg). Whether 6 mL/kg is superior or inferior to 8 mL/kg remains a matter of debate. However, until evidence to support the contrary emerges, 6 mL/kg PBW should be considered the standard of care. It is worth emphasizing that the ARDS Network trial based tidal volumes on the patient's PBW, and not measured body weight. In this study a tidal volume of 6 mL/kg based on predicted body weight was on average equivalent to a tidal volume of 5 mL/kg measured body weight.

THE PRESSURE-VOLUME CURVE IN ACUTE RESPIRATORY DISTRESS SYNDROME

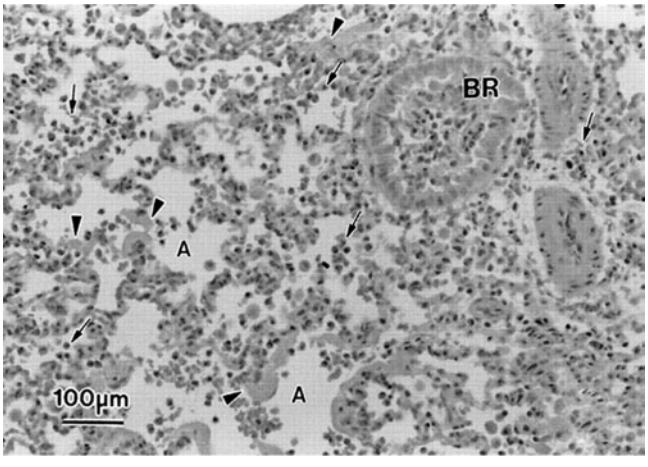
Some argue that ventilator settings should be individualized based on the pressure-volume (P-V) curve (see Fig. 37-3).[24] Examination of the P-V relationship of the lungs of patients with ARDS provides a good conceptualization of the changes that occur during ARDS, and has been instrumental in the development of strategies of mechanical ventilation to reduce lung injury in these patients. Indeed one approach to optimize ventilation in patients with ARDS makes use of the shape of the P-V curve, in order to maintain lung inflation between the upper and lower inflection points. With a progressive increase in static airway pressure, there is a gradual increase in lung volume, which depends on the compliance of the respiratory system. As lung inflation approaches total lung capacity, a similar increase in airway pressure produces less lung inflation, and the P-V curve begins to flatten. This is often referred to as the *upper inflection point*. Continued inflation beyond this point results in overdistention of alveoli and increases the risk for macroscopic and microscopic lung injury. Similarly (although more controversial a notion) the lower inflection point is felt to reflect opening of atelectatic regions of the lung. It has been suggested that the level of PEEP be maintained above this level to avoid cyclic injury (atelectrauma) to the lung. However, this attractive approach has a number of problems. First, use of PEEP a few cm H_2O above the lower inflection curve does not ensure that the lung is recruited; indeed recruitment takes place over the entire steep portion of the P-V curve.[91–93] Secondly, the upper inflection point may indicate the completion of recruitment, rather than the development of overdistension.[93] Furthermore, for the practicing intensivist, determining the lower inflection point may not be practical. Some guidance is provided by studies that suggest that in most patients with ARDS, PEEP levels above 15 cm H_2O are generally required to maintain lung inflation above the lower inflection point.[24,94]

PERMISSIVE HYPERCAPNIA



Permissive hypercapnia was first described in patients with asthma who were being mechanically ventilated. In an attempt to reduce dynamic hyperinflation and gas trapping, minute ventilation was decreased to allow sufficient expiratory time for the lung to empty via the obstructed airways. Relative to historical controls, patients managed in this manner had much better outcomes, with less barotrauma and less time spent receiving mechanical ventilation.[95,96] The concept of permissive hypercapnia was extended to the management of patients with ARDS, and follows occasionally from a mechanical ventilation strategy that demands a restriction in tidal volume. It should be emphasized that permissive hypercapnia does not represent a method of mechanical ventilation per se. Rather, it is the consequence of a strategy that limits lung volume excursions in an attempt to minimize alveolar overdistention and hence VILI. In an uncontrolled study, Hickling and associates described the use of a pressure-limited strategy and permissive hypercapnia in patients with advanced ARDS. Mortality was significantly lower than that which would have been predicted from the APACHE II score alone.[97] This was subsequently confirmed by some of the same authors in a prospective uncontrolled study in patients with ARDS.[98] These were landmark studies, but used historical controls, the method of ventilation was not well defined, and efforts were made concurrently to limit oxygen toxicity. Therefore, these studies suggested, but did not conclusively prove, that a pressure-limited strategy and disregard for the partial arterial pressure of carbon dioxide (Pa_{CO_2}) improved outcome. Importantly, serious side effects of an elevation of Pa_{CO_2} were not observed in either study.

The physiologic consequences of hypercapnia and respiratory acidosis have been reviewed extensively.[99,100] At present, the only absolute contraindication to a rise in Pa_{CO_2} is increased intracranial pressure, although acute hypercarbia may have adverse effects on the fetus in gravid individuals. In patients with critical illness and impaired oxygen delivery, there have been concerns about effects on cardiovascular performance. However, the potential myocardial depressant effects are usually short-lived owing to the buffering capacity of myocytes and the increase in sympathetic activity and decrease in afterload that accompany hypercapnia.[101] Caution, however, is warranted in patients with evidence of myocardial dysfunction. A final concern surrounds the increase in pulmonary arterial pressures that develops with hypercapnic acidosis. This response is likely mediated by a reduction in nitric oxide and has been shown to be reversible with nitric



oxide inhalation.[102] In the face of these concerns hypercapnia has been shown to be protective in a variety of settings.[103–106] Indeed it has been postulated that hypercapnia may attenuate the severity of acute lung injury, or at the very least that the development of hypocapnia may be harmful.[100,103,107,108] Hypercapnic acidosis has been shown to attenuate protein leakage, lung edema, lung lavage inflammatory mediators, and lung injury score, and preserve oxygenation and lung compliance in several models of lung injury (Fig. 37-5).[1,108–110]

More controversial is whether the resulting respiratory acidosis should be corrected by the infusion of a buffer solution. Although some advocate the use of a bicarbonate infusion, in the setting of impaired ventilation the additional CO_2 generated during the buffering of H^+ with bicarbonate might worsen intracellular pH. Second, as pointed out by Feihl and Perret, very large doses of bicarbonate are required to produce a significant improvement in pH during hypercapnia, owing to the large volume of distribution of the bicarbonate ion, to renal bicarbonate losses, and to conversion of bicarbonate to CO_2.[99] In addition, although extracellular pH is low, intracellular pH is rapidly corrected and seldom becomes critical. Consequently, the slow bicarbonate infusion recommended by some studies is not likely to be of benefit, and the routine administration of bicarbonate during permissive hypercapnia remains controversial. Indeed Laffey and coworkers demonstrated that correction of hypercapnic acidosis worsened lung function in an ischemia-reperfusion lung injury model.[107] Other buffers such as Carbicarb may theoretically be more efficacious in the setting of hypercapnia.[99,111]

FIGURE 37-5 A representative micrograph of lung tissue from a hypercapnic animal. The alveoli are free of edema and cellular infiltrate (*A*), normal parenchymal architecture is maintained, and only a small number of macrophages are present in the alveoli (*arrow*). *B*. A comparable micrograph from the eucapnic group. There is marked cellular infiltration in the interstitium and alveoli (*arrows*), which also fills the lumen of a bronchiole (BR). Alveolar and interstitial edema, as well as hyaline membrane formation (*arrowheads*) are also present (hematoxylin and eosin stained; 120× magnification; scale indicates 100 μm). CLINICAL TRIALS

Based on the foregoing discussions several controlled clinical trials have evaluated the effects of a lung protective strategy on outcome in ARDS (Table 37-3). However, initial randomized clinical trials evaluating the effect of lower tidal volumes on outcome were disappointing.[112–114] There was even a suggestion that tidal volume restriction was harmful, as it was associated with a greater use of neuromuscular blockers, a greater need for dialysis (perhaps related to the lower pH from a higher Pa_{CO_2}), and a trend toward higher mortality. In the study by Stewart and associates, the mortality in the tidal volume restriction arm was 50% compared to the control arm mortality of 47%, while in the study by Brochard and colleagues, the mortality was 47% and 39%, respectively.[112,114] However, the NIH-sponsored multicenter study of patients with ARDS has vindicated many of the earlier animal studies and clinical trials.[2] In this trial patients were randomized to receive either "conventional" tidal volumes (12 mL/kg PBW; tidal volume was reduced if plateau pressure was greater than 50 cm H_2O), or a lower tidal volume (6 mL/kg PBW, and maintenance of a plateau pressure between 25 and 30 cm H_2O). The trial was stopped early after an interim analysis demonstrated a survival benefit in the group with low tidal volume (Fig. 37-6). Mortality was reduced by 22% from 40% in the conventional arm to 31% in the low-lung-volume arm (CI 2.4 to 15.3 percent difference between the groups). The benefit of a lung-protection strategy seemed to be independent of the severity of the lung compliance at baseline. In addition to a mortality effect, the number of days alive and free of mechanical ventilation was lower in the intervention arm. However, this effect was solely due to the reduction in mortality, as the median duration of mechanical ventilation was 8 days for survivors in both groups. The benefit did not appear to differ when patients were stratified based on their risk factor for ARDS.[115] Interestingly the number of days with nonpulmonary organ failure was lower in the intervention arm, and the plasma interleukin-6 concentration was decreased compared to the control group. This again supported the notion that a lung protection strategy achieved its benefit through a reduction in the systemic release of inflammatory mediators

TABLE 37-3 Clinical Trials Evaluating the Effects of Different Lung-Protective Strategies on Outcome in Acute Respiratory Distress Syndrome

Study	Intervention Used	TIDAL VOLUMES USED, mL/kg		PEEP, cm H_2O		RECRUITMENT		Outcome
		Intervention	Control	Intervention	Control	Intervention	Control	
Brower (n = 52)	Low stretch	7.3 ± 0.1 (day 5)	10.2 ± 0.1 (day 5)	8 (day 3)	8 (day 3)	None	—	No differences
Amato (n = 53)	Low stretch, lung open; using P-V curve[a]	Not reported Goal <6	Not reported Goal >12	Not reported P-Flex	Not reported P-Flex	Yes	None	A, B, E
Brochard (n = 116)	Low stretch	7.1 ± 1.3 (day 1)	10.3 ± 1.7 (day 1)	—	—	None	None	No differences
Stewart (n = 120)	Low stretch	7.2 ± 0.8 (day 3)	10.8 ± 1.0 (day 3)	8.7 ± 3.6 (day 3)	8.4 ± 3.8 (day 3)	None	None	C
ARDS Network (n = 861)	Low stretch	6.2 ± 0.8 (day 3)	11.8 ± 0.8 (day 3)	9.2 ± 3.6 (day 3)	8.6 ± 4.2 (day 3)	None	None	A, D
ALVEOLI trial (n = 550) stopped early	Low stretch, lung open	Goal was 6	Goal was 6	Goal of 2–6 cm H_2O> controls	Same as ARDSNet trial	Yes	None	No differences in mortality; unpublished
LOVS trial (ongoing)	Low stretch, lung open; present PEEP levels depending on $F_{I_{O_2}}$	Ongoing goal is 6	Ongoing goal is 10	High	Same as ARDSNet trial	Yes	None	Ongoing

ABBREVIATIONS: [a] PEEP was adjusted in the intervention arm to 2 to 4 cm H_2O greater than the lower inflection point (P-Flex). PEEP, positive end-expiratory pressure; $F_{I_{O_2}}$, fraction of inspired oxygen.
A = Reduction in mortality compared to conventional group. B = Improvement in physiological parameters (oxygenation and compliance). C = Suggestion of worse outcome in the lung protection group. D = Reduction in inflammatory mediators. E = Reduction in barotrauma.

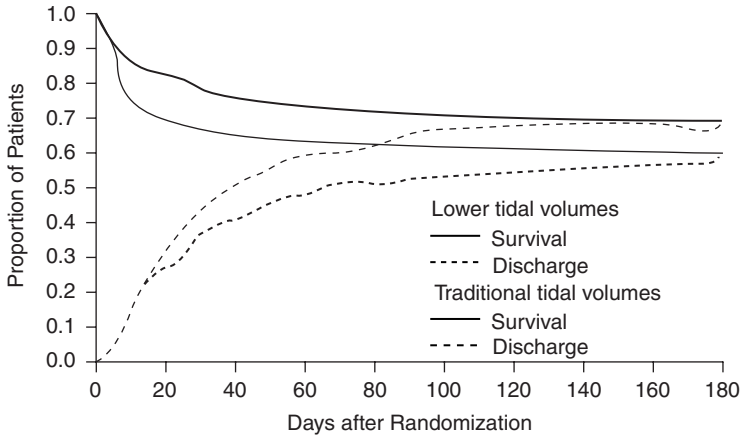

FIGURE 37-6 Probability of survival, being discharged home, and breathing without assistance during the first 180 days after randomization in patients with acute lung injury and ARDS randomized to either the 12 mL/kg PBW or 6 mL/kg PBW treatment arms. ***(Reproduced with permission from the ARDS Network Group.[2])***

and reduction in severity of multiple system organ failure. Unlike previous studies, however, there was no difference in the use of neuromuscular blockers.

It is difficult to reconcile the difference in the results of the ARDSNet study with earlier clinical trials evaluating a lung volume restriction strategy, because the ARDSNet study differed in several ways, making direct comparisons difficult.[116] First, the method of determining predicted body weight (and hence tidal volume) was different from earlier trials. Second, patients in the low-tidal-volume arm had higher respiratory rates that may have led to significant auto-PEEP, in turn leading to improved alveolar patency or recruitment. Third, the respiratory acidosis was more likely to be corrected with bicarbonate. This may have reduced the number of patients dialyzed, and could have reduced some of the yet to be determined effects of hypercapnic acidosis.

A concern regarding the safety of the ventilation trials conducted in patients with ARDS has recently been raised. In a review of the controlled trials of mechanical ventilation in ARDS, Eichacker and associates presented the argument that 12 mL/kg was potentially excessive, and that the use of this tidal volume as the reference intervention was inappropriate, placing patients in the control arm at risk.[117] The authors argued that there should have been a control group that better reflected "conventional" treatment. What tidal volume this control group would have actually been managed with is speculative. The reader is referred to an excellent review of the controversy and its consequences by Steinbrook.[118] The implications for this issue for the design and conduct of subsequent trials remain to be seen, but at present the ARDSNet strategy for ventilation of ARDS patients should be viewed as the standard.

In addition to lung overdistention, VILI also incorporates the concept that underdistention of alveolar units can also lead to injury. At present there are only two clinical trials that have evaluated the effects of an "open lung" approach to patients with ARDS. The first study by Amato and colleagues examined the effect of a multifaceted strategy that (1) minimized tidal volume, (2) recruited alveoli through a sustained inflation, (3) used a level of PEEP above the closing pressure of the lung, and (4) utilized a pressure-volume curve to define the optimum lung volume and PEEP.[119] Consequently the specific effects of maintaining alveolar patency cannot be determined from this trial. Nonetheless, using this strategy they demonstrated an impressive reduction in mortality. However, the major criticism of this study is that the control group was significantly disadvantaged by a protocol that allowed for significant overventilation, and that the observed results were not due to a benefit in the treatment arm, but rather a detrimental outcome in the control group.

In order to make specific recommendations about the optimum strategy, the relative effects of tidal volume reduction, alveolar recruitment, and level of PEEP need to be determined. To this end two multicenter trials are evaluating the effect of lung recruitment and high PEEP on outcome in ARDS. The ARDS Network has reported the results of their trial (ALVEOLI trial) that was closed after enrolling 550 patients, citing a finding of futility in the trial being able to determine a treatment effect during an interim analysis.[124] In an ongoing Canadian trial over 800 patients will be randomized to either low tidal volumes (identical to the ARDSNet low stretch trial) or a low tidal volume with an open lung approach. The open lung approach will utilize both periodic sustained inflations to 40 cm H_2O continuous positive airway pressure for 40 seconds and high levels of PEEP (up to 20 cm H_2O). It is hoped that this strategy will ensure both alveolar recruitment and maintenance of alveolar patency, respectively. Preliminary evidence suggests that this strategy may lead to a significant improvement in oxygenation in a subset of patients with early ARDS and no impairment in chest wall mechanics.[120] Whether this physiologic improvement and attendant reduction in atelectasis will lead to an improvement in survival has yet to be proven.

High-frequency oscillation (HFO) may accomplish many of the goals of a lung-protective strategy. It utilizes small tidal volume excursions at a high mean airway pressure. Consequently lung overdistention may be prevented and alveolar patency may be maintained. In a study of HFO in 70 pediatric patients with ARDS, Arnold and associates reported an improvement in oxygenation and requirement for supplemental oxygen at 30 days in the HFO group.[121] However there was no difference in duration of mechanical ventilation or survival. These observed improvements in physiologic parameters were also found in a study by Derdak and coworkers.[122] In a multicenter randomized controlled trial of HFO compared to what was at that time a conventional ventilatory strategy, in 148 adults with ARDS they found no difference in survival or duration of mechanical ventilation.

However the oxygenation was better in the HFO group during the study. These reports suggest that HFO is at least as safe as conventional mechanical ventilation, and may be associated with a more rapid improvement in oxygenation. However, both trials were hampered by the fact that the control group likely did not represent the current standard of care, namely tidal volumes of 6 mL/kg PBW. It remains to be seen if HFO is any more efficacious than a strategy that restricts tidal volume (with or without a strategy to maintain alveolar patency).

Even in the face of overwhelming experimental evidence and convincing results of a large controlled study, one of the major challenges faced by intensivists seems to be implementing these recommendations in practice. Two studies have demonstrated that compliance with the ARDS Network tidal volume goals are poor, even in those centers that participated in the original trial. Clearly education and protocolization of care will need to occur to allow best evidence to be translated into clinical practice.[3,116]

ARDS continues to be a common component of multisystem organ dysfunction and primary lung injury. Unfortunately, no pharmacologic intervention has proven to be efficacious in reducing mortality in patients with ARDS. An improved understanding of ARDS and the notion that prior ventilator strategies may have been injurious has led to rethinking how these patients should be supported.

Summary

In addition to theoretical concerns and experimental data in animals, evidence is evolving that our traditional goals of ventilation need to be modified to incorporate a lung-protective strategy (see Table 12-1). The low-lung-volume ARDSNet trial demonstrated a reduction in mortality with the implementation of a lung-protective strategy. However, it is a matter of perspective as to whether the intervention produced benefit, or simply that harm was avoided. Given the complex nature of ARDS, it is likely that a multifaceted strategy that incorporates several principles of VILI will need to be adopted. Limiting tidal volume may only be a component of a lung-protective strategy. Support is evolving for attempting to recruit alveoli and for the use of liberal PEEP. Future research on the effects of mechanical ventilation on regional and distal cellular signaling, apoptosis, and distal organ injury need to be explored further, incorporating recent advances in genomic and proteomic methods.[123]

Chapter 38

ACUTE LUNG INJURY AND THE ACUTE RESPIRATORY DISTRESS SYNDROME

JASON D. CHRISTIE
PAUL N. LANKEN

KEY POINTS

- *Acute lung injury (ALI) and its more severe form, the acute respiratory distress syndrome (ARDS), are common causes of acute hypoxemic respiratory failure (AHRF).*
- *Both ALI and ARDS are characterized by hypoxemia that is resistant to oxygen therapy; this is due to widespread alveolar filling or collapse.*
- *Initial therapy for all patients with ALI and ARDS should be supplemental oxygen in the highest concentration available; failure to achieve 95% arterial saturation or greater confirms the presence of a large right-to-left shunt.*
- *Most patients with ALI and ARDS require early intubation because their hypoxemic respiratory failure is typically severe and may be prolonged.*
- *If a patient with severe hypoxemia as indicated by arterial blood gas analysis has a clear chest radiograph, consider a possible error (e.g., incorrect fractional inspired oxygen [$F_{I_{O_2}}$] or arterial oxygen tension [Pa_{O_2}]); in such situations, also consider the possibility of other types of right-to-left shunts (e.g., intracardiac shunts or pulmonary arteriovenous malformations) or the continued perfusion of an unventilated or poorly ventilated lung (e.g., due to acute mucous plugging of one main bronchus).*
- *The acute phase of ALI and ARDS is characterized by an exudative alveolar flooding due to pulmonary capillary leak and by extensive alveolar collapse due to loss of normal surfactant activity; while interventions directed at modulating inflammatory or other pathways of lung injury or restoring surfactant function hold theoretical promise, at present no specific pharmacologic therapy has been shown to improve outcomes; in this phase one provides mechanical ventilation and other supportive care while identifying and treating the precipitating cause or causes of ALI or ARDS.*
- *Ventilator management of patients with ALI and ARDS should use a strategy with low tidal volumes and limits to end-inspiratory pressure (i.e., plateau pressures [Pplat]), to reduce the risk of ventilator-induced lung injury (VILI); such a strategy gives higher priority to the goal of decreasing the risk of VILI by limiting end-inspiratory volume and pressure than the traditional goal of keeping arterial carbon dioxide tension (P_{CO_2}) and pH in the normal range.*
- *The target for oxygenation should be a Pa_{O_2} between 55 and 80 mm Hg (88% to 95% saturation); one should achieve this by adjusting $F_{I_{O_2}}$ and positive end-expiratory pressure (PEEP) with the goal of decreasing $F_{I_{O_2}}$ to 0.5 to 0.6 (or less), concentrations that are less concerning for pulmonary oxygen toxicity.*
- *In general, the ventilatory strategy should use a tidal volume of 6 mL/kg of predicted body weight (PBW) with a Pplat target that does not exceed 30 cm H_2O; if Pplat exceeds 30 cm H_2O with a 6 mL/kg PBW tidal volume, the latter should be decreased to 5 mL/kg PBW; if Pplat still exceeds 30 cm H_2O, tidal volume should be further decreased to 4 mL/kg PBW.*
- *When changing to low tidal volume ventilation, one should increase the respiratory rate (RR) up to 35/min to maintain minute ventilation; the target for ventilation should be a pH of 7.30 to 7.45; if the pH is between 7.15 and 7.29, one may correct the respiratory acidosis by giving intravenous sodium bicarbonate ($NaHCO_3$) (if RR is 35/min and arterial carbon dioxide tension [Pa_{CO_2}] is <25 mm Hg); if the pH remains <7.15 with RR of 35/min and $NaHCO_3$ is considered or given, one can increase the tidal volume in 1–mL/kg PBW increments until pH exceeds 7.15 (i.e., the Pplat target may be exceeded).*
- *During assisted ventilation, use sedation to synchronize the patient's respiratory efforts with the ventilator and to decrease oxygen consumption ($\dot{V}_{O_2}$); one may also need to induce muscle paralysis by use of neuromuscular blocking agents, which despite their clinical utility, likely increase the risk of diffuse weakness in survivors.*
- *Despite the lack of results of a randomized clinical trial (RCT) to support its use, some clinicians favor a "dry" fluid management strategy to reduce edemagenesis and the duration of assisted ventilation; however, this approach generally lowers cardiac output and risks worsening or inducing nonpulmonary organ dysfunction.*
- *If one uses a "dry" fluid management strategy, one should be guided by daily and cumulative net intake and output volumes and laboratory indices of hypovolemia (blood urea nitrogen [BUN]:creatinine ratio and serum total bicarbonate) while monitoring for adequate urine output (>0.5 mL/kg PBW/h), effective circulation (by physical signs, or measurements of cardiac index or venous co-oximetry or both), adequate perfusing pressure (i.e., mean arterial pressure [MAP] ≥60 mm Hg), and electrolyte abnormalities (serum sodium and potassium).*
- *Caution! Although this strategy is supported by observational studies, no prospective RCT to date has established whether the "dry" fluid management strategy improves outcomes compared to a "non-dry" strategy; nor has the efficacy or safety of using a pulmonary artery or central venous catheter for this purpose been established.*
- *Late-phase or fibroproliferative-phase ARDS (corresponding to persistent ARDS of 1 week duration or more) is characterized by subacute inflammation, proliferation of alveolar lining cells and interstitial cells, and varying degrees of fibrosis.*
- *In severe late-phase ARDS, a prolonged course of high-dose methylprednisolone sodium succinate (MPSS) can improve gas exchange and mechanics in some patients; however, use of MPSS increases the risk of diffuse weakness that may be prolonged; preliminary results from one RCT found that MPSS administration when added to a low-tidal-volume ventilation strategy that limited Pplat as described above did not significantly improve mortality at 60 days (or ICU or hospital lengths of stay) compared with ventilation using a low tidal volume and limited plateau pressure strategy alone.*

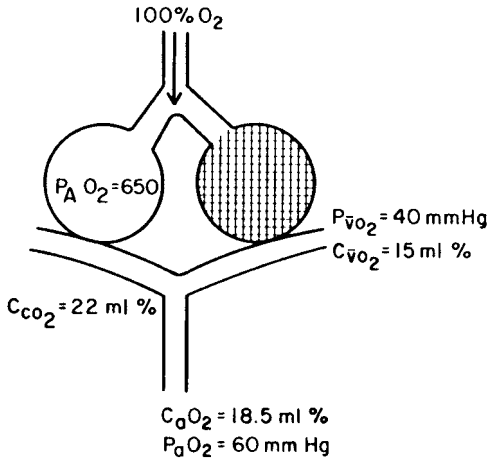

FIGURE 38-1 Diagram of a two-compartment model of lung perfusion and ventilation demonstrating the basis for failure of oxygenation in ALI and ARDS. When large portions of the lung are nonventilated owing to alveolar collapse or flooding (*hatched area*), blood flow to these units with mixed venous P_{O_2} ($P\bar{v}_{O_2}$) of 40 mm Hg and content of 15 vol% is effectively shunted through the lungs without being resaturated. Thus despite a high concentration of supplemental oxygen (100% in this example) and a high alveolar P_{O_2} in ventilated units, these blood flows mix in accord with their oxygen contents (i.e., the resulting left atrial blood has an oxygen content that is the weighted mean of the oxygen content of the shunted and non-shunted blood). In this example of a 50% shunt, the left atrial and systemic arteries have an arterial P_{O_2} of 60 mm Hg. Ca_{O_2}, arterial oxygen content; Cc_{O_2}, capillary oxygen content; $C\bar{v}_{O_2}$, mixed venous oxygen content; P_A, alveolar pressure; Pa_{O_2}, arterial oxygen pressure; $P\bar{v}_{O_2}$, partial pressure of oxygen in the mixed venous blood.

Severe arterial hypoxemia that is resistant to supplemental oxygen is a common reason for admission to the ICU. This form of respiratory failure, termed *acute hypoxemic respiratory failure* (AHRF), arises from widespread flooding or collapse of alveoli. As a result, a substantial fraction of mixed venous blood traverses nonventilated alveoli (i.e., alveoli with ventilation-perfusion ratio of 0). This in turn results in a large right-to-left intrapulmonary shunt (Fig. 38-1). In addition to its adverse effects on oxygenation, fluid that accumulates in alveoli and interstitial tissues increases lung stiffness, which decreases lung compliance. This imposes a larger mechanical load on the patient's respiratory system, resulting in an increased elastic work of breathing. Without treatment with supplementary oxygen and assisted ventilation, the gas exchange derangement and abnormal lung mechanics can result in progressive hypoxemia, respiratory muscle fatigue, and eventual respiratory arrest and death.

This chapter describes two notable forms of AHRF: *acute lung injury* (ALI) and its more severe subgroup, *the acute respiratory distress syndrome* (ARDS) (Fig. 38-2). ALI and ARDS affect an estimated 50,000 to 150,000 patients each year in the United States alone.[1,2] Despite recent advances in ventilatory management and improvements in nonrespiratory supportive ICU care, the mortality rate remains high (e.g., ~25% to over 50%, depending on the characteristics of the population studied and the ventilatory strategy utilized).[3–9]

The overall goal of this chapter is to provide a comprehensive and updated clinical approach to ALI and ARDS that

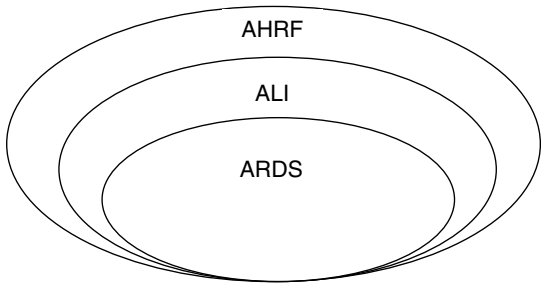

FIGURE 38-2 Schematic representation of the relationships among acute hypoxemic respiratory failure (AHRF), acute lung injury (ALI) and the acute respiratory distress syndrome (ARDS). Note that ALI is a more severe subgroup of AHRF and that ARDS is a more severe form of ALI.

is grounded in current concepts of pathogenesis and pathophysiology. Objectives include: (1) to present the definitions, epidemiology, and precipitating causes of ALI and ARDS; (2) to describe the pathogenesis and pathophysiology of ALI and ARDS; (3) to describe the differential diagnosis of ALI and ARDS and clinical approaches to distinguish among various causes of acute hypoxemic respiratory failure; (4) to review the current status of treatment for ALI and ARDS and their precipitating causes; and (5) to provide current recommendations for ventilatory management of ALI and ARDS. The last objective includes a detailed description of the low-tidal-volume ventilatory strategy used by the ARDS Clinical Trials Network (ARDSNet) investigators in the clinical trials sponsored by the National Heart, Lung and Blood Institute (NHLBI) of the National Institutes of Health (NIH).[3,4]

Description and Definitions of ALI and ARDS

ARDS was initially described in 1967 by Ashbaugh and coauthors as a syndrome characterized by the acute onset of dyspnea, severe hypoxemia, diffuse lung infiltrates, and decreased compliance of the respiratory system.[10] Following this initial report, different authors utilized varying definitions that incorporated the elements of acute timing of onset, hypoxemia, radiographic infiltrates, and absence of overt clinical congestive heart failure.[11–15] In 1988, Murray and coauthors proposed using a Lung Injury Score (LIS), in part to take into account the effects of respiratory system compliance and the pressures delivered using the mechanical ventilator.[14] The LIS combined elements of severity of chest radiograph infiltrates, hypoxemia, respiratory system compliance, and amount of administered positive end-expiratory pressure (PEEP) on the mechanical ventilator.[14]

AMERICAN EUROPEAN CONSENSUS CONFERENCE DEFINITIONS

In 1994, the first American European Consensus Conference (AECC) published these consensus-derived definitions of ALI and ARDS: acute onset, bilateral pulmonary infiltrates on chest radiograph consistent with pulmonary edema, poor systemic oxygenation, and the absence of evidence of left atrial hypertension (Table 38-1).[16] The ratio of arterial oxygen tension (Pa_{O_2}) to the fraction of inspired oxygen (FI_{O_2}), Pa_{O_2}:FI_{O_2},

TABLE 38-1 American European Consensus Conference Criteria for Acute Lung Injury (ALI) and the Acute Respiratory Distress Syndrome (ARDS)

Clinical Variable	Criteria for ALI	Criteria for ARDS
Onset	Acute	Acute
Hypoxemia	$Pa_{O_2}/F_{I_{O_2}} \leq 300$ mm Hg	$Pa_{O_2}/F_{I_{O_2}} \leq 200$ mm Hg
Chest radiograph	Bilateral infiltrates consistent with pulmonary edema	Bilateral infiltrates consistent with pulmonary edema
Noncardiac cause	No clinical evidence of left atrial hypertension **or,** if measured, pulmonary artery occlusion pressure ≤18 mm Hg	No clinical evidence of left atrial hypertension **or,** if measured, pulmonary artery occlusion pressure ≤18 mm Hg

SOURCE: Reproduced with permission from Bernard et al.[16]

was chosen to reflect the degree of hypoxemia even when measured at different $F_{I_{O_2}}$.[17] The syndrome is called ALI when this ratio is ≤300 and ARDS when ≤200. The AECC coined the term *acute lung injury* in order to identify patients who are early in the course of their ARDS and those who may have a form of AHRF that is milder than ARDS. The AECC definitions of ALI and ARDS were intentionally quite broad in order to encompass different types of AHRF occurring in a wide variety of settings. Most patients with ALI progress to ARDS, prompting some to use the use the term "ALI/ARDS" to describe all patients with a $Pa_{O_2}:F_{I_{O_2}}$ ratio ≤300 who also meet the other AECC criteria (see Table 38-1).

Several clinical trials have used these standardized definitions of ALI and ARDS to specify the trial's inclusion criteria for their study populations.[3,4,8] Using the AECC definition of ALI and ARDS in these and other clinical trials contributes to the comparability of their study populations and facilitates generalizability of their results. For example, in order for clinicians to extrapolate the results of a trial to their own patients, they must first be reasonably sure that their patients resemble those in the clinical trial. This requires that they meet the same inclusion criteria for ALI or ARDS as those used in the clinical trial. However, having the same inclusion criteria is necessary but not sufficient, since the clinician must also take into account the exclusion criteria used in the clinical trial to assess comparability.

VALIDITY AND RELIABILITY OF AECC DEFINITIONS

Despite standardization, these definitions have not been formally validated beyond their face validity. In addition, problems remain with the reliability of the various components of the definitions.[1] For example, interpretation of chest radiographs can be inaccurate and variable among different observers.[18,19] However, formal training sessions can improve this variability.[19] Likewise, the $Pa_{O_2}:F_{I_{O_2}}$ criterion also suffers from variability since it can be influenced by the level of PEEP used in mechanical ventilation and other transient factors, such as airway secretions or inadequate sedation. For example, higher PEEP generally increases Pa_{O_2} at a given $F_{I_{O_2}}$. This in turn may raise a patient's $Pa_{O_2}:F_{I_{O_2}}$ >300 so that the patient no longer meets the inclusion criteria for ALI. Conversely, in the absence of PEEP a $Pa_{O_2}:F_{I_{O_2}}$ <300 may reflect the presence of simple basilar atelectasis rather than ALI or ARDS. In such a case, adding PEEP may recruit enough atelectatic lung to raise $Pa_{O_2}:F_{I_{O_2}}$ >300, so that the patient no longer meets this criterion for ALI.[20]

Finally, exclusion of congestive heart failure (left atrial hypertension) also presents problems with reliability. Diagnostic criteria for left atrial hypertension on purely clinical grounds may be inaccurate.[1,21] Insertion of a pulmonary artery catheter for this purpose may also be inconclusive since the pulmonary artery occlusion pressure may be higher than 18 mm Hg due to intravascular volume loading (e.g., in patients with shock), rather than due to congestive heart failure.[21] Conversely, many patients with pulmonary edema due to congestive heart failure and high left atrial pressures may have normal pulmonary artery occlusion pressures by the time the catheter is inserted and measurements taken.[22]

Further refinement of the reliability and validity of definitions of ALI and ARDS are desirable goals. More reliable definitions will not only improve estimates of the public health impact of these syndromes, but also decrease misclassification errors that are especially problematic for research aimed at clarifying molecular and genetic mechanisms in ALI and ARDS.[23]

Epidemiology

INCIDENCE

Inconsistent definitions for ALI and ARDS in large databases of diagnoses for hospital admissions or complications, variations in the application of the AECC definition in different studies, and variations in different at-risk populations (such as sepsis, trauma, surgeries, and bone marrow transplants) have hampered obtaining accurate estimates of the incidence of ALI and ARDS. Recent studies have used data from the ARDSNet clinical trials, as well as regional cohort studies to arrive at estimates in the United States in the range of 25 to 65 cases per 10,000 person-years.[1,2,24] Thus the number of patients with ARDS and ALI in the U.S. each year is estimated to be between 53,000 and 140,000. If one assumes a short-term mortality of ~30% to 40%, the annual number of deaths in the U.S. directly attributable to ALI and ARDS is between 16,000 and 56,000. These estimates of attributable mortality are greater than from the acquired immune deficiency syndrome (AIDS), asthma, or cervical cancer.[1,2] In addition, ARDS and ALI contribute significantly to long-term mortality, morbidity, and diminished quality of life. (see Chap. 19).[25–28] In addition to these estimates in the U.S., two non-U.S. studies arrived at similar incidence rates for ARDS in Berlin[29] and Scandinavia.[29] Several useful reviews have

TABLE 38-2 Examples of Direct and Indirect Precipitating Causes of Acute Lung Injury (ALI) and the Acute Respiratory Distress Syndrome (ARDS)

Direct Precipitating Cause	Indirect Precipitating Cause[a]
Aspiration of gastric contents	Acute pancreatitis
Bacterial pneumonia (e.g., Legionnaire's disease)	Blood product transfusions with transfusion-related acute lung injury (TRALI)
Chest trauma with lung contusion	Post–cardiopulmonary bypass
Near-drowning	Primary graft failure of lung transplantation
Pneumonia due to *Pneumocystis carinii*	Severe sepsis and septic shock
Toxic inhalations (e.g., smoke inhalation, inhaled crack cocaine ["crack" lung])	Toxic ingestions (e.g., aspirin, tricyclic antidepressants)
Viral pneumonia (e.g., influenza, the severe acute respiratory syndrome [SARS])	Trauma with multiple fractures and fat-emboli syndrome

[a] In indirect or systemic mechanisms of lung injury the lung injury results from deleterious effects on the alveolar endothelium by inflammatory or other mediators delivered via the pulmonary circulation.

summarized the important public health impact of ALI and ARDS.[1,2,30]

PRECIPITATING CAUSES

ALI and ARDS can be considered to be a "final common pathway" reaction of the lung to a large variety of precipitating causes. Some authors have classified these causes as representing *direct* (pulmonary) or *indirect* (extrapulmonary or systemic) injury to the lung.[31,32] (Table 38-2). Although the methodology for applying these labels is not standardized and thus may be inconsistent between studies, this construct may have pathogenetic and pathophysiologic underpinnings since indirect causes may have different mechanisms of injury compared to direct injury to the lung.[33] Not all patients with these precipitating conditions develop ALI/ARDS. Indeed, the frequency of ALI/ARDS is quite variable. Depending on the precipitating cause, it ranges from ~10% to 40%. If patients have more than one of these precipitating causes, they are at an even higher increased risk for development of ALI or ARDS. Although most studies of the incidence of ARDS among different at-risk subgroups were performed before the AECC standardization of the definitions, they nonetheless provide broad estimates of the risk of development of ARDS in these subgroups.[11–13,34]

RISK FACTORS FOR THE DEVELOPMENT OF ALI AND ARDS

Why certain individuals with the same precipitating cause develop ALI and ARDS while others don't is not known. Some of this differential risk can be attributed to other acquired risk factors, such as chronic alcoholism.[35] In addition, certain individuals may have an inherent predisposition to developing ALI or ARDS while others may have inherent protections against ALI or ARDS. These considerations are discussed below.

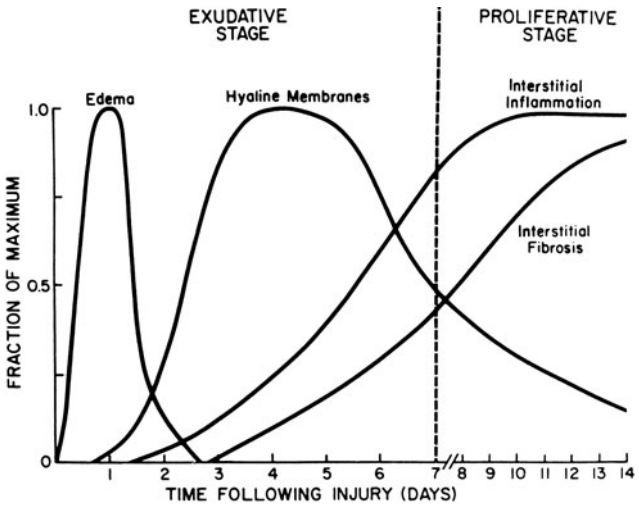
ALI and ARDS arise from diverse populations. Within these populations, specific clinical variables may affect both the risk of ARDS and ultimate outcomes if ARDS develops.[34,36,37] Clinical variables and outcomes associated with an increased risk of ARDS include chronic alcohol abuse;[38] lack of diabetes;[39] hypoproteinemia;[40] age and gender;[13] severity of injury and illness as measured by injury severity score (ISS) or Acute Physiology, Age, and Chronic Health Evaluation (APACHE) score;[13] hypertransfusion of blood products;[13] and possibly cigarette smoking.[41] The mechanistic underpinnings of these associations are the subject of ongoing research. Nonetheless, these observations highlight the influence of the heterogeneity of a diverse source population on the risks of ALI and ARDS. Human studies aimed at investigating genetic or molecular mechanisms that predispose or protect individuals from developing ALI and ARDS must take into account the effects of these population and environmental differences.

DETERMINANTS OF ARDS OUTCOME

Clinical variables with reported associations with increased mortality among patients with ALI and ARDS include advanced age, low Pa_{O_2}:FI_{O_2}, high plateau pressure (i.e., low compliance), extent of pulmonary infiltrates, chronic liver disease, nonpulmonary organ dysfunction, severity of illness, hypoproteinemia, and length of hospitalization prior to ARDS.[4,38,42–48] In addition, magnitude of the dead space fraction has been identified as a risk factor for mortality, possibly indicating the importance of loss of the pulmonary vascular bed in disease severity.[49]

Different precipitating causes of ALI and ARDS carry different prognoses. For example, trauma-associated ALI or ARDS has a better prognosis than other causes, even after adjustment is made for other baseline variables such as age.[48] Although response to some therapeutic interventions in ALI or ARDS varies according to direct or indirect cause of lung injury,[50,51] low-tidal-volume ventilation is equally efficacious in both of these subgroups.[52]

Despite recent advances in therapy, the mortality rates reported in clinical trials in the past decade have ranged from ~25% to more than 50%.[3–9] The lowest mortality rates have been achieved with low-tidal-volume ventilation, which also limited end-inspiratory (plateau) pressure.[3,4] Although no recent studies have explicitly examined the cause of death in nonsurvivors, previously the majority of deaths were found to be due to multiorgan failure or sepsis, while progressive respiratory failure accounted for only a small minority of deaths (e.g., ~15%).[53,54]



ALI and ARDS impact the health and lives of survivors beyond the ICU. Long-term functional, neuropsychiatric, and cognitive dysfunction following ALI and ARDS has been described (see Chap. 19). In the aggregate, these deficits represent an important aspect of the impact of ARDS and its associated morbidity on the general population.

Pathology and Pathophysiology

In cases of ALI and ARDS, it is useful to distinguish between the early phases of lung injury and subsequent events.[36,55,56] By light microscopy, the early appearance is of interstitial and alveolar edema, capillary congestion, and intra-alveolar hemorrhage with minimal evidence of cellular injury (Fig. 38-3). By electron microscopy, changes of endothelial cell swelling, widening of intercellular junctions, increased numbers of pinocytotic vesicles, and disruption and denudation of the basement membrane are prominent. Inflammatory cell infiltration of the lung interstitium may be seen (particularly in ARDS complicating sepsis or trauma) as well as neutrophil sequestration in alveolar capillaries, but it usually a subtle finding. During this early *exudative* phase of diffuse alveolar damage (DAD), pulmonary edema and its clinical effects are most pronounced (see Fig. 38-3). It is also a time when manipulations to decrease the rate of edemagenesis are most likely to have impact as discussed below.

Over the ensuing days, hyaline membrane formation in the alveolar spaces becomes prominent. Hyaline membranes contain condensed fibrin and plasma proteins. Intra-alveolar activation of the coagulation system results in the formation of the fibrin, while plasma proteins are deposited in the alveolar space as part of the inflammatory exudate that leaks across the alveolar-capillary membrane. Inflammatory cells become more numerous within the lung interstitium. As the process of DAD progresses, there is extensive necrosis of type I alveolar epithelial cells. If the patient with ALI and ARDS does not recover or die during the first week, they may have a prolonged course of illness, termed *late-phase ARDS*.

FIGURE 38-3 A schematic representation showing the time course of evolution of the acute respiratory distress syndrome (ARDS). During the early or exudative phase, the lesion is characterized by a pulmonary capillary leak with interstitial and alveolar edema and hemorrhage, followed by hyaline membrane formation. Within as short a period of time as 7 to 10 days, a proliferative phase may appear with marked interstitial and alveolar inflammation and cellular proliferation, which is followed by fibrosis and disordered healing (see text for discussion). ***(Reproduced with permission from Katzenstein AA, Askin FB*: Surgical Pathology of Non-Neoplastic Lung Diseases, *2nd ed. Philadelphia, Saunders, 1990.)***

The late phase of ARDS is dominated by disordered healing. This can occur as early as 7 to 10 days after initial injury and may eventually result in extensive pulmonary fibrosis. This has been termed the *proliferative* or *fibroproliferative* phase. Type II alveolar cells proliferate along alveolar septae and the alveolar walls; fibroblasts and myofibroblasts become more numerous. Evidence of lung flooding is less prominent and may be minimal at this point. Changes in the clinical manifestations of ALI and ARDS parallel the changes in pathology. One study found that patients in late-phase ARDS typically had a large dead space fraction, a high minute ventilation requirement, progressive pulmonary hypertension, slightly improved intrapulmonary shunt that is less responsive to PEEP, and a further reduction in lung compliance.[57]

Pathogenesis

A number of closely inter-related pathophysiologic mechanisms and systems contribute to the development of ALI and ARDS (Fig. 38-4). Inflammatory cytokines, oxygen radicals, activation of coagulation and complement, platelet and immune cell activation, proteases, leukotrienes, and eicosanoids have been hypothesized to play a role in the early stages of ALI and ARDS.[33,36,37,58] In addition to ongoing inflammation and oxidation, factors specific to apoptosis, edema fluid resolution, fibrosis, and repair are likely to be important in the resolving and late phases of ALI and ARDS.[33,36,37,58,59]

INFLAMMATORY CYTOKINES AND CHEMOKINES

Cytokines are small signaling proteins that participate in host defense by binding to cell surface receptors. Many types of cells produce cytokines in response to a variety of stimuli. Cytokines teleologically must provide a net benefit in terms of contributing to host defense. However, when inflammation is overly exuberant, they have been implicated in disease states, including ALI and ARDS.[60,61]

Two of the major early proinflammatory cytokines are *tumor necrosis factor-α* (TNF-α) and *interleukin-1* (IL-1), both of whose production can be increased by hypoxia.[62] These cytokines have similar effects in initiating and propagating inflammation.[60,63–66] Their actions include: (1) recruitment, differentiation, amplification, and localization of macrophages to the lung parenchyma; (2) stimulation of other inflammatory cytokines such as interleukins-6 and -8 (IL-6 and IL-8); and (3) adherence of neutrophils to endothelium (see Fig. 38-4).[58,67–70]

In clinical studies, the most convincing evidence of the involvement of TNF-α and IL-1 in ARDS has been from direct measurement in bronchoalveolar lavage (BAL) or pulmonary edema fluid. Both fluids have consistently been reported to contain elevated levels of TNF-α and IL-1 in ARDS patients.[71–75] Furthermore, some suggest that much of the proinflammatory state of BAL in ARDS may be mediated through IL-1.[76] More recent studies suggest that an imbalance between inflammatory cytokines and their soluble receptors are an important pathogenetic mechanism in ARDS.[77]

Not only do TNF-α and IL-1 play an important role in the early pathogenesis and risk of developing ALI and ARDS,

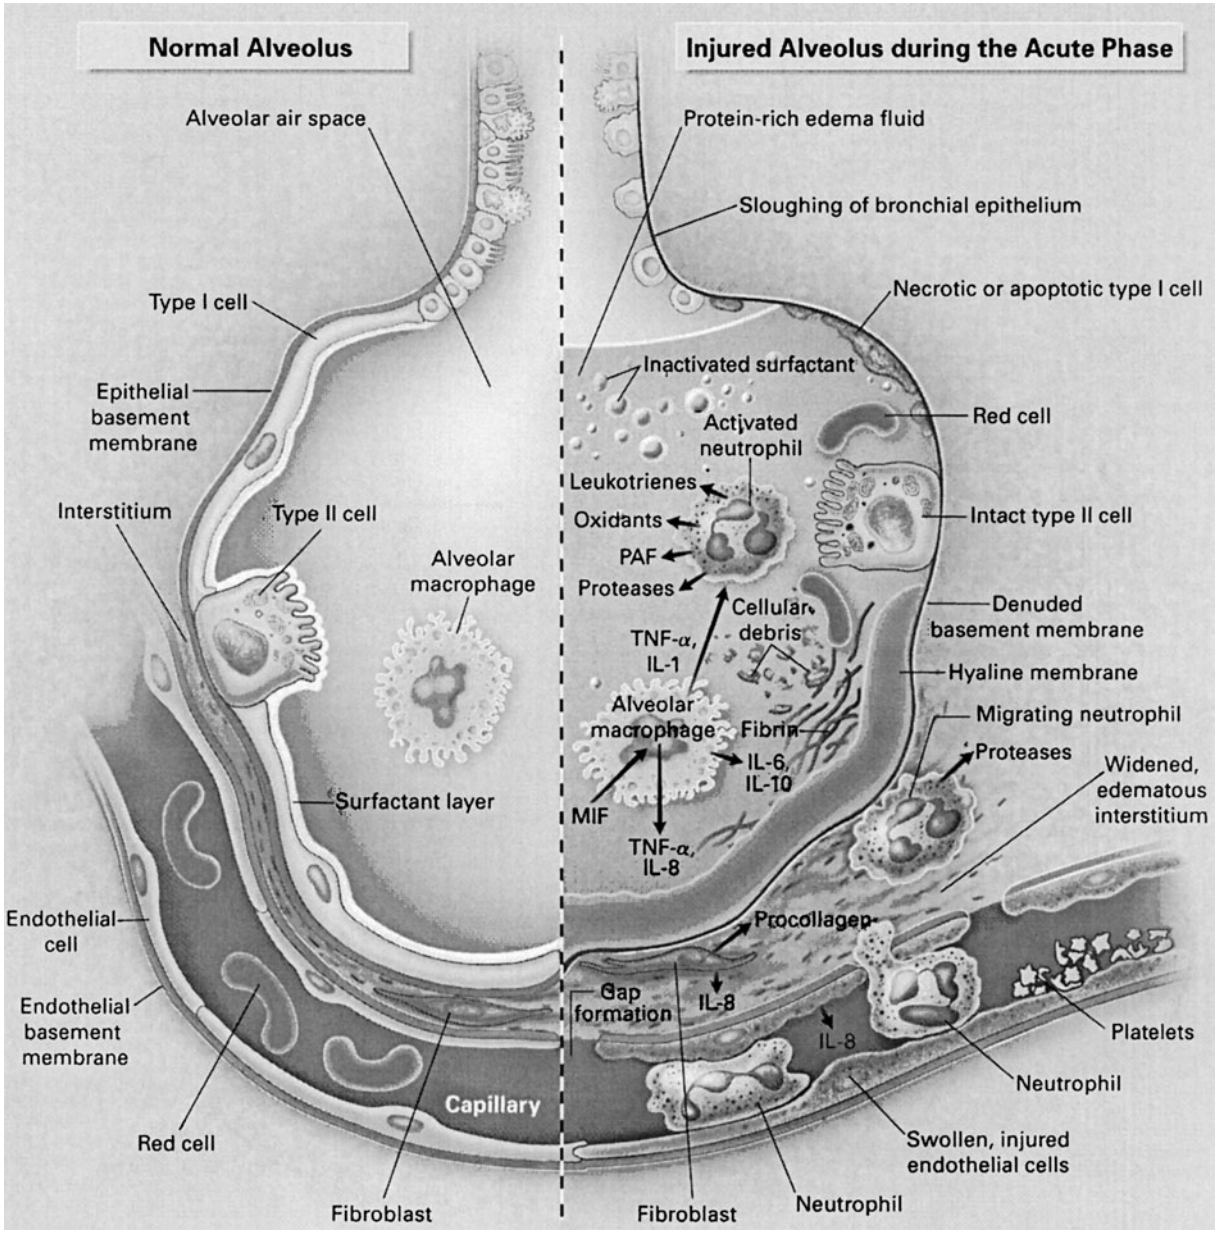


FIGURE 38-4 Schematic representation of the alveolus under normal conditions (*left-hand side*) and during development of acute lung injury (ALI) and the acute respiratory distress syndrome (ARDS) (*right-hand side*). In the acute phase of the syndrome (*right-hand side*), there is sloughing of both the bronchial and alveolar epithelial cells, with the formation of protein-rich hyaline membranes on the denuded basement membrane. Neutrophils are shown adhering to the injured capillary endothelium and marginating through the interstitium into the air space, which is filled with protein-rich edema fluid. In the air space, an alveolar macrophage is secreting cytokines such as interleukins-1, -6, -8, and -10, (IL-1, 6, 8, and 10), and tumor necrosis factor-α (TNF-α), which act locally to stimulate chemotaxis and activate neutrophils. Macrophages also secrete other cytokines, including interleukins-1, -6, and -10. Interleukin-1 can also stimulate the production of extracellular matrix by fibroblasts. Neutrophils can release oxidants, proteases, leukotrienes, and other proinflammatory molecules, such as platelet-activating factor (PAF). A number of anti-inflammatory mediators are also present in the alveolar milieu, including interleukin-1–receptor antagonist, soluble tumor necrosis factor receptor, autoantibodies against interleukin-8, and cytokines such as interleukins-10 and -11 (not shown). The influx of protein-rich edema fluid into the alveolus has led to the inactivation of surfactant. MIF denotes macrophage inhibitory factor. (*Reproduced with permission from Ware et al.*[36])

but persistently high levels of TNF-α and IL-1 in plasma and in BAL have also been associated with an increased risk of death in patients with ALI and ARDS.[61,78]

In addition to IL-1 and TNF-α, *interleukin-6* (IL-6) has been suggested as an important mediator of lung injury. IL-6, a product of macrophages that have been stimulated by TNF-α and IL-1, has diverse functions. In mediating acute lung injury, IL-6 has traditionally been viewed as a proinflammatory cytokine. This view is based largely on the clinical observations of elevated levels in sepsis and ARDS.[79,80] However, laboratory experiments indicate that IL-6 may also have anti-inflammatory effects.[81]

Like TNF-α and IL-1, persistently elevated IL-6 levels have been associated with an increased risk of death in ARDS patients.[78] In addition, in the ARDSNet randomized clinical trial (RCT) that compared lower- and higher-tidal-volume ventilatory strategies, the lung protective treatment arm that had decreased mortality showed a significantly steeper fall in IL-6 levels over the first 72 hours compared to the higher-tidal-volume arm.[3] In a separate RCT comparing low-tidal-volume versus traditional-tidal-volume ventilation in early ARDS, the former had lower concentrations of inflammatory mediators (TNF-α, IL-1, and IL-6) in BAL fluid and plasma over the first 36 hours of the trial.[82] Thus although the exact mechanisms of IL-6 in mediating acute lung injury are uncertain, it may have an important role in clinical ALI and ARDS.

Interleukin-10 (IL-10) is a potent anti-inflammatory cytokine produced by monocytes as well as by both T and B lymphocytes. IL-10 is a potent inhibitor of proinflammatory molecules including TNF-α and IL-1.[83] Lower levels of IL-10 in blood and lung lavage fluid have been association with development of ARDS.[77,84,85] Furthermore, lower circulating levels of IL-10 have been associated with death in patients with established ARDS.[86]

Chemokines are small polypeptides that certain cells elaborate in response to a variety of proinflammatory mediators. Chemokines act locally on modulating leukocyte immune response. The most studied chemokine in ARDS is *interleukin-8* (IL-8), which has been implicated in neutrophil chemotaxis. In a variety of lung injury models, blockage of IL-8 with directed antibodies has led to attenuation of the injury.[87–89] IL-8 has also been associated with greater numbers of neutrophils in BAL fluid of patients with ARDS as well as with mortality.[61,90–92]

Given the interrelationship and overlapping regulatory mechanisms of cytokine and chemokine molecules, future studies will need to focus on cytokine and chemokine imbalances, (i.e., their interactions with antagonist molecules and soluble receptors), as well as time-dependent differences. Finally, many studies have measured cytokine concentrations, whereas given the existence of inactivating molecules, measuring biological activity may be more productive.

NEUTROPHILS AND OXIDANT STRESS

Neutrophil migration into the airspaces is evident in the early histopathology of ARDS.[93,94] BAL fluid of subjects with ARDS reveals a predominance of neutrophils.[95] Conversely, recovery is associated with resolution of neutrophilia.[96] Normally, neutrophils become apoptotic and are then removed by macrophages. Recent evidence suggests that impaired neutrophil apoptosis may be an important mechanism in early ARDS,[97] and that elevated levels of granulocyte-macrophage colony-stimulating factor (GM-CSF) may play a role in this mechanism.[98–100]

Neutrophils in the alveolar and interstitial spaces may result in lung injury due to neutrophil-mediated release of reactive oxidant species (ROS) and resulting oxidant stress. Oxidant stress refers to an imbalance between endogenously produced oxidants and endogenous antioxidants. Products of oxidant stress include superoxide, hydroxyl radicals, and peroxynitrite.[101] Although some levels of ROS may be important in normal homeostasis, ROS are highly unstable and react quickly with surrounding proteins, DNA, and lipids, resulting in molecular damage.[101]

A widely held hypothesis is that excessive oxidant stress is a major early contributor in the pathogenesis of acute lung injury.[102–109] ROS can be generated by neutrophils (polymorphonuclear [PMN] cells),[102,104,110] or by the pulmonary endothelium.[111,112] Both PMN-mediated and endothelial generation of ROS may be important to initiation and development of lung injury.

Evidence from clinical studies supporting excess ROS in ALI and ARDS include findings of: increased hydrogen peroxide in exhaled breath of ARDS patients;[113,114] decreased levels of glutathione in lung lavage fluids of ARDS patients;[115,116] increased nitrotyrosine and chlorotyrosine in lavage fluids of ARDS patients;[117] increased lipid peroxidation products in plasma;[118,119] increased protein carbonyl levels;[120] increased plasma hypoxanthine;[121] increased levels of nitrated fibrinogen in the plasma of ALI/ARDS patients;[122] and increased serum ferritin levels in ARDS patients compared with at-risk patients.[123,124] Although some of these findings may be nonspecific for ARDS,[58] taken together, they make a strong case for the role of oxidant stress in the pathogenesis of ARDS. In addition, evidence of higher levels of oxidant stress in nonsurvivors of ARDS is illustrated by lower levels of plasma thiol groups,[125] and higher levels of hydrogen peroxide in urine of ARDS patients who are nonsurvivors.[126]

COAGULATION AND FIBRINOLYSIS

As noted above, the histopathology of the early exudative phase of ALI and ARDS is notable for diffuse alveolar fibrin deposition in the form of hyaline membranes (see Fig. 38-3).[55,56,94,127,128] In addition, a shift in the procoagulant and anticoagulant balance to favor coagulation has been demonstrated in the BAL fluid of patients with ARDS.[129–133] Furthermore, there are likely important links between the coagulation system activation and activation of the inflammatory system. For example, TNF-α and IL-1 can act synergistically to produce a procoagulant state through effects on tissue factor, thrombomodulin, and plasminogen activator inhibitor.[134–136] Given the success of intravenous activated protein C in treating sepsis (see Chap. 46),[137] as well as the observation that the mortality benefit in this trial was also evident in subjects with severe sepsis and pulmonary dysfunction as a single organ system dysfunction,[138] interventions aimed at correcting abnormalities in coagulation and fibrinolysis in ALI and ARDS are a promising future research direction.

ALVEOLAR EDEMA CLEARANCE

Considerable evidence supports the active transport of sodium and water by the pulmonary epithelium from the distal airspaces of the lung.[139] This process appears to be regulated by epithelial sodium channels predominantly on alveolar type I cells, potentially stimulated by catecholamines.[140,141] In addition, recent evidence suggests a potential role for the cystic fibrosis transmembrane conductance regulator (CFTR) in alveolar fluid transport.[142] Furthermore, the directional flow of fluid across the alveolus may be altered in conditions of hypoxia,[143,144] as well as by reactive nitrogen and oxygen species.[145]

In ALI and ARDS, the pulmonary epithelium is injured, resulting in altered fluid transport. Clinical studies in ventilated patients have illustrated impaired fluid transport in ARDS when compared with hydrostatic pulmonary edema.[36,146,147] In addition, subjects who could rapidly remove alveolar fluid had a lower hospital mortality.[147,148] Whether these findings are simply a result of disruption of the alveolar epithelium, or whether they represent a finding potentially amenable to therapy (such as with β-adrenergic receptor agonists), awaits the results of interventional clinical trials.

FIBROPROLIFERATION AND REPAIR MECHANISMS

Although there is considerable temporal overlap with the exudative and inflammatory phases (see Fig. 38-3), the late phase of ARDS is characterized by accumulation of matrix and cells in the interstitial and alveolar spaces, contributing to disruption of the alveolar architecture.[55,56] Recovery from ARDS requires resolution of this phase of the tissue injury–repair spectrum with some degree of the normal lung architecture. Clinical studies of ARDS patients indicate that the alveolus is repaired under conditions of ongoing inflammation.[61] In addition, soluble collagen precursor, type III procollagen peptide (PCP III), in the edema fluid of early ARDS can differentiate between subjects who will have longer or shorter courses of ARDS.[149] This suggests that fibroproliferation begins early in the course of lung injury. In addition to these findings with PCP III, other evidence of the prognostic significance of fibroproliferation in ARDS includes the finding that fibroblast mitogenic activity in BAL fluid is lower in survivors of ARDS than nonsurvivors.[150,151]

A complex balance of different growth factors, cytokines, and chemokines occurs in the fibroproliferative and reparative phases of acute lung injury.[58,152] A variety of animal, basic, and clinical studies have demonstrated the importance of transforming growth factor-β (TGF-β) to fibroproliferation in the lung.[153,154] A key step in fibroproliferation involves the activation of TGF-β from its latent form. This can be accomplished through interaction with a variety of mediators, including matrix metalloproteinases (MMPs), thrombospondin, plasmin, acid environments, α_2-macroglobulin, and reactive oxygen species.[153] In addition, TGF-β has extensive interactions with inflammatory cytokines, chemokines, and interferon-γ in regulating fibrosis.

Other important modulators of the remodeling process include matrix and cell surface proteoglycans and glycosaminoglycans;[155–157] matricellular proteins that affect cell adhesion;[158,159] matrix metalloproteases;[160] and the balance of coagulation and fibrinolysis (particularly through the actions of plasminogen activator inhibitor-1 [PAI-1]).[129] The interplay of these mediators with the potential for targeted therapies is the focus of current investigations.

Approach to Diagnosis of ALI and ARDS

CLINICAL PRESENTATION AND DIFFERENTIAL DIAGNOSIS

Acute hypoxemic respiratory failure has many etiologies besides ALI and ARDS (Table 38-3). However, the bedside appearance of patients with various forms of AHRF is remarkably similar. Marked tachypnea and dyspnea are invariably present. Physical examination reveals diffuse crackles in cases of cardiogenic pulmonary edema and focal findings of consolidation in cases of lobar pneumonia. Cardiogenic pulmonary edema may be accompanied by evidence of airflow obstruction, including wheezing and hypercapnia.[161] The presence of crackles, a radiologic appearance of high-pressure edema (see below), and hypoxemia refractory to oxygen therapy, all suggest cardiogenic pulmonary edema as the primary process. Cough and purulent sputum are hallmarks of infectious processes, while copious clear or pink-colored airway secretions result from fulminant ("flash") cardiogenic pulmonary edema.

TABLE 38-3 Differential Diagnosis of Acute Hypoxemic Respiratory Failure (AHRF)

- ALI or ARDS
- Acute (or "flash") cardiogenic pulmonary edema
- Bilateral aspiration pneumonia
- Lobar atelectasis of both lower lobes
- Severe unilateral lower lobe atelectasis, especially when patient is receiving vasodilators, such as intravenous nitrates, calcium channel blockers, or sodium nitroprusside, that blunt hypoxic vasoconstriction
- Acute loss of ventilation to one lung due to complete or near-complete obstruction of its main stem bronchus (e.g., due to a mucous plug or blood clot)
- Loss of ventilation to one or both lungs due to large pneumothorax/pneumothoraces
- Loss of ventilation to one or both lungs due to large pleural effusion(s)
- Diffuse alveolar hemorrhage, especially in patients post–bone marrow transplantation
- Massive pulmonary embolus
- Acute opening of a patent foramen ovale in patients with pre-existing pulmonary hypertension

ALI, acute lung injury; ARDS, acute respiratory distress syndrome.
SOURCE: Reprinted with permission from Christie JD, Schmidt G, Lanken PN: Acute respiratory distress syndrome. http://pier.acponline.org/physicians/diseases/d349/d349.html. Physicians' Information and Education Resource. Philadelphia, American College of Physicians, July 2004.

Distressed patients with AHRF typically have initial room air arterial blood gas results with Pa_{O_2} in the 30 to 55 mm Hg range and pulse oximetry less than 85% of arterial O_2 saturation. If supplemental oxygen by mask or cannula raises arterial saturation to above 95%, a large intrapulmonary shunt is unlikely. Other causes of respiratory distress should then be considered, including airways disease, pulmonary embolus, or severe metabolic acidosis. Failure to achieve >95% saturation of arterial blood with supplemental oxygen indicates the presence of a large right-to-left shunt. The specific process should be investigated via physical examination and chest radiograph. In the rare instances that the chest radiograph is entirely clear of alveolar infiltrates, one should consider that the blood gas data are erroneous, that there is an anatomic right-to-left shunt at another site (e.g., pulmonary arteriovenous malformations or intracardiac shunt), or that there is continued perfusion of an unventilated lung due to recent complete or nearly complete occlusion of its main bronchus (but before the lung has collapsed due to absorption atelectasis) (see Table 38-3).

The differential diagnosis of ALI and ARDS (i.e., AHRF with diffuse pulmonary infiltrates consistent with pulmonary edema in the absence of a cardiac etiology) includes a variety of disorders and etiologies. Identifying the etiologies of the

diffuse infiltrates is important because specific treatments exist for several of these conditions (e.g., acute eosinophilic pneumonia or diffuse alveolar hemorrhage). Table 38-4 lists the major clinical and diagnostic characteristics of these disorders.

CLINICAL SETTING

The clinical setting in which the disorder develops can provide important diagnostic information. *Cardiogenic edema* is most often accompanied by systolic left ventricular or valvular dysfunction, and the abnormal heart sounds and murmurs

TABLE 38-4 Differential Diagnosis of Acute Lung Injury (ALI) and Acute Respiratory Distress Syndrome (ARDS)

Disorder	Characteristics	Comments
Pulmonary edema due to left heart failure	History of cardiac disease, enlarged heart on chest radiograph, third heart sound (S_3)	Rapid improvement with diuresis and/or afterload reduction
Noncardiogenic pulmonary edema	History of one or more precipitating causes (see Table 38-2), crackles absent or not prominent, normal cardiac size on chest radiograph	Usual etiology for ALI and ARDS: rarely some patients with ALI or ARDS have no obvious precipitating cause
Diffuse alveolar hemorrhage (DAH)	Often associated with autoimmune diseases (e.g., vasculitis) or following bone marrow transplantation; often patients do not have bloody sputum; renal disease or other evidence of systemic vasculitis may be present; hemosiderin-laden macrophages in bronchoalveolar lavage (BAL) fluid can confirm diagnosis of DAH; may respond to apheresis, corticosteroids, or cyclophosphamide, depending on etiology	May meet diagnostic criteria for ARDS, but has different pathophysiology and management
Acute eosinophilic pneumonia	Cough, fever, pleuritic chest pain, and myalgia are often present; patients often do not have peripheral blood eosinophilia, but generally have >15% eosinophils in BAL fluid; usually responds rapidly to high-dose corticosteroid therapy	May meet diagnostic criteria for ARDS, but has different pathophysiology and management
Lupus pneumonitis	Usually associated with active lupus; may respond to high-dose corticosteroid therapy or cyclophosphamide	May meet diagnostic criteria for ARDS, but has different pathophysiology and management
Acute interstitial pneumonia (AIP)	Slower onset than ARDS (over 4–6 weeks) with progressive course; however, it may present in an advanced state, mimicking ARDS	Associated with >90% mortality; AIP includes Hamman-Rich syndrome
Pulmonary alveolar proteinosis (PAP)	Slower onset than ARDS (over 2–12 months) with progressive course; can be treated with whole lung lavage	Characteristic "crazy paving" pattern on high-resolution computed tomography scan
Bronchiolitis obliterans-organizing pneumonia (BOOP) or cryptogenic organizing pneumonia	May be precipitated by viral syndrome; slower onset than ARDS (over >2 weeks) with progressive course; however, it may present in an advanced state, mimicking ARDS; may respond to high-dose corticosteroid therapy	
Hypersensitivity pneumonitis	Typically slower onset than ARDS (over weeks) with progressive course; however it may present in an advanced state, mimicking ARDS; may respond to high-dose corticosteroid therapy and removal from offending agent	
Leukemic infiltration	May be rapid in onset during active disease states; usually leukemia is clinically apparent	
Drug-induced pulmonary edema and pneumonitis	May follow use of heroin, other opioids, overdose of aspirin, tricyclic antidepressants, or exposure to paraquat	May progress to overt ARDS
Acute major pulmonary embolus (PE)	Occurs acutely, occasionally accompanied by severe hypoxemia that may be resistant to O_2 therapy like ARDS, and by hypotension, requiring pressors, mimicking ARDS with sepsis; patients typically have risk factors for acute PE and may not have common precipitating causes of ARDS	Chest radiograph in ARDS should have bilateral infiltrates consistent with pulmonary edema; chest radiograph in acute major PE may have unilateral or no infiltrates; acute major PE needs a confirmatory study (e.g., pulmonary angiogram)
Sarcoidosis	The onset is not acute, but its clinical recognition may be; oxygenation is often impaired and the chest radiograph can be diffusely abnormal	Historical features and the frequent presence of hilar adenopathy in sarcoidosis usually eliminate confusion with ARDS
Interstitial pulmonary fibrosis	The onset is not acute, but its clinical recognition may be; oxygenation is often impaired and the chest radiograph can be diffusely abnormal	Prior chest radiographs and a history of chronic and progressive dyspnea characterize the collection of diseases causing interstitial pulmonary fibrosis

SOURCE: Reprinted with permission from Christie JD, Schmidt G, Lanken PN: Acute respiratory distress syndrome. http://pier.acponline.org/physicians/diseases/d349/d349.html. Physicians' Information and Education Resource. Philadelphia, American College of Physicians, July 2004.

associated with each should be sought. Electrocardiographic (ECG) and serum enzyme evidence of ischemia should be considered and suggest an obvious cause for cardiogenic edema. Review of intravascular volume administration often will supply information suggesting the explanation for pulmonary edema in patients with left ventricular or renal dysfunction.

ALI and ARDS commonly arise in a typical clinical context (see Table 38-2). Sepsis, pneumonia, trauma, transfusion of blood products, and acid aspiration account for the majority of cases of ALI and ARDS.[3,4,13,36] Less common causes include pancreatitis, near-drowning, leukoagglutination reactions, lung infections with viral agents or *Pneumocystis carinii*, fat embolism syndrome, and drug toxicities.[34]

CHEST RADIOGRAPH

The chest radiograph is a simple and widely available test used to assess patients with AHRF. Unfortunately, the accuracy of the routine radiograph in distinguishing hydrostatic from increased permeability edema is not high.[162,163] Criteria that have been suggested to support a diagnosis of hydrostatic edema include increased heart size, increased width of the vascular pedicle, vascular redistribution toward upper lobes, septal lines, and a centrifugal pattern of spread with a perihilar bat's-wing distribution of the edema. The lack of these findings and patchy peripheral infiltrates that extend to the lateral lung margins suggest ARDS. However, all these signs overlap, and in the best of hands this test is unlikely to yield better than a 60% to 80% accuracy of diagnosis when applied without other diagnostic tools.[162]

ECHOCARDIOGRAPHY

Echocardiography is a useful source of noninvasive information regarding cardiovascular function.[164,165] Left ventricular dilatation, regional or global wall motion abnormalities, and substantial mitral regurgitation on Doppler imaging support a diagnosis of cardiogenic edema. A heart with echocardiographically normal dimensions and function (both systolic and diastolic) in a patient with pulmonary edema suggests pulmonary vascular leakage, although prior ventricular or valvular dysfunction with intercurrent resolution of the high pulmonary vascular pressures predisposing to cardiogenic edema must be kept in mind.

RIGHT HEART CATHETERIZATION

Right heart catheterization is often performed in patients with pulmonary edema, although the benefits of this invasive procedure continue to be debated;[166–168] it has even been suggested that this technology itself contributes to a poor patient outcome.[169,170] An observational study suggested that routine right heart catheterization was harmful, with a 33% increased risk of death if used in seriously ill patients with acute hypoxemic respiratory failure.[169] In addition, several investigations have demonstrated that physician understanding of and facility with the information generated are remarkably poor.[169,171] Thus until results of the current NIH NHLBI ARDSNet clinical trial that is testing the safety and efficacy of pulmonary artery catheters versus central venous catheters in patients with ALI and ARDS are available, right heart catheterization cannot be recommended as a routine procedure in patients with ALI/ARDS.

However, it is recommended that clinicians use invasive hemodynamic methods, including right heart catheterization, to address specific questions regarding ventricular function, the adequacy of volume resuscitation, the degree of intrapulmonary shunt, and the adequacy of cardiac output and oxygen saturation of mixed venous or central venous blood. The specific pulmonary capillary wedge pressure (Ppw) that the AECC definition (see Table 38-1) used as the criterion to distinguish noncardiogenic from cardiogenic pulmonary edema (i.e., 18 mm Hg), was an arbitrary decision based on physiologic experiments, tradition, and volume resuscitation practices circa 1992. Since then, reports have indicated that some patients who originally met criteria for ALI or ARDS as listed in Table 38-1, but who have been volume loaded to increase their cardiac output, have periods when measurements of their Ppw are above 18 mm Hg.[21] In the mechanically ventilated patient with normal lung function and serum oncotic pressure, cardiogenic edema is typically associated with a Ppw of 28 mm Hg or above.[172] However, lower plasma oncotic pressure (e.g., due to hypoalbuminemia) will result in pulmonary edema at somewhat lower values of Ppw.[173] Finally, caution should be used when trying to rule in cardiogenic pulmonary edema by simply measuring the Ppw after a bout of acute pulmonary edema, since such patients often have Ppw less than 18 mm Hg by the time the catheter has been passed.[22]

BRONCHOALVEOLAR LAVAGE

Acute eosinophilic pneumonia is a rare disorder that is characterized by diffuse AHRF due to eosinophilic infiltrates in the lungs.[174–176] It is notable for its responsiveness to corticosteroid therapy. When the precipitating cause for ARDS is unclear, it is recommended to perform a bronchoalveolar lavage and measure the percentage of eosinophils in the lavage fluid.[174] Lavages can generally be done safely in many patients with ALI and ARDS except those with the lowest values of Pa_{O_2}: $F_{I_{O_2}}$ or hemodynamic instability.[177,178]

Likewise, a bedside bronchoscopy with BAL can be diagnostic for diffuse alveolar hemorrhage (DAH). In this case, the bronchoscopy may or may not reveal fresh blood in the trachea and major bronchi. However, BAL generally produces a bloody return, which may deepen in red color as the lavage continues. DAH occurs commonly in the first week or two post–bone marrow transplantation.[179,180] DAH also occurs in association with a variety of vasculitic disorders. These include Goodpasture's syndrome, Wegener's granulomatosis, systemic lupus erythematosus, and antiphospholipid antibody syndrome (see Chap. 104).[181–186] Finally, DAH also may result from inhalation of crack cocaine.[181] For this cause of DAH, careful history taking and sending the patient's urine for toxicology analysis for cocaine may help determine the etiology.

Approach to Treatment of Patients with ALI and ARDS

TREAT THE PRECIPITATING CAUSE OF ALI AND ARDS AND OTHER SERIOUS COMORBIDITIES

A key early step in treating patients with ALI and ARDS is to identify and treat the precipitating cause or causes of the ALI and ARDS as well as any other serious and life-threatening

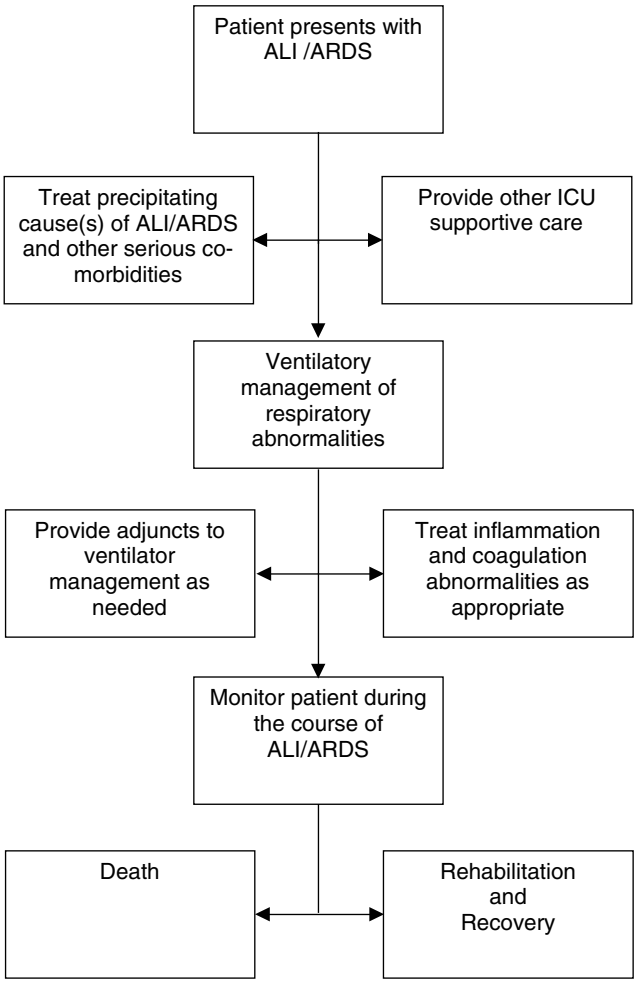

FIGURE 38-5 Schematic summary of approach to treatment of patients with ALI and ARDS. Note that the box, "Treat inflammation and coagulation abnormalities as appropriate," is currently limited to high-dose steroid therapy for late-phase ARDS (see text for details).

comorbidities (Fig. 38-5). The ventilatory and other supportive management of ALI and ARDS is inadequate if not accompanied by aggressive attempts at diagnosis and treatment of the precipitating cause(s) (Table 38-2). *Because ARDS is a syndrome based on nonspecific radiographic and physiologic criteria (Table 38-1), making the diagnosis of ALI or ARDS is* ***not*** *equivalent to diagnosing the patient's underlying problem.* Not appreciating this seemingly obvious fact will delay diagnostic procedures in these patients and may delay therapy of a potentially treatable underlying disorder (Table 38-5).

For example, although appropriate supportive therapy may transiently stabilize a patient with ARDS due to sepsis from an abdominal abscess, if clinicians delay performing diagnostic tests such as abdominal CT scan or ultrasonography of the biliary tract in a timely manner, the underlying source of sepsis will go undiagnosed and the patient will eventually deteriorate. Likewise, the timely start of empiric antimicrobial therapy in patients with ALI or ARDS associated with severe sepsis or septic shock is as important as a timely diagnostic work-up (see Chaps. 45 and 46). Finally, if the precipitating cause of ALI and ARDS is unclear, one should consider performing early fiberoptic bronchoscopy to obtain bronchial washings for cytologic and microbiologic analyses, or in selected cases, surgical lung biopsy.

TABLE 38-5 Treatable Precipitating Causes of Acute Lung Injury (ALI) and Acute Respiratory Distress Syndrome (ARDS)

Infectious etiologies
Bacterial or other sepsis responsive to antimicrobial therapy
Diffuse bacterial pneumonias (e.g., *Legionella* species)
Diffuse viral pneumonias (e.g., cytomegalovirus, influenza A)
Diffuse fungal pneumonias (e.g., *Candida* and *Cryptococcus* species)
Pneumocystis carinii pneumonia
Other diffuse lung infections (e.g., miliary tuberculosis)
Noninfectious etiologies
Diffuse alveolar hemorrhage post–bone marrow transplant
Diffuse alveolar hemorrhage due to vasculitis (e.g., Goodpasture's syndrome)
Acute eosinophilic pneumonia
Lupus pneumonitis
Toxic drug reactions (e.g., aspirin)

VENTILATOR MANAGEMENT OF RESPIRATORY ABNORMALITIES

MAINTAINING ADEQUATE ARTERIAL OXYGENATION

The hallmark respiratory abnormality of ALI and ARDS is hypoxemia that is resistant to oxygen therapy. This is due to the presence of a large right-to-left intrapulmonary shunt arising from fluid-filled and collapsed alveoli (see Fig. 38-1). Maintaining adequate arterial oxygenation is a goal given high priority by both traditional and more recent approaches to ventilator management, as noted below. One should use sufficient PEEP to reduce the right-to-left shunt to oxygenate the patient. By this approach, clinicians should be able to avoid prolonged exposure of such patients to potentially toxic concentrations of high inspired oxygen (e.g., $F_{I_{O_2}}$ of 0.7 and above).

PEEP improves arterial oxygenation, primarily by recruiting collapsed and partially fluid-filled alveoli and thereby increasing the functional residual capacity (FRC) at end-expiration.[187,188] PEEP also redistributes alveolar fluid into the interstitium,[189] which should also improve oxygenation.

NONINVASIVE VENTILATION

Assisted ventilation is generally done invasively via an endotracheal tube, but in selected cases noninvasive ventilation (NIV) may be successful[190,191] (see Chap. 33). Although NIV seems to be useful in respiratory failure in immunocompromised hosts,[190] we believe it is generally not a good choice for most patients with ALI and ARDS. This is because ARDS typically has a long course and is often associated with hemodynamic instability, coma, and multiorgan system failure (including ileus).[192]

COMPARISON OF TRADITIONAL AND CURRENT APPROACHES TO VENTILATOR MANAGEMENT

Goals and Priorities of the Traditional Approach

The traditional approach to ventilator management of patients with ALI and ARDS gave high priority to these goals: (1) to maintain arterial O_2 saturation (O_2sat) above 88% to 90% to provide for adequate tissue oxygenation while

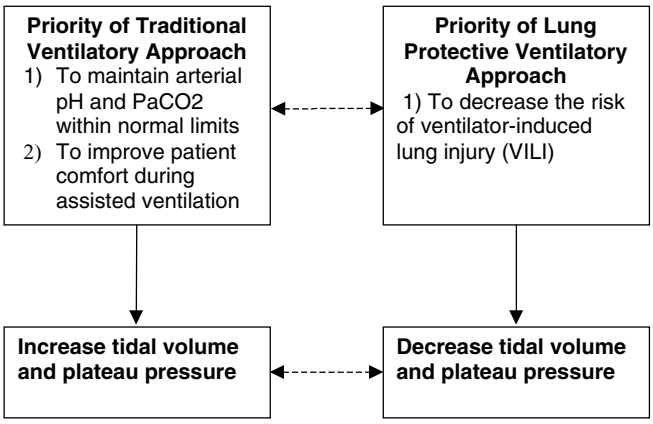

FIGURE 38-6 Schematic illustration that demonstrates how traditional and lung-protective approaches to mechanical ventilation of patients with ALI or ARDS have different priorities. The traditional approach gives higher priority to keeping arterial pH and Pa_{CO_2} normal (and possibly to keeping the patient more comfortable) than the lung-protective approach, which gives higher priority to prevention of ventilator-induced lung injury (VILI). Plateau pressure = static end-inspiratory pressure in the alveoli.

trying to minimize lung injury due to high concentrations of inspired oxygen (oxygen toxicity); (2) to provide sufficient ventilation to keep arterial pH and Pa_{CO_2} within normal limits[193] (Fig. 38-6).

To achieve the first goal, clinicians applied various levels of PEEP. This use of PEEP was first described in the initial description of ARDS by Ashbaugh and coworkers in 1967.[10] Clinicians increased levels of PEEP in order to decrease F_{IO_2} to below 70% while monitoring for adverse circulatory effects of PEEP.[194] Since arterial oxygenation was found to be determined in part by mean airway pressure, they also used relatively large tidal volumes of 10 to 15 mL/kg. These were double to triple spontaneous tidal volumes, which are of the order of 5 mL/kg. Both the use of PEEP and traditional large tidal volumes (delivered at high flow rates) generally result in relatively high peak and end-inspiratory pressures (plateau pressure [Pplat]) in patients with ALI or ARDS, whose lungs typically have decreased compliance.

To achieve the second goal, clinicians ventilated patients with ALI and ARDS with relatively large tidal volumes of 10 to 15 mL/kg at high respiratory rates if needed. The resulting high minute ventilation was needed to produce a normal alveolar ventilation. This is because patients with ALI and ARDS typically have increased physiologic dead spaces and elevated dead space:tidal volume ratios (VDS:VT) (e.g., up to 75%).[195,196] In some cases, patients were exposed to high peak and end-inspiratory pressures due to the large tidal volumes in order to maintain normal arterial blood P_{CO_2} and pH. Clinicians also used large tidal volumes and high inspiratory flow rates as a supplement to sedation to decrease patient discomfort while receiving assisted ventilation.

For example, if a patient with ARDS had a normal CO_2 production (e.g., 200 mL/min), and a normal VDS:VT of 0.3, then a minute ventilation of ~7 L/min is needed to keep the patient's Pa_{CO_2} at 40 mm Hg.[197] However, when the patient's VDS:VT increases, then additional minute ventilation is needed to keep Pa_{CO_2} at 40 mm Hg. In this example, *14 L/min* of minute ventilation is needed if the VDS:VT is 0.66, and *18 L/min* is needed if the VDS:VT is 0.75,[197] both of which occur in patients with ARDS.[195,196] For a patient with a predicted (lean) body weight (PBW) of 60 kg, one can easily achieve a minute ventilation of 18 L/min with tidal volumes of 600 to 900 mL at rates of 20 to 30 per minute.

Goals and Priorities of Lung-Protective Approach

The lung-protective approach to ventilator management has the same goal for oxygenation as the traditional approach (i.e., to maintain an arterial saturation greater than 88% to 90%). However, it gives higher priority to protection from ventilator-induced lung injury (VILI) (see Chap. 37) than to normalization of arterial P_{CO_2} and pH.[193] The lung-protective approach's goal to decrease risk of VILI often conflicts with the traditional approach's goal to provide a high minute ventilation to keep arterial pH and P_{CO_2} within normal limits (see Fig. 38-6). This conflict arises since the current lung-protective approach reduces the risk of VILI by decreasing the size of the tidal volume from the traditional 10 to 15 mL/kg body weight to tidal volumes of 4 to 6 mL/kg predicted body weight (PBW). Even with respiratory rates up to 35/min, such low tidal volumes will limit the resultant minute ventilation. This may result in a degree of permissive hypercapnia in some patients with ALI and ARDS.

For example, for a 60-kg PBW patient, a tidal volume of 6 mL/kg PBW (360 mL) with a respiratory rate of 35/min produces a minute ventilation of only 12.6 L. If one needs to reduce the tidal volume for the same 60-kg PBW patient to 4 mL/kg PBW (240 mL), in order to keep the Pplat from exceeding the threshold of 30 cm H_2O, at the same respiratory rate of 35/min it provides only 8.4 L of minute ventilation. It is likely that a patient with ARDS ventilated with tidal volumes of 4 to 6 mL/kg PBW has a VDS:VT of 0.66 or greater. This is due to the combined effects of an increased physiologic dead space in ARDS[195,196] and the fact that ventilating with a lower tidal volume ventilation decreases the denominator of the patient's VDS:VT. If the patient had a VDS:VT of 0.66, low tidal volume ventilation, which provides 8.4 to 12.6 L/min, will result in permissive hypercapnia since, as described above, 14 L/min is needed to maintain this patient's Pa_{CO_2} at 40 mm Hg. For example, for a patient with a VDS:VT of 0.66, a minute ventilation of 12.6 L/min would result in a Pa_{CO_2} of ~45 mm Hg, while 8.4 L/min of minute ventilation would result in a Pa_{CO_2} of ~65 mm Hg.[197]

Decreasing the Risk of Ventilator-Induced Lung Injury

The important change in priority of the lung protective approach of ventilator management of patients with ALI and ARDS compared to the traditional approach is the result of a remarkable confluence of two lines of scientific research that culminated in a landmark confirmatory randomized controlled clinical trial[3] (Fig. 38-7). The first line of basic research initially studied effects of mechanical forces (high pressure or high volume or both) in animal models of lung injury and then extended these observations to isolated lungs in situ or in vitro, and eventually to isolated lung cells. The second line of research involved careful clinical observations of patients with ALI and ARDS that examined the effects of systematic

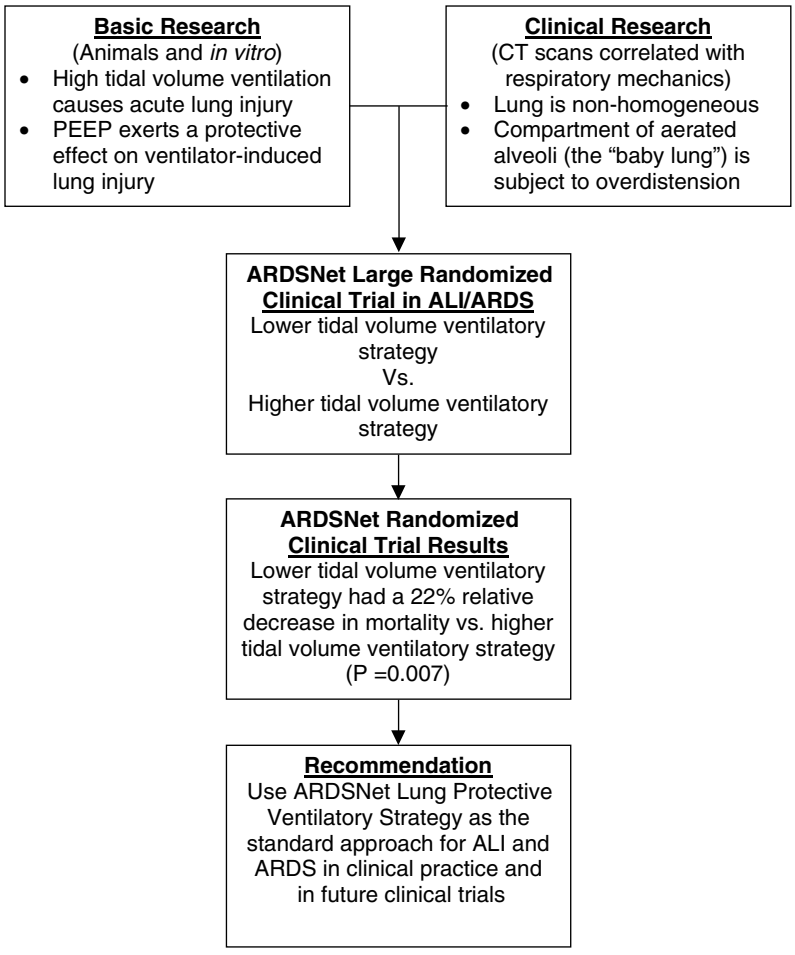

FIGURE 38-7 Schematic illustration of the confluence of basic and clinical research that resulted in a large randomized clinical trial by investigators in the NHLBI ARDS Clinical Trials Network (ARDSNet).[3] This trial showed that a lower-tidal-volume ventilatory strategy was superior to a traditional-tidal-volume ventilatory strategy. As such, it confirmed that the hypothesis of ventilator-induced lung injury was important in the augmentation of the lung injury in ALI and ARDS. It also established that a lung-protective ventilatory strategy should be generally used to treat patients with ALI and ARDS. Finally, until there is new evidence to suggest otherwise, the ARDSNet lung protective protocol is recommended as the standard approach in clinical practice and future clinical trials.

changes in selected ventilatory parameters with their physiologic effects and radiographic changes.[187]

BASIC RESEARCH RELATED TO VENTILATOR-INDUCED LUNG INJURY

Although Chap. 37 provides a more comprehensive description of this research, review of some of the early reports may prove useful since it specifically relates to this chapter's recommendations for ventilating patients with ALI and ARDS. In 1974 Webb and Tierney reported that mechanical ventilation using large tidal volumes and high inflation pressures could cause a fatal lung injury (similar morphologically to ARDS) in rats with otherwise normal lungs.[198] In 1985, Dreyfuss and colleagues[199] reproduced these experiments and carefully studied the changes that occurred within the lung. They observed that the injury that occurred was morphologically and pathophysiologically similar to ARDS and hypothesized that mechanical ventilation with large tidal volumes or high inflation pressures might exacerbate or perpetuate the lung injury in patients suffering from ARDS. Two major questions were raised by this early work: Did high inflation pressures or large tidal volume excursions cause the lung injury? Did positive end-expiratory pressure (PEEP) worsen or attenuate this injury?

Dreyfuss and associates[200] then designed a set of experiments to answer these questions. They studied animals with normal lungs subjected only to varied protocols of mechanical ventilation. Some were ventilated with high pressures and large tidal volumes. Others had chest banding to limit chest wall and lung excursion during ventilation at high airway pressures. Another group was subjected to negative-pressure ventilation to assess the effect of large tidal volume excursions in the absence of high airway pressures. PEEP (10 cm H_2O) was applied to the lungs of some animals undergoing high-pressure/large-tidal-volume ventilation. Finally, control animals were ventilated using parameters typical of conventional ventilation. These investigators found that large tidal volumes were associated with lung injury, but that high inflation pressure in the absence of large tidal volume excursion was not. Surprisingly, PEEP had the effect of limiting the injury that occurred in animals ventilated with large tidal volumes and high pressures. The application of PEEP not only preserved gas exchange, but also prevented the morphologic progression of the lesion caused by this pattern of ventilation. These observations have been verified in larger animals.[201–204] (see Chap. 37 for more details).

A summary of these and subsequent animal experiments indicated that: (1) high-tidal-volume ventilation results in a lung injury morphologically similar to ARDS in humans, (2) PEEP is protective to some degree against this injury, (3) high-tidal-volume ventilation also can result in multiorgan system failure in otherwise healthy animals,[205,206] and (4) high-tidal-volume ventilation results in the release of inflammatory cells and proinflammatory cytokines.[207,208]

Clinical Research Utilizing Lung Imaging

The second parallel line of research, noted above, studied patients with ARDS by use of CT scans (see Fig. 38-7). The initial observations indicated that despite a homogeneous "whiteout" pattern of diffuse pulmonary edema infiltrates on chest radiographs of patients with ALI and ARDS, the CT scans of the same patients often proved the infiltrates to have remarkable heterogeneity.[188,209] Based on strata of Hounsfield units to define different densities, the lung in ARDS could be partitioned into various compartments: nonaerated, poorly aerated, and normally aerated.[187] Moreover, these compartments could be tracked before and after PEEP was added or subtracted and before and after tidal volumes of different sizes were delivered to the lung.

The end result was a reconceptualization of the mechanical changes in the ARDS lung.[187] The traditional interpretation was that the stiffness of lungs in ARDS (e.g., low static compliances of 20 to 40 mL/cm H_2O) represented many alveoli with similarly low specific compliances (i.e., essentially a single compartment in terms of its mechanical properties). Instead, studies using the CT scans and their pathophysiologic correlations indicated that a more accurate picture is that the lung in ARDS is multicompartmental and that there is a small part of the ARDS lung that has relatively normal compliance. Gattinoni and coworkers coined the term "baby lung" when referring to this compartment and its vulnerability to overdistension.[187] In this revised conception of the acutely injured lung, some alveoli are normally compliant and vulnerable to overdistension while others are flooded or collapsed. The loss of functional alveoli necessitates that the tidal volume be distributed to far fewer aerated alveoli than in a healthy lung. Indeed, the apparent stiffness of the lungs of ARDS patients is regarded as the result of a small fraction of the lung containing relatively normal alveoli that becomes stiff as those alveoli reach their limits of distension, rather than due to generalized parenchymal "stiffness."

Based on the consistent results from the animal and in vitro studies referred to above and the insights provided by the results of the CT scans, it was hypothesized that traditional tidal volumes (e.g., 10 to 15 mL/kg) caused overdistension of alveoli in the lungs of patients with ALI and ARDS. This in turn not only resulted in exacerbation and perpetuation of their lung injury, but also, through the possible release of proinflammatory cytokines and other mechanisms, possibly contributed to the development and worsening of multiorgan system dysfunction and failure.

Intersection of Basic and Clinical Research

The intersection of these two lines of research, one basic and one clinical, resulted in two hypotheses of how patients with ALI and ARDS should be ventilated (see Fig. 38-7). First, the end-inspiratory lung volume should be limited to avoid alveolar overdistension (so-called "volutrauma") and second, sufficient PEEP should be applied so as to prevent cycles of end-expiratory derecruitment followed by inspiratory recruitment (Chap. 37 discusses the basis for both of these ventilatory recommendations in detail).

The next step was to test these hypotheses in prospective randomized controlled clinical trials (RCT) (see Fig. 38-7). Four large multicenter RCTs were conducted (Table 38-6). Three RCTs tested lower- vs. higher-tidal-volume strategies.[3,8,9] The fourth RCT tested a multifactorial lung-protective strategy (including lower tidal volume, higher PEEP based on static pressure-volume curves of the respiratory system, and recruitment maneuvers) against conventional ventilation.[7]

The strategies tested were based on interpretations of the static pressure-volume (P-V) curve of the respiratory system in ARDS (Fig. 38-8). The curve in Fig. 38-8 has a lower inflection point (LIP) and an upper inflection point (UIP). One of the RCTs used such curves, which were obtained by use of a super-syringe on paralyzed patients, to set PEEP above the LIP in the group receiving the lung protective strategy,[7] but examination of the schematicized curve in Fig. 38-8 can be useful for understanding the strategies for trying to prevent VILI used in all four of the RCTs.

It was hypothesized that the LIP indicated the point at which most of the collapsed or partially fluid-filled alveoli in the lung became recruited.[210,211] At pressures higher than the LIP these recruited alveoli exhibited near-normal specific compliance. It was also hypothesized that the UIP represented the point above which the ventilated alveoli in the lung were overdistended, with a resulting low specific compliance of aerated but overdistended alveoli. Based on such P-V curves, it was suggested that PEEP above LIP should prevent the recruitment-derecruitment cycles of alveoli, and

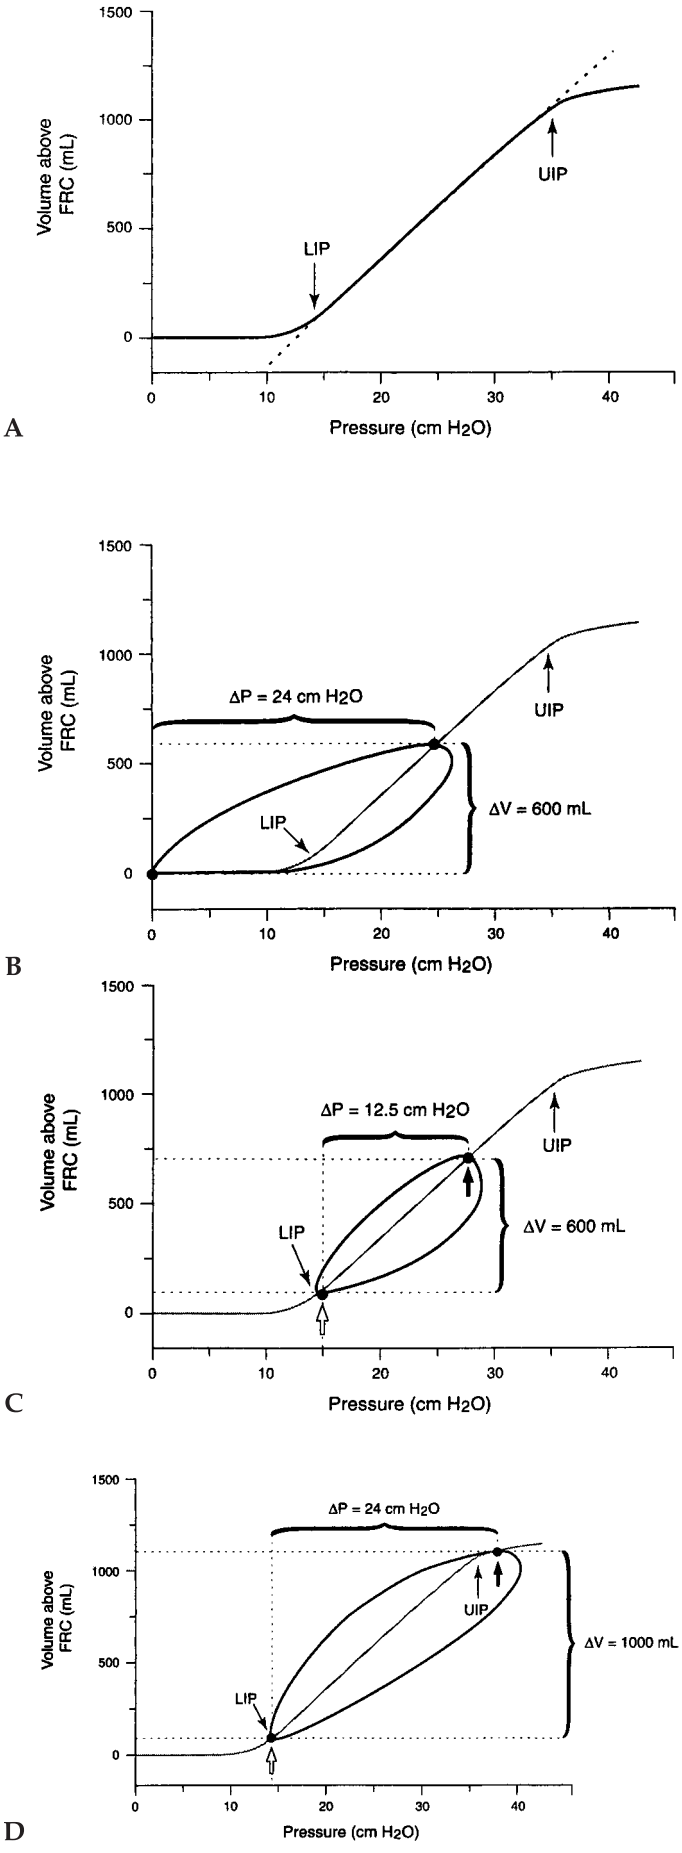

FIGURE 38-8 *A*. Schematic inspiratory static pressure-volume (P-V) curve of the respiratory system (lung and chest wall combined) in ARDS with a lower inflection point (LIP) at ~14 cm H_2O and an upper inflection point (UIP) at ~35 cm H_2O. The abscissa is recoil pressure of the respiratory system and the ordinate is lung volume above functional residual capacity (FRC). *B*. Same static P-V as in *A*, plus a dynamic P-V curve of 600 mL tidal volume starting at PEEP = 0, which is below the LIP. This tidal volume results in a plateau pressure of 25 cm H_2O, which is below the UIP. Static compliance (Cstat = $\Delta V/\Delta P$ = 600 mL/25 cm H_2O) is 24 mL/cm H_2O. *C*. PEEP of 15 cm H_2O has moved the starting point for the 600 mL tidal volume up the static P-V curve to a new FRC (*open arrow*), which is just above the LIP. The tidal volume results in a plateau pressure of 27.5 cm H_2O (*closed arrow*), which is well *below* the UIP. Cstat ($\Delta V/\Delta P$ = 600 mL/12.5 cm H_2O) is increased to 48 mL/cm H_2O, compared to *B*. *D*. Dynamic P-V curve of a 1000 mL tidal volume, starting at 14 cm H_2O PEEP, results in a plateau pressure of 38 cm H_2O (*closed arrow*). Note the decrease in Cstat ($\Delta V/\Delta P$ = 1000 mL/24 cm H_2O = 41.7 mL/cm H_2O) compared to Cstat derived from the tidal volume of 600 mL in *C*. The 1000 mL tidal volume's plateau pressure exceeds the UIP, which implies overdistension and is believed to put the lung at risk for ventilator-induced lung injury (see text). *(Reproduced with permission from Lanken PN: Acute respiratory distress syndrome, in Lanken PN, Hanson CW III, Manaker S (eds):* The Intensive Care Unit Manual. *Philadelphia, WB Saunders, 2001, p 824.)*

as such prevent the lung injury resulting from these cycles ("atelectrauma" [see Chap. 37]). Based on this interpretation, tidal volumes that resulted in end-inspiratory (plateau pressures) below the UIP should decrease alveolar overdistension and thus prevent VILI from this cause.

However, despite the attractiveness of this interpretation of the static pressure-volume curve, subsequent reports indicate that the situation is more complex and that recruitment of alveoli in experimental models and in patients with ALI and ARDS extends beyond the pressure at the LIP and continues over a wide range of airway pressures up to 45 cm H_2O.[212–214]

NHLBI ARDS Clinical Trials Network Low-Tidal-Volume Ventilatory Strategy Clinical Trial

The NHLBI ARDS Clinical Trials Network conducted the landmark RCT that investigated the use of lung-protective ventilation in patients with ALI and ARDS[3] This ARDSNet RCT compared a ventilator strategy with lower tidal volumes designed to limit stretch of the lungs during mechanical ventilation with a strategy that utilized traditional larger tidal volumes. The randomized clinical trial enrolled 861 patients at multiple centers. Briefly, one study arm received a tidal volume of 6 mL/kg PBW if the Pplat did not exceed 30 cm H_2O, and tidal volumes of 4 or 5 mL/kg PBW if Pplat did exceed 30 cm H_2O (see Table 38-9 for complete details of the protocol of this arm). The other arm received tidal volumes of 12 mL/kg PBW if the Pplat did not exceed 50 cm H_2O, and tidal volumes as low as 4 mL/kg PBW if the Pplat did exceed 50 cm H_2O. There was a 9% absolute mortality reduction (22% relative mortality reduction) in the group receiving the lower-tidal-volume ventilation strategy (see Table 38-6). This corresponds to a number needed to treat of ~11 patients in order to prevent one death. Importantly, plasma levels of IL-6 were lower among the 6-mL/kg group, as were the number of organ-failure-free days, indicating that the lower tidal volume strategy was associated with a faster clearance of IL-6, a proinflammatory cytokine, from the plasma, and less organ dysfunction.

This ARDSNet RCT differed from two prior, smaller studies that showed no apparent benefit to the lower-tidal-volume strategies[8,9] (see Table 38-6; Table 38-7). These differences may have been due to chance alone since the earlier studies were of limited sample size, with an associated lack of statistical power to detect this degree of difference in mortality. Other possible reasons for these differences include the fact that the ARDSNet RCT used smaller tidal volumes in the low-tidal-volume group than the others (see Table 38-7). In addition, the protocols differed in how they dealt with respiratory acidosis due to lower tidal volumes and permissive hypercapnia. Related to respiratory acidosis, the ARDSNet RCT protocol required increases in ventilator rate as the tidal volume was initially decreased, or if the pH fell below normal limits. In addition, bicarbonate infusions were allowed. In the other two earlier RCTs, similar respiratory rate increases were not mandated. Possibly as a result of these differences in protocols, there were smaller differences in Pa_{CO_2} and arterial pH between study groups in the ARDSNet RCT compared to the other two RCTs (see Table 38-7).

Although the ARDSNet RCT was subsequently criticized for its design in relying on strict ventilator protocols for the higher-tidal-volume group,[215–217] the ARDSnet lower-tidal-volume ventilatory strategy has become accepted as the standard for ventilator management of ALI-ARDS patients. This is based both on the results of the ARDSnet RCT, but also on the plethora of basic and clinical studies, as described above and in Chap. 37, relating to ventilator-induced lung injury that support its hypothetical mode of efficacy.

Using Higher Levels of PEEP to Decrease the Risk of VILI

There is controversy about whether higher-than-traditional levels of PEEP can decrease the risk of ventilator-induced lung injury in patients with ALI and ARDS. In addition, if

TABLE 38-7 Comparison of Pa_{CO_2}, Arterial pH, and Tidal Volume in Phase III Randomized Controlled Clinical Trials Using Lung-Protective Strategies

Authors	Group	Tidal Volume[a] on Study Day 1 (mL/kg)	Pa_{CO_2} (mm Hg)	Arterial pH
Amato et al[7]	Lower tidal volume	~6 mL/kg	55.0 ± 1.2[b]	7.25 ± 0.01[b]
Amato et al[7]	Higher tidal volume	~12 mL/kg	33.2 ± 1.7[b]	7.40 ± 0.01[b]
Brochard et al[8]	Lower tidal volume	7.1 ± 1.3	59.5 ± 15.0[c]	N/A

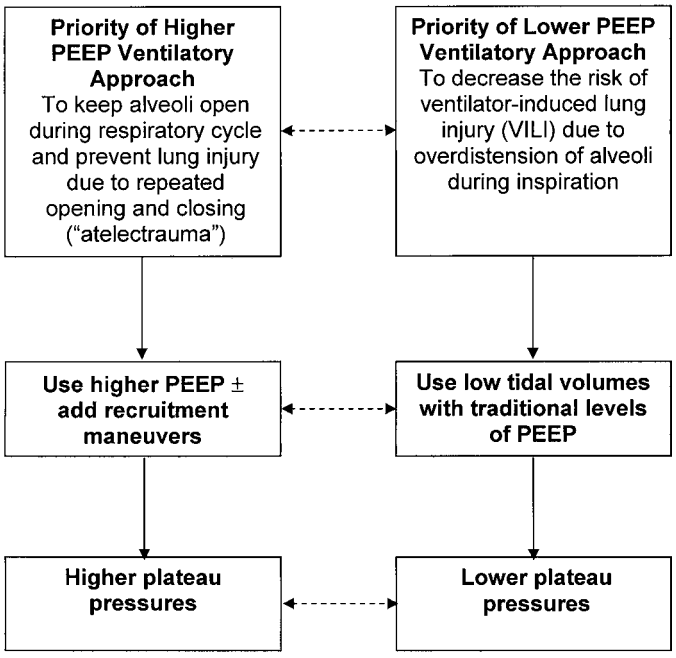

FIGURE 38-9 Schematic diagram illustrating the conflicting priorities of higher- and lower-PEEP ventilator approaches and their hypothetical associated effects. Studies that use a higher PEEP approach may combine the higher PEEP with recruitment maneuvers, which are sustained inflations (e.g., 35 to 40 cm H_2O of continuous positive airway pressure for 30 seconds or more[4,7]). For a given low tidal volume, using a higher PEEP will result in a higher plateau (end-inspiratory) pressure than using a lower PEEP. Hypothetically, this higher plateau pressure, which represents the static end-inspiratory distending pressure in open alveoli, may increase the risk of ventilator-induced lung injury due to overdistension (see text and Chap. 17 for details).

higher PEEP is effective against VILI, the question of what level of PEEP should be used clinically remains. When the pressure-volume relationship is measured in patients with ARDS, the lower inflection point (LIP) (see Fig. 38-8) is in the range of 8 to 15 cm H_2O.[7] In an earlier CT study of patients with ARDS,[211,218] the amount of reopening-collapsing tissue became insignificant only when PEEP reached 20 cm H_2O (although the greatest reduction was seen between 10 and 15 cm H_2O of PEEP).

However, as noted above, more recent animal and human studies have shown that the LIP is not the originally hypothesized simple threshold above which no further recruitment occurs. Instead, recruitment continues from below the LIP to inflation pressures of 45 cm H_2O.[212,213] In other words, there is a broad "inflection zone" from 0 to 45 cm H_2O over which there is progressive recruitment with progressively higher PEEP. The implication of these findings is that preventing cycles of recruitment and derecruitment in most of the alveoli necessitates that many open alveoli will be overdistended. Hence, prevention of injury to alveoli from cycles of recruitment-derecruitment will increase the risk of VILI from overdistention (see Figure 38-9).

Clinical Studies of Higher PEEP Ventilator Strategies

Proponents of a high-PEEP strategy (also called "open lung" strategy) were encouraged by a relatively small but statistically significant RCT performed by Amato and colleagues and published in 1998[7] (see Table 38-6). As noted above, in this RCT the group of subjects with ARDS in the "open lung" arm were treated by a combination of three interventions: (1) a low-tidal-volume ventilatory strategy, (2) higher-than-traditional levels of PEEP as dictated by the patient's LIP as described below, and (3) recruitment maneuvers. The control group of subjects was treated by a conventional ventilatory strategy for the participating ICUs, which did not include any of the three interventions of the open lung group and was not protocolized. In this study, the higher level of PEEP was determined by using a super-syringe to derive a static pressure-volume curve on paralyzed subjects at the start of the study. From inspection of the static pressure-volume curve, the LIP (see Fig. 38-8) was identified and the PEEP was set at 2 cm H_2O above the LIP. If a sharp LIP could not be determined on the pressure-volume curve, then the PEEP was set empirically at 16 cm H_2O.[7]

Although this study found that the group receiving the open lung approach had significantly lower mortality than the group receiving conventional ventilation (see Table 38-6), it was unclear which intervention or combination of interventions was responsible for the observed improvement. Was the lower mortality due to the low-tidal-volume ventilatory strategy, the higher-than-traditional levels of PEEP, or the recruitment maneuvers, or a combination of two or all three?

To try to answer these questions, which had also been raised in an earlier report by Amato and colleagues,[219] the NHLBI ARDSNet investigators decided to study one intervention at a time in separate RCTs. As noted above, the first ARDSNet RCT compared a lower-tidal-volume ventilatory strategy to a strategy using traditional tidal volumes.[3] This RCT found a significant decrease in mortality in the group treated with the lower-tidal-volume ventilatory strategy (see Table 38-6). After completion of this RCT, the ARDSNet investigators conducted a second RCT ("ALVEOLI") to try to answer the question: When used in addition to the lower-tidal-volume strategy of ventilation, do higher PEEP levels improve survival?

The results of the ALVEOLI study[4] are presented in Table 38-8. In summary, ALVEOLI found that mortality rates were similar in those treated with higher and traditional levels of PEEP despite significant increases in Pa_{O_2}: FI_{O_2}. The higher-PEEP group had a higher mean plateau pressure despite a lower mean tidal volume (see Table 38-8). Although hypothetical, it is possible that the benefits of the higher PEEP in reducing the acute lung injury due to shear stress created by recruitment-derecruitment were negated by its adverse effects, such as worsening lung injury by overdistension (see Figure 38-9).

RECOMMENDED CORE VENTILATOR MANAGEMENT

As the core ventilator management in ALI and ARDS, we recommend that clinicians use the lower-tidal-volume ventilatory strategy ("ARDSnet lung-protective strategy") that the ARDSNet investigators showed to be superior to traditional tidal volume strategy (Table 38-9). Because this strategy that used traditional levels of PEEP was shown to yield similar outcomes compared to using higher PEEP levels[4] (see Table 38-8), we also recommend using the same combinations of PEEP and FI_{O_2} that were an integral part of the ventilator protocol for the lower-tidal-volume strategy (see Table 38-9). Clinicians should be cautious in utilizing this protocol strictly for patients with ALI and ARDS who have conditions for which respiratory acidosis due to permissive hypercapnia are contraindicated (Tables 38-10 and 38-11).

In addition to this core ventilator management, some clinicians use various interventions as adjuncts (Table 38-12). Finally, clinicians may choose to use alternative ventilatory strategies whose efficacy is unproven (e.g., salvage therapies for patients in dire clinical circumstances) (Table 38-13).

Adjuncts to Core Ventilator Management

Clinicians may use one or more interventions as adjuncts to "customize" the recommended core ventilator management to try to improve pulmonary physiology and otherwise benefit individual patients (see Table 38-13). Most of these adjuncts hold the possibility of benefit based on extrapolation from animal or clinical research that generally uses physiologic end points as suggestions of efficacy. However, it is inaccurate to extrapolate from an improvement in physiologic outcomes to efficacy in terms of clinically meaningful outcomes (e.g., survival or days of mechanical ventilation). For example, in the first ARDSNet RCT, the lower-tidal-volume group had better survival than the higher-tidal-volume group, despite having lower mean values for Pa_{O_2}: FI_{O_2}.[3] Furthermore, the safety of these adjuncts is generally uncertain. Clinicians who want to use high-level evidence to guide care of patients with ALI and ARDS should be warned that to date, all of the following adjuncts fall short of that level of scientific evidence.

RESTRICTIVE ("DRY") FLUID MANAGEMENT The optimal fluid management in patients with ALI and ARDS remains uncertain. The rationale for restricting fluids in ALI and ARDS suggests that if edemagenesis could be diminished early after the lung injury, the duration of potentially dangerous ventilator, PEEP, and oxygen therapy could be reduced and outcome conceivably improved. In this regard it is interesting that most patients with ARDS do not die during the early phase of disease as a consequence of severe hypoxemia, but rather over days to weeks, frequently with evidence of hypermetabolism, nosocomial infection, and multiple organ system failure.[53,54] On the other hand, some have argued that maximizing oxygen delivery (so-called "supercharging") to peripheral tissues is a necessary strategy in critically ill patients such as those with sepsis and ARDS, and advocate approaches such as volume loading to achieve this goal.[220,221] This latter position has fallen out of favor because the oxygen extraction defect purported to exist in patients with sepsis and ARDS now seems to have been artifactual, or at least not clinically relevant.[222,223] Moreover, controlled clinical trials of such goal-oriented hemodynamic therapy showed no improvement in survival[224] or worse survival.[225] In patients with ALI and ARDS, the consequence of an approach of maximizing oxygen delivery could be escalating requirements for mechanical ventilation, oxygen, and PEEP. To the extent that intensity and duration of supportive therapy are major determinants of complications and organ dysfunctions, the net result could be detrimental. Fluid management strategies in ALI and ARDS are currently the focus of an ongoing ARDSNet investigation (the Fluids and Catheter Treatment Trial, or FACTT). FACTT also is comparing use of central venous catheters to pulmonary artery catheters to guide fluid management. Until the results of this study are known, we favor an approach that aims for a cautious reduction in central venous pressure (CVP) or pulmonary artery wedge pressure (Ppw) while maintaining adequate circulation early in the course of ARDS as a strategy to minimize edemagenesis and to avoid adverse effects of its treatment. Although this approach is controversial, its justification derives from both animal experiments[226–233] and clinical data (see below).

Several retrospective or noninterventional studies have reported data showing a correlation between survival and net diuresis or reduction in Ppw.[234–236] Prospective data collection also has demonstrated that titration of therapy to minimize extravascular lung water in patients with ARDS results in decreased ventilator and ICU days.[237] Until a prospective,

TABLE 38-9 NIH NHLBI ARDS Network Low-Tidal-Volume Ventilation Strategy

Part I. Ventilator set-up and adjustment

1. Calculate ideal body weight (IBW).[a]
2. Use assist/control mode and set initial tidal volume (TV) to 8 mL/kg IBW (if baseline TV >8 mL/kg).
3. Reduce TV by 1-mL/kg intervals every 2 hours until TV = 6 mL/kg IBW.
4. Set initial rate to approximate baseline minute ventilation (but not >35 bpm).
5. Adjust TV and respiratory rate (RR) to achieve pH and plateau pressure (Pplat) goals listed below.
6. Set the inspiratory flow rate above patient demand (usually >80 L/min); adjust flow rate to achieve goal of inspiratory : expiratory ratio of 1:1.0–1.3

Part II. Oxygenation goal: Pa_{O_2} = 55–80 mm Hg or Sp_{O_2} = 88–95%

1. Use these incremental F_{IO_2}-PEEP combinations to achieve oxygenation goal:

F_{IO_2}	0.3	0.4	0.4	0.5	0.5	0.6	0.7	0.7
PEEP	5	5	8	8	10	10	10	12
F_{IO_2}	0.7	0.8	0.9	0.9	0.9	1.0	1.0	1.0
PEEP	14	14	14	16	18	20	22	24

Part III. Plateau Pressure (Pplat) Goal: = 30 cm H_2O

1. Check Pplat (use 0.5-s inspiratory pause), Sp_{O_2}, total RR, TV, and arterial blood gases (ABG) (if available) at least every 4 hours and after each change in PEEP or TV.
2. If Pplat >30 cm H_2O, decrease TV by 1-mL/kg steps (minimum 4 mL/kg IBW).
3. If Pplat <25 cm H_2O and TV <6mL/kg, increase TV by 1 mL/kg until Pplat >25 cm H_2O or TV = 6 mL/kg.
4. If Pplat <30 cm H_2O and breath stacking occurs, one may increase TV in 1-mL/kg IBW increments (to a maximum of 8 mL/kg) as long as Pplat<30 cm H_2O.

Part IV. pH Goal: 7.30–7.45

Acidosis management: pH <7.30

1. If pH = 7.15 −7.30, increase RR until pH >7.30 or Pa_{CO_2} <25 mm Hg (Maximum RR = 35); if RR = 35 and Pa_{CO_2} <25 mm Hg, may give $NaHCO_3$.
2. If pH <7.15 and $NaHCO_3$ considered or infused, TV may be increased in 1-mL/kg steps until pH >7.15 (Pplat goal may be exceeded).

Alkalosis management: pH >7.45: Decrease RR if possible.

[a] Male IBW = 50 + 2.3 [height (inches) − 60]; female IBW = 45.5 + 2.3 [height (inches) − 60]. Sp_{O_2}, oxygen saturation by pulse oximetry, ABG, arterial blood gas.

randomized trial of a strategy of conservative fluid management in ALI and ARDS patients provides evidence regarding efficacy and safety, the circulatory management of these patients can be described as a therapeutic dilemma.[238,239] On the one hand, judicious volume reduction may improve lung function. In the extreme, however, hypoperfusion and other organ failure could occur.

In order to reduce Ppw safely in patients with ALI and ARDS, the clinician's attention should be focused on the parameters of organ function that should be followed in all critically ill patients (e.g., mental status, urine output and concentration, circulatory adequacy, and metabolic evidence of anaerobic metabolism). *This should not be misinterpreted as trading reduced pulmonary edema for a hypoperfused state.* Rather, the aim of this approach is to find the lowest Ppw or CVP compatible with *adequate* functioning of the circulatory system. Preload can be reduced in part by meticulous attention to limit all extraneous fluid administration. Furosemide is often used to achieve diuresis and net negative fluid balance. However, this may confound interpretation of renal function as an indicator of the adequacy of perfusion. In selected patients, particularly those with manifest systolic dysfunction, dobutamine can be used to maintain perfusion at a reduced Ppw.

Interpreting right heart catheterization data during mechanical ventilation with PEEP can be challenging.[240] The usual measurement made at right heart catheterization is the Ppw. Measurements of Ppw may fail to reflect left ventricular filling pressure for a number of reasons. First, if alveolar pressure is greater than left atrial pressure at the site of measurement (West zone 1 or 2), then the downstream pressure is not measured, and the right heart catheter reflects alveolar pressure. Existence of zone 1 or 2 conditions can be inferred from the excursion of the pulmonary arterial and wedge pressure waveforms during positive pressure ventilation.[241] *This possibility must be considered if one attempts preload reduction in patients with ARDS requiring high PEEP levels.*

Second, it is often difficult to identify end-inspiration in many patients with ALI or ARDS. This is especially problematic if patients are spontaneously breathing while receiving assisted ventilation. To improve accuracy in making routine measurements of Ppw as well as CVP, it is recommended that the airway pressure be transduced and its transducer's output be printed simultaneously with the pressure tracing.

TABLE 38-10 Effects of Permissive Hypercapnia and Respiratory Acidosis

Hemodynamic effects
Activation of sympathetic nervous system and catechol secretion, normally resulting in increased heart rate and stroke volume with peripheral vasodilatation
Impaired myocardial contractility and worse congestive heart failure
Coronary vasodilation and potential for vasodilation-induced steal resulting in less blood flow to ischemic myocardium
Pulmonary arteriolar vasoconstriction, potentiating hypoxic pulmonary vasoconstriction
Rightward shift of the oxygen dissociation curve with potential for less loading of O_2 at the alveolar level and arterial desaturation
Effects on the central nervous system
Increased cerebral blood flow due to arterial hypertension and cerebral vasodilatation (vasodilatation may be lost in areas subject to trauma or ischemia)
Cerebral vasodilation and potential vasodilation-induced steal resulting in less blood flow to ischemic regions of the brain
Increases intracranial pressure

SOURCE: Reproduced with permission from Feihl.[247]

The transduced airway pressure tracing clearly identifies the start of inspiration by the start of its positive deflection in patients who are not assisting the ventilator. Likewise the airway pressure tracing also easily identifies the start of an assisted breath by the occurrence of the associated negative pressure deflection. This simple change can significantly decrease interobserver variability.[242]

Some have suggested that the nadir in Ppw after an airway disconnect might better reflect left ventricular filling pressure.[243,244] This approach may be dangerous and is not recommended since even relatively short discontinuation of PEEP can have adverse effects on oxygenation that may take hours to recover.

PERMISSIVE HYPERCAPNIA Traditionally physicians have attempted to ventilate patients to a normal arterial P_{CO_2} (see Fig. 38-6). In patients with severe lung disease, however, this arbitrary goal has a mechanical cost: the probable amplification of lung injury (i.e., VILI). Increasing evidence points to the safety and efficacy of allowing the arterial P_{CO_2} to rise above 40 mm Hg when used in combination with a ventilatory strategy that uses low tidal volumes and low plateau pressures. When patients with ALI and ARDS are ventilated with volume- and pressure-limited ventilation as described above, the mean Pa_{CO_2} may rise modestly (into the low 40s mm Hg) or higher (into the mid-to-high 50s mm Hg) with corresponding falls in arterial pH (see Table 38-7). Occasional patients may have a Pa_{CO_2} above 100 mm Hg[245,246] (see Table 38-7).

TABLE 38-11 Contraindications to Permissive Hypercapnia and Respiratory Acidosis

Increased intracranial pressure from any cause (trauma, mass lesion, malignant hypertension)
Acute cerebrovascular disorders (e.g., stroke)
Acute or chronic myocardial ischemia
Severe pulmonary hypertension
Right ventricular failure
Uncorrected severe metabolic acidosis
Sickle-cell anemia
Tricyclic antidepressant overdose
Patients taking β-blockers
Pregnancy (potential for decreased fetal blood flow due to vasodilatation-induced steal syndrome; in addition, shift to the right of the oxygen dissociation curve may decrease maternal-fetal oxygen gradient)

TABLE 38-12 Adjuncts to Low-Tidal-Volume Ventilation for Treatment of Acute Lung Injury (ALI) and Acute Respiratory Distress Syndrome (ARDS)

Restrictive ("dry") fluid management strategy
Increasing cardiac output and/or oxygen delivery to supranormal levels
Permissive hypercapnia
Prone positioning
Recruitment maneuvers

Respiratory acidosis has many physiologic effects, including cellular metabolic dysfunction, depression of myocardial contractility, coronary vasodilation, systemic vasodilation, pulmonary vasoconstriction, enhanced hypoxic pulmonary vasoconstriction, cerebral vasodilation, increased intracranial pressure, and renal vasoconstriction, among others[247,248] (see Table 38-10). Yet even very high levels of P_{CO_2} seem remarkably well tolerated by adequately sedated patients. Perhaps this is related to highly efficient and rapidly acting cellular compensatory mechanisms that tend to defend intracellular pH. Because respiratory acidosis raises intracranial pressure, permissive hypercapnia should not be used in patients with cerebral edema, trauma, or space-occupying lesions. This and other contraindications are listed in Table 38-11.

PRONE POSITIONING Multiple studies have shown that about two-thirds of patients with ARDS exhibit improved oxygenation with prone positioning ("proned").[249–252] Hypotheses offered to explain the improvement in oxygenation include (1)increased FRC, (2) change in regional diaphragm motion, (3)redistribution of perfusion, and (4) better clearance of secretions.[253] FRC has been shown to be increased in the prone position in intubated, mechanically-ventilated patients without lung injury who are undergoing general anesthesia for surgery.[254] Animal models of ventilation-perfusion distribution have suggested that gravity has far less influence on the distribution of perfusion in the prone position, and that the distribution of blood flow to regions of the lung is relatively unaffected by the change from the supine to the prone position.[255] This, coupled with the observation that turning to the prone position is associated with a migration

TABLE 38-13 Salvage Interventions for Patients with Severe Hypoxemia in Acute Respiratory Distress Syndrome (ARDS)

Tracheal gas insufflation (TGI)
Pressure-controlled inverted ratio ventilation (PC-IRV)
Extracorporeal membrane oxygenation (ECMO)
High-frequency oscillatory ventilation (HFOV)
Inhaled nitric oxide (NO) or inhaled prostacyclin (epoprostenol)
Corticosteroids

of the edema fluid to the dependent portions of the lung (as demonstrated by CT scan), has suggested to some investigators that ventilation-perfusion relationships might be favorably altered by the prone position.[256] In patients managed in the prone position, special attention is necessary to prevent pressure necrosis of the nose, face, and ears, and to ensure maintenance and patency of the endotracheal tube. Pressure on the eye could lead to retinal ischemia, especially in hypotensive patients. Some patients experience cardiac arrhythmias or hemodynamic instability on being turned.

These considerations led to a large clinical trial performed by Gattinoni and colleagues.[252] In this study, subjects were placed in the prone position for six or more hours daily for 10 days. The results, published in 2001, revealed that although oxygenation was transiently improved, prone positioning offered no survival advantage over routine supine positioning.[252] Further post-hoc analyses indicated that a patient's response to prone positioning may have prognostic value. Patients whose Pa_{CO_2} *fell* by 1 mm Hg or more when placed in the prone position had a lower mortality rate than those whose Pa_{CO_2} didn't fall or rose (mortality of 35.1% vs. mortality of 52.2%).[257]

Prone positioning may have a role in the future, when combined with lower tidal volume ventilation, such as the ARDSNet protocol (see Table 38-9), ventilator sighs,[258] or when employed using a different treatment protocol. Clinicians may reserve use of prone positioning as salvage therapy for severe hypoxemia, but they should understand that there are no controlled studies that support its efficacy in this circumstance, even in those patients whose oxygenation improves (see below). Finally, although some advocate the routine use of prone positioning as part of a multifactorial lung protective strategy,[259] no controlled clinical trials support such routine use, especially given its potential adverse effects listed above.

RECRUITMENT MANEUVERS Recruitment maneuvers evolved from traditional "sighs," which are extra-large breaths of the order of two or three normal-sized tidal volume breaths. Sighs normally occur 4 to 10 times per hour and increase the surfactant's surface-tension-lowering properties, thus stabilizing small alveoli and resisting atelectasis.

Recruitment maneuvers were part of the "open lung" strategy in the clinical trial of low tidal volume ventilation by Amato et al[7] (see Tables 38-6 and 38-7). In the Amato trial, recruitment maneuvers consisted of application of continuous positive airway pressure (CPAP) of 35 to 40 cm H_2O for 30-second periods. Others have advocated longer periods at the same or higher airway pressures.[259] The justification for recruitment maneuvers is to "recruit" or open totally or partially collapsed alveoli, which then would be kept inflated during expiration by a high level of PEEP.[259]

Evidence is lacking that recruitment maneuvers alone improve clinically significant outcomes such as mortality or ventilator-free days. Most studies of recruitment maneuvers have used physiologic end points, such as improvement in oxygenation. The ARDSNet studied recruitment maneuvers as a substudy of 96 subjects in the higher-PEEP group in the ALVEOLI study[260] (see Table 38-8). There were no clinically relevant improvements in arterial saturation, but complications occurred, such as transient hypotension and slight drops in arterial saturation during the recruitment maneuver. Other studies have shown more consistent improvement in oxygenation after recruitment maneuvers if relatively low levels of PEEP were being used,[261–263] if larger tidal volumes were used,[264] or if the patients are paralyzed.[265]

Given the lack of controlled clinical trials that demonstrate efficacy in clinically relevant end points and the potential adverse effects, we don't recommend routine use of recruitment maneuvers. Furthermore, because they exceed the threshold of 30 cm H_2O used in the ARDSnet clinical trial that showed improved survival, and the lack of studies that demonstrate improved outcomes,[266–268] we don't recommend routine use of "sighs" either.

SALVAGE INTERVENTIONS When treating subjects with severe ARDS, some clinicians may try unproven interventions if the patient is deteriorating with severe hypoxemia (e.g., Pa_{O_2} less than 45 to 50 mm Hg) or needing an FI_{O_2} of 0.9 or more to maintain Pa_{O_2} above 55 mm Hg. These may be referred to as "salvage" interventions. These clinicians justify their use of these interventions on two grounds: (1) the dire condition of the patient, and (2) a hope of clinical efficacy. The latter is based on results from basic science studies suggesting a reasonable rationale, from their use in animal models, and from clinical usage that showed improvements in certain physiologic parameters (e.g., Pa_{O_2}: FI_{O_2}).

Despite the failure to improve survival in phase III clinical trials of patients with ALI/ARDS who were not necessarily in such dire straits, these clinicians may feel ethically obligated through the "Rule of Rescue[269]" to provide an intervention that may help as long as the risk is acceptable. Because of expense, lack of proven efficacy, and potential for harm, we do not advocate routine use of any of these "salvage interventions." Rather, we support a management strategy guided by evidence and including active observation of critically ill patients with ARDS. We urge those who advocate for their use to conduct clinical trials in the targeted population of patients with severe ARDS to assess their safety and efficacy.

Nonetheless, when there are severe problems with oxygenation in an otherwise salvageable patient, some clinicians will want to utilize certain adjunctive therapies. *It is important to realize that these therapies should not distract caregivers from the fundamentals of good critical care*, including nutrition, aspiration precautions, hygiene and prevention of nosocomial infections, appropriate sedation practices, and careful vigilance for complications of critical care.

TRACHEAL GAS INSUFFLATION Tracheal gas insufflation (TGI), involves introducing fresh gas near the carina through a modified endotracheal tube. This added flow washes CO_2-rich gas out of the trachea (and, through turbulence, out of smaller airways as well), reducing anatomic dead space.[270] The Pa_{CO_2}-reducing effect of TGI is lessened by acute lung injury, but this is partially counterbalanced by the higher Pa_{CO_2} values used during permissive hypercapnia.[271] In patients with ARDS, TGI with 100% humidified oxygen, delivered throughout the respiratory cycle at a flow of 4 L/min, successfully lowered P_{CO_2} from 108 to 84 mm Hg.[272] Potential risks of TGI include tracheal erosion, oxygen toxicity related to the unknown FI_{O_2}, hemodynamic compromise or barotrauma due to the occult presence of auto-PEEP, and a larger tidal volume than the ventilator is set to deliver (i.e., potentially increasing the risk of VILI).

INHALED NITRIC OXIDE AND INHALED PROSTACYCLIN (EPOPROSTENOL) Since Roissant and colleagues published their initial experience using inhaled nitric oxide as a therapy for ARDS, there has been a rapid expansion of interest and literature in this field.[273–278] Given via inhalation, NO has several potentially salutary effects in ARDS. It selectively vasodilates pulmonary capillaries and arterioles that subserve *ventilated* alveoli, diverting blood flow to these alveoli (and away from areas of shunting). The vasodilating effect, signaled by a fall in pulmonary artery pressure and pulmonary vascular resistance, appears maximal at very low concentrations (0.1 ppm) in patients with ARDS.[277] The beneficial effects on oxygenation take place at somewhat higher inspired concentrations of NO (1 to 10 ppm).[277] The rapid inactivation of NO via hemoglobin binding prevents unwanted systemic hemodynamic side effects, but also mandates the continuous delivery of gas to the ventilator circuit. Thus, if continuous delivery of NO is interrupted (e.g., during patient transport or due to supply exhaustion), precipitous and life-threatening hypoxemia and right-sided heart failure may occur.[279] A recent large clinical trial compared the use of NO to placebo in subjects with ALI not due to sepsis, with no other organ failures.[280] The trial showed no benefit in survival with use of NO despite some patients having a transient improvement in oxygenation. Trials in other subgroups of ALI may be the focus of future investigations, but there is no consensus evidence for routine use of NO in ALI.

Even as a salvage intervention, inhaled NO is unattractive since there is a reasonable alternative available at much less expense. Whereas the cost of inhaled NO for 1 day is in the thousands of dollars, the daily cost of inhaled prostacyclin (epoprostenol) is in the hundreds of dollars. Inhaled prostacyclin, although less well studied, appears to provide the same degree of improvement in oxygenation in a majority of patients with ALI and ARDS at much less expense.[281–284]

CORTICOSTEROIDS Although it is commonly accepted that steroids have little or no role to play in treating the early acute phase of ARDS,[285,286] their role in later phases remains controversial. A number of anecdotal reports and small series have suggested that high-dose corticosteroids may be of some benefit during the proliferative phase of ARDS.[287–289] The rationale behind this therapy is that much of the scarring that occurs during this phase of the illness is a consequence of unattentuated inflammation that can cause severe damage to the affected alveoli.[290] There is an obvious risk, however, of immunosuppressing already debilitated patients who are still in an environment in which they are exposed to multiple resistant organisms (and frequently have multiple indwelling appliances), as well as a potential risk for long-term neuromuscular sequelae. The NHLBI ARDSNet recently completed a double-blind RCT (Late Steroid Rescue Study or LaSRS) designed to evaluate the benefits and risks of this therapy in 180 patients with ARDS lasting 7 to 21 days. The ARDSNet presented preliminary results at the 2004 International Meeting of the American Thoracic Society. These indicated that there was no difference in 60-day mortality, or ICU or hospital length of stay between those treated with high-dose methylprednisolone and those treated with placebo.[291] In addition, investigators reported more adverse events related to weakness in the steroid-treated group than in the placebo-treated group. Pending publication of the final results of this study, the routine use of steroids, specifically for late-phase ARDS, cannot be advocated on firm scientific grounds.

PRESSURE-CONTROL VENTILATION AND INVERSE-RATIO VENTILATION Pressure-control ventilation (PCV) is favored by some clinicians because it limits the maximal peak airway pressure. It also limits static end-inspiratory or alveolar pressure. However, some intensivists and respiratory care providers may not appreciate what that limit is. For example, if a patient with ARDS is being ventilated with PCV with an inspiratory pressure of 30 cm H_2O and PEEP of 10 cm H_2O, then the total end-inspiratory pressure is the sum of 30 cm H_2O plus 10 cm H_2O, or 40 cm H_2O (Fig. 38-10). Some clinicians may mistakenly believe that the alveoli are being exposed to only 30 cm H_2O, and thus do not decrease the inspiratory pressure such that the end-inspiratory pressure does not exceed 30 cm H_2O, the threshold used in the pivotal ARDSNet study.[3]

Although one could possibly mimic the tidal volumes and end-inspiratory pressures that were used in the ARDSnet low-tidal-volume ventilatory strategy (see Table 38-9), it would be challenging. It is possible that the low tidal volume per se in the ARDSnet trial was a factor in decreasing the mortality, apart from the benefits of keeping the plateau pressures limited to 30 cm H_2O or less.

Inverse ratio ventilation (IRV) entails the use of prolonged inspiratory times (inspiratory:expiratory ratio >1) with either a volume-cycled or pressure-cycled mode of mechanical ventilation (see Fig. 38-10). A subset of patients with hypoxia refractory to conventional modes of mechanical ventilation responded to IRV.[292,293] Unfortunately, there is no way to prospectively identify which patients will respond to IRV. The exact mechanisms by which IRV improves gas exchange in some patients with ARDS remain obscure, but are believed to involve both alveolar recruitment at lower airway pressures and more optimal distribution of ventilation.[294,295] Although it is tempting to attribute the beneficial effect of IRV to intrinsic PEEP, anecdotal reports have excluded intrinsic PEEP or gas trapping as the mechanism by which gas exchange improves in at least some patients.[295] An important caution when using this mode is that both auto-PEEP and the higher mean alveolar pressure typical of IRV tend to reduce cardiac output. In one study that examined PCV with or without IRV, cardiac output fell with IRV so that systemic oxygen delivery actually worsened.[296] Some investigators have noted a very gradual (over several hours) but progressive tendency for oxygenation to improve following a change to IRV.[297] This phenomenon has led some to suggest that a subset of lung units may be recruitable only through the combined effects of prolonged inspiration and time. Further studies are needed to shed light on this interesting aspect of IRV.

Inverse ratio pressure-control ventilation has been employed as part of the open lung strategy for ventilating patients with ARDS, with specific attention to keeping the tidal volume at or less than 6 mL/kg and limiting the driving (inspiratory) pressure.[7] The role of volume-control IRV remains poorly defined, and it is best regarded as a salvage therapy for patients with hypoxia refractory to more conventional approaches. Whichever approach is used, the intensivist should monitor auto-PEEP regularly, since the shortened expiratory times of IRV predispose to this effect.

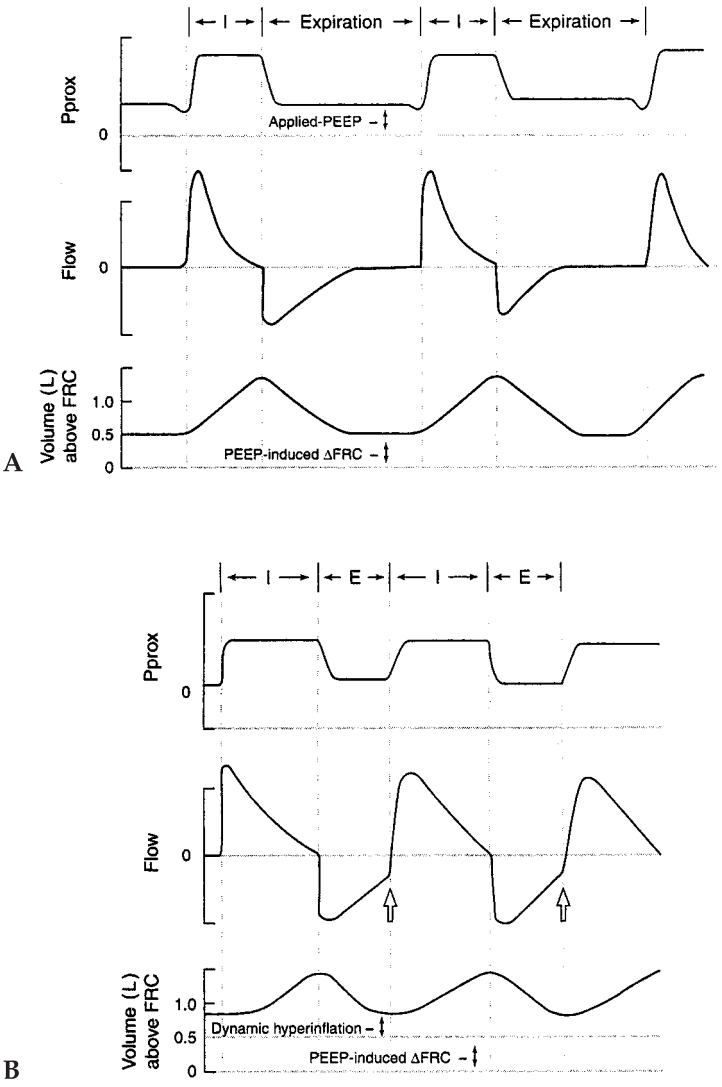

FIGURE 38-10 Schematic pressure, flow, and volume waveforms during pressure control ventilation (PCV) with applied PEEP. A. The inspiratory-to-expiratory (I:E) time is about 1:2. The pressure waveform resembles pressure support mode with the patient triggering each breath, but with a marked decelerating flow pattern. The applied PEEP increases the functional residual capacity (FRC) by about 500 mL (PEEP-induced ΔFRC). B. In pressure-controlled inverse ratio ventilation (PC-IRV), the I:E time is "reversed," with I>E. Because of this, the next breath starts before expiratory flow has returned to zero (open arrows), resulting in auto-PEEP and dynamic hyperinflation of about 300 mL. The latter is in addition to the increased FRC due to the applied PEEP (PEEP-induced ΔFRC). The patient is not initiating any breaths. E, expiration; I, inspiration; PEEP, positive end-expiratory pressure; Pprox, pressure at the proximal end of the endotracheal tube. ***(Reproduced with permission from Lanken PN: Acute respiratory distress syndrome, in Lanken PN, Hanson CW III, Manaker S (eds):*** **The Intensive Care Unit Manual.** ***Philadelphia, WB Saunders, 2001, p 829.)***

Clinicians have also used other modalities of ventilation that depend on computerized ventilators, none of which have been compared to current low-tidal-volume strategies in RCTs (see Chap. 32).

HIGH-FREQUENCY OSCILLATORY VENTILATION If excessive lung excursion during tidal volume breathing is associated with injury to the lung, then it seems reasonable that ventilation with very small tidal volumes at high frequencies would be associated with the least possible ventilator-induced lung injury and potentially with improved outcome. Although the FDA has approved a ventilator for adults that provides high-frequency oscillatory ventilation (HFOV), its role in clinical practice remains unclear.[298] A study of HFOV[299] published in 2002 demonstrated a trend towards decreased mortality compared to conventional mechanical ventilation. However, the conventional ventilation was not based on a low-tidal-volume strategy such as ARDSNet (see Table 38-9). Because the mean airway pressure (± SD) was higher in the group of patients treated with HFOV than the conventionally-treated group (e.g., 29 ± 6 cm H_2O vs. 23 ± 6 cm H_2O during the first 24 hours), caution must be raised about the possibility of VILI due to the high distending pressures. Until a RCT is done comparing HFOV to the ARDSNet protocol, clinicians will not have evidence to guide them about when or if to employ HFOV.

High-frequency jet ventilation is different from HFOV. High-frequency jet ventilation typically employs tidal volumes of 1 to 5 mL/kg (or higher) and respiratory rates of 60 to 300 breaths per minute. Multiple trials of high-frequency ventilation have failed to demonstrate any benefit compared with conventional mechanical ventilation.[300–302] Nor has high-frequency jet ventilation has been associated with either improved oxygenation, reduced barotrauma, or decreased days of mechanical ventilation. On the basis of these negative results and the potential promise of HFOV, we recommend avoiding the use of high-frequency jet ventilation, even as a salvage intervention.

EXTRACORPOREAL MEMBRANE OXYGENATION AND EXTRACORPOREAL CO_2 REMOVAL The use of extracorporeal gas exchange, such as extracorporeal membrane oxygenation (ECMO) or extracorporeal CO_2 removal ($ECCO_2R$), to adequately oxygenate and ventilate the patient while allowing the lung to remain at rest was viewed as an attractive strategy for the management of patients with acute lung injury.

However, this promise has not been supported by clinical outcome studies. The earliest large-scale attempt to use ECMO in patients with severe ARDS in the 1970s demonstrated no survival benefit to its use, although it did generate a large database and a great deal of insight into patients with this problem.[303] Unfortunately, enrollment criteria in this study were such that the mortality among all patients entered into it was certain to be high (e.g., ~90% in both groups). Hence it was unlikely that any difference would be demonstrated between groups. Some believe that more careful patient selection, earlier randomization of patients, and better technology might have demonstrated a benefit to ECMO. A second wave of studies using ECMO or $ECCO_2R$ was reported throughout the 1980s.[304–306] A number of techniques have been described, including venovenous ECMO, to assist in the elimination of carbon dioxide. However, the most recent report of ECMO in adult patients with ARDS also failed to demonstrate any survival benefit.[307] Despite these results, some specialized centers have continued to offer ECMO to adults with severe ARDS, based on their opinion that it is a relatively safe life-saving salvage intervention.[308]

Experimental (Non-FDA Approved) Interventions

PARTIAL LIQUID VENTILATION Partial liquid ventilation using perfluorocarbons instilled into the trachea of adults and children with the respiratory distress syndrome has been described.[309–312] Preliminary results from adult usage[313] and the more extensive experience in pediatric patients suggest that this mode of therapy may be both safe and efficacious in improving gas exchange. Partial liquid ventilation may allow oxygenation in patients who might otherwise be quite difficult to oxygenate with conventional modes of ventilation, in part because the perfluorocarbon is able to recruit dependent alveoli (by virtue of the hydraulic column) that PEEP is not. A practical problem is that perflubron is radiodense, making the lungs appear white, so it is impossible to use chest radiographs to detect infection or to follow the progress of healing. Currently, perfluorocarbons are available only as experimental agents.

EXOGENOUS SURFACTANT It has long been known from both animal models and human studies that surfactant levels are decreased or that the ratios of the surfactants are abnormal in humans and animals with ARDS.[314,315] Intensivists caring for adults have been encouraged by the dramatic results of surfactant therapy in infants with the respiratory distress syndrome (RDS) of prematurity. Surfactant therapy of RDS improves gas exchange and lung mechanics, decreases the requirement for CPAP, and lessens barotrauma.[316–318] Anzueto and associates[6] reported the first large prospective RCT of surfactant in ARDS. Their results were disappointing: There was no benefit associated with the exogenous surfactant delivered by inhalation. Because there were concerns about the appropriate dose, alternative modes of delivery, timing of therapy, and the precise surfactant formulation studied, investigators did not view this study as definitive evidence against the use of exogenous surfactant. Since then a number of RCTs, large and small, have been carried out and more are underway. Results so far have been mixed.[319–323] Large phase III trials with different surfactant preparations are underway. Like perflubron, currently exogenous surfactant for adults is available only as an experimental agent.

Supportive Care and Monitoring Patients with ALI and ARDS

SUPPORTIVE THERAPY Current management of ARDS does not benefit from proven pharmacologic interventions to limit acute lung injury or restore physiologic function. The largest strides in the recent management of ARDS have come from therapies aimed at the delivery of mechanical ventilation.[3] While it is possible that further explication of the mechanisms of lung injury will provide new avenues for pharmacologic intervention, at present, management of these patients relies on application of proven mechanical ventilation strategies, combined with meticulous supportive therapy. Appropriate management includes timely diagnosis and treatment of underlying diseases, nosocomial infections, and other problems. Indeed, even if new pharmacologic agents become available, the same supportive therapy will be necessary to maintain a viable patient to benefit from treatment. For a detailed description of elements of supportive care, please refer to the relevant other chapters in this text.

Reducing PEEP, even for short periods of time, is often associated with alveolar derecruitment and hence rapid arterial hemoglobin desaturation. Thus once endotracheal tube suctioning has been accomplished for diagnostic purposes, nursing and respiratory therapy staff should be instructed to keep airway disconnections to a minimum or to use an in-line suctioning system that maintains sterility and positive pressure, usually via the suctioning catheter residing in a sterile sheath and entering the endotracheal tube via a tight-sealing diaphragm. These suctioning systems generally are effective for lesser levels of PEEP (<15 cm H_2O) but often leak if higher levels are attempted.

MONITORING Patients with ARDS, by virtue of their serious gas exchange (and sometimes hemodynamic) impairment, combined with the effects of therapy (sedation, therapeutic paralysis, and PEEP), are at risk of sudden and life-threatening deterioration. Changes in intrapulmonary shunt, oxygen consumption, and systemic perfusion are frequent, making arterial saturation and oxygen delivery volatile. Accordingly, careful monitoring for hypoxemia and the adequacy of oxygen delivery is advisable. Continuous pulse oximetry is generally reliable (barring gross hypoperfusion) and should be used routinely. In addition, frequent sampling of arterial blood gases is advisable throughout the first day of management, as well as following major interventions or changes in clinical appearance of the patient.

Monitoring the patient's airway, ventilator function, and the ventilator-patient interface are equally important, as is assessment for liberation from assisted ventilation, and if needed, weaning (see Chap. 44).

Finally, hemodynamic monitoring, including use of a pulmonary artery catheter, has been discussed earlier in this chapter (see Chap. 13).

Long-term Sequelae of ARDS

Over the past two decades, as treatment for ARDS has decreased hospital mortality,[324] clinicians and clinical investigators have become more interested in the long-term health problems of ARDS survivors. Pulmonary function is usually mildly impaired after hospital discharge from ARDS and improves slightly over the next year.[325,326] Thus survivors with worsening dyspnea may have another superimposed

respiratory lesion, such as tracheal stenosis, and should be evaluated as such. Despite their young age, ARDS survivors score well below the reference standards and other critical care controls on quality-of-life measures,[27,326–329] and many have evidence of cognitive dysfunction,[330] posttraumatic stress disorder,[328] and physical debilitation,[25] many months after hospital discharge. The long-term sequelae of critical illness and ARDS are an active area of ongoing research, covered in detail in Chap. 19.

Conclusion

Standardization of the criteria that define ALI and ARDS has aided in identification of specific at-risk groups. This in turn has spurred further research into the underlying reasons why certain risk groups (such as alcoholics[331,332]) are at greater risk for ALI. A recent NHLBI consensus statement summarized the important directions for future research, including functional response to injury and interaction between biochemical pathways and different cell types.[23] The completion of the human genome project has led to characterization of many of the genes encoding mediators of lung injury.[333] The effect of variation in these genes on predisposition to ALI in at-risk groups, such as sepsis, pneumonia, and trauma, may help to identify subgroups whose genotypes place them at unusually high risk or low risk for developing ALI and ARDS. Identifying these putative enabling and protective polymorphisms for developing ALI will provide hypotheses for interventions for prevention and for treatment of patients with ALI and ARDS in the future.

However, while waiting for those new genetically tailored therapies, much can be done in the present. The landmark ARDSNet low-tidal-volume ventilation strategy trial proved that ventilator therapy can be protocolized to reduce ventilator-induced lung injury.[3] Arguably this simple and inexpensive strategy can save thousands of lives of ALI and ARDS patients if widely accepted and utilized. Unfortunately, studies since the publication of the ARDSnet study in 2000 have indicated that that there are challenges to the widespread and timely acceptance and implementation of this low-tidal-volume strategy.[334–336] Thus the present challenges include not only improving on this therapy, but also overcoming the obstacles so that clinicians can consistently make a diagnosis of ALI and ARDS early, and then begin appropriate ventilatory support.

Chapter 39

ACUTE-ON-CHRONIC RESPIRATORY FAILURE

IVOR S. DOUGLAS
GREGORY A. SCHMIDT
JESSE B. HALL

KEY POINTS

- *Acute-on-chronic respiratory failure (ACRF) occurs when relatively minor, although often multiple, insults cause acute deterioration in a patient with chronic respiratory insufficiency.*
- *ACRF is usually seen in patients known to have severe chronic obstructive pulmonary disease (COPD), but occasionally it manifests as cryptic respiratory failure or postoperative ventilator dependence in a patient with no known lung disease.*
- *The wide variety of causes of ACRF may be compartmentalized into causes of incremental load, diminished neuromuscular competence, or depressed drive, superimposed on a limited ventilatory reserve.*
- *Intrinsic positive end-expiratory pressure (PEEPi) is a central contributor to the excess work of breathing in patients with ACRF.*
- *The most important therapeutic interventions are administration of oxygen, bronchodilators, and corticosteroids, and noninvasive positive pressure ventilation (NIPPV).*
- *NIPPV can be used in most patients to avoid intubation and has been shown to improve survival.*
- *The decision to intubate a patient with ACRF benefits from clinical judgment and a bedside presence. Hypotension and severe alkalemia commonly complicate the immediate periintubation course, but they are usually avoidable.*
- *Ventilator settings should mimic the patient's breathing pattern, with a relatively rapid rate (e.g., 20/min) and small tidal volume (e.g., 450 mL); some positive end-expiratory pressure (e.g., 5 cm H_2O) should be added.*
- *Prevention of complications such as gastrointestinal hemorrhage, venous thrombosis, and nosocomial infection is a crucial component of the care plan.*
- *The key to liberating the patient from the ventilator is to increase neuromuscular competence while reducing respiratory system load.*
- *In selected patients, extubation to NIPPV despite failed spontaneous breathing trials reduces ventilator and ICU days and further improves survival.*

In the past three decades, mortality from chronic obstructive pulmonary disease (COPD) has risen dramatically, making COPD the fourth leading cause of death in 2000.[1] Compared with people with normal lung function, subjects with severe COPD (forced expiratory volume in 1 second [FEV_1] <50% predicted) followed for 22 years as part of the National Health and Nutrition Examination Survey (NHANES I) had a 2.7-fold increased risk of death (95% CI 2.1 to 3.5) in an adjusted analysis.[2] This trend is apparent in men and women, more prominent in black Americans, and clearly related to cigarette smoking. For the first time, in 2000 more women than men died of COPD in the U.S.[1] Admissions to ICUs for exacerbations of COPD account for a substantial portion of bed-days,[3] since these patients often require prolonged ventilatory support. In surgical ICUs, COPD is an important problem as well, since it is one of the more common reasons for a prolonged postoperative recovery. An approach to this disease is an essential component of the intensivist's armamentarium.

This chapter describes the pathophysiology and management of patients with chronic pulmonary disease (most with COPD) who require intensive care for decompensation of their normally precariously balanced ventilatory state. This acute deterioration superimposed on stable disease is termed acute-on-chronic respiratory failure (ACRF). Patients may present to the ICU with worsening dyspnea, deteriorating mental status, or respiratory arrest. Especially when there is a preexisting diagnosis of lung disease, the diagnosis of ACRF can be made easily. However, it is important to remember that not all patients with severe COPD will have been so identified. In many patients with respiratory distress, congestive heart failure or pulmonary thromboembolism is considered first; making a correct diagnosis of ACRF requires a high index of suspicion. On occasion the disease is even more occult, for example in a postoperative patient who fails extubation and then is noted to have hyperinflation on the chest radiograph. Since optimal therapy depends on accurate diagnosis, underlying COPD should be part of the differential diagnosis for most patients with dyspnea or inability to sustain unassisted ventilation.

A severe exacerbation of COPD is characterized by a sustained worsening from the stable state that is acute in onset and requires hospitalization.[4] The typical symptoms are dyspnea that has been worsening over days, often with increased cough and sputum production. Physical examination typically demonstrates respiratory distress, accessory muscle use, a prolonged expiratory time, recruitment of expiratory muscles, and wheezing. As discussed below, the absence of respiratory distress is not necessarily reassuring and when associated with somnolence is a grave and ominous sign of impending respiratory arrest. The chest radiograph is usually abnormal, reflecting the chronic lung disease, but only in 15% to 20% of cases reveals a finding (eg, pneumonia, pneumothorax, pulmonary infarction, or pulmonary edema) that results in a change of management.[5] Sometimes there are indicators of acute infection, such as purulent sputum, fever, leukocytosis, and a new radiographic infiltrate. Typical initial arterial blood gas values on room air show a partial oxygen pressure (P_{O_2}) of 35 to 45 mm Hg and a partial arterial carbon dioxide pressure (Pa_{CO_2}) of 60 to 70 mm Hg. Comparison with values obtained when the patient is stable can be useful, as many patients have compensated metabolic acidosis with chronically elevated Pa_{CO_2} at baseline. Electrocardiography (ECG) may show signs of right atrial enlargement or right ventricular hypertrophy and strain. P-wave amplitude >1.5 mm is universal in patients with acute exacerbation of COPD (but not necessarily ACRF), although classic P pulmonale (P-wave amplitude in leads II, III, and/or aVF >2.5 mm) is uncommon. Resolution of the exacerbation is associated with an amplitude reduction of approximately 0.8 mm.[6] Thus serial ECGs may be useful in assessing response to therapy.

Although the short-term risk of death is high for ACRF, the prognosis for patients with ACRF is not uniformly poor despite severe underlying pulmonary impairment. In a prospective analysis of 250 admissions (180 patients) to an ICU for acute respiratory failure complicating COPD, hospital mortality was 21% and was strongly associated with the development of extrapulmonary organ failures.[7] One-year survival following ACRF ranges from 22% to 72%.[8,9] Some patients will return to an acceptable quality of life, and some even go back to work. In a cohort of 1016 patients admitted with a COPD exacerbation and a Pa_{CO_2} >50 mm Hg, 1-year survival was 47%, but only 26% of the patients rated their quality of life as good or better when surveyed at 6 months.[3] Other than the underlying cause of chronic respiratory failure, predictors of poor survival include premorbid functional status, baseline dyspnea, lower body mass index,[3] older age,[3] lower ratio of oxygen pressure to fraction of inspired oxygen (P_{O_2}:$F_{I_{O_2}}$)[3], history of congestive heart failure, presence of serious comorbid disease,[10] development of extrapulmonary organ failures,[7] serum albumin level,[3,11] cor pulmonale,[3] and requirement for >72 hours of ventilation,[10] but these indicators are not refined enough to allow accurate prognostication for individual patients.

Critical care resource utilization and costs for ACRF and COPD are substantial. Ely and coworkers calculated that respiratory care costs were almost twice as much for patients with COPD compared with non-COPD–related respiratory failure ($2422 [$1157 to $6100] vs. $1580 [$738 to $3322]) respectively; $p = 0.01$, 1996 dollars), despite similar ICU lengths of stay and mechanical ventilation days.[12]

Ideally, patients followed in the clinic with known severe COPD will be encouraged to discuss with their physicians their wishes regarding intensive care before acute deterioration. Unfortunately this is only occasionally accomplished. It is our approach to fully support patients with ACRF who believe their quality of life is acceptable, especially since most will be successfully managed with noninvasive ventilation, and most of those intubated will eventually be successfully liberated from the ventilator and survive to hospital discharge.[8,13] On the other hand, when mechanical ventilation seems excessive to the patient or physician, defining the goals of care as the provision of comfort and relief from dyspnea and pain is appropriate. We urge clinicians caring for COPD patients with compensated respiratory failure to address advance directives and desire for life-sustaining therapies during routine ambulatory clinic appointments when informed and deliberate decision making can be shared by the patient and their loved ones.

Pathophysiology

Alveolar ventilation is maintained by the central nervous system, which acts through nerves and the respiratory muscles to drive the respiratory pump. The three subsets of ventilatory failure are loss of adequate drive, impaired neuromuscular competence, and excessive respiratory load. This concept is elucidated in Fig. 39-1. The central nervous system drives the inspiratory muscles via the spinal cord and phrenic and intercostal nerves. Inspiratory muscle contraction lowers pleural pressure, thereby inflating the lungs. The pressure generated by the inspiratory muscles (neuromuscular competence) must be sufficient to overcome the elastance of the lungs and chest wall (elastic load), as well as the flow resistance of the airways (resistive load). Spontaneous ventilation can be sustained only as long as the inspiratory muscles are able to maintain adequate pressure generation.[14]

Relatively few patients develop ventilatory failure from loss of drive. Most often this occurs in the setting of drug or alcohol overdose or physician-directed sedation. Typically these patients present little challenge, requiring only supportive care until the drug can be reversed or metabolized. One exception is the group of patients with undiagnosed sleep-disordered breathing. Although sleep-disordered breathing is no more common in people with mild COPD than in healthy controls,[15] many patients with chronic respiratory failure have a significant component of central apnea with nocturnal desaturation. Specific therapy directed at relief of their sleep disorder, including nocturnal bilevel pressure support

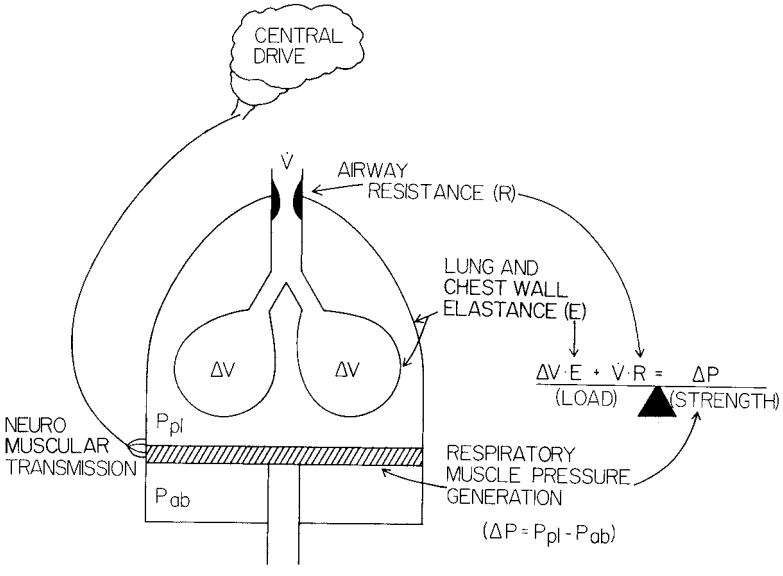

FIGURE 39-1 A drawing of the key elements of the respiratory system. The drive to breathe derives from CNS regulators of respiratory pattern. Neural afferents are the path for signals causing respiratory muscle contraction. Diaphragm contraction generates a pleural pressure (Ppl) and is opposed by any increased abdominal pressure (Pab). The Ppl generated must overcome the resistive (R) and elastic (E) forces acting on the respiratory system in producing a given minute ventilation ($\dot{V}_E$). (*Reproduced with permission from Schmidt et al.*[81])

and supplemental oxygen, may be required. Far more common and difficult are patients who have adequate drive but have inadequate neuromuscular function, excessive load, or both.

A useful approach to understanding the pathophysiology of ACRF is that inspiratory muscle fatigue is a primary determinant.[16] A muscle is fatigued when it can no longer develop the degree of tension possible before fatigue, no matter what the degree of stimulation, yet the muscle recovers with rest. Skeletal muscles fatigue when their rate of energy consumption exceeds the energy supplied by blood flow.[17] Similarly, for the respiratory muscles, endurance time during inspiratory resistive loading is closely tied to the oxygen cost of breathing ($\dot{V}_{O_2resp}$).[18] The primary determinants of $\dot{V}_{O_2resp}$ are the time-tension index, work rate, and lung volume.[19] Several experiments in humans indicate that the intensity required of the contracting respiratory muscles, as well as their strength, is a crucial factor in determining fatigue.[20] In contrast to patients with ACRF, patients with stable, moderately severe COPD do not demonstrate low frequency diaphragmatic fatigue after maximal exercise effort when measured with a nonvolitional magnetic coil–induced twitch,[21,22] despite excessive muscle loading manifest by significant slowing of the respiratory muscle maximal relaxation rate after a volitional sniff maneuver.[23] This would suggest that the superimposition of infection, heart failure, or other precipitants potentiates muscle fatigue. Once fatigue of the respiratory muscles is established, neuromuscular competence is unable to sustain the mechanical load imposed on the respiratory system, and ventilatory failure ensues. The intensivist must therefore address both the precipitant and resultant respiratory muscle fatigue for treatment to be successful.

In health, neuromuscular function far exceeds that necessary to sustain ventilation against the normally small load. Dramatic increments in load (as in status asthmaticus) or decrements in strength (as in the Guillain-Barré syndrome) are required to cause hypoventilation. In patients with COPD, however, the respiratory system load as judged by the $\dot{V}_{O_2resp}$ is elevated to 17% to 46% of the total body volume of oxygen utilization ($\dot{V}_{O_2}$), owing to abnormal airway resistance and increased elastance.[24] The increase in airway resistance is caused by bronchospasm, airway inflammation, and physical obstruction by mucus and scarring.

The most significant contributor to the elastic load is dynamic hyperinflation. Airflow obstruction, compounded by decreased elastic recoil in patients with emphysema, leads to prolongation of expiration. When the rate of alveolar emptying is slowed, expiration cannot be completed before the ensuing inspiration. Rather than reaching the normal static equilibrium of lung and chest wall recoil at functional residual capacity (FRC) at the end of each breath, the respiratory system empties incompletely. Expiration terminates at this higher, dynamically determined FRC. At end expiration, there remains a positive elastic recoil pressure, which is called intrinsic positive end-expiratory pressure (PEEPi). Accordingly, alveolar pressure remains positive with respect to end-expiratory pressure at the airway opening, such that a greater effort must be generated by the inspiratory muscles on the subsequent breath. This adds a threshold load to spontaneous inspiration, and in mechanically ventilated patients makes triggering of assisted breaths more difficult.[25] Determinants of the magnitude of PEEPi include the degree of expiratory obstruction (including both patient and ventilator), elastic recoil, minute ventilation, and expiratory time (and therefore the respiratory rate, inspiratory flow rate, and inspiratory flow profile). PEEPi of about 10 cm H_2O is present in most, if not all, COPD patients with acute ventilatory failure,[26,27] and PEEPi can be measured in many ambulatory outpatients as well.[28] As discussed more fully below, counterbalancing this PEEPi with external positive end-expiratory pressure (PEEP) provides a means by which to lower the work of breathing (or the work of triggering). The impact of PEEPi on the work of breathing is illustrated in Fig. 39-2.

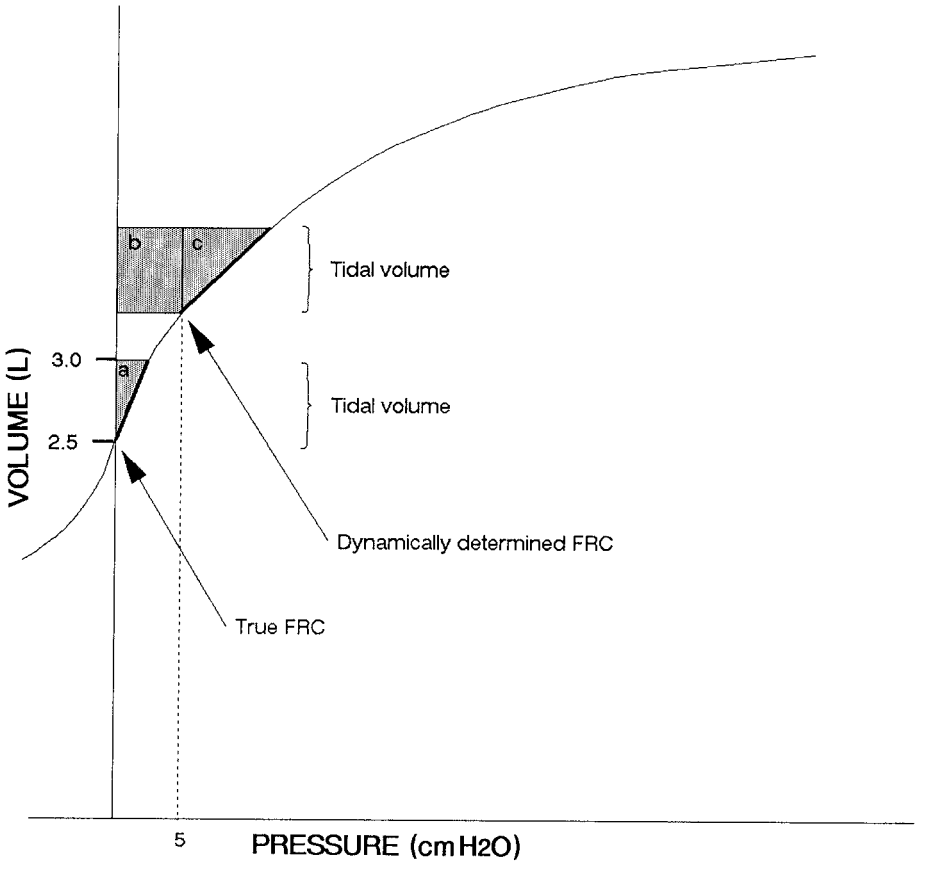
At the same time that the respiratory system load is elevated, the inspiratory muscles are poorly able to tolerate it. The hyperexpansion that occurs during COPD forces the inspiratory muscles to operate in a disadvantageous portion of their force-length relationship. Diaphragm strength (measured by sniff esophageal pressure) in patients with severe but stable COPD is only two-thirds that of normal individuals, virtually all of this ascribable to the diaphragm position rather than to inherent muscle weakness.[29] Still, patients presenting with ACRF may have not only worsening hyperinflation but also other conditions (e.g., protein-calorie malnutrition[30] or steroid myopathy[31]) that cause intrinsic muscle weakness. Even when patients with severe COPD are in a state of compensation, the increased load and diminished neuromuscular competence are precariously balanced. Only minor additional decrements in strength or increments in load are sufficient to precipitate inspiratory muscle fatigue and respiratory failure. It is this incremental deterioration in the balance of neuromuscular competence and respiratory system load that defines ACRF. Its many potential contributors are enumerated in Fig. 39-3.

ADDITIONAL CAUSES OF DECREASED NEUROMUSCULAR COMPETENCE

DEPRESSED DRIVE

In the usual patient who is dyspneic, tachypneic, diaphoretic, and using accessory muscles of respiration, impairment of drive is clearly not the cause of ACRF. When drive has been assessed in this setting it is greatly elevated,[32] as it is in most patients who fail to be weaned from mechanical ventilation.[33] Nevertheless, there are patients in whom new central nervous system (CNS) insults or drug effects contribute to respiratory failure. Even small doses of sedatives or narcotics may cause respiratory failure when superimposed on chronic ventilatory insufficiency; a careful history is essential to exclude this possibility. Occult hypothyroidism is not rare in the elderly, particularly in women. Thyroid function testing should be part of the routine screening of patients with ventilatory failure attributed to decreased drive.

It has been proposed that central depression of drive contributes to the terminal stages of respiratory failure, regardless of the precipitating factor. According to this "central wisdom" hypothesis, overworked respiratory muscles reach a threshold of loading at which point muscle injury results in the elaboration of inhibitory signals, which feedback to the CNS to reduce drive, thereby protecting the muscles from fatigue.[34–36] The relevance of this mechanism to respiratory failure remains to be demonstrated.



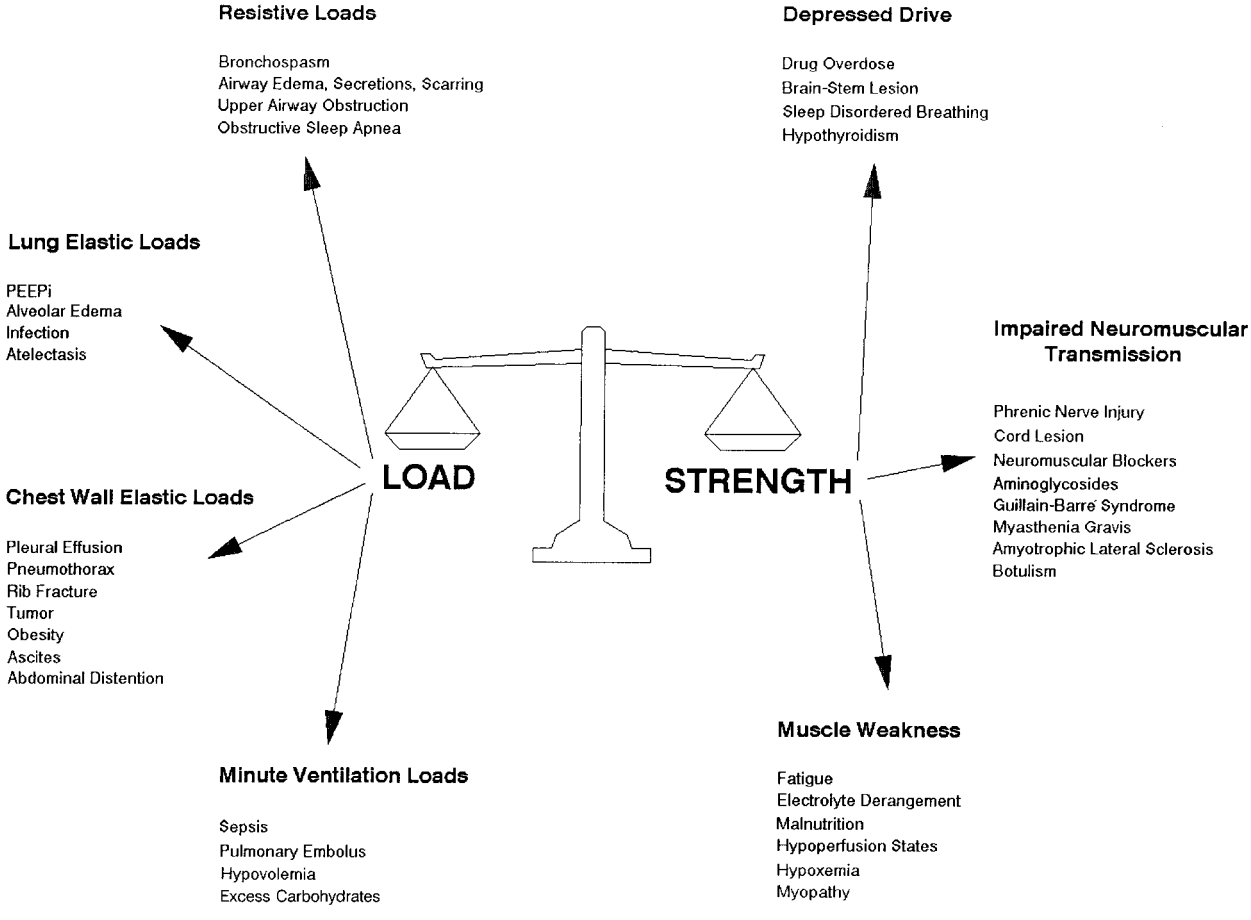


FIGURE 39-2 The effects of PEEPi on work of breathing. A volume-pressure curve for the respiratory system is shown. Under normal conditions, alveolar pressure is atmospheric at end expiration (shown as True FRC). As transpulmonary pressure is generated by the respiratory muscles, there is a tidal volume (VT) change (here from 2.5 to 3.0 L, a VT of 0.5 L). The pressure-volume product or the external work is shown by shaded area *a*. With gas trapping due to airflow obstruction, FRC can become dynamically determined. In this example, the end-expiratory pressure (PEEPi) is 5 cm H_2O, which raises the end-expired lung volume. Now, for the same VT generation, the respiratory muscles must overcome the positive alveolar pressure (PEEPi) before flow occurs, and the work of breathing is increased accordingly ($b + c$). In addition, the VT change can occur on a flatter portion of the volume-pressure curve, resulting in yet another increment in elastic load. The addition of continuous positive airway pressure (CPAP) in an amount to counterbalance the PEEPi has the ability to reduce the work of breathing from $b + c$ to c only.

FIGURE 39-3 The balance between the load on the respiratory system and the strength of the system determines progression to and resolution of ACRF.

FAILED NEUROMUSCULAR TRANSMISSION

In order to effect adequate ventilation, the CNS must transmit drive to the working muscles via the spinal cord and peripheral nerves. Therefore causes of neuromuscular failure such as spinal cord lesions, primary neurologic diseases, and neuromuscular blocking drugs, may produce ACRF. Aminoglycosides[37] and procainamide[38] act as mild neuromuscular blockers, a feature unimportant in the great majority of patients, but relevant in those with neuromuscular diseases such as myasthenia gravis. The clinical setting may be a clue to one of the unusual causes, such as phrenic nerve injury following cardiopulmonary bypass. This occult lesion may be induced by direct trauma to the nerve, or more indirectly by cold cardioplegia.

MUSCLE WEAKNESS

The most important causes of decreased neuromuscular competence fall into the category of muscle weakness. In patients with COPD, respiratory muscle changes represent a balance between factors capable of impairing respiratory muscle function and metabolic adaptation of the diaphragm (Table 39-1).

Changes in chest wall geometry and diaphragm position are particularly important and adversely affect the muscles of inspiration (diaphragm and intercostal muscles) and expiration (abdominal muscles). The inspiratory muscles are poorly able to tolerate the maximal loading that occurs in emphysema. Hyperexpansion forces them to operate on a disadvantageous portion of their force-length curve. The piston-like displacement of the diaphragm is compromised and expansion of the lower thoracic cage is disturbed. In addition, a flattened diaphragm generates less transmural pressure for a given tension than the normally curved one, as described above. Electrolyte disturbances such as hypokalemia, hypophosphatemia,[39] and hypomagnesemia[40] may potentiate muscle weakness. Disturbances of the myofibrillar contractile unit have been demonstrated in humans[41] and in animal models of loaded resistive breathing that simulates ACRF. Disturbances of the sarcomere length/tension relationship, activation of proteolytic enzymes such as calpain that can degrade actin and intercellular adhesions,[42] oxidative stress, and elaboration of proinflammatory cytokines have also been proposed to play a role.[43]

Hypophosphatemia may be exacerbated by many of the drugs used to treat ventilatory failure, such as methylxanthines, β-adrenergic agonists, corticosteroids, and diuretics, accounting for its striking prevalence in COPD patients (about 20%).[44] Malnutrition, which is present in 40% to 50% of hospitalized patients with emphysema,[45] has been suggested to be associated with respiratory muscle weakness,[44] yet one study demonstrated that diaphragmatic strength was comparable between stable COPD patients with reduced body mass index (BMI; 17.3 kg/m^2) and those with normal BMI.[46] Short-term refeeding can improve indices of respiratory muscle function[30] and immune response.

Myopathy due to corticosteroids may also contribute.[31,47] Rarely, other myopathies such as an adult variant of acid maltase deficiency or mitochondrial myopathy may cause cryptic respiratory failure due to muscle weakness. Cellular and molecular adaptations of the respiratory musculature differ between the diaphragm and the intercostal muscles. The diaphragmatic myocytes adopt an "aerobic" type I phenotype with prolonged loading (see Table 39-1). By contrast the intercostal muscles undergo relatively greater glycolytic adaptation to chronic loading.[48]

TABLE 39-1 Factors Impairing Respiratory Muscle Structure/Function and Mechanisms of Chronic Adaptation In Patients at Risk for Acute-on-Chronic Respiratory Failure

Respiratory Muscle Change	Impairment	Adaptation
Thoracoabdominal geometric changes	Changes in chest wall geometry and diaphragm position resulting from hyperinflation	Structural remodeling changes in the diaphragm and accessory muscles of respiration
Respiratory muscle sarcomeric changes	Deleterious shortening of diaphragm sarcomere length disturbs intrinsic sarcomeric length-tension relationship	Transformation of myosin isoforms from fast to slow phenotype
	Disorganization of contractile myofibrils (Z-band streaming and filament misalignment)	Increase in proportion and cross-sectional area of type I fibers, and decreased type II fibers
		Increases in mitochondrial volume density and oxidative capacity
Cytosolic protein changes	Local activation of proteases (e.g., calpain) cause respiratory muscle proteolysis	New contractile protein and protease inhibitor synthesis
Oxidant/antioxidant mediator changes	Generation of reactive oxygen species from respiratory muscles and inflammatory cells overwhelm endogenous antioxidants (e.g., catalase, superoxide dismutase), resulting in respiratory muscle injury	Increased inducible antioxidant acitivity
Nutritional, pharmacologic, and aging changes	Malnutrition, steroids, and aging can impair respiratory muscles by reduction in type II muscle fibers (atrophy); glycogen, high-energy phosphate and ketone accumulation	
Inflammatory changes	Deleterious effects of infection/inflammation on skeletal muscle and systemic organ function	

SOURCE: Modified with permission from Orozco-Levi.[48]

As discussed above, muscle fatigue is the reversible loss of force generation despite adequate neural stimulation. Fatigue is itself a cause of muscle weakness and can be short-lasting (high-frequency fatigue), or long-lasting (low-frequency fatigue) which can persist for days to weeks. To the extent that fatigue is central to the development of respiratory failure, it may be caused by an inadequate supply of nutrients, excess generation of metabolites such as lactate or hydrogen ion, or depletion of muscle glycogen. Evidence to support the importance of blood supply in the genesis of fatigue comes from studies of respiratory failure in animals with hemorrhagic, cardiogenic, or septic shock.[49,50] In these animals, fatigue is hastened by circulatory insufficiency. The magnitude of blood flow to the respiratory muscles seems to be important beyond aerobic needs, as demonstrated by experiments in which flow was manipulated independently of oxygen delivery.[51] Hypoperfusion states, hypoxemia, and severe anemia have the potential to contribute to muscle fatigue and thereby hasten respiratory failure. Although fatigue is likely to contribute to the precipitation of an ACRF event, systematic evaluation has failed to demonstrate that low-frequency fatigue contributes to prolonged mechanical ventilation and failure to liberate. For example, none of 17 "weaning-failure" patients developed objective fatigue (transdiaphragmatic pressure changes with phrenic nerve stimulation), despite three quarters of patients having a diaphragmatic tension-time index (TTdi) greater than 0.15—a level associated with diaphragmatic fatigue by several other investigators.[52]

ADDITIONAL CAUSES OF INCREASED LOAD

INCREASED RESISTIVE LOAD

In patients with COPD, the respiratory system load is chronically elevated owing to abnormal airway resistance and increased elastance. The increase in airway resistance is caused by bronchospasm, airway inflammation, and physical obstruction by mucus and scarring. One common cause of increased flow resistance, and the one most amenable to pharmacologic intervention, is bronchospasm. The disease course in most patients with COPD includes an asthmatic component, and bronchial hyperreactivity to provocation may be as common in COPD as in asthma.[53] Exacerbations of bronchospasm increase resistive workload, precipitating ACRF. Superimposed heart failure may also cause increased airway resistance, mimicking asthma ("cardiac asthma"). Upper airway obstruction is much less common, but since these patients frequently have a history of prior intubation, tracheal stenosis should be considered. Finally, sleep-disordered breathing, which commonly coexists with COPD, may need to be excluded. Especially once the patient is intubated, clues to this underlying cause of dynamic upper airway obstruction (e.g., snoring) may be impossible to discern. In the proper setting (an obese, hypersomnolent patient), this possibility should be vigorously pursued. The endotracheal tube (ETT) itself presents a significant resistive workload, especially when a small size (<7.5 mm internal diameter) is chosen.[54] The angulation and length of the tube and the presence of secretions also affect flow resistance. Additionally, ventilator circuit heat and moisture exchangers (HME filters) impose significantly greater dead space and tube resistance than heated humidifiers in ventilated ACRF patients.[55] Automatic tube compensation (ATC) algorithms available on some modern ventilators are designed to maintain airway pressure by continuously calculating pressure drop across the ETT during inspiration and to decrease airway pressure during expiration to maintain constant alveolar pressure. However, ATC may be insufficient to compensate fully for the imposed resistive load of the ETT.[56]

INCREASED LUNG ELASTIC LOAD

Contributors to lung stiffness include pulmonary edema (cardiogenic and noncardiogenic), pneumonia, interstitial fibrosis or inflammation, tumor, and atelectasis. As noted above, bronchospasm not only causes increased flow resistance, but simultaneously worsens the elastic load by augmenting PEEPi.

INCREASED CHEST WALL ELASTIC LOAD

The chest wall includes the thorax, diaphragm, and abdomen. Therefore obesity, rib fracture, pneumothorax, pleural effusion, ascites, chest wall abnormalities, and abdominal distention (see Chap. 42) contribute to the work of breathing. These factors are particularly relevant in the postoperative setting.

MINUTE VENTILATION LOADS

Dividing the work of breathing into resistive and static components is a useful way of analyzing the effort of each breath. However, even if the work of each breath remains constant, an increase in respiratory rate increases the load. Increased minute ventilation ($\dot{V}_E$) requirements can be divided into those due to excess carbon dioxide production ($\dot{V}_{CO2}$) and those from worsened dead space. The first category includes excessive caloric intake, fever, agitation, muscular exertion (including shivering and respiratory distress), and hypermetabolism due to injury or infection. New dead space may be caused by pulmonary embolism, hypovolemia, PEEP (including PEEPi), or shallower breathing (which raises the dead space fraction, V_D/V_T). Partitioning of the lung mechanics into resistive and static components in the intubated COPD patient may be inaccurate if the end-inspiratory pause maneuver is too short and if there is a rapid spontaneous respiratory rate.[57]

MULTIFACTORIAL RESPIRATORY FAILURE

In order to analyze respiratory failure in a way that facilitates management, it is important to dissect the very complex real-life patient into simple components of deranged neuromuscular competence and load. However, the patient with ACRF due to isolated rib fracture or hypokalemia is uncommon. More often numerous contributors to both decreased strength and increased load are implicated. For example, a patient admitted with pneumonia and worsening bronchospasm may also have hypophosphatemia, heart failure, and malnutrition. Aspiration at the time of intubation, abdominal distention related to attempts to feed enterally, and overzealous parenteral nutrition complete the picture of multifactorial ACRF. Although the situation in such a patient may seem overwhelmingly complex, we caution against a "shotgun" approach to evaluation and management of patients with multifactorial respiratory failure. Despite the temptation to provide all possible interventions for these very ill patients, a systematic approach to each component of respiratory failure leads logically to a plan for treatment.

Approach to the Patient

Failure to aggressively treat mild to moderate acute exacerbations of COPD prior to the development of ACRF and other organ failure is associated with an increased risk of emergency hospitalization and delayed recovery.[58] The unequivocal role of noninvasive positive pressure mechanical ventilation (NIPPV) justifies its position as the cornerstone in the therapeutic approach to critically ill patients with ACRF (see Chap. 33). We consider NIPPV to be the "bookends" in the therapeutic library of therapy for ACRF, providing firm support on either end of an exacerbation of ACRF. This approach is discussed below, but it incorporates early initiation of NIPPV to avoid mechanical ventilation (MV) and improve survival, and later use of this tool for early liberation from MV. We describe below three phases of management of the ACRF patient: early ACRF, late ACRF requiring intubation for MV, and liberation from the ventilator.

PHASE 1: EARLY ACUTE-ON-CHRONIC RESPIRATORY FAILURE

The goals of management in the patient not yet intubated are to avoid MV whenever possible and to recognize progressive respiratory failure when it is not. The proven efficacy of NIPPV, that its use can avert mechanical ventilation in about 75% of patients with ACRF, is one of the most important developments in the management of these patients, because it buys time for the physician to treat precipitants of ACRF and for the patient to improve.

Current guidelines recommend NIPPV as definitive and first-line therapy for COPD-related ACRF.[59,60] Most centers use a face or nasal mask and pressure-support ventilation, although helmet interfaces, poncho wraps, and other ventilator modes can support NIPPV. A tight-fitting mask allows substantial ventilatory assistance yet provides for brief periods off the ventilator during which patients can speak, inhale nebulized medications, expectorate, and swallow liquids. NIPPV has been systematically evaluated in several large studies. The outcomes from these studies have been synthesized in a Cochrane meta-analysis of 14 randomized controlled studies of NIPPV versus usual medical care (UMC) that enrolled a total of 758 patients with ACRF.[61] Age ranged from 63 to 76 years, admission pH was 7.26 to 7.34, admission partial pressure of arterial carbon dioxide (Pa_{CO_2}) was 57 to 87 mm Hg, admission Pa_{O_2} was 39 to 73 mm Hg, and the FEV_1 ranged from 0.68 to 1.03 L. The eight largest studies enrolled 40 or more patients. The combined analysis demonstrated that: treatment failure was less likely with NIPPV than UMC (RR 0.48; 95% CI 0.37, 0.63) with a number needed to treat (NNT) of 5 (95% CI 4, 6), and mortality was reduced by 48% (RR for death 0.52; 95% CI 0.35, 0.76; NNT 10; 95% CI 7, 20). Notably, the mortality reduction was evident regardless of whether ACRF was treated in an ICU or in a general ward. Additionally, there was a 60% reduction in requirement for intubation with NIPPV, and rapid improvements in respiratory rate, Pa_{CO_2} and pH. Hospital length of stay (LOS) was reduced by 3.24 days, although the trend to reduced ICU LOS (4.71 fewer days) did not reach significance.[61] Interestingly, the improvement in Pa_{O_2} was heterogeneous between studies and was not significantly different at 1 hour after initiation of treatment. The finding of another meta-analysis revealed essentially similar findings for survival and clinical improvement, but subgroup analysis suggested that the benefit was limited to patients with severe but not mild ACRF. This hypothesis has not been tested in a prospective stratified fashion.[62]

NIPPV has been used for prolonged periods (more than 1 week) and has been shown to relieve symptoms, reduce respiratory rate, increase tidal volume, improve gas exchange,[63] and to lessen the amplitude of both the diaphragmatic electromyogram and the transdiaphragmatic pressure.[64] Complications of the mask have been minor and few;[61] local skin breakdown has been attributed to the tight-fitting mask, but can be avoided by applying a patch of wound care dressing. Only a few patients cannot tolerate face or nasal masks, and some of these patients respond to judicious and carefully monitored use of anxiolytics. Aspiration of gastric contents has only rarely been noted in these patients, even when a nasogastric tube is not routinely placed; however, impaired mentation probably increases this risk.

Careful patient selection is essential for successful NIPPV in ACRF and is summarized in Table 39-2.[65] Although a nasal mask is objectively as effective and well tolerated as a full face mask,[66] we typically begin therapy with a full face mask held lightly against the face. Positive pressure of 5 to 8 cm H_2O is delivered using a pressure limited mode on a noninvasive ventilator until the patient is able to tolerate the mask comfortably and synchronize with the ventilator.[67] After applying head straps, we aim to achieve an expiratory positive pressure of 2 to 5 cm H_2O (to counterbalance PEEPi) and an inspiratory positive pressure of 15 to 18 cm H_2O (equivalently, 2 to 5 cm H_2O PEEP with 13 to 16 cm H_2O pressure support) to assist alveolar ventilation. Higher pressures can sometimes be used, but they tend to be limited by air leak or mask discomfort. The PEEP component of NIPPV is important[68] and does not usually cause incremental hyperinflation.[69] Indeed, continuous positive airway pressure (CPAP) alone (without ventilatory assistance) reduces the work of breathing, improves gas exchange, leads to subjective benefit, and sometimes can avert intubation[70–72] when applied to patients with ACRF. When PEEP was added to pressure-support ventilation in ventilated patients with COPD, inspiratory effort fell another 17%, and patient-ventilator synchrony improved.[45]

TABLE 39-2 Selection Criteria for Noninvasive Positive Pressure Ventilation (NIPPV) for Acute-on-Chronic Respiratory Failure

Appropriate diagnosis with potential reversibility
Establish need for ventilatory assistance:
Moderate to severe respiratory distress
Tachypnea
Use of accessory muscles or abdominal paradox
Blood gas derangement
pH <7.35, Pa_{CO_2} >45 mm Hg, or P_{O_2}:FI_{O_2} ratio <200
Exclude patients with contraindications to NIPPV:
Respiratory arrest
Medically unstable
Unable to protect airway
Excessive secretions
Uncooperative or agitated
Unable to fit mask
Recent upper airway or gastrointestinal surgery

FI_{O_2}, fraction of inspired oxygen; Pa_{CO_2}, partial pressure of arterial carbon dioxide; P_{O_2}, oxygen pressure.
SOURCE: Reproduced with permission from Liesching et al.[65]

NIPPV is not uniformly successful in patients with ACRF.[73] Essential to successful patient-NIPPV synchrony are trigger settings for inspiration, pressurization rates (rapid pressurization reduces diaphragm work but results in increased leakage), and inspiratory-to-expiratory cycling (mask leaks can result in delayed cycling). These aspects are reviewed in detail in Chap. 33. A salutary response is typically evident within 10 minutes of beginning NIPPV, as indicated by a falling respiratory rate and heart rate as well as by the patient's subjective assessment. Occasional patients feel claustrophobic and may show objective worsening with NIPPV. Although we occasionally use pharmacologic anxiolytic therapy with success, this course has obvious attendant risks and should only be undertaken with appropriate safeguards.

A risk of NIPPV that is not often discussed is its potential to lull the physician-nurse-respiratory therapist team into a sense of comfort while the patient continues to worsen. In these patients, time spent trying NIPPV may potentially lead to a later, more urgent intubation in a more exhausted patient with significantly greater tissue hypoxia.

Avoiding intubation and conventional mechanical ventilation nearly always depends on discerning the cause of ACRF and reversing it. Thus while NIPPV is initiated, each of the potential causes enumerated in Fig. 39-3 should be reviewed in light of the clinical presentation. On occasion, impending respiratory failure can be averted by a specific intervention targeted to one precipitant, such as rib fracture (intercostal nerve block) or pulmonary edema (diuresis or afterload reduction). More often, several contributors are identified, such as worsened bronchospasm, electrolyte derangement, and infection, and treatment must be broad-based. The treatments of many of these precipitants are discussed elsewhere in this text; here, the use of oxygen and drugs will be discussed.

OXYGEN

One of the most pervasive myths surrounding the treatment of ACRF is that these patients rely on hypoxic drive to breathe. Physicians are often hesitant to supply oxygen, fearing that patients will stop breathing, necessitating intubation. Since these patients are typically hypoxemic on presentation (P_{O_2} is usually about 30 to 40 mm Hg), failure to supply adequate oxygen is a potentially devastating treatment error. Unrelieved hypoxemia in the face of acidemia, fatiguing respiratory muscles, and an often failing right ventricle risks arrhythmia, myocardial infarction, cerebral injury, renal failure, and respiratory arrest.

In several studies performed over the past decade, patients with COPD have been convincingly shown to nearly maintain $\dot{V}_E$ despite treatment with even 100% oxygen,[74,75] and to augment their drive in response to hypercarbia.[76] When oxygen is given, the P_{CO_2} typically rises, but this effect is attributed largely to worsened matching of ventilation and perfusion and the Haldane effect, not to hypoventilation. In one series, patients with ACRF had a mean initial P_{O_2} of 38 mm Hg and P_{CO_2} of 65 mm Hg.[17] They were then placed on 100% oxygen, which caused a rise in the mean P_{O_2} to 225 mm Hg, while the mean P_{CO_2} plateaued at 88 mm Hg. $\dot{V}_E$ fell by a small amount, and drive remained supranormal. Three further studies have confirmed that worsened respiratory acidosis is modest and manageable in ACRF patients receiving O_2 therapy titrated to a functional oxygen saturation (Sp_{O_2}) of 90%.[77–79] Our point is not to claim that hypoxic drive in patients with ACRF does not exist—it clearly does[80]—but to emphasize that oxygen should nevertheless be given. High concentrations of inspired oxygen are not usually necessary in ACRF, unless pneumonia or pulmonary edema is present, since hypoxemia is due largely to ventilation-perfusion ($\dot{V}/\dot{Q}$) mismatching, not to shunting. Nevertheless, we believe that the risks of oxygen therapy have been greatly overstated,[81] often leading physicians to withhold a potentially life-saving therapy. The goal of oxygen therapy is to maintain 90% saturation of an adequate amount of circulating hemoglobin. This goal can usually be attained with a face mask at 30% to 35% or a nasal cannula at 3 to 5 L/min. A rise in P_{CO_2} is likely, but that in itself is of little importance. Patients may progress to respiratory failure despite oxygen therapy, but not because of it. For this reason, careful serial assessments by the ICU team of the physician, nurse, and respiratory therapist are essential.

PHARMACOTHERAPY

Bronchodilators are an essential part of the early management of these patients (Table 39-3). While much of the airflow obstruction of COPD is irreversible, most patients have some reversible component.[82,83] In stable COPD, combinations of a β-agonist and ipratropium have been demonstrated to be superior to either drug alone.[84] However, in a meta-analysis of four randomized studies, combination therapy for acute exacerbations of COPD does not result in greater short-term bronchodilation compared with either albuterol or ipratropium alone.[85] Despite these data, current practice continues to support combination therapy if airflow obstruction persists despite maximal doses of β-agonists or if treatment-limiting tachycardia is experienced. Respiratory stimulants would be predicted not to work in this setting, since drive is already supranormal. Indeed, doxapram and similar drugs are now rarely used since their toxicity is substantial and their efficacy minimal,[86,87] particularly when compared with NIPPV.[88] We believe there is no role for these drugs. Similarly there is no evidence to support routine use of mucolytic agents or chest percussion.

TABLE 39-3 Bronchodilator Therapy in Acute-on-Chronic Respiratory Failure

β-Agonists
Albuterol or metaproterenol by MDI (three to six puffs every 30 to 60 min)
or
Albuterol or metaproterenol by nebulizer (0.5 mL albuterol or 0.3 mL metaproterenol in 2.5 mL normal saline solution every 2 h)
Ipratropium
Three to ten puffs every 2 to 6 h by MDI
Consider high doses (400 μg every 2 to 6 h) in intubated patients
Aminophylline
Loading dose is 5 mg/kg
Maintenance dose is approximately 0.5 mg/(kg·h)
Must be titrated against serum levels
Corticosteroids
Methylprednisolone, 0.5 to 1 mg/kg every 6 h
Assess ongoing need after 72 h

MDI, metered-dose inhaler.

Beta-Agonists

Inhaled β_2-selective agents (albuterol, bitolterol, terbutaline, or metaproterenol) should be given by metered-dose inhaler (MDI), unless patient distress makes that impractical, since this route seems to be equally efficacious in nonventilated patients.[5] Administration may be facilitated by the use of a chamber device. Higher doses than usual can be given, such as 4 to 10 (or more) puffs every 20 to 60 minutes, although there is no clear benefit from frequent doses. A hand-held nebulizer (0.5 mL albuterol or 0.3 mL metaproterenol mixed with 2.5 mL saline solution) may be useful in patients who cannot use an MDI reliably, but otherwise this route confers no additional efficacy. Parenteral agents (e.g., epinephrine 0.3 mL subcutaneously) and their accompanying toxicity can nearly always be avoided. The longer-acting β_2-agonist formoterol (but not salmeterol) has a fast onset of action and has been demonstrated to provide equally effective bronchodilation in mild COPD exacerbations when administered in high doses.[89] However, because of concerns about activity as a partial receptor antagonist, significant additional cost, and therapeutic equivalence, we do not recommend long-acting inhaled β_2-agonist agonists for ACRF.

Ipratropium

The anticholinergic agent ipratropium bromide is as effective as metaproterenol in the treatment of ACRF,[85,90] and may even be better in stable COPD. An additional advantage of this drug is that compared to metaproterenol, its use is associated with a small rise in Pa_{O_2} rather than the small decline usually seen with β-agonists. The addition of ipratropium to a regimen containing inhaled β-agonists yields incremental benefit in patients with stable COPD,[84] but as discussed above, does not result in improved bronchodilation in acute exacerbations. The usual dose of ipratropium in ACRF is three puffs every 30 to 60 minutes. Much higher doses (400 μg) have been shown to be optimal in stable patients with COPD, but this question has not been examined in ACRF.[91]

Tiotropium

Tiotropium, a recently released long-acting inhaled anticholinergic, has demonstrated great promise in patients with stable COPD by reducing symptoms, the decline in FEV_1, and frequency of exacerbations. Preliminary evidence of its potential efficacy in patients with acute exacerbations was suggested by a randomized prospective study conducted by a Veterans Administration collaborative involving 1829 men with severe COPD (FEV_1 1 L, 36% predicted) at risk for exacerbations.[92] Significantly fewer patients treated with once-daily tiotropium experienced exacerbations (27.9% vs. 32.3%; $p = 0.037$) that were associated with 26% fewer hospital days ($p = 0.001$). To date, however, there is no published experience with tiotropium as a specific therapy for ACRF.

Phosphodiesterase Inhibitors

AMINOPHYLLINE Aminophylline is a mildly effective nonselective phosphodiesterase (PDE) inhibitor in patients with COPD. In addition to its actions as a bronchodilator, aminophylline has salutary effects on the diaphragm in experimental settings. These include inotropy and resistance to fatigue seen in patients on this agent, although the clinical relevance of these findings has yet to be demonstrated, and recent studies have challenged the underpinnings of these clinical trials.[93] Whether aminophylline should be given to patients with ACRF is controversial, and recent trends show it falling out of favor. A controlled trial in patients hospitalized for an acute exacerbation of COPD failed to show any benefit of aminophylline when added to a standard regimen of β-agonists and corticosteroids.[94] On the other hand, theophylline causes demonstrable (although generally minor) physiologic improvement in stable COPD patients, even when superimposed on a regimen of a β-agonist[83] or on a combination of a high-dose inhaled β-agonist plus ipratropium.[95] Meta-analysis of four randomized controlled trials including 169 patients demonstrated no improvement in bronchodilation or hospital LOS in patients with acute exacerbations. However, not all patients had severe ACRF.[96] Toxicity of these drugs is substantial, including arrhythmogenesis and CNS effects. In the meta-analysis, there were fivefold greater odds of gastrointestinal symptoms occurring in theophylline-treated patients.[96] Daily serum level measurement is necessary for safe use, especially in light of the significant interactions with other drugs. Even when serum levels are considered to be therapeutic, aminophylline may have important toxicity. In a multivariate analysis of 100 patients receiving theophylline, drug level was the most important predictor of arrhythmia,[97] ahead of age and gender. Both atrial and ventricular arrhythmias were seen and correlated with theophylline level. In the group with therapeutic levels 48% had arrhythmias. Particularly worrisome was the finding of multifocal atrial tachycardia in patients on theophylline, including those with nontoxic levels. Two of six patients with this rhythm disturbance died suddenly during hospitalization, without antecedent ventricular ectopy.

Consistent with guidelines from expert panels,[59,98] we rarely use intravenous aminophylline, and then only as an adjunct to other, more effective management (standard bronchodilators and steroids). Aminophylline is initiated as a loading dose of 5 mg/kg infused over 30 minutes, then continued as an intravenous infusion at a rate of 0.5 mg/kg per hour. In patients who are already taking an oral methylxanthine, intravenous loading and maintenance dosing should be guided by serum levels. Given the minor efficacy of the drug and its substantial toxicity, it is difficult to justify empirical partial loading doses.

Selective Phosphodiesterase Inhibitors

Selective inhibitors of type IV PDE (such as cilomilast) are likely to have a major impact on the management of patients with stable COPD with recent studies (unpublished at the time of this writing) demonstrating modest improvements in lung function compared to placebo and a significant reduction in acute exacerbations. However, as for many newer therapies, PDE-IV inhibitors have not been evaluated in the treatment of COPD exacerbations. Additionally, a single dose of cilomilast appears to confer no additional bronchodilatory effect in stable COPD patients who respond to albuterol or ipratropium.[82]

Corticosteroids

Patients with ACRF given methylprednisolone 0.5 mg/kg every 6 hours, in addition to standard bronchodilators, show greater improvement in spirometric values than patients who do not receive this drug.[99] This benefit is demonstrable at least

as early as 12 hours, and in some studies of patients with asthma possibly after 1 hour. In another study of patients with ACRF, 0.8 mg/kg of prednisolone given intravenously reduced the inspiratory resistance and PEEPi when measured at 90 minutes.[100] A meta-analysis that included 537 patients in 7 randomized controlled studies yielded an aggregate beneficial effect of steroid treatment that translated into an early FEV_1 improvement of 120 mL (95% CI; 5 mL to 190 mL) compared with controls, an effect that persisted for 3 to 5 days.[101] Although there was no survival benefit derived from the addition of steroids, treatment failure and hospital LOS were significantly reduced. Although there is significant debate about the optimal dose and duration of steroids,[5] current guidelines recommend methylprednisolone 0.5 to 1 mg/kg every 6 hours. Since these drugs have important detrimental effects on metabolic, muscular, and immune function, their continued use should be re-evaluated after the first 72 hours with a transition to oral therapy when tolerated. Although no effect of corticosteroids on respiratory muscle function can be shown in the short term (<2 weeks[102]), they do contribute to muscle weakness in the long term.[31] No additional benefit is derived from prolonging steroid therapy beyond 2 weeks. A possible alternative may be to use high doses of the nebulized steroid budesonide (2 mg every 6 hours), which may be as effective as an oral steroid regimen in patients with a COPD exacerbation.[103] Notably, hyperglycemia was less common in the budesonide-treated patients. However, this approach is significantly more expensive.

Antibiotics

Bacterial bronchitis is a common precipitant of ACRF. Nevertheless the efficacy of antibiotics is controversial. Since benefit has been demonstrated in several studies and a trend towards benefit in some others,[5] an inexpensive oral broad-spectrum antibiotic (e.g., ampicillin, doxycycline, or trimethoprim-sulfamethoxazole) should be provided in the absence of clinical features of pneumonia. Community-acquired pneumonia should be treated with a cephalosporin-macrolide combination or a high-dose single-agent fluoroquinolone.

Anabolic Steroids

Inflammation is not limited to the lungs during an acute exacerbation of COPD. Peripheral and diaphragmatic skeletal muscle weakness is pronounced during ACRF and is associated with markers of systemic inflammation such interleukin-6 and interleukin-8.[104] A combination of anabolic steroids (nandrolone decanoate 25 to 50 mg IM every 2 weeks) and caloric supplementation (420 kcal/d supplement) raised the mouth pressure during a maximal static inspiratory maneuver in patients with clinically stable COPD.[105] Similarly, COPD patients treated with oxandrolone experienced a significant increase in lean body mass.[106] However, this effect may only be clinically useful in patients receiving long-term oral steroids.[107] We are aware of no trials showing clinically important benefits in patients with ACRF.

ARRHYTHMIAS

Arrhythmias are common in the setting of respiratory failure. Fortunately, they are rarely a serious problem, but they can serve to distract the physician from more important issues, may limit the dose of bronchodilating drugs, and sometimes are significant in themselves. The most common rhythms are sinus tachycardia, atrial fibrillation, atrial flutter, multifocal atrial tachycardia, and ventricular premature beats. β-Agonists, macrolides, and electrolyte disturbances can cause transmural dispersion of repolarization abnormalities such as QT prolongation, T-wave alternans, and P-wave dispersion as precursors to serious arrhythmias. It can be difficult to judge the contributions of hypoxemia, cor pulmonale, metabolic derangements, underlying coronary artery disease, and drug toxicity to arrhythmogenesis. Treatment should focus on rectifying the underlying respiratory failure, since doing so usually has a beneficial impact on arrhythmias. Hypoxemia and electrolyte abnormalities should be corrected as a first priority. Monitoring should be initiated, and if arrhythmias continue despite correction of apparent exacerbating factors, myocardial ischemia should be excluded. Atrial fibrillation can be controlled with a calcium channel blocker or digoxin (see Chap. 24). β-Blockers should generally be avoided for fear of worsening lung function, although short-acting selective drugs have occasionally been used with success. Multifocal atrial tachycardia often responds to verapamil, sometimes with restoration of sinus rhythm,[108] and there appears to be a role for parenteral magnesium as well (see Chap. 24).

RECOGNIZING IMPENDING RESPIRATORY FAILURE

Despite aggressive attempts to find and reverse the causes of ACRF, some patients will progress to frank respiratory failure. The decision to intubate requires clinical judgment and is best assessed by a physician present at the bedside (Table 39-4). Assessment of respiratory failure based solely on results of arterial blood gas studies is fraught with error. Certainly a rising Pa_{CO_2} in a patient with progressively worsening symptoms and signs of distress should be interpreted as heralding respiratory arrest. However, the absolute level of the Pa_{CO_2}, isolated from other clinical data, may be less useful. We have taken care of a small number of patients in whom the Pa_{CO_2} rose to 150 mm Hg while the patients were alert and conversing, and mechanical ventilation did not become necessary. On the other hand, many patients with ACRF will progress to respiratory arrest long before progressive hypercarbia is clearly documented. Patients who have had an unsuccessful attempt at stabilization with NIPPV are at particular risk for underappreciated clinical instability. Those patients may have very little tissue oxygen reserve, low effective circulating volume, and are at substantial risk of cardiopulmonary arrest if transition to intubation is delayed. Respiratory arrest may be complicated

TABLE 39-4 Assessment of the Need for Intubation in Acute-on-Chronic Respiratory Failure

1. This judgment must be made by the physician at the bedside.
2. Predictors of frank ventilatory failure:
   Respiratory rates that remain >36/min despite NIPPV
   Worsening tachycardia
   Continued use of all accessory muscles
   Mental status deterioration
   Patient's subjective sense of exhaustion
3. Arterial blood gas studies are of limited use in making this judgment, usually merely confirming clinical assessment.
4. Concomitant hemodynamic instability or inability to protect the airway may mandate intubation.

NIPPV, noninvasive positive pressure ventilation.

by aspiration or cardiovascular instability, compromising future efforts to return the patient to spontaneous breathing. Indeed, the survival of patients who are allowed to progress to respiratory arrest is significantly lower than that of patients ventilated for acute deterioration of COPD who are intubated electively prior to arrest. The goal at this stage of management is to intubate the patient electively once mechanical ventilation becomes unavoidable. In some cases this will require foregoing NIPPV and opting for immediate airway intubation for mechanical ventilation to avoid respiratory arrest.

Useful bedside parameters of impending respiratory arrest include respiratory rate, mentation, pattern of breathing, and the patient's own assessment. The patient may be able to tell the physician whether improvement is occurring or not; the degree of dyspnea over time is a useful guide to the likelihood of success without intubation. Most patients with ACRF are tachypneic, reflecting their excessive drive. A rate that remains above 35 to 40 breaths/min, or a rate that continues to rise despite therapy and NIPPV is predictive of respiratory failure. Deterioration of mentation commonly precedes respiratory arrest. Patients become confused, less able to converse, then poorly rousable. Thoracoabdominal paradox and respiratory alternans are rarely seen and are probably not useful signs.

PHASE 2: LATE ACUTE-ON-CHRONIC RESPIRATORY FAILURE REQUIRING INTUBATION

This phase consists of the immediate peri-intubation management and the first few days of mechanical ventilation. In many respects, treatment begun in the preintubation phase (bronchodilator administration in particular) is continued, but several additional concerns become relevant. Care consists of stabilizing the patient on the ventilator, ensuring rest of the patient and respiratory muscles, improving neuromuscular competence, reducing load, and giving prophylaxis against complications, while optimizing definitive therapy for any precipitant such as infection. Optimal treatment at this time is likely to facilitate eventual liberation from mechanical ventilation.

PERI-INTUBATION RISKS

There are two common pitfalls in the immediate postintubation period: life-threatening alkalosis and hypotension. Both are related to overzealous ventilation, and both are avoidable by taking the patient's own ventilatory pattern prior to intubation into consideration. Hypotension is a consequence of escalating PEEPi following intubation. The degree of dynamic hyperinflation is proportional to $\dot{V}_E$. PEEPi has the same deleterious consequences on venous return as externally applied PEEP and can cause serious hypoperfusion. This can be particularly prominent in patients with ineffective circulating volumes (preload) and concomitant right heart dysfunction when vasodilatory and sympatholytic sedatives are used for intubation. The key to avoiding this pitfall is to prevent excessive ventilation, particularly during bag-valve-mask preoxygenation before intubation attempts. When hypotension occurs, the circulation can usually be promptly restored by simply ceasing ventilation for 30 seconds, then reinstituting ventilation along with measures to reduce PEEPi and restore circulating volume. It is also our practice in patients without decompensated left heart failure to administer a fluid bolus immediately prior to sedation for intubation.

Most patients with ACRF have a minute ventilation of 10 L/min or less and breathe at tidal volumes of about 300 mL. Physicians commonly choose ventilator settings with a higher tidal volume and a correspondingly lower ratio of dead space to tidal volume. In addition, a minute ventilation higher than 10 L/min often is employed, particularly during the first few minutes of manual-assisted ventilation. Finally, as the work of breathing is assumed by the ventilator, $\dot{V}_{CO_2}$ drops by as much as 20%. All of these factors join to dramatically lower the patient's Pa_{CO_2} once assisted ventilation begins. Since preexisting compensatory metabolic alkalosis is the rule, life-threatening alkalemia (pH >7.7) can easily be achieved. This scenario can be avoided by simply aiming for a more reasonable minute ventilation, approximating the patient's own pattern of breathing. Typical initial ventilator settings are described below. There is no need to attempt to normalize pH, a maneuver that merely serves to waste the bicarbonate that has been so vigorously conserved during the evolution of respiratory failure.

We generally recommend head-up intubation with a large-diameter endotracheal tube, not laryngeal mask. Depolarizing muscle relaxants should be avoided and if necessary, short-acting nondepolarizing agents such as rocuronium or cisatracurium should be considered.

INITIAL VENTILATOR SETTINGS

We generally initiate ventilation using the assist-control mode, since one of the goals in this phase is to rest the loaded respiratory muscles (see Chap. 36). Tidal volumes of about 5 to 7 mL/kg are used (about 350 to 500 mL) with a respiratory rate of 20 to 24 breaths/min. As discussed above, PEEPi presents an inspiratory threshold load to the patient with ACRF. The patient must generate enough force to counterbalance PEEPi before the breathing effort results in any inspiratory flow and before it can trigger the ventilator. This difficulty cannot be sidestepped by lowering the triggering sensitivity on the ventilator or by using flow triggering. Applying external PEEP that is roughly equal to the PEEPi does reduce the work of breathing (and triggering) by a significant amount, as depicted in Fig. 39-2.[68,109] In some patients, externally applied PEEP causes additional hyperinflation, with detrimental hemodynamic effects and a potentially increased risk of barotrauma.[110,111] However, most patients with ACRF demonstrate flow limitation so that external PEEP (in amounts up to about 85% of the PEEPi) has no significant impact on the expiratory flow-volume relationship, lung volume, or hemodynamics.[112,113] Strategies to shorten ventilator inflation time are not generally helpful unless inspiratory flow is inordinately low (we typically use 60 L/min), although PEEPi can be reduced modestly.[114]

ENSURING REST AND RECOVERY

Following intubation, most patients are exhausted and will sleep for the first day and experience significant diuresis. Little or no sedation is typically necessary, although close monitoring for delirium and alcohol or substance withdrawal may be required. The respiratory muscles will require 48 to 72 hours for full recovery, so that resumption of breathing efforts before that point is counterproductive and is likely to lead to recurrence of respiratory muscle fatigue.[115] However,

as discussed below this does not preclude extubation to NIPPV if there is convincing evidence that extrapulmonary organ dysfunction has stabilized and cognitive function has improved. We continue to encourage rest by maintaining ventilation, adding sedation and antidelirium agents when necessary. Rest can be achieved using any mode of ventilation, including bilevel NIPPV, as long as settings are chosen that minimize patient effort. It is important to emphasize that having the patient connected to a ventilator is no guarantee that the patient is relieved of the work of breathing. Even when the ventilator is set at a very sensitive trigger point, the presence of PEEPi causes the patient to have to make a substantial inspiratory effort to get a breath, even on volume assist-control mode. For example, with a triggered sensitivity of 1 cm H_2O and PEEPi of 10 cm H_2O, the patient must lower his airway pressure by 11 cm H_2O to trigger a breath. It is incumbent on the physician to ensure that the patient is in fact rested. We evaluate inspiratory muscle activation, synchrony, and the presence of PEEPi by palpating the epigastric area during the respiratory cycle[116] while monitoring the pressure-time and flow-time waveforms on the mechanical ventilator. When optimal ventilatory rest is achieved, respiratory muscle strength usually improves demonstrably over the first few days.

IMPROVING NEUROMUSCULAR COMPETENCE

Each of the factors discussed in phase 1 (and shown in Fig. 39-3) that contribute to depressed neuromuscular competence should be reviewed daily in the ventilated patient. In this phase the importance of nutrition must be recognized. Malnutrition is a common comorbidity of advanced COPD[117] and may contribute to respiratory muscle dysfunction as well as to immune suppression. In a randomized trial of standard feeding versus supplementation (1000 kcal above usual), malnourished inpatients with COPD were shown to develop greater respiratory muscle endurance and strength in only 16 days when given extra calories.[30] However, excessive refeeding should be avoided since unnecessarily high levels of carbon dioxide production ($\dot{V}_{CO_2}$) may result. Harris-Benedict predictions of resting energy expenditure provide a reasonable estimate in stable COPD patients;[117] however, detailed nutritional information including indirect calorimetry may be helpful to guide nutritional management in ACRF (see Chap. 11). When caloric requirements have been assessed, it is usually advisable to supply a large fraction (50% or more) of total calories in the form of lipids, to minimize the respiratory quotient (RQ) and hence $\dot{V}_{CO_2}$. Especially with refeeding, hypophosphatemia commonly develops while the patient is in the ICU, and serum phosphate content should be assessed on a daily basis.

Once the respiratory muscles are rested, a program of exercise should be initiated in conjunction with daily evaluations of readiness for liberation from mechanical ventilation. The goal is to encourage muscle power, tone, and coordination by allowing the patient to assume nonfatiguing respirations, possibly in combination with inspiratory resistive training. This can be achieved by progressively lowering the triggered sensitivity on assist-control, lowering the inspiratory pressure on pressure-support, or through graded T-piece sprints. After a period of work, the patient is returned to full rest to facilitate sleep at night. As strength improves, the amount of exercise can be increased in stepwise fashion until the breathing can be sustained and the patient passes a trial of spontaneous breathing.

During this phase, meticulous attention should be paid to harm reduction and risk avoidance. Prevention and early recognition of venous thromboembolism, gastrointestinal stress ulceration, ventilator-associated pneumonia, integument breakdown (including nasal bridge integrity in NIPPV patients), corneal desiccation, drug side effects, drug-drug interactions, substance withdrawal, and delirium are recommended.

DECREASING LOAD

Efforts to decrease load should continue. Once the patient is ventilated, it becomes possible to apportion the load into resistive and elastic components (see Chap. 36). These determinations may provide insight into the precipitants of respiratory failure and serve to guide therapy. For example, if the resistive load and PEEPi are minimal, but the elastic load is excessive, there is little to be gained from more aggressive use of bronchodilators. Rather, the source of the elastic load (lung, chest wall, or abdomen; see Fig. 39-3) should be determined and corrected.

It is important to continue treatment with bronchodilators, but whether MDIs and nebulizers are equally effective is controversial.[60,118] On the one hand, in a study of drug deposition in ventilated patients, a MDI (plus a holding chamber) was more efficient than a nebulizer.[119] In another trial of ventilated patients, MDIs were completely ineffective, despite a cumulative dose in 1 hour of 100 puffs.[120] The magnitude and duration of effectiveness of medications given via an MDI and a nebulizer appear to be similar.[118] There may be substantial differences related to the method of administration or to the specific equipment used to deliver the drug. We recommend that these drugs be given to effect, whether by MDI or nebulizer. If MDIs are used, the usual number of puffs should be doubled as a starting point to compensate for the reduced delivery of drug to the patient, and the dose increased as needed until bronchodilation is achieved (as assessed by determining respiratory mechanics).

Other contributors to increased load, such as congestive heart failure, pulmonary embolization, and respiratory infection, may be easier to discern once the patient is mechanically ventilated, and they should be sought during this phase. Congestive heart failure can usually be excluded by the physical examination and chest radiograph, although pulmonary edema may have an atypical appearance in patients with advanced emphysema. Only occasionally is the additional information from pulmonary artery catheterization useful. Pulmonary embolism (PE) is much more difficult to exclude. The incidence of PE as a precipitant of ACRF is unknown. The reported frequency of deep venous thrombosis ranges from 9% to 45%.[17,121] Large pulmonary emboli are much less common, although the incidence of smaller emboli may not be. Nevertheless, PE is commonly found at autopsy. In patients with ACRF, pulmonary hypertension is virtually universal and diagnosis of PE is difficult. Ventilation-perfusion lung scanning nearly always gives abnormal results, and computed tomographic angiography has been incompletely evaluated in patients with underlying structural lung disease (see Chap. 27). Noninvasive leg studies have been challenged in this setting

as well. Capnography has been suggested as a method for excluding PE in patients with ACRF.[122]

PHASE 3: LIBERATION FROM THE VENTILATOR

The fundamental principle that guides management in this phase is that successful liberation from the ventilator requires that the premorbid compensated relationship between neuromuscular competence and load be re-established. Therefore a strategy for successfully discontinuing mechanical ventilation emphasizes increasing the strength and decreasing the load, while avoiding sedatives that may impair drive. We use a nurse- or respiratory therapist–led protocol that emphasizes daily testing of readiness for spontaneous breathing, targeted sedation strategies with daily sedation withdrawal, formal spontaneous breathing trials, and triggers for liberation including early extubation to NIPPV as discussed below and reviewed in further detail in Chap. 44. This approach has been demonstrated to be particularly effective in achieving successful ventilator liberation.[123] However, similar results may be achieved in well-staffed, well-organized closed-management ICUs where decisions to liberate are directed by expert intensivists.[124] Therapy may be highly focused, by measures such as repleting inorganic phosphate, relieving a pneumothorax, addressing neuropsychiatric components including delirium, or managing right heart syndrome. More often a broad assault on many potential precipitants, namely bronchospasm, infection, electrolyte derangement, and fatigue, is used. In either case, when load has been reduced and neuromuscular competence promoted, the patient will be able to breathe free of assistance. On the other hand, if a compensated balance of strength and load cannot be restored, attempts at spontaneous breathing will be futile. A corollary is that the specifics of ventilator management, such as the mode chosen or the device used, are less important.[125,126] Only the patient's improving physiology determines the ability to maintain ventilation as determined by the patient's ability to tolerate short periods of unassisted breathing (spontaneous breathing trial). This point has been confirmed by recent trials of weaning methods, which have shown that frequent T-piece trials are superior to intermittent mandatory ventilation (and in some cases, also to pressure-support ventilation), probably because they more readily demonstrate to the physician that the ventilator is no longer necessary.[123,126–128] This issue is more fully elaborated in Chap. 44.

Respiratory parameters (negative inspiratory force [NIF], peak pressure [Ppk], plateau pressure [Pplat], and PEEPi; see Chaps. 32 and 36) have historically been used to evaluate the progress of the patient and resolution of the load-strength imbalance. However, the poor individual performance characteristics of these maneuvers make them unreliable for predicting sustained spontaneous breathing and successful liberation.[129] However, by daily integrating respiratory parameters of load-strength balance with other validated parameters such as the frequency:tidal volume ratio, the readiness for a spontaneous breathing trial can be determined. Additionally, the impact of therapeutic maneuvers can be assessed by serially evaluating respiratory parameters. For example, while PEEPi remains at 10 cm H_2O, there is little point in trying to make the patient breathe without assistance. Indeed, in such a circumstance efforts should be directed to attempting to reduce the work of breathing.[130] On the other hand, when PEEPi has resolved and strength is adequate (usually when the NIF >30 cm H_2O), mechanical ventilation is no longer necessary and the patient should be able to tolerate at least 30 minutes of spontaneous minimally-assisted breathing.

When discontinuation of mechanical ventilation is imminent, it is useful to anticipate the respiratory pattern that the patient will soon assume. We have been impressed that patients ventilated at supraphysiologic tidal volumes, such as 800 to 1000 mL, experience respiratory distress and agitation when they resume their usual pattern of 30 breaths/min at a tidal volume of 300 mL. By choosing a pattern of mechanical ventilation that more closely approximates spontaneous respiration (e.g., assist-control mode, tidal volume of 420 mL, and a rate of 20 breaths/minute), the transition from the ventilator is smoothed.

For patients that fail to re-establish load-strength balance within 72 hours of initiating therapy, there is a significant prospect of prolonged mechanical ventilation, tracheostomy, and complications that increase the attributable morbidity and mortality. A significant shift in approach involves elective extubation to NIPPV for patients who consistently fail spontaneous breathing trials after 48 to 72 hours. In a randomized controlled trial of NIPPV versus continued intubation and ventilation in 50 ACRF patients failing a T-piece trial at 24 to 36 hours of initial ventilation via an endotracheal tube, NIPPV reduced the period of mechanical ventilation (16.6 ± 11.8 days vs. 10.2 ± 6.8 days; $p = 0.021$), ICU days (24.0 ± 13.7 days vs. 15.1 ± 5.4 days; $p = 0.005$), the incidence of nosocomial pneumonia, and mortality at 60 days (8% NIPPV vs. 28% of those on invasive ventilation; $p = 0.009$), while increasing approximately fourfold the number of patients liberated from ventilation at day 21.[131] These findings have been confirmed by others randomizing patients (75% of whom had ACRF) after three failed daily T-piece trials.[132] In a meta-analysis of five studies involving 171 patients, extubation to NIPPV translated into an aggregate relative risk reduction of 0.41 [95% CI 0.22 to 0.76].[133] NIPPV is likely to tide the patient over the additional days until the balance of neuromuscular competence and respiratory system load is re-established.

Even with appropriate institution of rest on the ventilator, rapid application of the algorithms given above or correction of abnormalities of neuromuscular competence and load, and progressive exercise of the patient, some patients require protracted periods of ventilator support. Indeed, with the wider use of NIPPV and the avoidance of intubation in all but the most severely impaired patients, it may be the case that in the future ICUs will encounter truly difficult-to-wean patients. The principles elaborated above still apply to this group, with a few additional comments. After approximately 7 days of ventilator dependence, we typically assess the patient for tracheostomy (see Chap. 35). If it appears that liberation from mechanical ventilation may succeed within another week, tracheostomy is usually not performed, and efforts continue to extubate the patient. If we judge that the course will be protracted, we prefer bedside percutaneous tracheostomy for purposes of patient comfort, communication, and avoidance of complications associated with translaryngeal intubation. If progress to liberation is likely to be very slow after the first couple of weeks, many ICUs will consider

transferring the stable patient to a long-term acute care facility with dedicated expertise in pulmonary rehabilitation and liberation from mechanical ventilation. Despite the overall poor prognosis for such compromised patients, these facilities have demonstrated superior expertise in liberating a significant proportion even after long periods of ventilation for ACRF.[134] Optimal results are achieved when a protocolized multidisciplinary care pathway involves specialist respiratory care, rehabilitation, nutrition, and physical therapy departments.

Following extubation, careful serial assessments are in order. Deterioration in the hours just following extubation suggests upper airway edema. In the uncomplicated patient, the respiratory rate falls slightly through the first day, most often into the mid-twenties to low thirties. Efforts to build strength and reduce load should continue in order to protect the gains that have been made. Once the patient is stable off the ventilator, a prompt transfer to the more benign setting of the general ward should be encouraged.

Recurrence of respiratory failure is an ominous but not infrequent complication for which efforts to stave off intubation may prove fruitless and potentially harmful. When 221 patients with recurrent respiratory failure within 48 hours of initial ventilator liberation (only 12% had COPD) were randomized to either NIPPV or usual care, equal numbers progressed to intubation (48%), but the ICU mortality rate at an interim analysis was 25% in the NIPPV vs. 14% in the usual care arm (RR 1.78; 95% CI 1.03 to 3.20; $p = 0.048$).[135]

For many patients, liberation from prolonged mechanical ventilation is associated with a decision to change the goals of care from "treatment-for-cure" to "treatment-for-comfort." Decisions to withhold and withdraw life-sustaining therapy entail extensive involvement of the patient, as well as their care providers, ICU staff, chaplaincy, hospital ethics, and social work support. Pertinent to the terminal care of the ACRF patient are meticulous attention to palliation of terminal dyspnea, pain, and delirium. This subject is covered in Chap. 17.

Chapter 40
STATUS ASTHMATICUS

THOMAS CORBRIDGE
JESSE B. HALL

KEY POINTS

- *Severe asthma exacerbation is defined by several, but not necessarily all, of the following features: dyspnea at rest, upright positioning, inability to speak in phrases or sentences, respiratory rate >30 breaths per minute (bpm), use of accessory muscles of respiration, pulse >120 beats/min, pulsus paradoxus >25 mm Hg, peak expiratory flow rate <50% predicted or personal best, hypoxemia, and eucapnia or hypercapnia.*
- *Altered mental status, paradoxical respirations, bradycardia, a quiet chest, and absence of pulsus paradoxus from respiratory muscle fatigue identify imminent respiratory arrest.*
- *Airway wall inflammation, bronchospasm, and intraluminal mucus cause progressive airflow obstruction. Fewer patients develop sudden-onset asthma from a more pure form of bronchospasm.*
- *Severe exacerbations and death can occur in patients with mild asthma.*
- *Airflow obstruction causes ventilation-perfusion inequality, lung hyperinflation, and increased work of breathing.*
- *Oxygen, β agonists, and systemic corticosteroids are first-line treatments. Agents of debated efficacy include ipratropium bromide, magnesium sulfate, leukotriene modifiers, theophylline, inhaled steroids, and heliox.*
- *Noninvasive ventilation is potentially useful in hypercapneic patients not requiring intubation.*
- *Postintubation hyperinflation decreases preload to the right ventricle and may cause barotrauma, hypotension, or cardiac arrest. A ventilator strategy that lowers lung volume decreases complications.*
- *Treating airflow obstruction and prolonging expiratory time decreases lung hyperinflation. Expiratory time is prolonged on the ventilator by lowering minute ventilation (even at the cost of hypercapnia) and increasing inspiratory flow rate.*
- *Deep sedation allows for safe and effective mechanical ventilation in most intubated patients. Paralysis increases the risk of myopathy.*
- *Patient education, environmental control, and pharmacotherapy are crucial to prevent exacerbations and death.*

Asthma is characterized by wheezing, dyspnea, cough, hyperreactive airways, and reversible airflow obstruction.[1–3] In the vast majority of cases, the disease is managed uneventfully in the ambulatory setting. However, severe attacks and death can occur regardless of severity classification, and in some cases there is little warning before a terminal event.[4] Deaths often occur outside the hospital; patients who have not arrested prior to emergency department (ED) arrival generally have a good prognosis.[5] Underestimation of severity, a gap in communication between health care provider and patient, airway inflammation (even in mild disease), and failure to use inhaled corticosteroids all contribute to asthma morbidity and mortality.[6–10]

Severe asthma exacerbation is defined by several, but not necessarily all, of the following features: dyspnea at rest, upright positioning, inability to speak in phrases or sentences, respiratory rate >30 bpm, use of accessory muscles of respiration, pulse >120/min, pulsus paradoxus >25 mm Hg, peak expiratory flow rate <50% predicted or personal best, hypoxemia, and eucapnia or hypercapnia.[1] Altered mental status, paradoxical respirations, bradycardia, a quiet chest, and absence of pulsus paradoxus from respiratory muscle fatigue identify imminent respiratory arrest.[1]

The objectives of this chapter are to review the pathophysiology of severe asthma exacerbations, discuss clinical assessment and differential diagnosis, assess pharmacologic treatment, and provide a ventilatory strategy for intubated patients. It is perhaps in this last area of acute severe asthma management that intensivists have made their greatest strides over the last two decades, with indirect evidence suggesting that current strategies decrease morbidity and mortality. In the final analysis, however, the greatest gains will come from optimal outpatient management and prevention of attacks.

Pathophysiology

Exacerbations often evolve over hours to days before patients seek medical help.[11,12] There is thus a window of opportunity to treat inflammation through initiation or escalation of corticosteroids. Indeed, the "best treatment of status asthmaticus is to treat it three days before it occurs [with corticosteroids]."[13] Instead, too many patients rely on increasing doses of inhaled β agonists, eventually to no avail.

One consequence of airway inflammation is plugging of large and small airways with tenacious mucus. This can be quite striking at postmortem analysis.[14] Mucus plugs consist of sloughed epithelial cells, eosinophils, fibrin, and other serum components that leak readily through the denuded airway epithelium. In a smaller subset of patients, an unexpected exacerbation, termed sudden-onset asthma, results from a more pure form of smooth muscle–mediated bronchospasm. Sudden-onset asthma can be lethal, but it can also improve rapidly with bronchodilators.[15,16] Compared to attacks of slower tempo, there are more submucosal neutrophils and fewer airway secretions.[17,18] Triggers of sudden attacks include use of nonsteroidal anti-inflammatory agents and β-blockers in susceptible patients, allergen or irritant exposure, exercise, stress, sulfites, and inhalation of crack cocaine or heroin.[19–22] Respiratory tract infection is not a usual trigger; commonly no cause is found.[23]

ABNORMALITIES OF GAS EXCHANGE

Airway obstruction causes ventilation-to-perfusion (V/Q) mismatch. Intrapulmonary shunting is trivial, so modest enrichment of oxygen (1 to 3 L/min by nasal cannula) generally corrects hypoxemia.[24] Refractory hypoxemia is rare and suggests additional pathology: pneumonia, aspiration, acute lobar atelectasis, or barotrauma. There is a rough correlation between airflow obstruction as measured by the forced expiratory volume in 1 second (FEV_1) or peak expiratory flow rate (PEFR) and hypoxemia.[25,26] However, there is no cutoff value that accurately predicts hypoxemia. In recovering

patients, multiple inert gas elimination technique (MIGET) analysis demonstrates that airflow rates commonly improve before partial pressure of arterial oxygen (Pa_{O_2}) and V/Q inequality.[27] One explanation for this is that spirometry tracks large-airway function and indices of gas exchange reflect the function of smaller peripheral airways.[27,28]

Supplemental oxygen improves oxygen delivery to respiratory muscles, reverses hypoxic pulmonary vasoconstriction, and bronchodilates airways. It further protects from β-agonist–induced hypoxemia resulting from pulmonary vasodilation and increased blood flow to low V/Q units.[29,30]

Increases in dead space are expected when regions of hyperinflated lung limit blood flow to create West's zone 1 conditions (where alveolar pressure exceeds pulmonary capillary pressure).[27] However, MIGET analysis demonstrates only small areas of high V/Q and slightly increased dead space in acute asthma.[24,30]

Respiratory alkalosis is a feature of mild acute asthma. If present long enough, there is compensatory renal bicarbonate wasting that may subsequently manifest as a normal anion-gap metabolic acidosis (posthypocapneic metabolic acidosis). As the severity of airflow obstruction increases, the partial pressure of arterial carbon dioxide ($PaCO_2$) generally increases due to inadequate alveolar ventilation (reflecting a decrease in minute ventilation as the patient nears respiratory arrest) and possible elevated CO_2 production from increased work of breathing. Hypercapnia usually does not occur unless the FEV_1 is less than 25% of predicted.[25] Importantly the absence of hypercapnia does not preclude a severe attack or potential for respiratory arrest.[26]

LUNG MECHANICAL ABNORMALITIES

Incomplete emptying of alveolar gas and positive end-expiratory alveolar pressure are hallmarks of expiratory airflow obstruction. In ventilated patients, end-expiratory alveolar pressure is not reflected at the airway opening if the expiratory port of the ventilator is open (which allows airway-opening pressure to approach atmospheric pressure or the level of ventilator-applied positive end-expiratory pressure [PEEP]). If the expiratory port is closed at end-expiration, central airway pressure generally equilibrates with alveolar pressure, permitting measurement of auto- or intrinsic PEEP (PEEPi). PEEPi reflects gas trapping only in relaxed patients, since expiratory muscle contraction elevates end-expired pressure. Low levels of PEEPi may underestimate the degree of lung hyperinflation. Leatherman and Ravenscraft[31] measured low levels of PEEPi in four ventilated asthmatics with significant lung hyperinflation, suggesting the presence of noncommunicating airspaces.

The pressure-volume relationship of the lung parenchyma predicts that hyperinflation correlates with decreased static compliance. However, lung compliance may be normal despite hyperinflation, suggesting a stretch-relaxation response in parenchymal tissue.[32] This state is not favorable to expiratory flow, but may protect against complications of lung hyperinflation.

CIRCULATORY EFFECTS OF SEVERE AIRWAY OBSTRUCTION

Circulatory abnormalities reflect a state of cardiac tamponade resulting from dynamic hyperinflation (DHI) and pleural pressure changes associated with breathing against obstructed airways. During expiration, high intrathoracic pressures decrease right-sided preload. Vigorous inspiration augments right ventricular filling and shifts the intraventricular septum leftward to cause a conformational change in the left ventricle (LV), diastolic dysfunction, and incomplete LV filling. Additionally, large negative pleural pressures directly impair LV emptying.[33,34] Rarely diastolic dysfunction and increased LV afterload cause pulmonary edema. Finally, lung hyperinflation increases RV afterload and may cause transient pulmonary hypertension.[35] The net effect of these cyclical events is to accentuate the normal inspiratory reduction in stroke volume, a phenomenon termed *pulsus paradoxus* (PP). Pulsus paradoxus is a valuable marker of asthma severity;[36] however, the absence of a widened PP does not ensure a mild attack.[37] The PP falls in improving patients, but also in the fatiguing asthmatic who is unable to generate large changes in pleural pressure.

PROGRESSION TO VENTILATORY FAILURE

Several pathophysiologic mechanisms appear to be responsible for ventilatory failure in acute asthma. PEEPi is a threshold pressure that must be overcome before inspiratory flow occurs, increasing inspiratory work of breathing. Airway resistance is increased, and if lung compliance is low, greater transpulmonary pressure is required. Work of breathing can overwhelm the fatiguing respiratory muscles to cause ventilatory failure, even in young and otherwise healthy individuals.

These mechanical loads are imposed on a diaphragm that is placed in a disadvantageous position by hyperinflation and at a time when circulatory abnormalities may result in hypoperfusion. Respiratory acidosis further decreases diaphragm force generation.[38] Lactic acidosis is a marker of severity rather than a cause of diaphragm dysfunction per se.[38–40]

Clinical Presentation, Differential Diagnosis, and Assessment of Severity

Multifactorial analysis including the history, physical examination, measures of airflow obstruction, response to therapy, arterial blood gases, and chest radiography is important to assess disease severity and risk for deterioration. Such analysis is necessary because no single clinical measurement predicts outcome reliably.[41]

MEDICAL HISTORY

Characteristics of prior exacerbations that predict a fatal or near fatal episode include intubation, hypercapnia, barotrauma, hospitalization despite corticosteroids, psychiatric illness, and medical noncompliance.[42,43] Prior intubation is the greatest single predictor of subsequent asthma death.[44] Substance abuse, alcohol ingestion, and excessive, long-term use of β agonists are also associated with increased risk of death.[45,46] Pharmacogenetic studies have suggested an association between polymorphisms of β adrenoreceptors, the severity of asthma, and its response to therapy.[47] Survivors of near-fatal asthma may also have diminished ventilatory drive in the face of hypoxemic or mechanical stimuli (i.e., poor perceivers of airflow obstruction).[48] Other concerning features

include symptoms of long duration (which suggests a substantial component of airway wall inflammation and slow recovery), late arrival for care, fatigue, altered mental status, and sleep deprivation. Deterioration despite optimal treatment, including the concurrent use of oral steroids, identifies patients who are unlikely to improve quickly.

"All that wheezes is not asthma" is an appropriate clinical aphorism to consider. In most cases, the history and examination identify conditions that are confused for or complicate acute asthma. The absence of a history of asthma should alert the physician to other diagnoses (although asthma can first occur at any age). A history of smoking suggests chronic obstructive pulmonary disease (COPD), which may be associated with fixed airflow obstruction, pulmonary hypertension, and chronic respiratory acidosis. Cardiac asthma refers to the airway hyperreactivity that occurs in congestive heart failure.[49] Heart failure is generally discernible by examination, but the distinction between LV dysfunction and airway obstruction can be difficult. As discussed above, severe airflow obstruction is a rare cause of pulmonary edema, and bronchodilators may improve airflow obstruction in LV failure.[50] Foreign body aspiration must be considered in children and in adults with an abnormal swallow, a history of altered mental status, or recent dental work. Upper airway obstruction from granulation tissue, tumor, laryngeal edema, or vocal cord dysfunction may be confused for acute asthma. In classic extrathoracic obstruction, there is flattening of the inspiratory portion of the flow-volume loop and poor response to asthma medication. Fiberoptic laryngoscopy can confirm laryngeal obstruction. For patients with tracheal stenosis (e.g., from prior intubation), CT imaging and fiberoptic bronchoscopy establishes the diagnosis. Important clues to focal obstruction include localized wheeze, and rarely, asymmetric hyperinflation on the chest radiograph.[51] Pneumonia complicating asthma is unusual but should be considered when there is fever, purulent sputum, localizing signs, and refractory hypoxemia. Purulent sputum in asthma contains an abundance of eosinophils and not polymorphonuclear leukocytes. In large series of patients with pulmonary embolus, wheezing was not a reported sign. However, this association has been described anecdotally.[52] If dyspnea is out of proportion to measures of airflow obstruction, this diagnosis should be considered.

PHYSICAL EXAMINATION

The general appearance of the patient (i.e., posture, pattern of speech, positioning, and level of alertness) allows for quick assessment of status, response to therapy, and need for intubation. Adults who assume the upright position have a higher heart rate (HR), respiratory rate (RR), and PP and a significantly lower Pa_{O_2} and PEFR than patients who are able to lie supine.[53] Diaphoresis is associated with an even lower PEFR. Accessory muscle use and PP indicate severe airflow obstruction; the absence of either finding does not rule out severe obstruction.[37]

Examination of the head and neck should focus on identifying barotrauma and upper airway obstruction. Tracheal deviation, asymmetric breath sounds, a "mediastinal crunch," and subcutaneous emphysema suggest pneumomediastinum or pneumothorax. Rarely, atelectasis from a central mucus plug causes tracheal deviation. The mouth and neck should be inspected for mass lesions or signs of previous surgery. The lip and tongue should be inspected for angioedema.

Wheezing correlates poorly with the degree of airflow limitation.[54] A silent chest suggests insufficient airflow for wheezes to occur, and in general, wheezes that emerge in a previously silent chest signal clinical improvement. Localized wheezing or crackles should prompt consideration of atelectasis, pneumonia, pneumothorax, endobronchial lesions, or foreign body.

Asthmatics are generally tachycardic on presentation.[55] Bradycardia is an ominous sign of impending arrest. The usual rhythm is sinus tachycardia. Supraventricular and ventricular arrhythmias are not uncommon, particularly in older patients.[56]

Clinical signs of right-sided and left-sided heart failure suggest primary cardiac disease. Yet, acute asthma alone can cause examination and electrocardiographic findings of right-sided heart strain and pulmonary edema which resolve within hours of response to therapy.[55,57] Jugular venous distention also occurs when DHI or tension pneumothorax limit venous return to the right heart. Myocardial ischemia should be considered in older patients with coronary artery disease. Asthma may cause myocardial oxygen supply/demand imbalance if large drops in intrathoracic pressure increase LV afterload and decrease coronary blood flow.[58] β Agonists, theophylline, and hypoxemia may further disrupt this balance.

MEASUREMENT OF AIRFLOW OBSTRUCTION

The degree of airflow obstruction is determined by measuring PEFR or FEV_1. A PEFR or FEV_1 <50% of predicted or the patient's personal best characterizes severe exacerbation.[1] Objective measures are necessary because physician estimates are often wrong.[59] In most cases it is easier to measure PEFR than FEV_1, but neither is easy to obtain in critical patients. In these patients it is wise to defer measurements, since they may worsen bronchospasm[60] and rarely precipitate respiratory arrest.[61] In most cases, however, peak flow determinations are safe.

Measurement of the change in PEFR or FEV_1 is a good way to assess and follow patients. Several studies have demonstrated that failure of initial therapy to improve expiratory flow after 30 minutes predicts a refractory course and need for hospitalization or continued treatment in an ED.[41,62–64] Changes in PEFR before 30 minutes of treatment have elapsed do not predict clinical outcome.[65]

ARTERIAL BLOOD GASES

When FEV_1 is less than 50% predicted or of the patient's personal best, an arterial blood gas should be considered. In early (mild) acute asthma, mild hypoxemia and respiratory alkalosis are common. Hypercapnia indicates severe disease and impending respiratory failure, but not necessarily the need for intubation.[66] Importantly, hypercapnia is not always present in cases of severe obstruction and impending respiratory arrest.[67]

Metabolic acidosis with a normal anion gap occurs when there is bicarbonate wasting in response to respiratory alkalosis. An elevated anion gap suggests excess serum lactate, possibly secondary to increased work of breathing, tissue hypoxia, intracellular alkalosis, or decreased lactate clearance

by the liver. Lactic acidosis correlates with the severity of airflow obstruction, is more common in men, and occurs more frequently when β agonists are administered parenterally.[68,39]

Serial blood gases are usually not necessary to determine clinical course. Physical examinations and peak flows allow for valid judgements in most cases. Patients who deteriorate on clinical grounds with impending respiratory failure should be intubated regardless of Pa_{CO_2}. Conversely, improving patients should not be intubated despite hypercapnia. Serial blood gases are helpful in intubated patients to guide ventilator management.

RADIOGRAPHIC STUDIES

Chest radiography plays little role in the assessment or management of patients with acute asthma. Even in hospitalized patients, radiographic findings influence treatment in 1% to 5% of cases.[69–72] In one study[72] that reported major radiographic abnormalities in 34% of cases (which the authors felt impacted management), the majority of findings were classified as focal parenchymal opacities or increased interstitial markings, common indicators of atelectasis in asthma. Chest radiography is indicated when there are localizing signs, barotrauma is suspected, or it is not clear that asthma is the cause of respiratory distress. In mechanically ventilated patients, chest radiography further identifies endotracheal tube position.

ADMISSION CRITERIA

Patients demonstrating a good response to initial therapy in the ED may be discharged home with close follow-up. There should be significant improvement in breathlessness, improved air movement on physical examination, and a FEV_1 or PEFR $\geq$70% of predicted or personal best.[1] Observation for 60 minutes after the last β-agonist dose helps ensure stability prior to discharge. Written medication instructions and an action plan to be followed in the event of worsening symptoms should be provided. In general, patients should be discharged on oral corticosteroids. We advise initiation and/or continuation of inhaled corticosteroids by proper technique in the ED. Follow-up appointments are essential.

Patients with severe airflow obstruction demonstrating a poor response to therapy (e.g., <10% increase in PEFR) or patients who deteriorate despite therapy should be admitted to an ICU. Other indications for ICU admission include respiratory arrest, altered mental status, arrhythmias, myocardial ischemia or infarction, and need for frequent inhaler treatments.

An incomplete response to treatment is defined as the persistence of wheezing or dyspnea and a PEFR or FEV_1 between 50% and 70% of predicted.[1] Patients in this group require ongoing treatment either in the ED or medical ward. In general, we treat for up to 6 hours in the ED before deciding on disposition. This length of time allows for assessment of the initial response to steroids, and for those who are discharged home decreases the risk of relapse and return to the ED.[37] If the patient has demonstrated a good response to treatment over that period of time and close follow-up can be established, discharge home is appropriate. Discharged patients not optimally treated prior to the ED have better outcomes if they receive a course of oral steroids.[73] Patients who continue to have an incomplete response should be admitted to a medical ward. Admission is also recommended when there is a harmful home environment or when noncompliance favors directly observed therapy.

Therapy Prior to Intubation

PHARMACOTHERAPY

BETA AGONISTS

Asthmatic smooth muscle has increased shortening capacity and increased velocity of shortening[74] that mandate treatment in the setting of an acute attack. Use of a β agonist by inhalation is preferred and should begin immediately regardless of prior use (Table 40-1).[75] Large and frequent doses are needed in acute asthma because the dose-response curve and duration of action are adversely affected by airway narrowing. Fortunately, high doses are generally well tolerated. In one study, albuterol delivered by metered dose inhaler (MDI) and spacer to a total dose of 1600 μg over 90 minutes did not increase cardiovascular morbidity in well-oxygenated patients with acute asthma.[76]

Albuterol is preferred over metaproterenol because of its greater β_2 selectivity and longer duration of action.[77,78] Some clinicians prefer metaproterenol or isoetharine for initial therapy, despite the tendency of these drugs to increase side effects, because of their faster onset of action.[79] Levalbuterol is the R-isomer of racemic albuterol. Preclinical data demonstrate that the S-isomer has undesirable proinflammatory effects.[80] The clinical relevance of these effects (particularly in those receiving high doses of the racemate) is under investigation. Clinical data do show that 1.25 mg levalbuterol increases FEV_1 to a greater extent than 2.5 mg of the racemate in stable patients with FEV_1 $\leq$60% of predicted.[81] In acute asthma, an open-label study of 91 patients with an FEV_1 of 20% to 55% of predicted, stratified into cohorts receiving 0.63 to 5 mg levalbuterol or 2.5 to 5 mg albuterol (three treatments

TABLE 40-1 Drugs Used in the Initial Treatment of Acute Severe Asthma

Albuterol: 2.5 mg by nebulization every 20 minutes or 4–6 puffs by MDI with spacer every 20 minutes; for intubated patients titrate to physiologic effect. Alternative: levalbuterol (see text)

Epinephrine: 0.3 mL of a 1:1000 solution subcutaneously every 20 minutes × 3. Terbutaline is favored in pregnancy when parenteral therapy is indicated. Use with caution in patients >age 40 and in the presence of cardiac disease

Ipratropium bromide: 0.5 mg combined with albuterol by nebulization every 20 minutes or 4–6 puffs by MDI with spacer combined with albuterol every 20 minutes

Corticosteroids: Methylprednisolone 60 mg IV every 6 hours or prednisone PO 40 mg every 6 hours

Magnesium sulfate: 2 g IV over 20 minutes, repeat in 20 minutes if clinically indicated (total 4 g unless hypomagnesemic)

Theophylline: 5 mg/kg IV over 30 minutes loading dose in patients not on theophylline, followed by 0.4 mg/kg per hour IV maintenance dose. Watch for drug interactions and disease states that alter clearance. Follow serum levels

Leukotriene modifiers: Consider montelukast 10 mg PO (the chewable formulation may have quicker onset of action)

Heliox: 80:20 or 70:30 helium:oxygen mix by tight-fitting, nonrebreathing face mask. Higher helium concentrations are needed for maximal effect

in 1 hour), demonstrated faster onset of action and a greater degree of bronchodilation with levalbuterol.[82] Results from a larger multicenter study are expected in the near future.

Long-acting β agonists are not indicated in the initial treatment of acute asthma, but may be considered as add-on therapy in hospitalized patients. The addition of salmeterol to albuterol in hospitalized asthmatics is safe and improves FEV_1 after 48 hours compared with placebo.[83]

Subcutaneous administration is not indicated unless the patient is unable to carry out inhaled therapy (such as those with an altered mental status or cardiopulmonary arrest), and is associated with greater toxicity.[84–86] Subcutaneous epinephrine, however, benefits some patients not responding to several hours of an inhaled β agonist.[87] Known cardiac disease and age >40 years are relative contraindications to parenteral therapy,[88] although older patients without recent myocardial ischemia or infarction tolerate subcutaneous epinephrine reasonably well. Intravenous infusion of β agonists is not recommended. Inhaled drug achieves greater airflow rates with lesser toxicity compared to intravenous drug.[89–92] Combinations of inhaled and intravenous treatment have not been adequately studied.

Inhaled β agonists are delivered equally well by MDI with spacer or hand-held nebulizer.[93] Even in severe obstruction, four puffs of albuterol (0.36 mg) delivered by MDI with an InspirEase is as effective as 2.5 mg of albuterol by nebulization.[94] MDIs with spacers are less expensive and able to achieve faster drug delivery times; hand-held nebulizers require fewer instructions, less supervision, and less coordination.

The recommended initial dose is albuterol 2.5 mg by nebulization; three treatments can be given in the first hour depending on clinical response and side effects. A single high-dose treatment (e.g., 7.5 mg) is no better than multiple treatments (2.5 mg every 20 minutes 3 times), and causes more side effects.[95] Depending on the study, there is either no difference in efficacy or toxicity between continuous or intermittently nebulized albuterol, or a slight benefit to continuous nebulization (at the same total dose per hour) in severe obstruction.[96–98]

There are two dose response patterns to high and cumulative doses of albuterol. Approximately two-thirds of patients respond to inhaled albuterol in a dose-dependent fashion, generally allowing discharge home from the ED.[99] In these patients 1.2 to 2.4 mg albuterol delivered by MDI and spacer or 5 to 7.5 mg by nebulizer in the first hour is effective. In the remaining one-third of patients, even in high doses, albuterol has minimal effect, presumably because of airway inflammation and mucus plugging.

IPRATROPIUM BROMIDE

Data support the addition of ipratropium bromide to albuterol in acute asthma.[100–106] Karpel and colleagues studied 384 patients randomized to nebulized albuterol 2.5 mg or albuterol 2.5 mg with ipratropium 0.5 mg at entry and at 45 minutes.[107] At 45 minutes, there were more responders in the ipratropium group; however, the median change of FEV_1 from baseline did not differ between groups, and by 90 minutes there was no difference between groups in the percentage of responders and median change in FEV_1. There was no difference in the number of patients requiring additional ED or hospital treatment. Garrett and colleagues randomized 338 asthmatics to a single dose of nebulized ipratropium bromide 0.5 mg combined with salbutamol 3.0 mg, or salbutamol 3.0 mg alone.[108] Mean FEV_1 at 45 and 90 minutes was significantly higher with combined therapy. Lin and colleagues demonstrated that combination therapy resulted in greater improvement in PEFR than albuterol alone in 55 adult asthmatics.[109] O'Driscoll and colleagues also demonstrated a benefit to combination therapy, particularly in patients with PEFR <140 L/min.[110] In children, combination therapy decreases ED treatment time, albuterol dose requirements, and hospitalization rates.[106,111,112]

To the contrary, Weber and colleagues performed a prospective, randomized, double-blind, placebo-controlled trial of 67 patients receiving combination albuterol and ipratropium bromide or albuterol alone by continuous nebulization for a maximum of 3 hours.[113] Primary outcome measures were improvement in PEFR, hospital admission rates, and length of stay in the ED. All outcome measures favored combination therapy, but differences were not statistically significant. Fitzgerald and coworkers reported similar results.[114] McFadden and colleagues showed no benefit in PEFR, admission rate, or ED length of stay with combination therapy used for the first hour.[115] In children, Ducharme and Davis did not demonstrate benefit from combination therapy in their study of nearly 300 asthmatics with mild to moderate acute asthma.[116]

The above studies demonstrating modest (or no) benefit to combination therapy generally used small doses of ipratropium bromide. Few trials have studied high and cumulative doses of both ipratropium bromide and albuterol. In one such study, Rodrigo and Rodrigo conducted a double-blind, randomized, prospective trial of albuterol and ipratropium bromide (120 μg of albuterol and 21 μg of ipratropium per puff, combined in one inhaler) vs. albuterol (120 μg per puff) and placebo in 180 patients with acute asthma.[117] Four puffs were administered through an MDI with a spacer every 10 minutes for 3 hours. Combination therapy resulted in a 20.5% greater improvement in PEFR and a 48.1% greater improvement in FEV_1 compared with albuterol alone. The rate of hospitalization decreased significantly, from 39% in the albuterol with placebo group to 20% with combination therapy. Subgroup analysis showed that patients most likely to benefit from high doses of ipratropium bromide were those with FEV_1 <30% of predicted and symptoms for >24 hours prior to ED presentation.

Overall, the data suggest an advantage in maximal bronchodilation response when high doses of ipratropium bromide and albuterol are combined in the emergency treatment of asthma. Combination therapy is recommended in any patient who is extremely ill on first presentation or not responding quickly (e.g., within 30 minutes) to albuterol alone.

CORTICOSTEROIDS

Systemic corticosteroids should be administered quickly to treat the inflammatory component of acute asthma. The data are mixed regarding benefit in the first few hours. McFadden's group demonstrated no differences in physiologic or clinical variables in the first 6 hours in 38 patients receiving hydrocortisone.[118] Rodrigo and Rodrigo similarly showed that early administration of steroids did not improve spirometry in the first 6 hours.[119] However, Littenberg and Gluck demonstrated that methylprednisolone 125 mg IV

on arrival decreased admission rates compared to placebo,[120] and Lin and colleagues demonstrated improved peak flows after 1 and 2 hours of solumedrol.[121] A systematic review of 12 studies for the Cochrane Review demonstrated that corticosteroids within 1 hour of arrival in the ED reduced admissions.[122] Use of early systemic steroids also reduces the number of relapses in the first 7 to 10 days and the risk of death.[123–126] In hospitalized patients, systemic steroids speed the rate of improvement.[127] Oral and intravenous routes are equally effective,[128] but oral steroids should be avoided if there is concern regarding intubation.

There is no clear dose-response relationship to steroids in acute asthma.[129,130] In one meta-analysis by Manser and colleagues, there was no difference in clinical outcomes between low-dose corticosteroids (≤80 mg/d solumedrol or ≤400 mg/d hydrocortisone) and higher doses in the initial management of hospitalized asthmatics.[131] Haskell and colleagues demonstrated that 125 mg IV methylprednisolone every 6 hours resulted in faster improvement compared to 40 mg every 6 hours, but there was no difference in peak improvement.[132] Both doses were superior to 15 mg every 6 hours in terms of rate and absolute response. Emerman and Cydulka compared 500 mg and 100 mg of methylprednisolone and found no benefit to the higher dose.[133]

The Expert Panel from the National Institutes of Health (NIH) recommends 120 to 180 mg per day of prednisone or methylprednisolone in three or four divided doses for 48 hours, then 60 to 80 mg/d until PEFR reaches 70% predicted or personal best.[1] Prednisone is tapered at variable rates depending on a number of factors, including PEFR, the duration of high-dose therapy required to treat the acute exacerbation, and whether oral steroids had been used for maintenance therapy. Automatic tapering schedules are not recommended because patients may taper prematurely.

Recent trials have demonstrated efficacy of inhaled corticosteroids in acute asthma. In children discharged from the ED, short-term use of budesonide, starting at a high-dose and tapered over 1 week, was as effective as a tapering course of oral prednisolone.[134] Rodrigo and Rodrigo conducted a randomized, double-blind trial of the addition of flunisolide 1 mg or placebo to 400 μg salbutamol every 10 minutes for 3 hours in 94 ED subjects not receiving systemic steroids.[135] They found that PEFR and FEV_1 were approximately 20% higher in the flunisolide group, beginning at 90 minutes. McFadden suggests this benefit stems from steroid-induced vasoconstriction, decreasing airway wall edema, vascular congestion, and plasma exudation, and not anti-inflammatory effects.[136] Recently Rodrigo and Rodrigo demonstrated therapeutic benefit from triple drug therapy (flunisolide, albuterol, and ipratropium bromide) in high doses in patients not receiving systemic steroids.[137]

To the contrary, Guttman and colleagues found no benefit from the addition of beclomethasone 7 mg every 8 hours by MDI with spacer to nebulized salbutamol and systemic corticosteroid therapy.[138] Further study demonstrated that beclomethasone (5 mg delivered by MDI) during the initial 4 hours of ER treatment did not confer added benefit to albuterol in adults with mild to moderately severe asthma.[139]

Our view is that there is little benefit to the addition of inhaled steroids to high-dose β agonists and systemic corticosteroids in the management of acute asthma. Still, consideration should be given to the use of high-dose inhaled corticosteroids in refractory patients.

AMINOPHYLLINE

There is no benefit to adding aminophylline to inhaled β agonists in the initial treatment of acute asthma.[140] In a meta-analysis by Parameswaran and colleagues there was a trend toward higher PEFR at 12 and 24 hours, but at the cost of arrhythmias and vomiting.[141] Others have reported a delayed benefit.[142] In another recent meta-analysis in children, aminophylline was shown to improve FEV_1 by 6 to 8 hours and provide sustained benefit for 24 hours.[143] Nonbronchodilating properties of aminophylline may be useful in refractory cases. Anti-inflammatory effects and enhanced diaphragm function may explain one report that ED administration of aminophylline decreased hospitalizations, even when airflow rates were no different than placebo.[144]

We rarely use aminophylline in refractory patients, but generally continue its use (after confirming a nontoxic serum concentration) in patients already taking theophylline. This approach is safe if attention is paid to serum drug levels and to factors that increase levels, such as congestive heart failure, ciprofloxacin, macrolide antibiotics, and cimetidine, and if the drug is discontinued in the presence of side effects.

MAGNESIUM SULFATE

Three prospective trials failed to confirm a benefit to administering magnesium sulfate ($MgSO_4$) to asthmatics in the ED.[145–147] In 135 asthmatics randomized to 2 g $MgSO_4$IV or placebo after 30 minutes and followed for 4 hours, admission rates and FEV_1 were no different between magnesium-treated patients and controls.[147] However, subgroup analysis revealed $MgSO_4$ decreased admission rates and improved FEV_1 in subjects with FEV_1 <25% of predicted. Subsequently, a placebo-controlled, double-blind, randomized trial in 248 patients with FEV_1 ≤30% showed a small but statistically significant increase in FEV_1 after 240 minutes in the magnesium group, but no difference in hospitalization rates.[148] Meta-analysis of 9 trials and 665 patients demonstrated nonsignificant improvements in peak flows and admission rates for all patients, but in those with severe exacerbations, $MgSO_4$ increased FEV_1 by nearly 10% compared to placebo, and decreased admissions.[149] Additional evidence supporting benefit in severe disease comes from an uncontrolled study of five intubated asthmatics given magnesium.[150] In this study, there was a fall in peak airway pressure (43 cm H_2O to 32 cm H_2O) after high doses of $MgSO_4$ (10 to 20 g) were administered over 1 hour. Other investigators have suggested that gender may play a role in magnesium responsiveness, since estrogen augments the bronchodilator effect of magnesium.[151] Routine use of $MgSO_4$ is not justified, but $MgSO_4$is safe, inexpensive, and may be beneficial in severe exacerbations.

Magnesium sulfate can also be administered by inhalation. Nannini and colleagues studied the effects of $MgSO_4$ (225 mg) vs. saline as the vehicle for nebulized albuterol in a randomized, double-blind fashion.[152] At 20 minutes, patients treated with $MgSO_4$ and albuterol had a greater PEFR compared to the saline-albuterol group (134 ± 70 L/m vs. 86 ± 64 L/m). Hughes and colleagues have published similar data.[153]

LEUKOTRIENE MODIFIERS

Cysteinyl leukotrienes are elevated in asthmatic sputum compared to controls and higher in subjects studied within 48 hours of exacerbation.[154] Preliminary data demonstrating benefit to a leukotriene receptor antagonist came from a double-blind, randomized trial of two doses (20 mg and

160 mg) of zafirlukast orally versus placebo in 641 asthmatics after 30 minutes of standard treatment.[155] Zafirlukast 160 mg decreased admission rates, relapses, and treatment failures. In another double-blind, placebo-controlled study of 20 patients not receiving systemic steroids in an ED, oral montelukast 10 mg resulted in a trend toward a shorter duration of stay and higher peak flows, and fewer patients requiring aminophylline or steroids.[156] In the most compelling trial to date, Camargo and colleagues randomized 201 acute asthmatics to standard therapy plus montelukast 7 mg or 14 mg IV or placebo.[157] Montelukast improved FEV_1 over the first 20 minutes (14.8% vs. 3.6% with placebo). Benefits were seen within 10 minutes and lasted for 2 hours; both treatment doses were equivalent. Montelukast also tended to result in less β-agonist use and fewer treatment failures.

HELIOX

Heliox is a mixture of 20% oxygen and 80% helium (30%:70% and 40%:60% mixtures are also available). As the percentage of helium decreases, so does the benefit of breathing this gas blend. Concentrations of helium less than 60% are ineffective, precluding its use in significant hypoxemia. Heliox is slightly more viscous than air, but significantly less dense, resulting in a more than threefold increase in kinematic viscosity (the ratio of gas viscosity to gas density) compared to air. Theoretically, this property decreases the driving pressure required for gas flow by two mechanisms. First, for any level of turbulent flow, breathing low-density gas decreases the pressure gradient required for flow. Second, heliox decreases the Reynolds number, favoring conversion of turbulent flow to laminar flow.[158] Heliox does not treat bronchospasm or airway wall inflammation.

Heliox promptly improves dyspnea, work of breathing, and arterial blood gases in upper airway obstruction.[159] Benefits have also been reported in acute asthma. In adults treated in an ED, an 80:20 mix delivered by tight-fitting face mask increased PEFR and decreased PP, suggesting improved airway resistance and work of breathing.[160] Similar results have been published in children.[161] Other studies have failed to demonstrate benefit.[162–164] In a recent meta-analysis by Rodrigo and colleagues of four randomized trials and 288 patients, the authors concluded that the evidence does not support the use of heliox in nonintubated asthmatics in the ED.[165] However, methodologic differences between studies limit the ability to draw conclusions.

If heliox is effective, it may give time for concurrent therapies to work, and thereby avert the need for intubation in some cases. Of theoretical concern is the potential for heliox to mask worsening airflow obstruction, so there is less time (and no margin for error) to control the airway when intubation is required.

Whether heliox augments the bronchodilator effect of inhaled β agonists compared to delivery in air (presumably due to low-density gas facilitating albuterol deposition) is unclear. Data are available demonstrating benefit to heliox as a driving gas,[166] but there are also data to the contrary.[167]

ANTIBIOTICS

Because viruses trigger most infectious exacerbations of asthma and bacterial pneumonia is rare, there is likely no role for antibiotics in treating acute asthma. Antibiotics are frequently prescribed for an increase in sputum volume and purulence. However, purulence may reflect an abundance of eosinophils, not polymorphonuclear leukocytes. The importance of *Mycoplasma pneumoniae* in acute asthma is unknown. A recent study by Lieberman using paired serology demonstrated evidence for mycoplasma infection in 18% of patients hospitalized for acute asthma.[168] In their 2002 update, the Expert Panel from the NIH did not recommend the use of antibiotics in asthma exacerbation unless there was fever with purulent sputum, evidence for pneumonia, or suspected bacterial sinusitis.[169] In a separate review of the literature, Graham and associates recently selected 2 out of 128 possible studies adequate for review, concluding that the role of antibiotics is difficult to assess.[170]

NONINVASIVE POSITIVE PRESSURE VENTILATION

Noninvasive positive pressure ventilation (NPPV) by face mask is an option for patients with hypercapneic respiratory failure who do not require intubation. Continuous positive airway pressure (CPAP) helps overcome the adverse effects of PEEPi and decreases the inspiratory work of breathing.[171] Bronchial dilation also occurs during CPAP.[172] Advantages of NPPV over intubation include decreased need for sedation and paralysis, decreased incidence of nosocomial pneumonia, decreased incidence of otitis and sinusitis, and improved patient comfort.[173] Disadvantages include increased risk of aspiration when there is gastric insufflation, skin necrosis, and diminished control of ventilatory status compared with invasive ventilation. Data regarding the efficacy of NPPV in acute asthma are limited. In one study[174] of 21 acute asthmatics with a mean PEFR of 144 L/min, nasal CPAP of 5 or 7.5 cm H_2O decreased respiratory rate and dyspnea compared to placebo. In another study,[175] Meduri and colleagues reported their observational experience with NPPV during 17 episodes of acute severe asthma. NPPV was achieved using a loose-fitting full-face mask with initial settings of 0 cm H_2O CPAP and 10 cm H_2O pressure support ventilation. CPAP was increased to 3 to 5 cm H_2O and pressure support was titrated to achieve an exhaled tidal volume of $\geq$7 mL/kg and a respiratory rate of <25/min. The average duration of NPPV was 16 hours. NPPV generally improved dyspnea, HR, RR, and blood gases. Two NPPV-treated patients required intubation for worsening Pa_{CO_2}. There were no NPPV complications.

Management of the Intubated Asthmatic

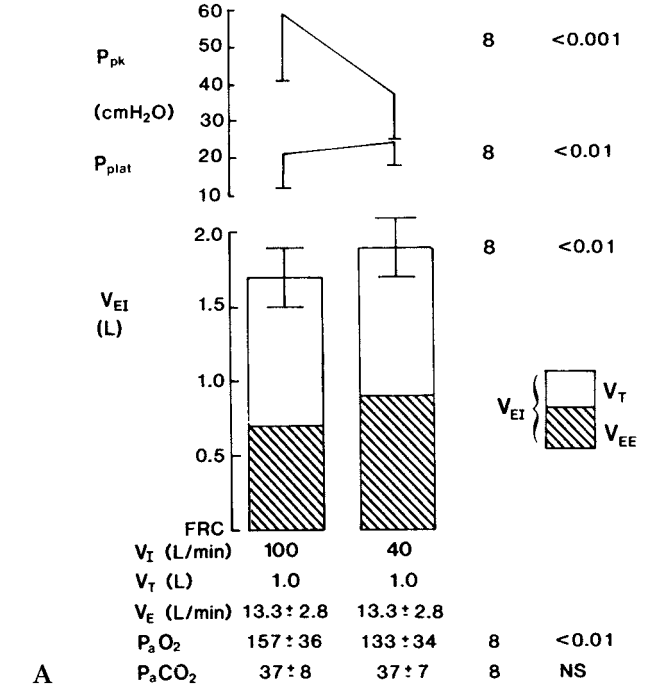
INTUBATION

The goals of intubation and mechanical ventilation are to maintain oxygenation and prevent respiratory arrest. Patients who are intubated before they arrest generally do well (if ventilated appropriately); patients who are intubated after respiratory arrest and the development of anoxic brain injury do not. Approximately 40% of deaths in ventilated asthmatics are due to cerebral anoxia resulting from respiratory arrest prior to mechanical ventilation.[176]

Intubation is indicated for impending respiratory failure and cardiopulmonary arrest. Changes in posture, mental status, speech, accessory muscle use, and RR can indicate progressive ventilatory failure that does not need blood-gas or PEFR confirmation. In the final analysis, the decision to intubate rests on a clinician's estimate of the patient's ability to maintain spontaneous respiration.

Oral intubation is preferred because it allows for placement of an adequately sized endotracheal tube (e.g., 8.0 mm inside diameter [ID] for adult women, 8.0 to 9.0 mm ID for adult men) to facilitate removal of mucus and decrease airflow resistance. Nasal intubation is acceptable in an awake patient anticipated to be difficult to position and intubate (fiberoptic guidance may facilitate intubation in this setting), but is complicated by the need for a smaller endotracheal tube and the high incidence of nasal polyps and sinusitis in asthma.

POSTINTUBATION HYPOTENSION



Hypotension has been reported in 25% to 35% of patients following intubation.[176] It occurs for several reasons. First, there is loss of vascular tone due to a direct effect of sedation and loss of sympathetic activity. Second, patients may be hypovolemic from high insensible losses and decreased oral fluid intake. Third, overzealous Ambu Bag ventilation results in DHI because adequate time is not provided for exhalation. When this occurs, breath sounds diminish, BP falls, and HR rises. Manual breaths take considerable effort because the hyperinflated lung is stiff (noncompliant). A trial of hypopnea (2 to 3 breaths/min) or apnea in a preoxygenated patient deflates the lung. After 30 to 60 seconds of hypoventilation, intrathoracic pressure falls, allowing for greater preload to the right atrium; BP rises, HR falls, and breaths become easier to deliver, confirming DHI.

A trial of hypopnea or apnea is both diagnostic and therapeutic for DHI. However, hemodynamic improvement during such a trial does not exclude tension pneumothorax. Tension pneumothoraces may have been responsible for >6% of deaths of patients who required mechanical ventilation for severe asthma.[176] Careful inspection of the chest x-ray is mandatory because the lungs may not collapse completely in the setting of DHI and widespread mucus plugging. Unilateral pneumothorax conceivably increases ventilation to the contralateral lung, increasing the risk of bilateral pneumothoraces. Given these considerations, chest tubes should not be placed until a trial of hypoventilation has failed or there is radiographic evidence of pneumothorax.

INITIAL VENTILATOR SETTINGS AND DYNAMIC HYPERINFLATION

Expiratory time, tidal volume, and severity of airway obstruction determine the level of DHI (Fig. 40-1). Minute ventilation and inspiratory flow determine expiratory time.[177,178] To avoid dangerous levels of DHI, initial minute ventilation should not exceed 115 mL/kg per minute or approximately 8 L/min in a 70-kg patient.[179] To this end, we recommend a RR between 12 and 14/min and a tidal volume between 7 and 8 mL/kg. The use of low tidal volumes avoids excessive peak lung inflation, which can occur even with low minute ventilation.

Shortening the inspiratory time by use of a high inspiratory flow rate further prolongs expiratory time. We favor a flow rate of 80 L/min, using a constant flow rate pattern. High inspiratory flows increase peak airway pressure by elevating airway resistive pressure, but peak airway pressure per se does not correlate with morbidity or mortality. Rather it is the state of lung hyperinflation that predicts outcome (see below). High inspiratory flow and high airway pressures

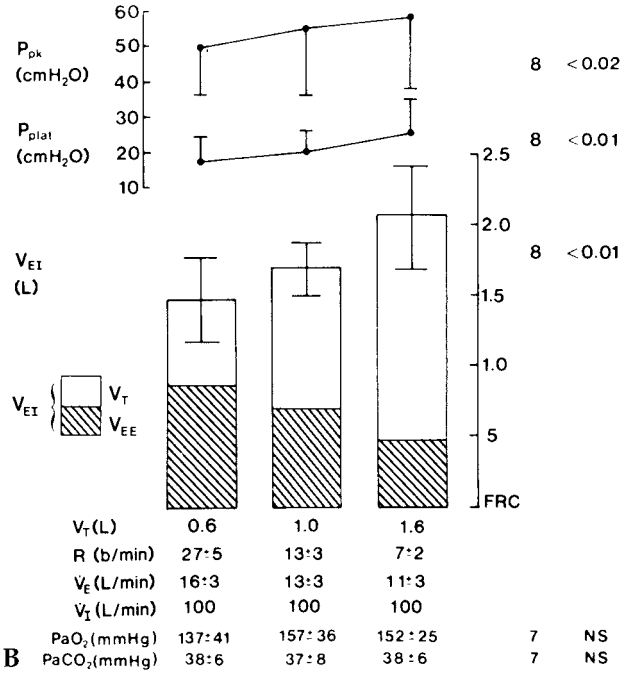


FIGURE 40-1 Effects of ventilator settings on airway pressures and lung volumes during normocapneic ventilation of eight paralyzed asthmatic patients. V_{EE} = lung volume at end expiration; V_{EI} = lung volume at end inspiration; Ppk = peak airway pressure; Pplat = end inspiratory plateau pressure; V_E = minute ventilation; V_I = inspiratory flow. *A.* As inspiratory flow is decreased from 100 L/min to 40 L/min at the same V_E, Ppk falls, but hyperinflation increases due to dynamic gas trapping. *B.* Dynamic hyperinflation is reduced by low respiratory rates and high tidal volumes (as long as V_E is decreased), but high tidal volumes result in high Pplat. *(Reproduced with permission from Tuxen et al.[178])*

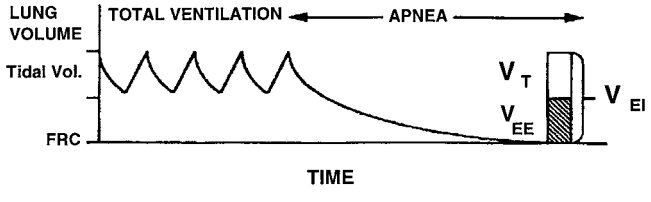
may redistribute ventilation to low-resistance lung units, risking barotrauma, but these concerns are based largely on mathematical and mechanical lung models,[180,181] and have no supporting clinical data. Another concern in spontaneously breathing patients is that high inspiratory flow rates in the assist-control mode can increase RR and thereby decrease expiratory time.[182]



There is no consensus as to which ventilator mode should be used in asthmatics. In paralyzed patients, synchronized intermittent mandatory ventilation (SIMV) and assist-controlled ventilation (ACV) are equivalent. In patients triggering the ventilator, SIMV is generally preferred because of the unproven concern that minute ventilation will be higher during ACV, since each triggered breath receives a guaranteed tidal volume.[183] However, in spontaneously breathing patients, SIMV may increase work of breathing and machine-patient dyssynchrony if set minute ventilation is low.[184] Volume-controlled ventilation (VCV) is recommended over pressure-controlled ventilation (PCV) for several reasons, including staff familiarity with its use. PCV offers the advantage of limiting peak airway pressure to a predetermined set value. However, during PCV, tidal volume is inversely related to PEEPi and minute ventilation is not guaranteed. Peak inspiratory flow rates may be extremely high in PCV (to compensate for decelerating flow) to maintain a short inspiratory time.

Ventilator-applied PEEP is not recommended in sedated and paralyzed patients because it may increase lung volume if used excessively.[185] In spontaneously breathing patients, small amounts of ventilator-applied PEEP (e.g., 5 cm H_2O) decrease inspiratory work of breathing by decreasing the pressure gradient required to overcome PEEPi.

ASSESSING LUNG INFLATION

Determining the level of DHI is central to risk assessment and ventilator adjustment. Numerous methods have been proposed to measure DHI. The volume at end-inspiration, termed V_{EI}, is determined by collecting all expired gas from the end-inspiratory volume to functional reserve capacity (FRC) during 40 to 60 seconds of apnea (Fig. 40-2). Although V_{EI} may underestimate the degree of air trapping if there are very slowly emptying air spaces, V_{EI} greater than 20 mL/kg correlates with barotrauma.[179] The utility of this measure is limited by the need for paralysis, and the fact that most clinicians and respiratory therapists are unfamiliar with expiratory gas collection.

FIGURE 40-2 One way to measure lung hyperinflation is to collect the total exhaled volume during a period of apnea (usually 20 to 60 seconds). This volume, termed V_{EI}, is the volume of gas at end-inspiration above FRC, and is the sum of the tidal volume and volume at end-exhalation above FRC (V_{EE}). V_{EI} above a threshold value of 20 mL/kg (1.4 L in an average-size adult) has been shown to predict complications of hypotension and barotrauma. (*From Tuxen et al.*[177])

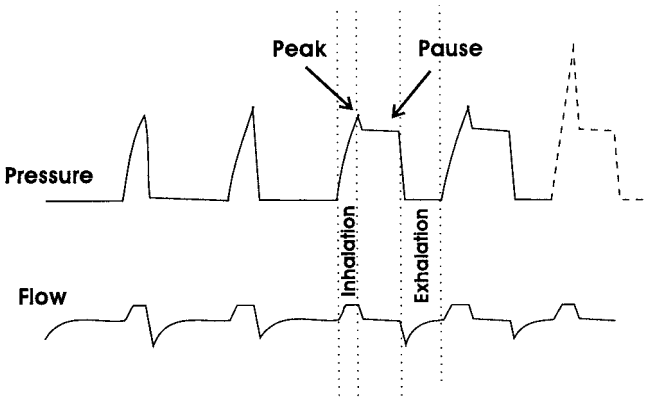


FIGURE 40-3 Simultaneous plots of flow and airway pressure in a mechanically ventilated patient. The peak-to-pause or peak-to-plateau gradient is determined by temporarily occluding inspiratory flow. End-inspiratory occlusions should be done cautiously and briefly in patients with status asthmaticus, since expiratory time may be shortened and gas trapping may worsen. Under conditions of constant inspiratory flow and absence of patient effort, the peak-plateau gradient can be used as a measure of the severity of inspiratory airway resistance, and of the efficacy of bronchodilator therapy. The dotted line indicates a high peak-pause gradient as one would see in status asthmaticus. The plateau pressure is a reflection of the respiratory system pressure change resulting from the delivery of the tidal volume, added to any level of intrinsic PEEP (PEEPi). Hence the plateau pressure is a useful marker for the degree of lung hyperinflation, and should be maintained at <30 cm H_2O.

Surrogate measures of DHI include the single-breath plateau pressure (Pplat) and PEEPi. Neither is perfect. Pplat is an estimate of average end-inspiratory alveolar pressures that is determined by stopping flow at end-inspiration (Fig. 40-3). PEEPi is the lowest average alveolar pressure achieved during the respiratory cycle. It is obtained by measuring airway-opening pressure during an end-expiratory hold maneuver (Fig. 40-4). In the presence of PEEPi, airway-opening pressure increases to the amount of PEEPi present. Persistence of expiratory gas flow at the beginning of inspiration (which can be detected by auscultation or monitoring of flow tracings) also demonstrates PEEPi.[186]

Accurate measurement of Pplat and PEEPi requires patient-ventilator synchrony and patient relaxation. Paralysis is generally not required. Unfortunately neither measure has been validated as a predictor of complications. Pplat is affected by the lung and surrounding structures so that variations in DHI occur at the same pressure. For example, an obese patient will have a higher Pplat than a thin patient for the same degree of DHI. Despite these limitations, experience suggests that a Pplat <30 cm H_2O is generally safe.

PEEPi may underestimate the severity of DHI (see above). This may occur when airway closure limits communication between the alveolus and airway opening, so that during an end-exhalation hold maneuver, airway-opening pressure does not rise. In most cases, however, PEEPi <15 cm H_2O is acceptable.

VENTILATOR ADJUSTMENTS

Relying on Pplat as a measure of DHI, we provide the following suggestions for ventilator adjustments. If initial settings

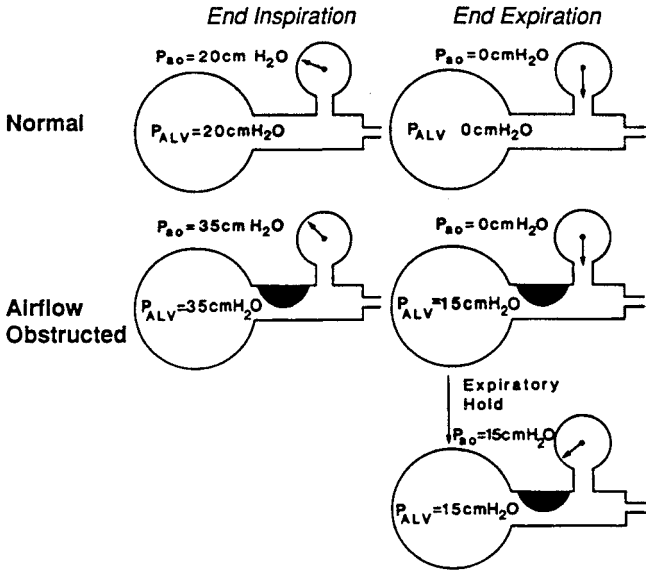

FIGURE 40-4 Measurement of auto- or intrinsic PEEP (PEEPi). Under normal conditions, alveolar pressure (P_{ALV}) closely tracks pressure at the airway opening (Pao), which is reported on the ventilator manometer. At end-expiration, P_{ALV} falls to atmospheric pressure (0 cm H_2O) and is accurately reflected by Pao. In severe airflow obstruction, P_{ALV} may increase because of gas trapping, and at end-expiration P_{ALV} has not fallen to atmospheric pressure and does not equal Pao. If an expiratory hold maneuver is performed, Pao will rise, reflecting the degree of gas trapping.

result in Pplat >30 cm H_2O, RR is decreased until this goal is achieved, even at the cost of hypercapnia. Hypercapnia is generally well tolerated in oxygenated patients, even to Pa_{CO_2} values nearing 90 mm Hg, as long as sudden changes do not occur.[187,188] Anoxic brain injury and myocardial dysfunction are contraindications to permissive hypercapnia, which may induce cerebral vasodilation, decrease myocardial contractility, and constrict the pulmonary vascular bed.[189] Lowering minute ventilation may not cause the expected rise in P_{CO_2} if dead space decreases concurrently.

If hypercapnia results in a blood pH of less than 7.20 (and RR can not be increased because of the Pplat limit), we consider a slow infusion of sodium bicarbonate, although this has not been shown to improve outcome.[190] If Pplat is less than 30 cm H_2O and pH is less than 7.20, RR can be safely increased for the purpose of lowering Pa_{CO_2} and elevating arterial pH until Pplat nears the threshold pressure. Commonly, patients can be ventilated to a pH >7.20 with a Pplat <30 cm H_2O.

SEDATION AND PARALYSIS

Sedation is indicated to improve comfort, safety, and patient-ventilator synchrony. This is particularly true when hypercapnia serves as a potent stimulus to respiratory drive. Some patients (such as those with sudden-onset asthma) may be ready for extubation within hours. In these patients, propofol is attractive because it can be rapidly titrated to a deep level of sedation, and there is quick reversal of sedation after discontinuation.[191] Lorazepam and midazolam are less expensive alternatives.[192] Time to awakening after discontinuation of benzodiazepines is longer and less predictable than with propofol.

In order to provide the best combination of amnesia, sedation, analgesia, and suppression of respiratory drive, we recommend the addition of a narcotic by continuous infusion to propofol or a benzodiazepine.[193] Morphine and fentanyl are the two most commonly used narcotics. Fentanyl has a quicker onset of action than morphine. Narcotics may release histamine and worsen bronchospasm if they are delivered by bolus administration. Daily interruption of sedatives avoids unwanted drug accumulation.[194]

Ketamine, an IV anesthetic with sedative, analgesic, and bronchodilating properties, is reserved for use in intubated patients with severe bronchospasm that precludes safe mechanical ventilation.[195–197] Ketamine must be used with caution because of its sympathomimetic effects and ability to cause delirium.

When safe and effective mechanical ventilation cannot be achieved by sedation alone, short-term muscle paralysis is indicated. Short- to intermediate-acting agents include atracurium, cis-atracurium, and vecuronium. Pancuronium is longer acting and less expensive, and its vagolytic effects cause tachycardia. Pancuronium and atracurium release histamine, but this is of doubtful clinical significance.[198] We prefer cis-atracurium because it is essentially free of cardiovascular effects, does not release histamine, and does not require hepatic and renal function for clearance.

Paralytics may be given intermittently by bolus or continuous IV infusion. If a continuous infusion is used, a nerve stimulator should be used or the drug should be withheld every 4 to 6 hours to avoid drug accumulation. Paralytic agents should be minimized whenever possible because of the risk of postparalytic myopathy.[199–201] In one study of 25 ventilated asthmatics, 19 (76%) patients had an increase in serum creatine kinase, and 9 (36%) had clinically detectable myopathy.[201] Elevated creatine kinase was associated with prolonged mechanical ventilation whether or not there was clinically detectable myopathy. In a retrospective cohort study of 107 episodes of asthma requiring intubation, the concurrent use of steroids and a paralytic was associated with muscle weakness in 29% of episodes; steroid treatment alone was not associated with weakness.[199] Importantly, this study demonstrated that the duration of paralysis correlated with the incidence of myopathy, which is rare when paralytics are used for less than 24 hours. Findings of a separate study confirm this correlation.[200] Most patients with postparalytic myopathy recover, but may require weeks of rehabilitation.

ADMINISTRATION OF BRONCHODILATORS DURING MECHANICAL VENTILATION

Many questions remain regarding the administration of inhaled bronchodilators to intubated patients. In one study,[202] only 2.9% of a radioactive aerosol delivered by nebulizer was deposited in the lungs of mechanically ventilated patients. Manthous and colleagues compared the efficacy of albuterol delivered by MDI via a simple inspiratory adapter (no spacer) to nebulized albuterol in intubated patients.[203] Using the peak-to-pause pressure gradient at a constant inspiratory flow to measure airway resistance, they found no effect (and no side effects) from the administration of 100 puffs (9.0 mg) of albuterol. Albuterol delivered by nebulizer to a total dose of 2.5 mg reduced the inspiratory flow-resistive pressure 18%. Increasing the nebulized dose to a total of 7.5 mg reduced airway resistance further in 8 of 10 patients, but caused side

effects in half of the patients. Thus if MDIs are used during mechanical ventilation, use of a spacer on the inspiratory limb of the ventilator improves drug delivery.[204]

Regardless of whether an MDI with spacer or nebulizer is used, higher drug dosages are required and the dosage should be titrated to achieve a fall in the peak-to-pause airway pressure gradient. Nebulizers should be placed close to the ventilator, and in-line humidifiers stopped during treatments. Inspiratory flow should be reduced to approximately 40 L/min during treatments to minimize turbulence, although this strategy may worsen DHI and must be time-limited. Patient-ventilator synchrony is crucial to optimize drug delivery. The use of heliox as a driving gas may enhance the delivery of albuterol to target airways. When no measurable drop in airway resistance occurs, other causes of elevated airway resistance such as a kinked or plugged endotracheal tube should be excluded. Bronchodilator nonresponders should also be considered for a drug holiday. Data from randomized controlled trials are needed to determine the effects of bronchodilators in intubated patients, and to provide evidence for or against usual clinical recommendations for bronchodilator use.[205]

OTHER CONSIDERATIONS

Rarely, the above strategies are unable to stabilize the patient on the ventilator. In these situations other therapies are available. Halothane and enflurane are general anesthetic bronchodilators that acutely reduce Ppk and Pa_{CO_2}.[206,207] These agents cause myocardial depression, arterial vasodilation, and arrhythmias, and their benefit does not last after drug discontinuation. Heliox delivered through the ventilator circuit may decrease Ppk and Pa_{CO_2}.[208] However, safe use of heliox requires significant institutional expertise and careful planning. Flow meters (which are gas-density dependent) must be recalibrated for heliox, and a spirometer should be placed on the expiratory port of the ventilator during heliox administration to measure tidal volume. A trial of heliox use in a lung model is recommended prior to patient use.

Strategies to mobilize mucus such as chest physiotherapy or treatment with mucolytics or expectorants have not been proven effective in controlled trials. Bronchoalveolar lavage using either saline or acetylcysteine may be useful in nonintubated patients.[209–211] This procedure is theoretically risky because the bronchoscope increases expiratory airway resistance and may worsen bronchospasm and PEEPi.

EXTUBATION

Patients with sudden-onset asthma may respond quickly to bronchodilators. More often 24 to 48 hours of bronchodilator/anti-inflammatory therapy is required before patients are ready for extubation. As a general rule, we perform a spontaneous breathing trial once Pa_{CO_2} normalizes at a minute ventilation that does not cause significant DHI, airway resistive pressure is <20 cm H_2O, mental status is intact, and significant muscle weakness is not seen. Depending on clinical status, we extubate within 30 to 120 minutes (as the endotracheal tube itself may perpetuate bronchospasm). Shortly after extubation, we administer albuterol and ipratropium bromide by nebulization. Observation in the ICU is recommended for an additional 12 to 24 hours. During this period, the focus can switch to safe transfer to a medical ward and maximizing outpatient management.

Chapter 41

MASSIVE HEMOPTYSIS

RICHARD K. ALBERT

KEY POINTS

- *Assure adequate oxygenation.*
- *Look for and correct coagulation abnormalities.*
- *For localized bleeding, bronchoscopy and/or computed tomography scanning can generally establish the region of the lung from which the bleeding is coming.*
- *Kidney or lung biopsy may be needed to establish the cause of diffuse bleeding.*
- *Treatment depends on cause, but bronchial arterial embolization should generally be considered prior to surgery.*

Hemoptysis is defined as coughing of blood, and can be caused by numerous diseases and conditions (Table 41-1). Most series indicate that bronchiectasis is the most common cause, but the prevalence of any specific causal entity is a function of the time frame studied (with tuberculosis being more common in older series), and the nature of the population encountered (e.g., bronchiectasis in patients with cystic fibrosis, cancer in older smokers).

Most patients with hemoptysis do not require intensive care. Those who do generally have either such rapid rates of bleeding that they are hemodynamically unstable, or they have life-threatening hypoxemia as a result of diffuse parenchymal hemorrhage or extensive aspiration of blood that originates from a localized source.

"Massive" hemoptysis has been variably defined as production of more than 300 to 600 mL of blood in 12 to 24 hours, depending on the study. Although this connotation is perhaps important from a descriptive standpoint, the distinction has little clinical utility, as it is difficult for patients to accurately quantify the volume of blood they are producing, and the volume of hemoptysis may vary considerably from hour to hour (or even from minute to minute). In addition, some patients with diffuse pulmonary hemorrhage can present with life-threatening hypoxemia and diffuse parenchymal infiltrates, meeting all the criteria for the acute respiratory distress syndrome (ARDS), yet have no hemoptysis. Although any of the conditions listed in Table 41-1 may cause hemoptysis, those more commonly associated with massive hemoptysis are bronchiectasis, mycetoma, tuberculosis, bronchogenic carcinoma, lung abscess, and vascular-bronchial fistulas. A recent study of 29 patients from Singapore found that 62% had bronchiectasis, 13% had mycetomas, 10% had tuberculosis, 6% had tumors, and 3% had a pulmonary hemorrhage syndrome.[1]

Older reviews of hemoptysis comment that bleeding from the nose, pharynx, or even the gastrointestinal system may present with what was thought to be hemoptysis. The point has been made that blood coming from the lungs is usually bright red and has an alkaline pH, whereas that from the stomach will be dark and acidic. Clinically, the distinction is only rarely difficult.

Stabilization

Attention should initially be directed at assuring adequate ventilation and perfusion as with any patient requiring intensive care. The most common cause of death in patients with hemoptysis is asphyxia from aspirated blood. Clearance of blood from the airway may be facilitated by utilizing the Trendelenburg position. If the site of bleeding is known, right or left lateral decubitus positioning may serve to protect the opposite lung.

Some patients (particularly those with diffuse parenchymal hemorrhage) may require intubation and mechanical ventilation. While intubation generally facilitates removal of blood from the lower airway, the tube may become obstructed by coagulated blood with a resultant limitation in ventilation. In extreme circumstances the mainstem bronchus of the nonbleeding lung can be intubated in an attempt to protect the other lung. Alternatively, many reports describe placing occluding catheters in the mainstem bronchus of the bleeding lung. In the setting of extensive bleeding, however, intubation and/or precise placement of endotracheal tubes may be extremely difficult because of the inability to visualize the airway.

Small doses of codeine or morphine may be used to blunt the cough reflex and perhaps slow the rate of bleeding, but agents that depress the sensorium must be used cautiously as they may also increase the risk of aspiration.

Initial Evaluation

Bleeding disorders should be sought; in the appropriate setting the patient should be screened for conditions associated with pulmonary hemorrhage syndromes, and attempts made to determine the site of bleeding. The nose and mouth should be carefully inspected to exclude an upper airway source of bleeding. Rhinoscopy and/or laryngoscopy may at times be useful. A history consistent with rheumatic fever might lead to the suspicion of mitral stenosis, which is readily diagnosed by echocardiography.

Coagulation screening should include a platelet count, a prothrombin time, and a partial thromboplastin time. If patients have had substantial bleeding for a prolonged period of time, a fibrinogen level should also be determined.

Blood should be sent for urea nitrogen and creatinine, a urinalysis should be obtained, and if clinical indications point to diffuse parenchymal hemorrhage, serology should be sent to screen for connective tissue disease and vasculitis (e.g., antinuclear antibodies, rheumatoid factor, complement levels, cryoglobulins, the anti–glomerular basement antibody causing Goodpasture syndrome, anti-phospholipid antibodies, and the antinuclear cytoplasmic antibody that is seen in Wegener granulomatosis and pauci-immune vasculitis) (see Table 41-1).

DETERMINING THE SITE OF BLEEDING

The chest x-ray will identify the region of bleeding in approximately 60% of patients. Fiberoptic or rigid bronchoscopy can be used to determine the site of bleeding, as can CT imaging. In most instances the site may be investigated electively after the patient stabilizes and the rate of bleeding slows. However,

TABLE 41-1 Causes of Hemoptysis and Pulmonary Hemorrhage

Localized bleeding
- Infections
  - Bronchitis
  - Bacterial pneumonia (particularly *Streptococcus pneumoniae* and *Klebsiella*)
  - Tuberculosis (particularly in the setting of cavitary disease)
  - Fungal infections (particularly mycetomas from *Aspergillus* or *Candida*)
  - Bronchiectasis (e.g., cystic fibrosis or immune deficiencies)
  - Lung abscess
  - Leptospirosis
- Tumors
  - Bronchogenic (i.e., squamous cell)
  - Necrotizing parenchymal cancer (usually adenocarcinoma)
  - Bronchial adenoma
- Cardiovascular problems
  - Mitral stenosis
- Pulmonary vascular problems
  - Pulmonary arteriovenous malformations (e.g., Rendu-Osler-Weber syndrome)
  - Pulmonary embolus with infarction
  - Behçet syndrome
  - Pulmonary artery catheterization with pulmonary arterial rupture
- Trauma
- Others
  - Broncholithiasis
  - Sarcoidosis (usually from cavitary lesions with mycetoma)
  - Ankylosing spondylitis

Diffuse bleeding
- Drug- and chemical-induced
  - Anticoagulants
  - D-penicillamine (rare, seen with prior treatment of Wilson disease)
  - Trimellitic anhydride (encountered during manufacturing of plastics, paint, and epoxy resins)
  - Cocaine
  - Propylthiouracil
  - Amiodarone
  - Phenytoin
- Blood dyscrasias
  - Thrombotic thrombocytopenic purpura
  - Hemophilia
  - Leukemia
  - Thrombocytopenia
  - Uremia
  - Antiphospholipid antibody syndrome
- Pulmonary-renal syndrome
  - Goodpasture syndrome (anti–glomerular basement membrane antibody disease)
  - Wegener granulomatosis
  - Pauci-immune vasculitis
- Vasculitis
  - Pulmonary capillaritis (with or without a connective tissue disease, pauci-immune vasculitis, lung transplant rejection, propylthiouracil, or the retinoic acid syndrome)
  - Polyarteritis
  - Churg-Strauss syndrome
  - Henoch-Schönlein purpura
  - Necrotizing vasculitis
  - Connective tissue diseases (i.e., systemic lupus erythematosus, rheumatoid arthritis, mixed connective tissue disease, or rarely scleroderma)
  - Pulmonary veno-occlusive disease
- Hemosiderosis

TABLE 41-2 Comparative Utility of Chest X-Ray, Fiberoptic Bronchoscopy, and Chest Computed Tomography

	SITE OF BLEEDING		CAUSE OF BLEEDING	
Diagnostic Modality	N	%	N	%
Chest x-ray	37	46	28	35[a]
Fiberoptic bronchoscopy	58	73	6	7
Chest CT	56	70	62	77

in selected patients (e.g., trauma), immediate surgical intervention may be needed. In others, especially those with rapid rates of ongoing bleeding, the choice of diagnostic evaluation may be more difficult. A recent study of 29 consecutive patients admitted to intensive care with more than 300 mL/d of hemoptysis found that fiberoptic bronchoscopy localized the bleeding in 90% of cases.[1]

Fiberoptic bronchoscopy may demonstrate a specific endobronchial lesion, or may at least indicate a specific lung lobe or segment from which the bleeding is coming. However, with rapid rates of bleeding, visualization through a fiberoptic scope is likely to be suboptimal because of an inability to clear blood from the airway. Rigid bronchoscopy allows for better suctioning, but is more invasive and only the central airways can be inspected. Nonetheless, when the rate of bleeding precludes accurate assessment of the airway anatomy by fiberoptic bronchoscopy, there should be no delay in moving to rigid bronchoscopy.

A retrospective study of 80 patients with "large or massive" hemoptysis compared the utility of chest x-rays, fiberoptic bronchoscopy, and chest computed tomography (CT).[2] The results indicated that chest CT was superior in determining the cause of bleeding, and suggested that it should become the first-line procedure (Table 41-2). A recent study of 40 consecutive patients assessed the accuracy of CT angiography for determining whether patients with massive hemoptysis (i.e., 300 to 600 mL/d) had a systemic artery as the source of the bleeding.[3] Using conventional angiography as the gold standard, CT angiography had an 80% sensitivity, an 84% specificity, and an 84% positive predictive value. More than 3 mm of pleural thickening in a region located adjacent to a parenchymal abnormality, and contrast-enhancing vascular structures in the extrapleural fat correlated with the presence of a nonbronchial systemic arterial supply.[3]

Patients with diffuse alveolar hemorrhage more commonly have diffuse rather than localized infiltrates on their chest x-rays or CT scans, but diffuse infiltrates may also result from localized bleeding if the blood is extensively aspirated. The diagnosis of diffuse alveolar hemorrhage is suggested by finding blood in bronchoalveolar lavage fluid.

Treatment

GENERAL MEASURES

The platelet count should be maintained above 50,000 mm^3 in an actively bleeding patient. Immune platelet destruction may be treated with intravenous gamma globulin prior to platelet transfusion. The platelet dysfunction associated with

uremia may be treated with dialysis or by administration of cryoprecipitate and desmopressin (DDAVP). DDAVP has also recently been shown to be remarkably effective in stopping the massive hemoptysis associated with leptospirosis,[4] and may, along with cryoprecipitate, be useful in treating patients with von Willebrand disease and hemophilia A.

The prothrombin time and partial thromboplastin time should be corrected to near normal. Deficiencies are treated with vitamin K, or for a more rapid effect, with large volumes of fresh frozen plasma.

SPECIFIC INTERVENTIONS

A number of treatment modalities may be used to treat life-threatening hemoptysis. These include endobronchial ablation of specific lesions, bronchial arterial embolization, external beam irradiation, and surgical resection.

Endobronchial ablation is generally reserved for tumors affecting the larger airways as a form of palliative therapy for patients with unresectable disease. External beam irradiation has been used successfully in a few patients with massive hemoptysis resulting from mycetomas[5] and can also be used for patients with unresectable neoplasms if the rate of bleeding is sufficiently slow that the course of treatment can be completed.

Bronchial arterial embolization is the treatment of choice for most patients with life-threatening hemoptysis resulting from a localized parenchymal lesion. Recent studies indicate that the hemoptysis is controlled in as many as 85% of patients up to 1 month following the procedure, although recurrence is seen in approximately 15% of patients within the first 30 days.[6]

SURGICAL VERSUS MEDICAL MANAGEMENT

When hemoptysis occurs in the setting of diffuse disease (e.g., cystic fibrosis, extensive pulmonary tuberculosis, or other forms of bronchiectasis), surgery is precluded. For patients with localized disease the decision about when to operate continues to be based on clinical judgement and individual patient assessment, as there are no randomized trials comparing the outcomes achieved with surgery versus repeated embolization. The major indications for surgery are: **1.** recurrence of bleeding after bronchial arterial embolization, **2.** inability to perform the embolization because of anatomic problems, and **3.** multiple bleeding vessels seen on angiography.[7] Accordingly, with the possible exception of endobronchial carcinomas that require ablation, bronchial arterial embolization should generally be the initial treatment of choice for patients with localized disease who can be sufficiently stabilized to attempt the procedure.

DIFFUSE ALVEOLAR HEMORRHAGE

Diffuse alveolar hemorrhage (DAH) occurs in conjunction with, and may be the initial manifestation of, numerous diseases, conditions, and effects of medications (see Table 41-1). Up to one-third of patients with DAH will *not* have hemoptysis, but many will have other systemic manifestations of a systemic disease (e.g., rash, myalgias, arthralgias, or conjunctivitis). Chest x-rays generally show diffuse infiltrates, but localized disease may also be seen. DAH occurs in up to 10% of patients with Wegener granulomatosis, and up to 33% of patients with microscopic polyangiitis (all of whom will have evidence of glomerulonephritis). DAH is also seen in approximately 5% of patients with systemic lupus erythematosus, and rarely in conjunction with polymyositis, rheumatoid arthritis, and mixed connective tissue disease. Most patients with Goodpasture syndrome (which is caused by an antibody to the type 4 collagen found in the basement membranes of alveolar walls and glomeruli) present with DAH and glomerulonephritis, but up to 10% may have only DAH.

DIAGNOSIS

Establishing a diagnosis of DAH is not difficult when patients present with hemoptysis, diffuse pulmonary infiltrates, a falling hematocrit, and other manifestations of systemic disease. However, in those without hemoptysis or diffuse infiltrates the diagnosis becomes much more difficult. Bronchoalveolar lavage showing progressively more blood with serial aspirations may be considered diagnostic, but DAH must be suspected before this procedure is considered. When DAH is diagnosed, a kidney biopsy or an open or thoracoscopic lung biopsy is frequently recommended to allow differentiation among the various types of vasculitis, and to definitively either diagnose or exclude Goodpasture syndrome, as patients with vasculitis are treated with high doses of systemic corticosteroids and with cyclophosphamide, whereas those with Goodpasture should receive plasmapheresis.

Unfortunately, despite treatment, over half of patients with DAH resulting from a systemic vasculitis or a collagen vascular disease require mechanical ventilation, and the mortality ranges from 25% in patients with Wegener granulomatosis to 50% in patients with lupus. The 5-year survival rate for these conditions is also reduced.

Chapter 42

RESTRICTIVE DISEASE OF THE RESPIRATORY SYSTEM AND THE ABDOMINAL COMPARTMENT SYNDROME

THOMAS CORBRIDGE
LAWRENCE D.H. WOOD

KEY POINTS

- *Scoliotic curves greater than 100 ° may cause dyspnea; curves greater than 120° are associated with alveolar hypoventilation and cor pulmonale.*
- *Most patients with chest wall deformity survive their first episode of acute respiratory failure. Common precipitants include upper and lower respiratory tract infections and congestive heart failure.*
- *Biphasic positive airway pressure may be effective in patients with acute hypercapnic respiratory failure.*
- *Low tidal volumes and high respiratory rates likely minimize the risk of barotrauma during mechanical ventilation; however, gradual institution of anti-atelectasis measures may improve gas exchange and static compliance.*
- *Nocturnal hypoxemia is common and may contribute to cardiovascular deterioration; routine polysomnography is recommended.*
- *Strategies for management of patients with chronic ventilatory failure include daytime intermittent positive pressure ventilation, nocturnal noninvasive ventilation, and ventilation through tracheostomy.*
- *Abdominal compartment syndrome (ACS) is caused by an acute increase in intra-abdominal pressure resulting from a number of surgical and medical conditions.*
- *By elevating the diaphragm and decreasing respiratory system compliance, ACS causes a restrictive defect. However, ACS affects a number of other organs and may cause multiorgan system failure.*
- *Diagnosis relies on measurement of intra-abdominal bladder pressure and identification of organ dysfunction.*
- *The abdomen should be decompressed before critical organ dysfunction develops.*
- *Failure to recognize and treat ACS portends a poor prognosis.*
- *Acute deterioration in respiratory status can occur from disease progression or a number of other infectious and noninfectious processes.*
- *Patients with idiopathic pulmonary fibrosis admitted to the ICU with acute respiratory failure have an extremely poor prognosis.*
- *If mechanical ventilation is deemed appropriate, the use of low tidal volumes and high respiratory rates during mechanical ventilation likely minimizes ventilator-induced lung injury.*
- *Idiopathic pulmonary fibrosis is typically refractory to drug treatment.*
- *Lung transplantation is a viable option in selected patients with end-stage fibrosis.*

Thoracic cage deformity and pulmonary fibrosis both result in a restrictive limitation to breathing. Although relatively rare in the context of pulmonary intensive care, these disorders present unique challenges that complicate ICU management. More commonly a tense and distended abdomen decreases thoracic volume and respiratory system compliance. In this chapter, we describe the pathophysiologic derangements in cardiopulmonary function associated with these disorders and how they affect management during acute illness. A primary goal of this chapter is to offer a strategy for cardiovascular management and mechanical ventilation that minimizes the risk of ventilator-induced complications and maximizes the chance for early, successful extubation.

Patients with Thoracic Cage Deformity

Although a number of disorders can deform and restrict the movement of the respiratory system (Table 42-1), kyphoscoliosis (KS) is the prototypical cause of severe thoracic deformity. Kyphoscoliosis is the combination of kyphosis (posterior deformity of the spine) and scoliosis (lateral deformity of the spine). It is far more common than isolated cases of kyphosis or scoliosis, placing as many as 200,000 people in the United States at risk of developing respiratory failure.[1] Most cases are idiopathic and begin in childhood. Other cases result from congenital defects, poliomyelitis, thoracoplasty, syringomyelia, vertebral and spinal cord tumors, and tuberculosis.

The pathophysiologic consequences of KS correlate with the degree of spinal curvature, but there is considerable variability.[1,2] Patients with severe deformity can lead long and relatively symptom-free lives,[3] while patients with lesser degrees of curvature may develop ventilatory failure and cor pulmonale at a relatively young age. The reason for this variability is not clear, although sleep-disordered breathing appears to contribute to clinical deterioration in some cases.[4,5]

The combination of a moderate kyphotic deformity and a moderate scoliotic deformity is functionally equivalent to a severe deformity of either alone.[2] Of the two, however, scoliosis produces greater physiologic derangements. In KS, scoliotic curves less than 70° (Fig. 42-1) rarely cause problems, while angles greater than 70° increase the risk of respiratory failure.[1] The earlier in life this angle is achieved, the greater the risk of eventually developing respiratory failure because curvature increases by an average of 15° over 20 years from an initial angle of 70°.[6,7] Angles greater than 100° can cause dyspnea. Angles ≥120° can result in alveolar hypoventilation and cor pulmonale.[1]

In order to decrease respiratory effort, patients with severe deformity take rapid and shallow breaths. Examination of the chest reveals decreased excursion and crackles or coarse wheezes from atelectasis or failure to clear secretions. Cardiac examination may demonstrate a loud P_2, right ventricular

heave, or jugular venous distention, indicating the presence of pulmonary hypertension.[2]

RESPIRATORY MECHANICS

Kyphoscoliosis reduces total lung capacity (TLC) and functional residual capacity (FRC) (Fig. 42-2). Residual volume (RV) may be normal or decreased to a lesser extent than FRC. Vital capacity (VC), inspiratory capacity (IC = TLC − FRC), and expiratory reserve volume (ERV = FRC − RV) are all decreased. Interestingly, in adolescents pulmonary function is only weakly related to the angle of scoliosis. In these patients, VC is also influenced by the degree of thoracic kyphosis, location of the curve, and number of vertebral bodies involved.[8] Furthermore, spinal column rotation, respiratory muscle strength, and duration of the curve are not clearly related to pulmonary function in these patients.[8] Decreasing chest wall compliance with age increases the risk of developing ventilatory failure.[9]

FIGURE 42-1 Determination of the scoliotic angle by the Cobb method. The scoliotic deformity consists of a primary initiating curve and a secondary compensatory curve. The scoliotic angle is commonly determined by the intersection of lines estimating the position of the upper and lower components of the primary curve. ***(Reprinted with permission from Grippi et al.[13])***

Patients with fibrothorax or thoracoplasty have similar abnormalities.[1] By contrast, obesity mainly reduces FRC and ERV without much change in RV, VC, or TLC. In patients with ankylosing spondylitis, ERV and IC excursions are restricted around a normal FRC, such that RV increases and TLC decreases to reduce VC, a pattern similar to that seen in neuromuscular diseases of the chest wall.

In each of these disorders, it is the chest wall that limits the excursion of the respiratory system; the lungs and respiratory muscles are affected secondarily and to a lesser degree. In health, TLC is largely determined by the pressure-volume (P-V) curve of the lung, but in KS the P-V curve of the noncompliant chest wall dominates, lowering TLC and FRC while RV is relatively spared (Fig. 42-3). Note that the P-V curve of the respiratory system is shifted downward and to the right, requiring patients to generate large efforts to take in little air. Normal lung compliance and respiratory muscle strength are assumed in Fig. 42-3, although reductions in both contribute to low lung volumes in selected patients. Indeed in four patients with severe KS requiring mechanical ventilation for acute respiratory failure, both lung and chest wall compliance was decreased.[10] Decreased lung compliance may occur as a result of infection, edema, atelectasis, or abnormalities in alveolar surface tension and may respond to intermittent positive-pressure ventilation (see below).[11]

Inspiratory muscle dysfunction occurs when the deformed thorax places inspiratory muscles at a mechanical disadvantage or there is respiratory muscle fatigue.[12] When KS is a manifestation of neuromuscular disease (e.g., postpolio syndrome), inspiratory muscles may be affected directly by the neuromuscular disease.

GAS EXCHANGE

Significant daytime hypoxemia rarely occurs until the development of daytime hypercapnia.[1] However, nocturnal hypercapnia with hypoxemia occurs early, particularly during rapid eye movement (REM) sleep, and may underlie cardiovascular deterioration in some patients.[4,5]

The alveolar-arterial gradient [$(A\text{-}a)_{O_2}$] is usually ≤25 mm Hg, even in late stages of KS.[1] This modest increase in $(A\text{-}a)_{O_2}$ results primarily from ventilation-perfusion ($\dot{V}/\dot{Q}$) inequality caused by atelectasis or underventilation of one hemithorax. $\dot{V}/\dot{Q}$ inequality further contributes to a low diffusing capacity, as does the failure of the vascular bed to grow normally in a distorted chest.

Alveolar hypoventilation results in part from an increase in the dead space to tidal volume ratio (V_D/V_T). This ratio is increased because V_T is reduced in hypercapnic patients, whereas anatomic and alveolar dead space are usually normal.[1] Minute ventilation is often normal but maintained by higher respiratory rates. The use of small V_T minimizes the work of breathing and is a sign of inspiratory muscle dysfunction.[12,13] As inspiratory muscle strength falls, the partial pressure of arterial carbon dioxide (Pa_{CO_2}) rises and further affects diaphragm function.[11,14]

Ventilatory response to high concentrations of inspired CO_2 is normal in normocapnic patients with KS. However, in hypercapnic patients, the response is blunted by buffering of

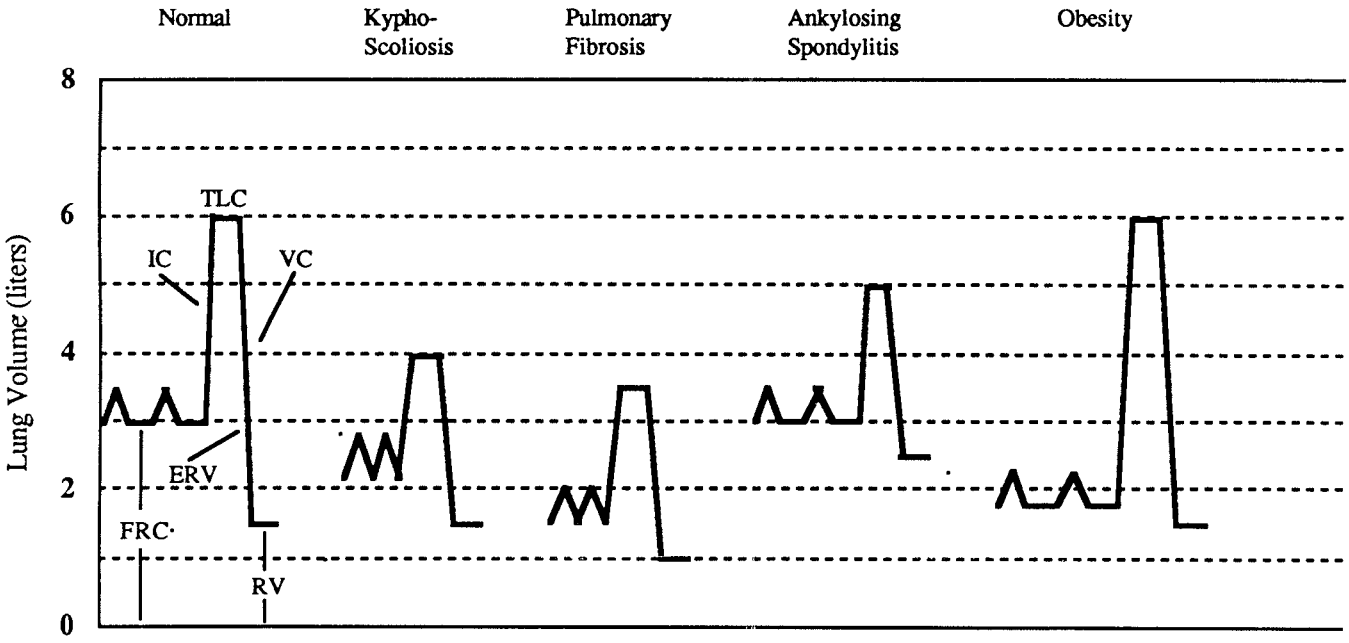

FIGURE 42-2 Schematic drawing of the abnormalities of lung volumes in common restrictive diseases. By contrast with normal subdivisions (*left trace*) of plethysmographic gas volumes (TLC, FRC, and RV) and spirometric volumes (IC, VC, and ERV), kyphoscoliosis and pulmonary fibrosis reduce VC and TLC by restricting IC, with lesser reductions in FRC (*traces 2 and 3*). Ankylosing spondylitis (like neuromuscular diseases of the chest wall) limits IC and ERV excursions around a normal FRC, so TLC is reduced and RV is increased, causing a large decrease in VC (*panel 4*). Obesity greatly reduces FRC to eliminate ERV without much change in TLC or RV, so VC is normal and IC is increased (*panel 5*).

the signal by elevated cerebrospinal fluid bicarbonate, or by a derangement in the central drive to breathe.[13]

EFFECTS ON THE PULMONARY CIRCULATION

A further consequence of severe KS is pulmonary hypertension and cor pulmonale. Left untreated, patients with cor pulmonale typically die within 1 year.[2] Initially, pulmonary hypertension occurs only with exercise, but over time it occurs at rest as well. Pulmonary hypertension is usually caused by increased pulmonary vascular resistance (PVR) and not elevated left atrial pressure.[1] Thus there is an increased gradient between the pulmonary artery diastolic pressure and the pulmonary capillary wedge pressure. Identifying and treating reversible conditions such as pulmonary embolism, hypoxemia, and sleep-disordered breathing lowers pulmonary artery pressure and delays the onset of right ventricular failure.[15–17] However, there also may be irreversible changes associated with proliferation of the media in smaller, precapillary pulmonary vessels.[2] The mechanism by which this occurs is not known, but blood flow through vessels narrowed by low lung volumes, blood flow through fewer vessels, and the

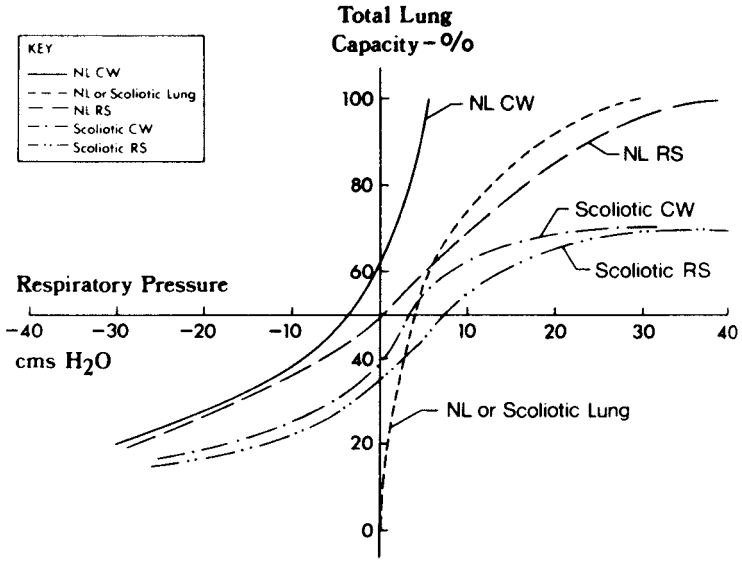

FIGURE 42-3 Pressure-volume curves of the chest wall, lung, and respiratory system in scoliosis. The P-V curve is shifted downward and to the right, requiring patients to generate large transpulmonary pressures for small amounts of air. CW = chest wall; NL = normal lung; RS = respiratory system. *(Reprinted with permission from Bergofsky.[1])*

vascular effects of chronic hypoxia and hypercapnia are likely important. Kinking of larger vessels as they travel through deformed lung may further increase pulmonary artery pressures in some cases.[1]

Acute Cardiopulmonary Failure

OUTCOME

In 20 patients with mean deformity of 113° in acute respiratory failure (ARF) for the first time, admission blood gases showed severe arterial hypoxemia (partial pressure of arterial oxygen [Pa_{O_2}] of 35 ± 7 mm Hg), acute-on-chronic hypercapnia (Pa_{CO_2} of 63 ± 9 mm Hg), and mild arterial acidemia (pH of 7.34 ± 0.08).[18] Cor pulmonale was present in 60% of patients. Seven (35%) patients required intubation and mechanical ventilation, while the remaining patients were managed successfully without mechanical ventilation in an age when noninvasive positive-pressure ventilation (NPPV) was not routinely available. There were no statistical differences in admission blood gases, cause of respiratory failure, age, or degree of spinal curvature between patients who required mechanical ventilation and those who did not. Outcome was surprisingly good. All patients survived their initial episode of ARF and subsequently experienced 2.4 episodes of ARF each during the follow-up period (median of 6 years). Median survival after the first episode of ARF was 9 years. On discharge, mean Pa_{O_2} was 63 mm Hg and mean Pa_{CO_2} was 55 mm Hg. This study demonstrates the utility of aggressive treatment of ARF, even in cases of severe deformity.

ETIOLOGY

ARF is usually precipitated by pneumonia, upper respiratory tract infection, or congestive heart failure.[18] Triggers are often minor and may remain obscure, but even trivial insults can precipitate ARF when respiratory muscle reserve is decreased and work of breathing is increased. Because chest wall deformity theoretically affects the swallowing mechanism, aspiration should be considered in the differential diagnosis of ARF. Risk factors for clotting (pulmonary hypertension and decreased mobility) mandate consideration of pulmonary embolism, particularly when the cause of deterioration is obscure. Finally, identifying and treating airflow obstruction can help restore the delicate balance between strength and respiratory system load. Limited data suggest that airway resistance is increased in mechanically ventilated patients with KS (~20 cm H_2O/L per second) and refractory to bronchodilators.[10] Bronchoscopic examination of patients with bronchodilator-unresponsive increases in airway resistance may reveal torsion and narrowing of central airways.[19]

OXYGEN THERAPY

A primary goal is to correct hypoxemia. This is best accomplished by increasing the fraction of inspired oxygen until an oxygen saturation of 90% to 92% is achieved. Adequate saturation by pulse oximetry should be confirmed by subsequent blood gas analysis, which also helps establish the acid-base status. If adequate oxygenation cannot be achieved with face-mask oxygen, biphasic positive airway pressure (BIPAP) should be initiated unless there are indications for intubation (see below).

Hypoxemia, in addition to its many adverse effects, causes pulmonary vasoconstriction and may precipitate right ventricular failure in patients with pre-existing right heart disease (see Chap. 26). Its causes include alveolar hypoventilation, $\dot{V}/\dot{Q}$ inequality, and intrapulmonary shunt. Right-to-left intracardiac shunts have also been reported in the setting of thoracic deformity.[20] Low mixed venous P_{O_2} ($P\overline{v}_{O_2}$), a frequent finding in patients with pulmonary hypertension and low cardiac output, further lowers arterial oxygenation when there is $\dot{V}/\dot{Q}$ inequality.

HEMODYNAMIC MANAGEMENT

Evaluation of shock in patients with KS is similar to that described elsewhere in this text. When sepsis causes shock, patients with KS and pulmonary hypertension may not mount the usual hyperdynamic response. Hypotensive patients not responding to an initial aggressive volume challenge should be considered for right heart catheterization and/or bedside echocardiography to further direct therapy. Mechanical ventilation is indicated for nearly all patients with persistent shock, in part to redirect blood flow from the diaphragm, which can be as much as 25% of the cardiac output. Mechanical ventilation and sedation decrease oxygen consumption (and thus supplemental oxygen requirement) and lactic acid generation.

When right ventricular failure causes shock, a vicious cycle ensues. As the right ventricle fails, cardiac output and systemic blood pressure fall, limiting perfusion to the right ventricle from the aortic root. Right ventricular end-diastolic volume increases and shifts the interventricular septum to the left, decreasing left ventricular compliance, and further reducing cardiac output and blood pressure. Ensuring an adequate circulating volume and correcting hypoxemia to reduce pulmonary vasoconstriction are the first goals of therapy. Increasing systemic blood pressure and thus perfusion pressure to the right ventricle with norepinephrine may be helpful.[21]

To exclude venous thromboembolism we routinely perform lower extremity Doppler exams; however, roughly 50% of patients with acute pulmonary embolism have negative lower extremity Doppler exams. Serially negative Doppler exams provide an added sense of security, as does a negative D-dimer. Chest computed tomography (CT) with pulmonary embolism protocol is preferable to ventilation-perfusion imaging in chest wall deformity, and may provide additional clues regarding the etiology of respiratory failure. In select cases, pulmonary angiography is required to establish a firm diagnosis. In the absence of venous thromboembolism, preventive therapy with unfractionated heparin or low molecular weight heparin is indicated.

NONINVASIVE VENTILATION

Decreased pulmonary compliance lowers lung volume, which in turn limits cough efficiency and mucus clearance.[22] To improve compliance and treat atelectasis, short periods (15 to 20 minutes) of intermittent positive-pressure ventilation (IPPV) delivered by mouthpiece 4 to 6 times daily using inflation pressures between 20 and 30 cm H_2O have been recommended.[11] IPPV increases lung compliance by 70% for up to 3 hours in acutely ill patients, suggesting that IPPV lowers surface tension by altering the surfactant lining layer.[11]

Alternatively, a volume-preset, time-cycled device may be used.[23]

In patients with acute ventilatory failure, NPPV by full face mask or nasal mask should be considered first-line therapy (see Chap. 33). Advantages of NPPV over invasive ventilation include decreased need for sedation and paralysis, decreased incidence of nosocomial pneumonia, decreased incidence of otitis and sinusitis, and improved patient comfort. Disadvantages include increased risk of aspiration and skin necrosis, and less control of the patient's ventilatory status compared with invasive ventilation.[24]

Although nocturnal NPPV is firmly established in the management of KS patients with chronic respiratory failure,[25,26] there are limited data regarding its efficacy in acutely ill patients.[27–29] In one report of the use of noninvasive ventilation in 164 patients with heterogeneous forms of ARF, only five patients had restrictive lung disease.[30] All five patients improved on noninvasive ventilation, although one subsequently required intubation. Noninvasive ventilation was also helpful in four patients with KS and ARF failing conventional medical therapy.[31]

Following the guidelines of Meduri and colleagues,[30] we initiate NPPV using a loose-fitting full face mask. We start with 0 cm H_2O continuous positive airway pressure (CPAP) and 10 cm H_2O pressure support, and increase CPAP to 3 to 5 cm H_2O and pressure support to the level required to achieve an exhaled tidal volume $\geq$7 mL/kg and a respiratory rate $\leq$25/min.

Noninvasive negative pressure ventilators are not feasible in most acute situations because they generally require patients to lie flat and coordinate their breaths with the ventilator. Difficulties with fit and applying the device adequately to the distorted chest wall further complicate their use. Still, negative pressure ventilators have averted intubation in rare cases,[18] and have been used successfully in the long-term management of patients with KS.[32]

INTUBATION AND MECHANICAL VENTILATION

Intubation is indicated for cardiopulmonary arrest, impending arrest, refractory hypoxemia, mental status changes, and shock. Intubation can be difficult because of spinal curvature and tracheal distortion, and because patients with small lung volumes desaturate quickly. Assessment of the upper airway with fiberoptic bronchoscopy may be useful in some cases. During the peri-intubation period, a fraction of inspired oxygen ($F_{I_{O_2}}$) of 1.0 is desirable, although it should be decreased to nontoxic levels if possible once the patient has been stabilized on the ventilator. Decreasing O_2 consumption with sedatives, use of positive end-expiratory pressure (PEEP), and increasing $P\bar{v}_{O_2}$ are strategies that allow for nontoxic $F_{I_{O2}}$ in most patients. Positional maneuvers, such as placing the patient in the lateral decubitus position, may improve oxygenation in patients with asymmetric chest walls, but care must be taken to secure the airway.

Ventilatory failure results from an imbalance between respiratory muscle strength and respiratory system load. Thus identifying and correcting reversible elements of this imbalance is fundamental to restoring the ability to breathe. While this occurs, patients should be ventilated to baseline values of Pa_{CO_2} to avoid alkalemia and bicarbonate wasting.

Respiratory muscle fatigue is treated with 48 to 72 hours of complete rest on the ventilator, with early nutritional supplementation and correction of metabolic irregularities. To rest, patients must be comfortable, quiet, and synchronized with the ventilator. If the patient is not synchronized, work of breathing remains high despite ventilator settings that appear to supply most of the minute ventilation.

In patients with bronchospasm and an increase in the peak-to-plateau gradient, we add inhaled bronchodilators and consider systemic steroids. With attention to delivery technique, bronchodilator responsiveness is assessed by measuring airway resistance 15 to 30 minutes after a treatment. Bronchoscopy may be indicated in nonresponders to exclude bronchial torsion that may benefit from placement of an endobronchial stent.[19] Theophylline titrated to a serum level of 10 μg/mL may increase respiratory muscle strength, help clear secretions, and decrease airway resistance without significant toxicity.

Although there are no controlled trials to help guide ventilator management in patients with thoracic deformity, we suggest small tidal volumes (6 to 7 mL/kg) and high respiratory rates (20 to 30/min) to minimize the hemodynamic effects of positive-pressure ventilation and the risk of barotrauma. We maintain plateau pressures <30 cm H_2O to avoid overdistention beyond physiologic TLC and hyperinflation-induced lung injury (pneumothorax, pneumomediastinum, interstitial emphysema, and volutrauma). One consequence of small tidal volume ventilation is reduced alveolar ventilation and hypercapnia. Fortunately, hypercapnia is generally well tolerated as long as Pa_{CO_2} does not exceed 90 mm Hg and acute increases in Pa_{CO_2} are avoided. Associated low values of arterial pH are generally well tolerated. Hypercapnia does cause cerebral vasodilation, cerebral edema, decreased myocardial contractility, vasodilation with a hyperdynamic circulation, and pulmonary vasoconstriction. Accordingly, it should be avoided in patients with raised intracranial pressure (as might occur in the setting of anoxic brain injury after arrest) and severely depressed myocardial function. The use of small tidal volumes demands added attention to lung volume recruitment and prevention of atelectasis. To this end, we initially apply 5 cm H_2O of PEEP to prevent alveolar closure at end-expiration, and gradually increase tidal volume when atelectasis is suspected, keeping plateau pressure <30 cm H_2O.

In refractory hypoxemia a trial of increasing PEEP (in an attempt to achieve 90% saturation of the arterial blood with a $F_{I_{O_2}} \leq 0.6$) helps clarify the pathophysiology. To avoid overdistention at end-inspiration, tidal volume should be decreased during PEEP titration. Since the chest wall is stiff in KS, high alveolar pressures increase pleural pressure more than in diseases characterized by stiff lungs, thereby further decreasing venous return to the right atrium and reducing cardiac output. PEEP may also increase pulmonary vascular resistance and worsen right-to-left intracardiac shunt.

The approach to liberation from mechanical ventilation is similar to that described elsewhere in this text. We favor early determination of respiratory muscle strength as assessed by the maximum negative inspiratory force (NIF), and of respiratory system load as determined by the resistive and static pressures generated during positive pressure ventilation. Inadequate strength for a given load manifests as a rapid shallow breathing pattern, which generates a high frequency:tidal

volume ratio. A slower and deeper pattern is achieved when strength increases and/or load decreases. Respiratory muscle strength is improved by correction of shock, anemia, acidosis, electrolyte abnormalities, and with the institution of nutrition, and a nonfatiguing graded program of respiratory muscle exercise. Treating pulmonary edema, atelectasis, pneumonia, and airflow obstruction decreases load. When time of extubation is near, ventilation with tidal volumes that mimic the patient's spontaneous tidal volume allows for a smoother transition to spontaneous breathing. In borderline cases, NPPV can be used to facilitate return to spontaneous breathing and reduce ICU length of stay.[33] Tracheostomy may be required in more difficult cases and may be technically difficult in patients with cervical spine curvature and a distorted airway.

LONG-TERM MANAGEMENT

Primary considerations for long-term management include the use of home oxygen therapy and nocturnal NPPV. Patients with moderate to severe KS may demonstrate significant oxygen desaturation on exercise that is prevented by ambulatory oxygen therapy.[34] Derangements in breathing pattern and oxygen desaturation during sleep should be excluded with polysomnography once the patient is stable. A broad spectrum of abnormalities, including central and obstructive sleep apnea, has been identified that may contribute to chronic hypoxemia, cor pulmonale, and early death. Chronic ventilatory failure is an indication for noninvasive nocturnal ventilatory support, which can improve daytime blood gases, sleep pattern, and respiratory muscle strength.[35] Other useful strategies include daytime IPPV (25 cm H_2O for several minutes, 4 to 6 times daily), negative-pressure ventilation, and nighttime mechanical ventilation through a tracheostomy. The role of orthopedic surgery in adolescents is debated and beyond the scope of this chapter.

We recommend serial assessments of right ventricular function and pulmonary artery pressure by echocardiography. The presence of pulmonary hypertension gives added importance to oxygen therapy and mandates exclusion of other treatable causes such as pulmonary embolism.

Abdominal Compartment Syndrome

DEFINITION AND ETIOLOGY

Abdominal compartment syndrome (ACS) is characterized by critical organ dysfunction within and beyond the abdomen resulting from increased intra-abdominal pressure.[36–38] Importantly, the critical value for intra-abdominal hypertension that defines ACS varies from patient to patient, and is dependent on abdominal wall compliance and tissue perfusion pressure.[39] Studies have suggested that an intra-abdominal pressure >25 mm Hg is associated with the development of ACS; other reports have demonstrated that pressures as low as 10 mm Hg can lead to organ dysfunction in select cases.[40,41] Conditions that increase abdominal wall compliance (e.g., prior pregnancy, obesity, and cirrhosis) appear to be protective, while inflexible surgical closures or scars increase risk.[42,43] Given these considerations, the use of a strict cutoff value for intra-abdominal hypertension to define ACS is not recommended. Rather a combination of elevated intra-abdominal pressure and the presence of organ dysfunction is required for proper diagnosis (see below).

TABLE 42-2 Selected Conditions Associated with Abdominal Compartment Syndrome

Abdominal trauma
Burns
Liver transplantation
Pancreatitis
Bowel obstruction
Peritonitis
Intraperitoneal hemorrhage
Tense ascites

A number of surgical and nonsurgical conditions have been associated with intra-abdominal hypertension. Particularly at risk is the trauma patient requiring large-volume resuscitation and emergent abdominal surgery. Use of temporary closure techniques as an alternative to tight surgical closure increases abdominal wall compliance and minimizes intra-abdominal pressure in patients at risk.[44] Other conditions associated with ACS are included in Table 42-2.

CARDIOPULMONARY EFFECTS

Cephalad displacement of the diaphragm results in mechanical compression, atelectasis, $\dot{V}/\dot{Q}$ inequality, decreased respiratory system compliance, and increased work of breathing.[45] These effects are associated with a fast and shallow respiratory pattern, hypoxemia, and hypercapnia. In mechanically ventilated patients peak and plateau pressures are elevated, leading to a common recommendation to lower tidal volume until plateau pressure is <30 cm H_2O.

Elevation of the diaphragm also reduces ventricular compliance and contractility; by reducing inferior vena caval blood flow, ACS decreases cardiac preload to further drop cardiac output.[46] Hypovolemia further aggravates this physiology, whereas hypervolemia is protective as intra-abdominal pressure increases.[47,48] Despite decreased venous return, pulmonary capillary wedge pressure does not always fall; however, intravascular pressure in this setting does not adequately reflect transmural pressure or intravascular volume.

GASTROINTESTINAL, RENAL, AND CENTRAL NERVOUS SYSTEM EFFECTS

Intra-abdominal hypertension decreases mesenteric arterial flow, an effect that is amplified by decreased cardiac output, hemorrhage, and hypovolemia.[49] Direct compression of mesenteric veins increases venous pressure, promoting visceral edema and further increases in intra-abdominal pressure that decrease gut perfusion.[50] The final event is bowel wall ischemia and translocation of bacteria through a disrupted mucosal barrier that may be central to multiorgan system failure.[51]

Increased venous resistance is also central to the rise in renal venous pressure and renal failure in ACS.[52] As intra-abdominal pressure increases, urine output falls with oliguria potentially developing at an intra-abdominal pressure of 15 mm Hg and anuria at 30 mm Hg.[53]

There is an association between abdominal compartment syndrome and raised intracranial pressure, likely mediated

by the effects of intra-abdominal pressure on central venous pressure.[54] A critical situation occurs when systemic hypotension and increased intracranial pressure combine to decrease cerebral perfusion pressure.

DIAGNOSIS

The diagnosis of ACS should be considered in any patient with a tense or distended abdomen who also has hemodynamic instability, a falling urine output, mental status changes, or progressive lactic acidosis. Failure to recognize that intra-abdominal hypertension can occur in the absence of abdominal distension or that multiorgan failure is a manifestation of ACS can lead to a missed diagnosis. The importance of early detection is emphasized because mortality rates in established ACS are generally >50%.[55]

Although there are clues to ACS on abdominal CT imaging, definitive diagnosis requires measurement of intra-abdominal pressure.[56] The usual approach is to use intra-abdominal bladder pressure (IABP) as a surrogate measure of intra-abdominal pressure, based on extensive data that indicate that the two are strongly correlated.[57] The technique relies on measurements taken directly from a Foley catheter with a pressure-transducer zeroed to the level of the pubic symphysis.[57] Accurate measurements rely on ready transmission of intra-abdominal pressure to the bladder, and the bladder not adding its own effects to pressure measurements. Thus there is potential for inaccuracy when the bladder is diseased or when there is critical pathology in the vicinity of the bladder. In general, ACS is not likely when IABP is <10 mm Hg, but should be considered when the pressure is >25 mm Hg. As mentioned, however, strict cutoff values for IABP are neither sensitive nor specific enough to establish ACS, requiring concurrent assessment of organ dysfunction at any level of intra-abdominal pressure.[55]

TREATMENT

Abdominal compartment syndrome resulting from tense ascites is an indication for immediate paracentesis. Pre- and postparacentesis measurements of IABP, urine output, hemodynamics, and airway pressures help confirm ACS and demonstrate the benefit of therapeutic intervention. In most other cases of ACS, prompt surgical decompression is indicated. Determining the appropriate timing for surgical intervention is challenging and may require serial measurement of IABP and assessment of organ function. It is vital to intervene before the development of critical organ dysfunction. To aid in the determination of timing of surgery, some surgeons assess abdominal perfusion pressure (APP = MAP − IABP). An APP <50 mm Hg is associated with a poor outcome and the need for quick intervention.[58] While the operating room is prepared, volume resuscitation and low tidal volume ventilation are useful temporizing measures.

Pulmonary Fibrosis

When normal air spaces and blood vessels are replaced by fibrotic tissue, the lungs become small and stiff. In some disease processes there may be adjacent areas of inflammation amenable to immunosuppressive therapy. However, it is generally well accepted that fibrosis without inflammation is unresponsive to current pharmacologic treatment.

A number of acute and chronic disorders of known and unknown etiology are associated with pulmonary fibrosis. These include idiopathic pulmonary fibrosis (IPF), which is highlighted in this chapter.

As the name implies, IPF is a disease of unknown etiology, characterized by the histologic appearance of usual interstitial pneumonia.[59,60] It most often presents insidiously in patients >50 years old and is progressive regardless of therapy. The hallmarks of IPF are dyspnea and cough. Initially dyspnea occurs only with exercise, but even limited dyspnea can bring about a sedentary lifestyle that further adds to functional disability. As dyspnea progresses, patients develop a rapid and shallow breathing pattern, often maintaining higher-than-normal levels of minute ventilation.[61] Constitutional symptoms include fatigue, malaise, and weight loss; symptoms of sleep-disordered breathing may occur.

Auscultation of the chest frequently reveals dry, "velcro-like" crackles heard loudest at the bases of the lungs; in the late stages of the disease, cardiac examination may reveal signs of pulmonary hypertension. Clubbing of the fingers and toes commonly occurs in IPF (and asbestosis) and rarely in other interstitial lung diseases.

LABORATORY ABNORMALITIES

Hypoxemia that worsens with exercise or sleep and respiratory alkalosis are common in IPF. The development of hypercapnia is an ominous sign of imminent death. Despite hypoxemia, polycythemia is rare.[62] Elevations of sedimentation rate, serum immunoglobulins, antinuclear antibodies, and rheumatoid factor can occur; an increase in angiotensin-converting enzyme or antineutrophil cytoplasmic antibodies suggests a different diagnosis.[59]

The radiographic distribution of infiltrates often suggests the underlying disorder. Peripheral reticular opacities most prominent at the bases and low lung volumes are classic in IPF. Traction bronchiectasis occurs when fibrotic lung tissue tethers open adjacent airways. Ground-glass opacifications are either absent or minimal.[59] Subpleural honeycombing at bases of both lungs is characteristic of IPF.[59]

Other causes of lower lobe–predominant infiltrates include fibrosis associated with connective tissue disorders, asbestosis, and chronic aspiration. Upper lobe–predominant lesions include sarcoidosis, tuberculosis, fungal infections, silicosis, allergic bronchopulmonary aspergillosis, eosinophilic granuloma, ankylosing spondylitis, berylliosis, cystic fibrosis, and hypersensitivity pneumonitis. If hilar adenopathy is present, sarcoidosis, tuberculosis, histoplasmosis, malignancy, and berylliosis should be considered. Pleural effusion suggests lymphangioleiomyomatosis, connective tissue disorder, asbestosis, or drug-induced lung disease. Extensive parenchymal cysts occur in eosinophilic granuloma or lymphangioleiomyomatosis. These conditions can result in diffuse infiltrates with normal or increased lung volumes, as can a mixed process of emphysema and IPF.

RESPIRATORY MECHANICS

In end-stage pulmonary fibrosis, pulmonary function tests typically show reduced TLC, VC, and IC (see Fig. 42-2). FRC and RV are also reduced, though usually to a lesser extent

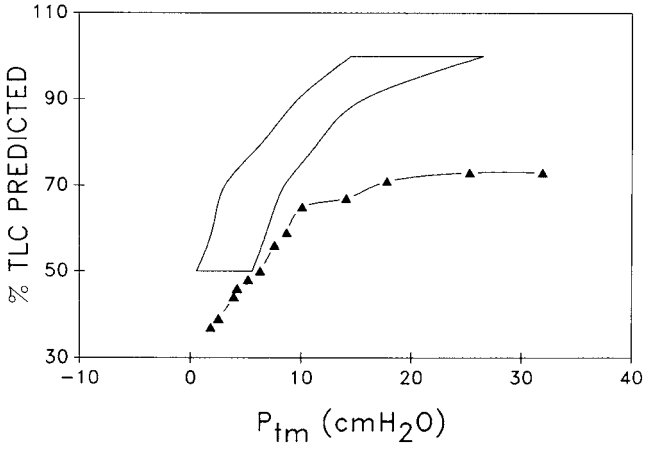

FIGURE 42-4 Pressure-volume curve of the lung in a 48-year-old man with sarcoidosis. The P-V curve is shifted downward and to the right of the normal range, such that increased elastic recoil of the lung limits TLC despite a large maximum transpulmonary pressure. This requires patients to generate prohibitively large negative pleural pressures to inspire minimal amounts of air.

than TLC or VC. Rarely, RV is normal when there is early airway closure or decreased elastic recoil pressure at low lung volumes.[63] Both the forced vital capacity (FVC) and the forced expiratory volume in 1 second (FEV_1) are decreased, but FEV_1/FVC is increased; in this instance, high expiratory flow rates relative to volume reflect increased elastic recoil pressure. Airway resistance is usually normal or low, although reversible and irreversible obstructive defects do occur.

Since chest wall compliance and respiratory muscles are normal in most patients with pulmonary fibrosis,[64] lung volumes are affected by changes in the pressure-volume relationship of the noncompliant lung (Fig. 42-4).[64] The P-V curve is shifted downward and to the right, such that increased elastic recoil of the lung limits TLC despite a very large transpulmonary pressure. This requires patients to generate large negative pleural pressures during inspiration, and is the reason why patients prefer a fast and shallow respiratory pattern. Smaller tidal volumes are an adaptive response to minimize work of breathing, which can be five to six times normal.[65]

GAS EXCHANGE

Exercise-induced hypoxemia and a low single-breath diffusing capacity (DLCO) are hallmarks of early disease. Indeed they may occur before dyspnea or radiographic changes.[63] With time, arterial hypoxemia and a widened $(A\text{-}a)_{O_2}$ are found at rest. In 20% of patients, arterial hypoxemia is worse when they are in the upright position and is improved on recumbency.[62] This paradoxical pattern is also seen with patent foramen ovale, intrapulmonary arteriovenous malformation, and hepatopulmonary syndrome. Arterial saturation also falls significantly in many patients during REM sleep.[66] Sleep-related desaturation is due to the exaggerated effects of normal nocturnal hypoventilation and $\dot{V}/\dot{Q}$ variance, or to abnormal alveolar hypoventilation from respiratory muscle dysfunction or obstructive sleep apnea.

The importance of an anatomic barrier to the diffusion of oxygen (secondary to a thickened, fibrotic interstitium) has been debated. In eight patients with varying types of interstitial lung disease, multiple inert gas analysis $\dot{V}/\dot{Q}$ inequality was the principal defect; diffusion limitation contributed to none of the $(A\text{-}a)_{O_2}$ at rest and only 19% of the $(A\text{-}a)_{O_2}$ during exercise.[67] However, in 15 patients with IPF also studied by multiple inert gas elimination, 19% of the $(A\text{-}a)_{O_2}$ at rest and 40% of the $(A\text{-}a)_{O_2}$ during exercise was attributed to diffusion limitation.[68] $\dot{V}/\dot{Q}$ inequality remained the principal defect, contributing to 81% of the $(A\text{-}a)_{O_2}$ at rest, and a combination of low $P\bar{v}_{O_2}$ from an inadequate cardiac output, diffusion limitation, and high $\dot{V}/\dot{Q}$ variance accounted for the widening of the $(A\text{-}a)_{O_2}$ during exercise. Intrapulmonary shunt was small, averaging 2% of cardiac output at rest and 3% during exercise.

The dead space:tidal volume ratio (V_D/V_T) may exceed 0.4 (normal = <0.3) in end-stage fibrosis.[69] This reflects an increase in the volume of alveolar dead space and a decrease in tidal volume. When V_D/V_T is high, greater minute ventilation is required to maintain alveolar ventilation and a normal Pa_{CO_2}. Patients may surpass these heightened requirements to achieve respiratory alkalosis, perhaps in response to greater afferent stimuli from the fibrotic lung.[61] The development of hypercapnia is an ominous sign of imminent death.

EFFECTS ON THE PULMONARY CIRCULATION

Pulmonary hypertension and cor pulmonale are common in patients with end-stage pulmonary fibrosis, correlating with a DLCO <45% predicted and a VC <50% predicted.[70] Pulmonary hypertension occurs when blood vessels are altered by the fibrotic process, microthrombi, or hypoxic pulmonary vasoconstriction. Since polycythemia and high cardiac output are rare in IPF, they rarely contribute to pulmonary hypertension. Supplemental oxygen may alleviate hypoxic pulmonary vasoconstriction, but pulmonary hypertension resulting from destroyed and distorted vasculature is likely irreversible. Pulmonary hypertension has been associated with redistribution of pulmonary blood flow to the upper lobes,[62] a pattern that rarely normalizes after corticosteroids.[69] Because pulmonary vascular resistance is high, the gradient between the pulmonary artery diastolic pressure and the pulmonary capillary wedge pressure is wide.

ACUTE CARDIOPULMONARY FAILURE

Whether acute deterioration is reversible depends on the severity of pulmonary fibrosis, the extent of comorbidities, the nature and severity of the acute insult, and whether the acute insult accelerates the underlying disease process.

OUTCOME

ICU management including the use of mechanical ventilation may be appropriate for select patients with pulmonary fibrosis: (1) patients with early/mild disease, particularly in absence of a firm diagnosis, (2) patients with previously mild disease who present with an acute, seemingly reversible insult, (3) patients who have experienced adverse effects of therapy (e.g., drug-induced lung disease), (4) patients who may undergo imminent lung transplant, and (5) patients with pulmonary fibrosis associated with connective tissue disease or vasculitis with ground-glass opacifications or consolidation that may represent a treatable form of pneumonitis or alveolar hemorrhage. Appropriately excluded from this practice are patients with progressive, end-stage disease in whom

outcome is invariably poor. In these cases, a prospective discussion and decision not to initiate resuscitative efforts should precede the anticipated terminal event.

The results of several recent studies demonstrate the grim prognosis of patients with IPF admitted to the ICU for acute respiratory failure. Blivet and colleagues described the course of 15 patients admitted to the ICU with IPF and respiratory failure.[71] Twelve patients required intubation either at the time of admission or after failure of noninvasive ventilation; three patients received only noninvasive ventilation. Eleven patients died either from respiratory failure or septic shock; four patients were discharged alive from the ICU, but two died shortly thereafter. Stern and colleagues reported their experience in 23 patients with IPF requiring intubation for acute respiratory failure.[72] With the exception of one patient who received a single-lung transplant 6 hours after initiating mechanical ventilation, all patients died while receiving mechanical ventilation. Fumeaux and colleagues similarly reported 100% mortality in 14 consecutive patients with IPF admitted to the ICU for mechanical ventilation after a mean of 7.6 days.[73] Finally, in the study by Saydain and colleagues of 38 patients with IPF admitted to the ICU mainly for respiratory failure, ICU mortality was 43% and hospital mortality was 61%.[74] However, 92% of hospital survivors died a median of 2 months after discharge.

DETECTING REVERSIBLE FEATURES

Although clinical deterioration may reflect disease progression, the differential diagnosis of an acute change in status is quite broad (Table 42-3).[59] In our experience it is often difficult to distinguish disease progression from respiratory tract infection. Frequently the cause of acute respiratory failure is not identified.[72] Acute deterioration stemming from IPF progression is essentially an untreatable condition (see above).

Pneumonia in IPF generally results from community-acquired bacteria; opportunistic infection is rare despite the widespread use of immunosuppressive agents.[70] However, *Pneumocystis carinii* pneumonia should be considered in immunosuppressed patients, particularly when ground-glass infiltrates are identified on CT imaging. Mycobacterial infection should also be considered. The incidence of tuberculosis is increased in patients with chronic interstitial lung disease, particularly in those with silicosis;[75] atypical mycobacterial superinfection may also underlie clinical deterioration in some cases. When fibrosis is associated with connective tissue disease or vasculitis, an acute deterioration may represent pneumonitis, bronchiolitis obliterans-organizing pneumonia, or alveolar hemorrhage. Patients with diffuse alveolar opacifications not responsive to antibiotics or diuresis should be considered for bronchoalveolar lavage or lung biopsy in selected cases to confirm the diagnosis.

When pneumothorax causes acute deterioration, re-expansion is countered by low parenchymal compliance occasionally requiring high levels of negative pleural pressure for prolonged periods of time.

Clinical deterioration may represent acute right or left heart failure. Right ventricular ischemia or pulmonary embolism may provoke right ventricular failure. Left-sided failure is difficult to establish without echocardiography or hemodynamic measurements because bibasilar crackles are invariably present and jugular venous distention may reflect isolated right ventricular failure.

If deterioration occurs over a period of weeks to months, progressive fibrosis, bronchogenic carcinoma, steroid myopathy, drug toxicity, cor pulmonale, and left ventricular failure should be considered.

TABLE 42-3 Selected Causes of Deterioration in Patients with Pulmonary Fibrosis

Bronchogenic carcinoma

OXYGEN THERAPY

Identification and correction of arterial hypoxemia are vital to the initial evaluation. We recommend titration of supplemental oxygen until 90% saturation is achieved. It is not unusual for patients with fibrosis to require higher flow rates than patients with chronic obstructive pulmonary disease or asthma. Hypoxemia, in addition to its many other adverse effects, causes hypoxic pulmonary vasoconstriction and may precipitate right ventricular failure in patients with pre-existing pulmonary hypertension.

CARDIOVASCULAR MANAGEMENT

Evaluation of shock in patients with pulmonary fibrosis is similar to that described elsewhere in this text (see Chaps. 20 and 21). Hypotension with cool and clammy extremities and a narrow pulse pressure suggests an inadequate cardiac output from hypovolemia, left ventricular failure, cor pulmonale, pericardial effusion, or valvular heart disease. Hypotension with a warm and bounding circulation and a wide pulse pressure suggests sepsis; however, patients with pulmonary hypertension may be unable to mount a hyperdynamic response to peripheral vasodilation. Adrenal insufficiency contributing to shock should be excluded, particularly when corticosteroids have been used for therapy.

VENTILATOR MANAGEMENT

When deemed appropriate, intubation is indicated for cardiopulmonary arrest, refractory hypoxemia, progressive ventilatory failure, mental status changes, and shock. Once the decision to intubate has been made, the goals are to achieve adequate arterial oxygen saturation and avoid ventilator-induced lung injury. Although there are no controlled trials to guide specific recommendations, we advocate an approach to mechanical ventilation that is similar to that recommended in the acute respiratory distress syndrome.[76] To avoid excessive tidal volume excursions and alveolar overinflation, we use tidal volumes in the range of 6 to 7 mL/kg combined with respiratory rates of 20 to 30 breaths/min when ventilating patients with pulmonary fibrosis. The goal is to maintain airway plateau pressures below 30 cm H_2O in an attempt to avoid overdistention beyond physiologic TLC and

hyperinflation-induced lung injury. A consequence of small tidal volume ventilation is reduced alveolar ventilation and hypercapnia. Hypercapnia can be reduced for a given minute ventilation by decreasing CO_2 production (i.e., treating fever and agitation and avoiding excessive caloric intake), repleting intravascular volume, and avoiding excessive PEEP to decrease V_D/V_T. Still, in order to achieve desired airway pressures, hypercapnia is unavoidable in many cases. In patients with chronic ventilatory failure, we further desire a minute ventilation that maintains Pa_{CO_2} greater than or equal to baseline to avoid alkalemia and bicarbonate wasting.

The use of PEEP avoids tidal collapse of alveoli at low lung volumes and may help recruit fluid-filled and atelectatic lung units. We generally start with 5 cm H_2O PEEP and increase in an attempt to achieve 90% saturation of the arterial blood with a $F_{I_{O_2}}$ of 0.6 or less. Though $F_{I_{O_2}}$ of 1.0 is desirable in the peri-intubation period, it should be decreased as quickly as possible (to no greater than 0.6) to avoid oxygen toxicity. The use of sedatives and muscle relaxants to decrease oxygen consumption, PEEP, and increasing $P\bar{v}_{O_2}$ allows for nontoxic $F_{I_{O_2}}$ in many cases.

High alveolar pressures compress alveolar vessels, diverting blood flow from ventilated units and increasing dead space. Increasing V_D/V_T from 0.4 to 0.6 requires an increase in minute ventilation of 50% to maintain a constant Pa_{CO_2}.[77] Increasing minute ventilation, however, increases alveolar pressure and V_D/V_T further, creating a vicious cycle if minute ventilation is continually increased in a misguided attempt to lower Pa_{CO_2}. High alveolar and pleural pressures also increase right atrial pressure and thereby decrease venous return to the right atrium, cardiac output, $P\bar{v}_{O_2}$, and blood pressure. Additionally, diversion of blood flow using high alveolar pressure increases flow to nonventilated units, as in pneumonic consolidation.

LONG-TERM MANAGEMENT OF IDIOPATHIC PULMONARY FIBROSIS

Because no drug therapy has clearly been demonstrated to benefit patients with IPF, long-term management is largely supportive.[60] We suggest referral to a regional center of expertise for consideration of enrollment in a clinical trial or evaluation for lung transplantation. The poor outcomes in patients with IPF admitted to the ICU underscores the importance of advance directives.

Chapter 43

VENTILATOR-ASSOCIATED PNEUMONIA

JEAN CHASTRE
JEAN-YVES FAGON

KEY POINTS

- *The risk of nosocomial pneumonia is considerably higher in the subset of ICU patients treated with mechanical ventilation, with an incremental risk of about 1% per day of ventilation.*
- *Ventilator-associated pneumonia (VAP) is associated with mortality in excess of that caused by the underlying disease alone, particularly in case of infection due to high-risk pathogens, such as* Pseudomonas aeruginosa *and* Acinetobacter *spp. and when initial antibiotic therapy is inappropriate.*
- *The predominant organisms responsible for infection are* Staphylococcus aureus, P. aeruginosa, *and Enterobacteriaceae, but etiologic agents differ widely according to the population of hospital patients, duration of hospital stay, and prior antimicrobial therapy.*
- *Although appropriate antibiotics may improve survival in patients with VAP, use of empirical broad-spectrum antibiotics in patients without infection is potentially harmful, facilitating colonization and superinfection with multiresistant microorganisms. Any strategy designed to evaluate patients suspected of having developed VAP therefore should be able to withhold antimicrobial treatment in patients without pneumonia.*
- *Because even a few doses of a new antimicrobial agent can negate results of microbiologic cultures, pulmonary secretions in patients suspected of having developed VAP always should be obtained before new antibiotics are administered.*
- *Bronchoscopic techniques, when performed before introduction of new antibiotics, enable physicians to identify most patients who need immediate treatment and help to select optimal therapy in a manner that is safe and well tolerated.*
- *Empirical treatment of patients with VAP should be selected based on available epidemiologic characteristics, information provided by direct examination of pulmonary secretions, intrinsic antibacterial activities of antimicrobial agents, and their pharmacokinetic characteristics.*
- *Once the microbiologic data become available, antimicrobial therapy should be re-evaluated in order to avoid prolonged use of a broader spectrum of antibiotic therapy than is justified by the available information. For many patients, including those with late-onset infection, the culture data will not show the presence of highly resistant pathogens, and in these individuals, therapy can be narrowed or even reduced to a single agent in light of the susceptibility pattern of the causative pathogens without risking inappropriate treatment.*
- *Some very simple, no-cost measures, such as judicious use and prompt removal of a useless nasogastric tube, removal of ventilator tubing condensates with minimal exposure to patients, placement of ventilated patients in a semirecumbent position, prevention of sinusitis, and use of sucralfate instead of H_2 blockers, may have an impact on the frequency of VAP.*

Ventilator-associated pneumonia (VAP) remains a major cause of mortality and morbidity despite the introduction of potent broad-spectrum antimicrobial agents, major advances in the management of ventilator-dependent patients admitted to ICUs, and the use of preventive measures, including the routine use of effective procedures to disinfect respiratory equipment. Rates of pneumonia are considerably higher among patients hospitalized in ICUs compared with those in hospital wards, and the risk of pneumonia is increased three- to tenfold for the intubated patient on mechanical ventilation (MV).[1–10] In contrast to infections of more frequently involved organs (e.g., urinary tract and skin), for which mortality is low, ranging from 1% to 4%, the mortality rate for VAP, defined as pneumonia occurring more than 48 hours after endotracheal intubation and initiation of MV, ranges from 24% to 50% and can reach 76% in some specific settings or when lung infection is caused by high-risk pathogens.[8–18] Because several studies have shown that appropriate antimicrobial treatment of patients with VAP significantly improves outcome, more rapid identification of infected patients and accurate selection of antimicrobial agents represent important clinical goals.[12,19,20] However, consensus on appropriate diagnostic, therapeutic, and preventive strategies for VAP has yet to be reached.

Epidemiology

Accurate data on the epidemiology of VAP are limited by the lack of standardized criteria for its diagnosis. Conceptually, VAP is defined as an inflammation of the lung parenchyma caused by infectious agents not present or incubating at the time MV was started. Despite the clarity of this conception, the past three decades have witnessed the appearance of numerous operational definitions, none of which is universally accepted. Even definitions based on histopathologic findings at autopsy may fail to find consensus or provide certainty. Pneumonia in focal areas of a lobe may be missed, microbiologic studies may be negative despite the presence of inflammation in the lung, and pathologists may disagree on the findings.[21–24] The absence of a "gold standard" continues to fuel controversy about the adequacy and relevance of many studies in this field. Prolonged (>48 hours) MV is the most important factor associated with nosocomial pneumonia. However, VAP may occur within the first 48 hours following intubation. Since the seminal study by Langer and colleagues,[25] it is usual to distinguish early-onset VAP, which occurs during the first 4 days of MV, from late-onset VAP, which develops 5 days or more after initiation of MV. Not only are the causative pathogens commonly different, but the disease also is usually less severe and the prognosis better in early-onset than late-onset VAP.[26,27]

INCIDENCE

The majority of studies have reported incidence rates of nosocomial pneumonia in general ICU populations varying between 8% and 20%. These rates are much higher than the mean annual incidence of nosocomial lower respiratory tract

infection of approximately 0.6 episodes per 100 hospitalizations recorded by the National Nosocomial Infection Study (NNIS), which included all patients regardless of their location in the hospital.[28]

The risk of pneumonia seems to be considerably higher in the subset of ICU patients treated with mechanical ventilation. Cross and Roup[5] have published specific data on overall rates of nosocomial pneumonia in relation to the use of respiratory devices. Pneumonia rates in patients with an endotracheal tube and mechanical ventilation were increased 10-fold over patients with no respiratory therapy devices. Similarly, in the Study on the Efficacy of Nosocomial Infection Control (SENIC), the pneumonia rate was 21-fold higher for patients treated with continuous ventilatory support than for patients not receiving mechanical ventilation.[28]

The VAP rates reported in the more recent studies evaluating homogeneous groups of patients receiving mechanical ventilation are shown in Table 43-1. In their prospective investigation on pneumonia in 23 Italian ICUs that included 724 critically ill patients who had received prolonged (>24 hour) ventilatory assistance since admission, Langer and colleagues[6] found a mean rate of nosocomial pneumonia of 23%; the incidence rose from 5% in patients receiving 1 day of respiratory assistance to 68.8% in patients mechanically ventilated for more than 30 days. Using quantitative culture of specimens obtained with a protected specimen brush (PSB) during fiberoptic bronchoscopy (FOB) to define pneumonia in 567 ventilated patients, Fagon and colleagues[9] reported a nosocomial pneumonia rate of 9%. Using an actuarial method, the cumulative risk of pneumonia in this context was estimated to be 6.5% at 10 days and 19% at 20 days after the onset of MV. Furthermore, the incremental risk of pneumonia was virtually constant thoughout the entire ventilation period, with a mean rate of about 1% per day. In contrast, Cook and colleagues[29] demonstrated in a large series of 1014 mechanically ventilated patients that although the cumulative risk for developing VAP increased over time, the daily hazard rate decreased after day 5. The risk per day was evaluated at 3% on day 5, 2% on day 10, and 1% on day 15. Independent predictors of VAP retained by multivariable analysis were a primary admitting diagnosis of burns (risk ratio [RR] = 5.1; 95% confidence interval [CI] = 1.5–17.0), trauma (RR = 5.0; 95% CI = 1.9–13.1), central nervous system (CNS) disease (RR = 3.4; 95% CI = 1.3–8.8), respiratory disease (RR = 2.8; 95% CI = 1.1–7.5), cardiac disease (RR = 2.7; 95% CI = 1.1–7.0), MV during the previous 24 hours (RR = 2.3; 95% CI = 1.1–4.7), witnessed aspiration (RR = 3.2; 95% CI = 1.6–6.5), and paralytic agents (RR = 1.6; 95% CI = 1.1–2.4). Exposure to antibiotics conferred protection (RR = 0.4; 95% CI = 0.3–0.5), but this effect was attenuated over time. Thus the daily risk for developing VAP is highly dependent on the population being studied as well as on many other factors, particularly the number of patients in the given population who received antibiotics immediately after their admission to the ICU.

VAP is thought to be a common complication of the acute respiratory distress syndrome (ARDS) (see Table 43-1). Most clinical studies have found that pulmonary infection affects between 34% and more than 70% of patients with ARDS, often leading to the development of sepsis, multiple-organ failure, and death. When the lungs of patients who died of ARDS were examined histologically at autopsy, pneumonia could be demonstrated in as many as 73%.[10,30] The diagnosis of pulmonary infection in patients with ARDS, however, is often difficult. Several studies have clearly demonstrated the inability of physicians to accurately diagnose nosocomial pneumonia in this setting based on clinical criteria alone.[30] Using PSB and/or bronchoalveolar lavage (BAL) techniques at predetermined times from days 3 to 21 after the onset of the syndrome in a series of 105 patients with ARDS, Sutherland

and colleagues[31] concluded that VAP indeed may occur far less frequently than expected in this group of patients. Only 16 (15.2%) of their 105 patients met the quantitative criteria for pneumonia (PSB > 10^3 colony-forming units [cfu]/mL or BAL > 10^4 cfu/mL), and no correlations were found between total colony counts in BAL fluid or PSB cultures and severity of ARDS, as judged by Pa_{O_2}/FI_{O_2} ratios, days on MV, static lung compliance, and/or survival. Unfortunately, these results are probably not of general value because most patients included in the study were lavaged while receiving antibiotics and at predetermined times during the course of ARDS rather than at the time of clinically suspected infection. According to four other studies, the VAP rate was higher in ARDS patients than in other mechanically ventilated patients.[14–16,32] In one study on 56 ARDS patients, PSB and BAL were used to define pneumonia, and the VAP rate was 55%,[14] whereas it was only 28% for 187 non-ARDS patients diagnosed with the same criteria during the same period. It was specified that early-onset VAP (occurring before day 7) was relatively rare in ARDS patients: only 10% of the first VAP episodes, as opposed to 40% of non-ARDS patients. These observations were confirmed in 30 ARDS patients for whom repeated quantitative culture results of specimens obtained with a plugged catheter were available and in 94 ARDS patients with suspected VAP who underwent 172 bronchoscopies, with VAP rates of 60% (incidence density = 4.2/100 ventilator-days) and 43%, respectively.[15,32] In another prospective multicentric study, VAP was confirmed bacteriologically in 49 (37%) of 134 ARDS patients versus 23% of ventilated non-ARDS patients ($p < 0.002$).[16]

MORTALITY, MORBIDITY, AND COST

Crude ICU mortality rates of 24% to 76% have been reported for VAP at a variety of institutions[6,9,12,13,29,33–41] (see Table 43-1). ICU ventilated patients with VAP appear to have a two- to tenfold higher risk of death compared with patients without pneumonia. In 1974, fatality rates of 50% for ICU patients with pneumonia versus 4% for patients without pneumonia were reported.[42] The results of several studies conducted between 1986 and 2001 have confirmed this observation. Despite variations among studies that partly reflect the populations considered, overall mortality rates for patients with or without VAP were, respectively, 55% versus 25%,[13] 71% versus 28%,[9] 33% versus 19%,[12] 38% versus 9%,[37] and 44% versus 19%.[40] These rates correspond to increased risk ratios of mortality of VAP patients of 2.2, 2.5, 1.7, 4.4, and 2.3, respectively.

Although these statistics indicate that VAP is a severe disease, previous studies have not demonstrated clearly that pneumonia is indeed responsible for the higher mortality rate of these patients. Two independent factors make it difficult to assign responsibility unambiguously. The first is, once again, the difficulty in establishing a firm diagnosis, i.e., to clearly identify patients with VAP; thus the widely diverging VAP mortality rates reported may reflect not only differences in the populations studied but also differences in the diagnostic criteria used. Second, numerous studies have demonstrated that severe underlying illness predisposes ICU patients to the development of pneumonia, and their mortality rates are, consequently, high.[3,4,8,37,43–45] Therefore, it is difficult to determine whether such patients would have survived if VAP had not occurred.

The prognosis for aerobic gram-negative bacilli (GNB) VAP is considerably worse than that for infection with gram-positive pathogens when these organisms are fully susceptible to antibiotics. Death rates associated with *Pseudomonas* pneumonia are particularly high, ranging from 70% to more than 80% in several studies.[9,42,46–50] According to one study, mortality associated with *Pseudomonas* or *Acinetobacter* pneumonia was 87% compared with 55% for pneumonias due to other organisms.[9] Similarly, Kollef and colleagues[51] demonstrated that patients with VAP due to high-risk pathogens (*Pseudomonas aeruginosa, Acinetobacter* spp., and *Stenotrophomonas maltophilia*) had a significantly higher hospital mortality rate (65%) than patients with late-onset VAP due to other microbes (31%) or patients without late-onset pneumonia (37%). Concerning gram-positive pathogens, in a study comparing VAP due to methicillin-resistant *Staphylococcus aureus* (MRSA) or methicillin-sensitive *S. aureus* (MSSA), mortality was found to be directly attributable to pneumonia for 86% of the former cases versus 12% of the latter, with a relative risk of death equal to 20.7 for MRSA pneumonia.[52]

Multivariate analyses conducted to evaluate the independent role played by VAP in inducing death failed to identify VAP as a variable independently associated with mortality in two studies.[13,37] In contrast, the EPIC study's stepwise logistic regression analyses demonstrated that ICU-acquired pneumonia increased the risk of death with an odds ratio of 1.91 (95% CI = 1.6–2.3) independently of clinical sepsis and bloodstream infection.[3] Another study based on 1978 ICU patients including 1118 patients on MV demonstrated that in addition to the severity of illness, the presence of dysfunctional organ(s); stratification according to the McCabe and Jackson criteria of underlying disease as fatal, ultimately fatal, or not fatal; and nosocomial bacteremia and nosocomial pneumonia independently contributed to the deaths of ventilated patients.[38] Using the Cox model in a series of 387 patients, it was demonstrated that patients with clinically suspected pneumonia had an increased risk of mortality; however, confirmation of the diagnosis with invasive techniques added no prognostic information (respective RR = 2.1 and 1.7).[39]

Case-control studies have been used to assess mortality attributable to nosocomial pneumonia, i.e., the difference between the mortality rates observed for case patients (patients with pneumonia) and control subjects (patients without pneumonia). The results of matched cohort studies evaluating mortality and relative risk attributable to nosocomial pneumonia are given in Table 43-2.[36,50,53–57] Of these seven studies, five concluded that VAP was associated with a significant attributable mortality. For example, it was reported that the mortality rate attributable to VAP exceeded 25%, corresponding to a relative risk of death of 2.0 (with respective values of 40% and 2.5 for cases of pneumonia caused by *Pseudomonas* or *Acinetobacter* spp.).[50] These results were supported by those of other authors, who reported that the risk of mortality was almost three times higher in patients with pneumonia (RR = 2.95; 95% CI = 1.73−5.03) than those without, with a major impact being observed for patients with intermediate-grade severity.[58]

A recent clinical investigation to determine whether VAP is an independent risk factor for death matched 108 nonsurvivors with 108 survivors for their underlying diseases, age,

admission date, severity of illness, and duration of MV[59]; 39 patients in each group developed VAP. This finding contrasts with those of other investigations, which identified the occurrence of VAP as an independent determinant of hospital mortality. Other factors beyond the simple development of VAP, such as the severity of the disease or the responsible pathogens, may be more important determinants of outcome for patients in whom VAP as well as other nosocomial infections develop. Indeed, it may well be that VAP increases mortality only in the subset of patients with intermediate severity[58] and/or in patients with VAP caused by high-risk pathogens, as indicated earlier.[9,51,52] It is probable that several case-control studies were confounded by the fact that patients with very low severity and early-onset pneumonia due to organisms such as *Haemophilus influenzae* or *Streptococcus pneumoniae* have excellent prognoses with or without VAP, whereas very ill patients with late-onset VAP occurring while they are in a quasi-terminal state would die anyway.

It is impossible to accurately evaluate the morbidity and excess costs associated with nosocomial pneumonia. However, with respect to morbidity measures, the prolonged hospital stay as a direct consequence of pneumonia has been estimated in several studies. Jimenez and colleagues[45] demonstrated that nosocomial pneumonia extended the duration of MV from 10 to 32 days, and Craig and Connelly[53] found that pneumonia lengthened the ICU stay threefold. Fagon and colleagues[50] observed that the median length of stay in the ICU for the patients who developed VAP was 21 days versus a median of 15 days for controls ($p < 0.02$). Recently, Baker and colleagues[36] reported mean durations of MV, ICU stay, and hospital stay of 12.0, 20.5, and 43.0 days in trauma patients with pneumonia compared with 8.0, 15.0, and 34.0, respectively, in their matched controls ($p < 0.001$). Similarly, Cunnion and colleagues[54] demonstrated that the mean hospital stay after admission to the ICU was greater for cases of nosocomial pneumonia in surgical ICU patients (30.0 days versus 22.3 days in controls) and in medical and respiratory ICU patients (40.9 days versus 23.1 days in controls).

These prolonged hospitalizations underscore the considerable financial burden imposed by the development of nosocomial pneumonia. For Baker and colleagues,[36] the extra hospital charges related to nosocomial pneumonia occurring in trauma patients were evaluated to be $40,000.

ETIOLOGIC AGENTS

Microorganisms responsible for VAP may differ according to the population of ICU patients, the durations of hospital and ICU stays, and the specific diagnostic method(s) used. The high rate of respiratory infections due to GNB in this setting has been documented repeatedly.[9,12,17,60–64] Several studies have reported that more than 60% of VAPs are caused by aerobic GNB. More recently, however, some investigators have reported that gram-positive bacteria have become increasingly common in this setting, with *S. aureus* being the predominant gram-positive isolate. For example, *S. aureus* was responsible for most episodes of nosocomial pneumonia in the EPIC study, accounting for 31% of the 836 cases with identified responsible pathogens.[64] The data from 24 investigations conducted on ventilated patients, for whom bacteriologic studies were restricted to uncontaminated specimens, confirmed those results: GNB represented 58% of recovered organisms[9,12,14,16–19,32,36,39,65–78] (Table 43-3). The predominant GNB were *P. aeruginosa* and *Acinetobacter* spp., followed by *Proteus* spp., *Escherichia coli*, *Klebsiella* spp., and *H. influenzae*. A relatively high rate of gram-positive pneumonias also was reported in those studies, with *S. aureus* involved in 20% of the cases.

The high rate of polymicrobial infection in VAP has been emphasized repeatedly. In a study on 172 episodes of bacteremic nosocomial pneumonia, 13% of lung infections were caused by multiple pathogens.[46] Similarly, when the PSB technique was used to identify the causative agents in 52

consecutive cases of VAP, a 40% polymicrobial infection rate was found,[9] a value similar to that observed in another study conducted at the same time on a comparable population of ventilated patients.[63]

Underlying diseases may predispose patients to infection with specific organisms. Patients with chronic obstructive pulmonary disease (COPD) are, for example, at increased risk for *H. influenzae, Moraxella catarrhalis,* or *S. pneumoniae* infections; cystic fibrosis increases the risk of *P. aeruginosa* and/or *S. aureus* infections, whereas trauma and neurologic patients are at increased risk for *S. aureus* infections.[26,36,52,79] Furthermore, the causative agent for pneumonia differs among ICU surgical populations,[80] with 18% of the nosocomial pneumonias being due to *Haemophilus* or pneumococci, particularly in trauma patients but not in patients with malignancy, transplantation, or abdominal or cardiovascular surgery.

Despite somewhat different definitions of early-onset pneumonia, varying from less than 3 to less than 7 days,[26,77] high rates of *H. influenzae, S. pneumoniae,* MSSA, or susceptible Enterobacteriaceae were constantly found in early-onset VAP, whereas *P. aeruginosa, Acinetobacter* spp., MRSA, and multiresistant GNB were significantly more frequent in late-onset VAP.[26,76,77] This different distribution pattern of etiologic agents between early- and late-onset VAP is also linked to the frequent administration of prior antimicrobial therapy in many patients with late-onset VAP. In a prospective study that included 129 episodes of nosocomial pneumonia documented by PSB specimens, the distributions of responsible pathogens were compared according to whether or not the patients had received antimicrobial therapy before pneumonia onset.[17] The most striking finding was that the rate of pneumonia caused by gram-positive cocci or *H. influenzae* was significantly lower ($p < 0.05$) in patients who had received antibiotics, whereas the rate of pneumonia caused by *P. aeruginosa* was significantly higher ($p < 0.01$). A stepwise logistic regression analysis retained only prior antibiotic use (odds ratio [OR] = 9.2; $p < 0.0001$) as significantly influencing the risk of death from pneumonia.[17] Very similar results were obtained when multivariate analysis was used to determine risk factors for VAP caused by potentially drug-resistant bacteria such as MRSA, *P. aeruginosa, A. baumannii,* and/or *S. maltophilia* in 135 consecutive episodes of VAP.[77] Only three variables remained significant: duration of MV before VAP onset $\geq$ 7 days (OR = 6.0), prior antibiotic use (OR = 13.5), and prior use of broad-spectrum drugs (third-generation cephalosporin, fluoroquinolone, and/or imipenem) (OR = 4.1).[77] Not all studies, however, have confirmed this distribution pattern. For example, one recent study found that the most common pathogens associated with early-onset VAP were *P. aeruginosa* (25%), MRSA (18%), and *Enterobacter* spp. (10%), with similar pathogens being associated with late-onset VAP.[81] Their finding may be due in part to the prior hospitalization and use of antibiotics in many patients developing early-onset VAP before their transfer to the ICU.

The incidence of multiresistant pathogens is also closely linked to local factors and varies widely from one institution to another. Consequently, each ICU has to collect meticulous epidemiologic data continuously. With these aims, variations of VAP etiology among three Spanish ICUs were analyzed[76] and compared with data collected in Paris.[77] The authors concluded that VAP pathogens varied widely among these four treatment centers, with marked differences in all the microorganisms isolated from VAP episodes in Spanish centers as compared with the French site. Clinicians clearly must be aware of the common microorganisms associated with both early- and late-onset VAP in their own hospitals in order to avoid the administration of initial inadequate antimicrobial therapy.

Legionella spp.[82,83] anaerobes,[67] fungi,[84] viruses,[85] and even *Pneumocystis carinii* should be mentioned as potential causative agents but are not considered to be common in the context of pneumonia acquired during MV. However, several of these causative agents may be more common and potentially underreported because of difficulties involved with the diagnostic techniques used to identify them, including anaerobic bacteria and viruses.[67,85] In a study conducted to determine the frequency of anaerobes in 130 patients with a first episode of bacteriologically documented VAP with special precautions taken to preserve anaerobic conditions during PSB transport and microbiologic procedures,[67] anaerobes were involved in 23% of the total number of episodes, and the main strains isolated were *Prevotella melaninogenica* (36%), *Fusobacterium nucleatum* (17%), and *Veillonella paravula* (12%). The probability of recovering anaerobic bacteria was particularly high in orotracheally intubated patients and patients in whom pneumonia occurred during the 5 days after ICU admission. However, in a study conducted among 143 patients who developed 185 episodes of suspected VAP and 25 patients with aspiration pneumonia, only 1 anaerobic organism (*V. paravula*) was isolated from 1 patient with aspiration pneumonia, and none from patients with VAP.[66] Thus, examining currently available data, the clinical significance of anaerobes in the pathogenesis and outcome of VAP remains unclear, except as etiologic agents in patients with necrotizing pneumonitis, lung abscess, or pleuropulmonary infections. Anaerobic infection and coverage with antibiotics, such as clindamycin or metronidazole, probably also should be considered for patients with Gram-stained respiratory secretions documenting numerous extra- and intracellular microorganisms in the absence of positive cultures for aerobic pathogens.

Isolation of fungi, most frequently *Candida* species, at significant concentrations poses interpretative problems. Invasive disease has been reported in VAP, but more frequently, yeasts are isolated from respiratory tract specimens in the apparent absence of disease. One prospective study examined the relevance of isolating *Candida* spp. from 25 nonneutropenic patients who had been mechanically ventilated for at least 72 hours.[84] Just after death, multiple culture and biopsy specimens were obtained with bronchoscopic techniques. Although 10 patients had at least one biopsy specimen positive for *Candida* spp., only 2 had evidence of invasive pneumonia, as demonstrated by histologic examination. Many of the endotracheal aspirates, PSB specimens, and BAL specimens also yielded positive cultures for *Candida* spp., sometimes in high concentrations, but they did not contribute to diagnosing invasive disease. Based on these data, the use of the commonly available respiratory sampling methods (bronchoscopic or nonbronchoscopic) in mechanically ventilated patients appears insufficient for the diagnosis of *Candida* pneumonia. At present, the only sure method to establish that *Candida* is the primary lung pathogen is to demonstrate yeast or pseudohyphae in a lung biopsy. However, the significance of *Candida* isolation from the respiratory samples of mechanically

TABLE 43-4 Independent Factors for VAP Identified by Multivariate Analysis in Selected Studies

Host Factors	Intervention Factors	Other
Serum albumin <2.2 g/dL	H_2 blockers ± antacids	Season
Age ≥60 years	Paralytic agents, continuous intravenous sedation	
ARDS		
COPD, pulmonary disease	>4 units of blood products	
Coma or impaired consciousness	Intracranial pressure monitoring

Gastric colonization and pH	Nasogastric tube	
Upper respiratory tract colonization	Supine head position	
Sinusitis	Transport out of the ICU	
	Prior antibiotic or no antibiotic therapy	

ventilated patients merits being investigated in greater depth.[86]

Predisposing Factors

A number of factors have been suspected or identified to increase the risk of pneumonia in the ICU, including those identified in the subset of mechanically ventilated patients; these factors are listed in Table 43-4. The data indicated specific high-risk populations (patients with COPD and ARDS, patients undergoing MV for more than 3 days, those requiring intracranial pressure monitoring, those with coma or impaired consciousness, and more generally, those with severe underlying medical conditions as evaluated by a high APACHE II or APACHE III score or the presence of organ failure) and specific treatment modalities or therapeutic intervention (use of H_2 blockers or antacids; previous antibiotics; use of drugs that are markers for severe underlying disease such as dopamine, dobutamine, or barbiturate therapy; reintubation; and frequent changes of ventilator circuits, bronchoscopy, or nasogastric tube) as being independently associated with nosocomial pneumonia.

SURGERY

Postoperative patients are at increased risk for pneumonia. In a study reported in 1981 by Garibaldi and colleagues,[44] the incidence of pneumonia during the postoperative period was 17.2%. In this study, the authors stated that development of pneumonia was closely associated with preoperative markers of the severity of the underlying disease, such as low serum albumin concentration and a high score on the American Society of Anesthesiologists (ASA) preanesthesia physical status classification. A history of smoking, longer preoperative stays, longer surgical procedures, and thoracic or upper abdominal operative sites also were significant risk factors for postoperative pneumonia. In their study comparing adult critical care populations, Cunnion and colleagues[54] demonstrated that surgical ICU patients were found to have consistently higher rates of nosocomial pneumonia than medical ICU patients with a risk ratio of 2.2. Multiple logistic regressions were performed to determine independent predictors for nosocomial pneumonia in the two groups; in SICU patients, mechanical ventilation (>2 days) and APACHE II score were identified by the model; in MICU patients, only mechanical ventilation (<2 days) remained significant. The relative importance of the surgical procedure itself versus intubation, prophylactic antibiotics, and/or other variables therefore remains to be clearly elucidated in surgical patients.

ANTIMICROBIAL AGENTS

The use of antibiotics in the hospital setting has been associated with an increased risk of nosocomial pneumonia and selection of resistant pathogens.[17,37,49,64,77,79,87–89] In a cohort study of 320 patients, prior antibiotic administration was identified by logistic regression analysis to be one of the four variables independently associated with VAP along with organ failure, age greater than 60 years, and the patient's head positioning (i.e., flat on the back or supine versus head and thorax raised 30 to 40 degrees or semirecumbent).[37] However, other investigators found that antibiotic administration during the first 8 days was associated with a lower risk of early-onset VAP.[90,91] For example, Sirvent and colleagues[92] showed that a single dose of a first-generation cephalosporin given prophylactically was associated with a lower rate of early-onset VAP in patients with structural coma. Moreover, multiple logistic regression analysis of risk factors for VAP in 358 medical ICU patients identified the absence of antimicrobial therapy as one of the factors independently associated with VAP onset.[75] The same result was obtained for a particular subset of 250 patients with very early onset VAP, occurring within 48 hours of intubation, that was investigated to identify potential risk factors for developing VAP.[93] Multivariate analysis selected cardiopulmonary resuscitation (OR = 5.13) and continuous sedation (OR = 4.40) as significant risk factors for pneumonia, whereas antibiotic use (OR = 0.29) had a protective effect. Finally, the results of the multicenter Canadian study on the incidence of and risk factors for VAP indicated that antibiotic treatment conferred protection against VAP.[29] This apparent protective effect of antibiotics disappears after 2 to 3 weeks, suggesting that a higher risk of VAP cannot be excluded beyond this point. Thus risk factors for VAP change over time, thereby explaining why they differ from one series to another.

In contrast, prolonged antibiotic administration to ICU patients for primary infection is thought to favor selection and

subsequent colonization with resistant pathogens responsible for superinfections.[9,77,87,94–96] According to our data on 567 ventilated patients, those who had received antimicrobial therapy within the 15 days preceding lung infection were not at higher risk for development of VAP,[9] but 65% of the lung infections that occurred in patients who had received broad-spectrum antimicrobial drugs versus only 19% of those developing in patients who had not received antibiotics were caused by *Pseudomonas* or *Acinetobacter* spp. In a 1988 investigation on mechanically ventilated baboons treated with a variety of regimens of intravenous and topical antibiotics or no antibiotics at all,[94] polymicrobial pneumonia occurred in almost all untreated animals. However, baboons that had received prophylactic topical polymycin had only a slightly lower incidence of pneumonia, and the prevalence of drug-resistant microorganisms in the tracheal secretions was very high: 60% and 78% after 4 and 8 days of MV, respectively. Therefore, strong arguments suggest that the prophylactic use of antibiotics in the ICU increases the risk of superinfection with multiresistant pathogens while only delaying the occurrence of nosocomial infection.

STRESS ULCER PROPHYLAXIS

According to meta-analyses of the efficacy of stress-ulcer prophylaxis in ICU patients, respiratory tract infections were significantly less frequent in patients treated with sucralfate than in those receiving antacids or H_2 blockers.[97–106] However, this conclusion was not fully confirmed in a very large, multicenter, randomized, blinded, placebo-controlled trial that compared sucralfate suspension (1 g every 6 hours) with the H_2-receptor antagonist ranitidine (50 mg every 8 hours) for the prevention of upper gastrointestinal bleeding in 1200 patients who required MV.[107] Clinically relevant gastrointestinal bleeding developed in 10 of the 596 (1.7%) patients receiving ranitidine as compared with 23 of the 604 (3.8%) patients receiving sucralfate (RR = 0.44; 95% CI = 0.21−0.92; $p = 0.02$). In the ranitidine group, 114 of 596 (19.1%) patients had VAP, as diagnosed by an adjudication committee using a modified version of the Centers for Disease Control and Prevention (CDC) criteria, versus 98 of 604 (16.2%) in the sucralfate group (RR = 1.18; 95% CI = 0.92−1.51; $p = 0.19$). Thus, although pneumonia rates were similar for the two groups, the relative risks suggest a trend toward a lower pneumonia rate for patients receiving sucralfate. Furthermore, VAP occurred significantly less frequently in patients receiving sucralfate when the diagnosis of pneumonia was based on Memphis VAP Consensus Conference criteria (if there was radiographic evidence of abscess and a positive needle aspirate or histologic proof of pneumonia at biopsy or autopsy) ($p = 0.03$).[107]

Sucralfate appears to have a small protective effect against VAP because stress-ulcer prophylactic medications that raise the gastric pH might themselves increase the incidence of pneumonia. This contention is supported by direct comparisons of trials of H_2-receptor antagonists versus no prophylaxis, which showed a trend toward higher pneumonia rates among the patients receiving H_2-receptor antagonists (OR = 1.25; 95% CI = 0.78−2.00).[105] Furthermore, the comparative effects of sucralfate and no prophylaxis are unclear. Among 226 patients enrolled in two randomized trials, those receiving sucralfate tended to develop pneumonia more frequently than those given no prophylaxis (OR = 2.11; 95% CI = 0.82–5.44).[108,109]

ENDOTRACHEAL TUBE—REINTUBATION

The presence of an endotracheal tube by itself circumvents host defenses, causes local trauma and inflammation, and increases the probability of aspirating nosocomial pathogens from the oropharynx around the cuff. Sottile and colleagues[110] studied 25 endotracheal tubes by scanning electron microscopy and found that 96% had partial bacterial colonization and 84% were completely covered by bacteria in a biofilm or glycocalyx. The authors suggested that aggregates of bacteria in biofilm dislodged during suctioning may not be killed by antibiotics or cleared effectively by host immune defenses. Clearly, the type of endotracheal tube also may influence the incidence of aspiration. With low-volume, high-pressure endotracheal cuffs, an incidence of 56% was reported, which decreased to 20% with the advent of high-volume, low-pressure cuffs. In addition to the presence of endotracheal tubes, reintubation is per se a risk factor for nosocomial pneumonia, as indicated by Torres and colleagues.[111] This result is probably related to an increased risk of aspiration of colonized oropharyngeal secretions into the lower airways in patients with glottic dysfunction and/or impaired consciousness after several days of intubation. Another explanation is direct aspiration of gastric contents into the lower airways, particularly when a nasogastric tube is kept in place after extubation.

TRACHEOSTOMY

The role of early tracheostomy in VAP prevention remains controversial, with only a few studies that examined this issue.[112–119] While some studies found a reduction in the rate of VAP in patients with early tracheostomy,[115,116,118] others could not demonstrate any benefit.[112] For example, in a randomized, prospective multicenter trial on 112 patients who were thought to need prolonged MV, there were no differences, at least until day 14, among ICU length of stay, pneumonia rate, and mortality between the 53 patients who underwent early (days 3 to 5) tracheostomy and the 59 who were managed using translaryngeal intubation.[112] The major problem that doomed that study was the overwhelming physician bias, which led to limited patient entry and premature arrest of the study. In the absence of any meaningful data, practice patterns are influenced and guided by strong assumptions and quasi-religious dogma. Until a properly constructed randomized trial is performed to define the timing and utility of tracheostomy in the ICU, its true impact on decreasing VAP will remain merely speculative.[120]

NASOGASTRIC TUBE, ENTERAL FEEDING, AND PATIENT POSITION

Nearly all patients receiving mechanical ventilation have a nasogastric tube inserted to manage gastric and enteral secretions, prevent gastric distention, or provide nutritional support. The nasogastric tube is not widely considered to be a potential risk factor for pneumonia, but it may increase oropharyngeal colonization, cause stagnation of oropharyngeal secretions, and increase reflux and the risk of aspiration. Using multivariate analysis, Joshi and colleagues[43] identified the presence of a nasogastric tube as one of the three

independent risk factors for nosocomial pneumonia in a series of 203 patients admitted to the ICU for 72 hours or more.

Early initiation of enteral feeding generally is regarded as beneficial in critically ill patients, but it may increase the risk of gastric colonization, gastroesophageal reflux, aspiration, and pneumonia. Pingleton and colleagues[121] evaluated simultaneous daily gastric, tracheal, and oropharyngeal cultures in 18 ventilator-dependent patients not receiving antacids or H_2 antagonists. After starting enteral feeding, the number of gram-negative isolates increased significantly, and 5 patients (28%) had gram-negative rods that were first recovered in the stomach and subsequently identified in the trachea.

Maintaining mechanically ventilated patients with a nasogastric tube in place in the supine position is also a risk factor for aspiration of gastric contents into the lower airways. Torres and colleagues[122] injected radioactive material via a nasogastric tube directly into the stomachs of 19 mechanically ventilated patients and found that mean radioactive counts in endobronchial secretions were higher in a time-dependent fashion in samples obtained while patients were in the supine position than in those obtained while patients were in the semirecumbent position. The same microorganisms were isolated from stomach, pharynx, and endobronchial samples in 32% of the specimens taken while patients were semirecumbent and in 68% of those taken while patients were in the supine position. These results suggest that placing mechanically ventilated patients in the semirecumbent position is a simple and effective means to minimize aspiration of gastric contents into lower airways and hence constitutes a recommendable, no-cost prophylactic measure for those who can tolerate this position. Such experimental results were confirmed indirectly by Kollef,[37] who demonstrated that supine patient head positioning during the first 24 hours of mechanical ventilation was an independent risk factor for acquiring VAP.

RESPIRATORY EQUIPMENT

Respiratory equipment itself may act as a source of bacteria responsible for nosocomial pneumonia. In past years, the major risk of infection was associated with contaminated reservoir nebulizers designed to deliver small-sized particles suspended in the effluent gas. These observations led to current trends in respiratory therapy toward the use of cascade humidifiers, which do not generate microaerosols. Nevertheless, respiratory equipment continues to provide a source of bacterial contamination. For example, medication nebulizers inserted into the inspiratory-phase tube of the mechanical ventilator circuit may produce bacterial aerosols after a single use.

Mechanical ventilators with humidifying cascades often have high levels of tubing colonization and condensate formation that also may be risk factors for pneumonia. The rate of condensate formation in the ventilator circuit is linked to the temperature difference between the inspiratory-phase gas and the ambient temperature and may be as high as 20 to 40 mL/h.[123] Craven and colleagues[124] examined condensate colonization in 20 circuits and found a median level of 2.0×10^5 organisms/mL, and 73% of the 52 gram-negative isolates present in the patient's sputum were isolated subsequently from condensate. Since most of the tubing colonization was derived from the patient secretions, the highest bacterial counts were present near the endotracheal tube. Simple procedures such as turning the patient or raising the bed rail may accidently wash contaminated condensate directly into the patient's tracheobronchial tree. Inoculation of large amounts of fluid with high bacterial concentrations is an excellent way of overwhelming pulmonary defense mechanisms and producing pneumonia. Heating ventilator tubing markedly reduces the rate of condensate formation, but heated circuits often are nondisposable and are expensive. To date, no scientific evidence confirms that heated circuits reduce the incidence of VAP. In-line devices with one-way valves to collect condensate are probably the easiest way to handle this problem. They should be positioned correctly into disposable circuits and emptied regularly.

SINUSITIS

While many studies have compared the risk of nosocomial sinusitis as a function of the intubation method used and the associated risk of VAP,[125–141] only a few were powered adequately to give a clear answer. In one study on 300 patients who required MV for at least 7 days and were randomly assigned to undergo nasotracheal or orotracheal intubation, computed tomographic (CT) evidence of sinusitis was observed slightly more frequently in the nasal than oral endotracheal group ($p = 0.08$), but this difference disappeared when only bacteriologically confirmed sinusitis was considered.[137] The rate of infectious maxillary sinusitis and its clinical relevance also were studied prospectively in 162 consecutive critically ill patients who had been intubated and mechanically ventilated for 1 hour to 12 days before enrollment.[135] All had a paranasal CT scan within 48 hours of admission that was used to divide them into three groups (no, moderate, or severe sinusitis) according to the radiologic appearance of the maxillary sinuses. Patients who had no sinusitis at admission ($n = 40$) were randomized to receive endotracheal and gastric tubes via the nasal or oral route, and based on radiologic images, respective sinusitis rates were 96% and 23% ($p < 0.03$), yet, no differences in the rates of infectious sinusitis were documented according to the intubation route. However, VAP was more common in patients with infectious sinusitis, with 67% of them developing lung infection in the days following the diagnosis of sinusitis.[135] Therefore, whereas it seems clear that infectious sinusitis is a risk factor for VAP, no studies have yet been able to demonstrate definitively that orotracheal intubation decreases the infectious sinusitis rate compared with nasotracheal intubation, and thus no firm recommendations on the best route of intubation to prevent VAP can be advanced.

INTRAHOSPITAL PATIENT TRANSPORT

A prospective cohort study conducted on 531 mechanically ventilated patients evaluated the impact of transporting the patient out of the ICU to other sites within the hospital.[142] Results showed that 52% of the patients had to be moved at least once for a total of 993 transports and that 24% of the transported patients developed VAP compared with 4% of the patients confined to the ICU ($p < 0.001$). Multiple logistic regression analysis confirmed that transport out of the ICU was independently associated with VAP (OR = 3.8; $p < 0.001$).

Diagnosis

BACKGROUND AND DESCRIPTION

The diagnosis of VAP usually is based on three components: systemic signs of infection, new or worsening infiltrates seen on the chest roentgenogram, and bacteriologic evidence of pulmonary parenchymal infection.[30] The systemic signs of infection, such as fever, tachycardia, and leukocytosis, are nonspecific findings and can be caused by any condition that releases cytokines.[143] In trauma and other surgical patients, fever and leukocytosis should prompt the physician to suspect infection, but during the early posttraumatic or postoperative period (i.e., during the first 72 hours), these findings usually are not conclusive. However, later, fever and leukocytosis are more likely to be caused by infection, but even then, other events associated with an inflammatory response (e.g., devascularized tissue, open wounds, pulmonary edema, and/or infarction) can be responsible for these findings.

Although the plain (usually portable) chest roentgenogram remains an important component in the evaluation of hospitalized patients with suspected pneumonia, it is most helpful when it is normal and rules out pneumonia. When infiltrates are evident, the particular pattern is of limited value for differentiating among cardiogenic pulmonary edema, noncardiogenic pulmonary edema, pulmonary contusion, atelectasis (or collapse), and pneumonia. Because atelectasis is common in ICU patients, the contribution of repeating the chest x-ray after vigorous pulmonary physiotherapy was emphasized to differentiate infiltrates caused by atelectasis from those due to infection.[144] Few studies have examined the accuracy of the portable chest radiograph in the ICU.[30,145–150] In a review of 24 patients with autopsy-proven pneumonia who were receiving MV, no single radiographic sign had a diagnostic accuracy of more than 68%.[145] The presence of air bronchograms was the only sign that corresponded well to pneumonia, correctly predicting 64% of pneumonias in the entire group. When the group was divided into patients with and without ARDS, however, a significant difference was noted. The presence of air bronchograms or alveolar opacities in patients without ARDS correlated with pneumonia, whereas no such correlation was found for patients with ARDS. A number of causes other than pneumonia can explain asymmetric consolidation in patients with ARDS, e.g., atelectasis, emphysema, pulmonary edema, and thromboembolic disease. Marked asymmetry of radiographic abnormalities also has been reported in patients with uncomplicated ARDS.[151]

Microscopic evaluation and nonquantitative culture of tracheal secretions and/or expectorated sputum also frequently are inconclusive for patients clinically suspected of having pneumonia because the upper respiratory tract of most ICU patients is colonized with potential pulmonary pathogens whether or not parenchymal pulmonary infection is present.[63,89,152–154] Based on specimens obtained simultaneously from the deep trachea and lung for culture from 48 patients with respiratory failure undergoing open-lung biopsy, culture results agreed for only 40% of these paired samples.[155] For patients with histologically documented pneumonia, endotracheal aspirate sensitivity was 82%, but its specificity was only 27%.

Ideally, any diagnostic strategy intended to be used in patients suspected clinically of having developed VAP should be able to reach the three following objectives: (1) to accurately identify patients with true pulmonary infection and, in case of infection, to isolate the causative microorganisms (in order to initiate immediate appropriate antimicrobial treatment and then to optimize therapy based on susceptibility patterns), (2) to identify patients with extrapulmonary sites of infection, and (3) to withhold and/or withdraw antibiotics in patients without infection.

Two diagnostic algorithms can be used in case of VAP suspicion. One option is to treat every patient suspected clinically of having a pulmonary infection with new antibiotics, even when the likelihood of infection is low, arguing that several studies showed that immediate initiation of appropriate antibiotics was associated with reduced mortality.[19,156–158] In this option, the selection of appropriate empirical therapy is based on risk factors and local resistance patterns and involves qualitative testing to identify possible pathogens, antimicrobial therapy being adjusted according to culture results or clinical response (Fig. 43-1). This "clinical" approach has two potential advantages: First, no specialized microbiologic techniques are requested, and second, the risk of missing a patient who needs antimicrobial treatment is minimal, at least when all suspected patients are treated with new antibiotics. However, such a strategy leads to overestimation of the incidence of VAP because tracheobronchial colonization and noninfectious processes mimicking it are included. Qualitative endotracheal aspirate cultures contribute indisputably to the diagnosis of VAP only when they are completely negative for a patient with no modification of prior antimicrobial treatment. In such a case, the negative-predictive value is very high, and the probability of the patient having pneumonia is close to null.[24]

Concern about the inaccuracy of clinical approaches to VAP recognition had led numerous investigators to postulate that "specialized" diagnostic methods, including quantitative cultures of endotracheal aspirates or specimens obtained with bronchoscopic or nonbronchoscopic techniques such as BAL and/or PSB, could improve identification of patients with true VAP and facilitate decisions about whether or not to treat and thus clinical outcome.[19,27,74,159,160] Using such a strategy, the decision algorithm is similar to the one described in Figure 43-1, except that therapeutic decisions are taken based on results of direct examination of distal pulmonary samples and results of quantitative cultures (Fig. 43-2).

SUMMARY OF THE EVIDENCE

Other than decision-analysis studies[161,162] and one retrospective study,[163] only four trials have so far assessed the impact of a diagnostic strategy on antibiotic use and outcome of patients suspected of having VAP using a randomized scheme.[72–74,164] No differences in mortality and morbidity were found when either invasive (PSB and/or BAL) or noninvasive (quantitative endotracheal aspirate cultures) techniques were used to diagnose VAP in three Spanish randomized studies.[72,73,164] However, those studies were based on relatively few patients (51, 76, and 88, respectively), and antibiotics were continued in all patients despite negative cultures, thereby neutralizing one of the potential advantages of any diagnostic test in patients clinically suspected of having VAP. Concerning the latter, several prospective studies have concluded that antibiotics indeed can be stopped in patients with negative

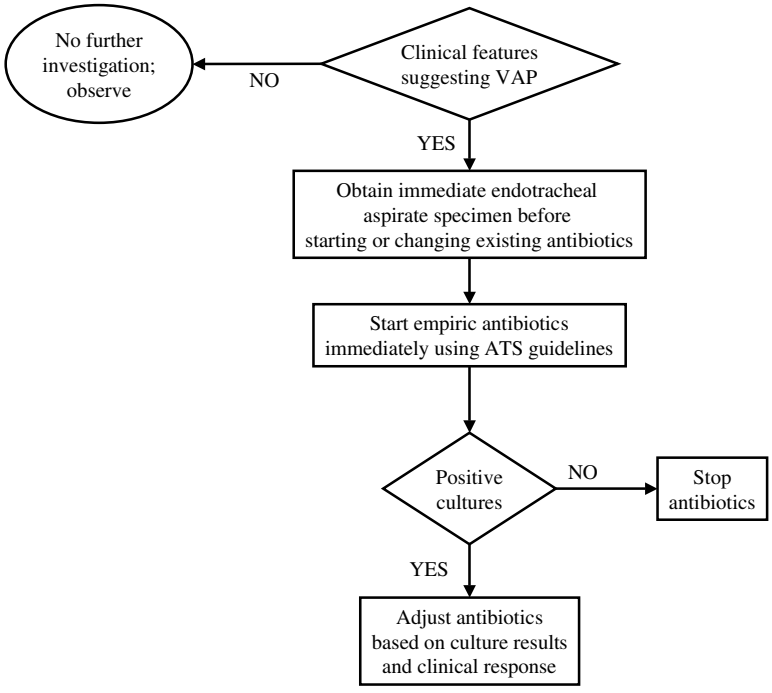

FIGURE 43-1 Diagnostic and therapeutic strategy applied to patients with a clinical suspicion of VAP managed according to the "clinical" strategy. ATS, American Thoracic Society.

quantitative cultures with no adverse effects on the recurrence of VAP and mortality.[19,70,163,165,166] One of the first studies to clearly demonstrate a benefit in favor of invasive techniques was a prospective, randomized trial that compared the two strategies in 413 patients suspected of having VAP.[74] Compared with patients managed clinically, those receiving invasive management had a lower mortality rate on day 14 (16% and 25%; $p = 0.02$) and lower mean sepsis-related organ failure assessment scores on days 3 and 7 ($p = 0.04$). At 28 days, the invasive-management group had significantly more antibiotic-free days (11 ± 9 versus 7 ± 7; $p < 0.001$), and only multivariate analysis showed a significant difference in mortality (hazards ratio [HR] = 1.54; 95% CI = 1.10–2.16; $p = 0.01$).[74] Thus implementation of bronchoscopic techniques for the diagnosis of VAP may reduce antibiotic use and improve patient outcome.

Because VAP in the ICU has substantial attributable mortality, there is justification, albeit unwarranted at times, to use antibiotics for patients with pulmonary infiltrates despite a low likelihood of infection. A recent randomized study proposed to minimize excessive use of antibacterial agents but still allow clinicians flexibility in managing patients with a perceived treatable infection.[167] Patients with a clinical pulmonary infection score (CPIS) of 6 or less (implying low likelihood of pneumonia) were randomized to receive either standard therapy (choice and duration of antibiotics at the discretion of physicians) or ciprofloxacin monotherapy with re-evaluation on day 3; ciprofloxacin was discontinued when CPIS remained 6 or less. Antibiotics were continued beyond 3 days for 90% (38 of 42) of the patients receiving standard therapy compared with 28% (11 of 39) in the ciprofloxacin group ($p = 0.0001$). Mortality and length of ICU stay did not differ despite the shorter duration ($p = 0.0001$) and lower cost ($p = 0.003$) of antimicrobial therapy in the monotherapy than in the standard-therapy arm. Antimicrobial resistance, superinfections, or both developed in 15% of the patients in the ciprofloxacin versus 35% of the patients in the standard-therapy group ($p = 0.017$). Such an approach thus may lead to significantly lower antimicrobial therapy costs, antimicrobial resistance, and superinfections without adversely affecting the length of stay or mortality and merits prospective analysis in a large study sample. However, it should be emphasized that this strategy was tested in relatively few patients ($n = 81$) and that only 42% of patients included in the study did not require MV. Thus it remains to be precisely determined whether this strategy can perform as well when it is applied to mechanically ventilated patients.

Operating characteristics of nonbronchoscopic techniques for diagnosing VAP are probably very similar to those based on bronchoscopy, with only small differences in their sensitivities, specificities, positive predictive values, and likelihood ratios.[168] Therefore, the choice of procedure(s) eventually may depend on the preferences and experiences of individual physicians and the patient's underlying disease(s). Despite broad clinical experience with the PSB and BAL techniques, it remains, nonetheless, unclear which one should be used in clinical practice. Most investigators prefer to use BAL rather than PSB to diagnose bacterial pneumonia because BAL (1) has a slightly higher sensitivity to identify VAP-causative microorganisms, (2) enables better selection of an empirical antimicrobial treatment before culture results are available, (3) is less dangereous for many critically ill patients, (4) is less costly, and (5) may provide useful clues for the diagnosis of other types of infections.[27] However, it must be acknowledged that a very small return on BAL may contain only diluted material from the bronchial rather than alveolar level and thus give rise to false-negative results, particularly for patients with very severe COPD. In these patients, the diagnostic value of BAL techniques is greatly diminished, and the PSB technique should be preferred.[169]

Cultures of pulmonary secretions for diagnostic purposes after initiation of new antibiotic therapy in patients suspected

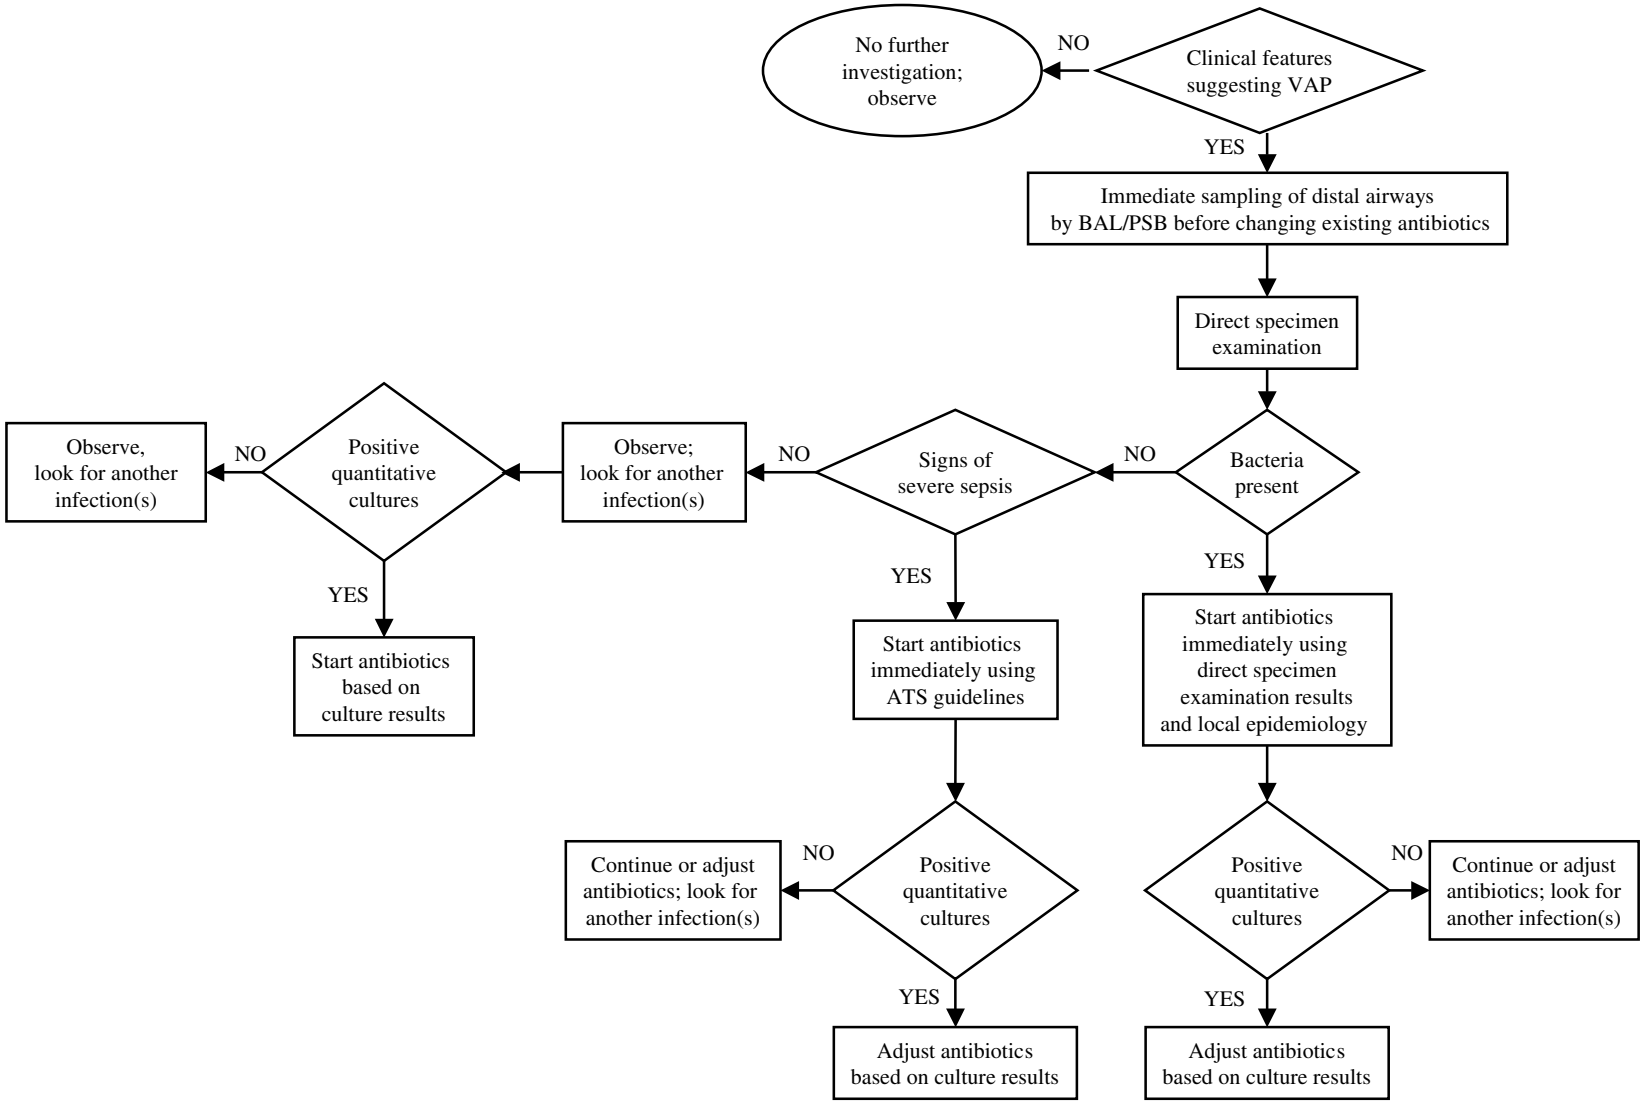

FIGURE 43-2 Diagnostic and therapeutic strategy applied to patients with a clinical suspicion of VAP managed according to the "invasive" strategy. ATS, American Thoracic Society.

of having developed VAP clearly can lead to a high number of false-negative results regardless of the way in which these secretions are obtained. Using a lower threshold to define a positive quantitative result in such a setting may be inaccurate because follow-up cultures can be completely negative in at least 40% of true cases of VAP.[65,170,171] Pulmonary secretions therefore need to be obtained before new antibiotics are administered, as is the case for all microbiologic samples.

CONCLUSIONS AND RECOMMENDATIONS

Available evidence suggests that reliance on clinical signs and endotracheal aspirate culture results leads to overdiagnosis of VAP. When performed before introduction of new antibiotics, the use of quantitative culture techiques after having obtained PSB and/or BAL specimens from the lung of patients with signs suggestive of VAP allows definition of a therapeutic strategy that is superior to that based exclusively on clinical evaluation, minimizing the use of unnecessary antibiotics with no adverse effects on patient outcome (see Fig. 43-2). In patients with clinical evidence of severe sepsis or patients with a very high pretest probability of the disease, the initiation of antibiotic therapy should not be delayed, and patients should be treated immediately with broad-spectrum antibiotics, even when no bacteria are detected using microscopic examination of pulmonary secretions. Although the true impact of this decision tree on patient outcome remains controversial, being able to withhold antimicrobial treatment from some patients without infection may constitute a distinct advantage in the long term by minimizing the emergence of resistant microorganisms in the ICU and redirecting the search for another (the true) infection site.

When quantitative culture techniques are not available to physicians treating patients clinically suspected of having VAP, we recommend following a clinical strategy, emphasizing that antimicrobial treatment should be re-evaluated on day 3, when susceptibility patterns of the microorganism(s) considered to be causative are available, in order to select treatment with a narrower spectrum or even to stop antimicrobial therapy if the clinical outcome is barely compatible with a diagnosis of pneumonia.[167]

Treatment

EVALUATION OF CURRENT ANTIMICROBIAL STRATEGIES

Despite many advances in antimicrobial therapy, successful treatment of patients with nosocomial pneumonia remains a difficult and complex undertaking. No consensus has been reached concerning issues as basic as the optimal antimicrobial regimen for therapy or duration of treatment. Although some investigators have recommended two-drug parenteral therapy for most cases, recent data have demonstrated the efficacy of newer β-lactam antibiotics as monotherapy for some patients. Similarly, the efficacy of endotracheal or aerosolized antibiotics as either the sole or adjunctive therapy for gram-negative pneumonia remains controversial. In fact, to date, evaluation of various antimicrobial strategies for the treatment of bacterial pneumonia in mechanically ventilated patients has been difficult for several reasons.

First, as indicated earlier, obtaining a definitive diagnosis of pneumonia in critically ill patients is far from easy. Although clinically distinguishing between bacterial colonization of the tracheobronchial tree and true nosocomial pneumonia is difficult, nearly all previous therapeutic investigations have relied solely on clinical diagnostic criteria and therefore probably have included patients who did not have pneumonia. Second, most of these studies used cultures of tracheal secretions as the major source of samples for microbiologic analysis despite the fact that the upper respiratory tract of most ventilated patients usually is colonized with multiple potential pathogens. Finally, the lack of an adequate technique to directly sample the infection site in the lung has hampered study of both the ability or inability of antibiotics to eradicate the causative pathogens from the lower respiratory tract and therefore the ability to predict their bacteriologic efficacy.

Recently, Montravers and colleagues[65] evaluated the bacteriologic and clinical efficacy of antimicrobial therapies selected on the basis of the etiologic microorganisms identified by cultures of PSB samples obtained during bronchoscopy for the treatment of nosocomial bacterial pneumonia in 76 patients receiving MV. Using follow-up PSB sample culture to assess the infection site in the lung directly, their results demonstrated that the administration of an antimicrobial therapy combining, in most cases, two effective agents was able to sterilize or contain the lower respiratory tract infection after only 3 days of treatment in 67 (88%) of the patients included in the study. The only two bacteriologic failures were observed in patients who did not receive adequate treatment because of errors in the selection of antimicrobial drugs. Early superinfection caused by bacteria resistant to the initial antibiotics was, however, documented in 7 (9%) patients, emphasizing the need to monitor carefully the impact of treatment on the initial microbial flora for optimal management of such patients when the clinical response is suboptimal. Furthermore, results of cultures of follow-up PSB samples were well correlated with the clinical outcome noted during the 15-day observation period, making this test a good prognostic indicator in patients with nosocomial bacterial pneumonia. Whereas the percentage of patients with clinical improvement was 96% and 82% in those with sterilized or persistent low-grade infection, respectively, it was only 44% in those with persistent high-grade infection.[65] Using such techniques to sample the infection site in the lung directly therefore may provide a more rigorous evaluation of different antimicrobial strategies.

FACTORS CONTRIBUTING TO SELECTION OF INITIAL TREATMENT

The important prognostic role played by the adequacy of the initial empirical antimicrobial therapy was analyzed by several investigators and is summarized in Table 43-5.[19,73,158,164,172–174] Factors to be considered for the optimal selection of initial antibiotic therapy include (1) putative causative pathogens and their patterns of antibiotic susceptibilities, based on the clinical setting and previous epidemiologic studies, (2) data obtained by surveillance cultures in the same patient, (3) information given by direct microscopic examination of pulmonary secretions, and (4) intrinsic antibacterial activities of antimicrobial agents and their pharmacokinetic characteristics.

TABLE 43-5 Mortality Rates According to Initial Empirical Antibiotic Therapy

First Author, Ref.	CRUDE MORTALITY RATES OF PATIENTS RECEIVING: Inadequate Antibiotic Therapy	Adequate Antibiotic Therapy	*p* Value
Luna, 172	92.2% ($n = 34$)	37.5% ($n = 15$)	<0.001
Alvarez-Lerma, 158	34.9% ($n = 146$)	32.5% ($n = 284$)	NS

Ruiz, 73	50.0% ($n = 18$)	39.3% ($n = 28$)	NS
Dupont, 174	60.7% ($n = 56$)	47.3% ($n = 55$)	NS

CLINICAL SETTING

Underlying diseases and specific risk factors may predispose patients to infection with specific organisms, as well as some intrinsic factors linked to each hospital or ICU.[26] Therefore, selection of initial antimicrobial therapy needs to be tailored to each institution's local patterns of antimicrobial resistance.[76] Patients with COPD, for example, are at increased risk of *H. influenzae* infection, whereas cystic fibrosis would increase the risk of *P. aeruginosa* and *S. aureus* infection. On the other hand, trauma and neurosurgical patients are at increased risk of *S. aureus* infection. Based on the results of a French prospective study in which the responsible microorganisms for infection in 135 consecutive episodes of VAP observed in the ICU were documented using bronchoscopic specimens, the distribution of infecting pathogens was influenced markedly by prior duration of MV and prior antibiotic use.[77] While early-onset pneumonias in patients who had not received prior antimicrobial treatment were caused mainly by susceptible Enterobacteriaceae, *Haemophilus* spp., MSSA, or *S. pneumoniae,* early-onset pneumonias in patients who had received prior antibiotics commonly were caused by nonfermenting GNB such as *P. aeruginosa,* in addition to streptococci and *Haemophilus* spp. On the other hand, late-onset pneumonias that occurred without antibiotics during the 15 days preceding the onset of infection largely were caused by streptococci, MSSA, or Enterobacteriaceae; however, some of these GNBs were class I cephalosporinase producers, which may require treatment with a new cephalosporin, such as cefepime or cefpirome, for optimal therapy. Late-onset pneumonias in patients having recently received antibiotics were caused by multiresistant pathogens such as *P. aeruginosa, A. baumannii,* or MRSA in more than 40% of cases. Taking these epidemiologic characteristics into account allowed the authors to devise a rational decision tree for selecting initial treatment in this setting that prevents resorting to broad-spectrum drug coverage in all patients (Table 43-6). A computerized decision-support program linked to computer-based patient records can facilitate the dissemination of such information to physicians for immediate use in therapy decision making and improve the quality of care.[175]

ROUTINE SURVEILLANCE CULTURE RESULTS

Several investigators have recommended routine surveillance cultures of ICU patients because they may be predictive of patients who are at high risk of invasive disease, and furthermore, should invasive disease develop, empirical therapy can be selected based on the predominant pathogens identified in these cultures.[15] However, the accuracy of this approach for selecting initial antimicrobial treatment for ICU patients requiring new antibiotics for VAP has not yet been established. This hypothesis was retested recently in a prospective study conducted on 125 patients who required MV for more than 48 hours and for whom strict bronchoscopic criteria were applied to diagnose pneumonia and identify the causative pathogens.[176] Although a large number of various prior microbiologic specimen culture results (mean = 45 ± 43 per episode) were obtained before FOB for each VAP episode, only 73 (33%) of the 220 VAP-causative microorganisms were isolated by these routine analyses and their susceptibility patterns available to guide initial antimicrobial treatment. When the analysis focused on VAP episodes for which prior (within 72 hours) respiratory secretion culture results were available, hypothesizing that this microbiologic information might be particularly useful for identifying the responsible organisms in the case of subsequent pneumonia, results were better but still disappointing because all causative pathogens were recovered for less than 60% of them. Such a strategy also may increase the workload of the microbiology laboratory considerably without having any positive impact on patient management.

Colonization with potentially drug-resistant pathogens, such as MRSA or extended-spectrum β-lactamase-producing strains of *Klebsiella pneumoniae* or other Enterobacteriaceae, is associated with an increased risk of infection caused by the corresponding microorganism. These results were confirmed

TABLE 43-6 Recommended Initial Antimicrobial Therapy in Patients with VAP

Early-onset VAP, no prior antibiotics:
- Nonpseudomonal third-generation cephalosporin *or*
- β-Lactam–β-lactamase inhibitor combination

Early-onset VAP, prior antibiotics; or late-onset VAP, no prior antibiotics:
- Aminoglycoside or ciprofloxacin
- *Plus* one of the following:
  - Ceftazidime
  - Cefepime
  - Cefoperazone
  - Piperacillin-tazobactam
  - Ticarcillin-clavulanic acid

Late-onset VAP, prior antibiotics:
- Aminoglycoside or ciprofloxacin
- *Plus* piperacillin-tazobactam or imipenem
- *Plus* vancomycin

in the study by Hayon and colleagues,[176] with positive predictive values of recovering such a microorganism from a specimen of 62%, 52%, or 24% for VAP caused by MRSA, *P. aeruginosa*, or *A. baumannii*, respectively. However, because the sensitivity of prior microbiologic culture results for identifying bacteria causing VAP do not exceed 70%, selection of initial antimicrobial therapy for patients with VAP hardly can be based only on these results, especially for deciding to use (or not) vancomycin and/or a broad-spectrum β-lactam, which are effective against *P. aeruginosa* and/or *A. baumannii*. However, when one of the three microorganisms (or any pathogen) is isolated from respiratory secretions within 72 hours of VAP, it probably should be covered by the antimicrobial regimen selected, even though predictive values do not exceed 50% to 60%.

INFORMATION GIVEN BY DIRECT EXAMINATION OF PULMONARY SECRETIONS

Direct microscopy of pulmonary secretions is extremely important not only to identify patients with true VAP but also to select appropriate treatment, especially when BAL specimens are used to prepare cytocentrifuged Gram-stained smears. In patients with pneumonia, the morphology and Gram staining of bacteria are closely correlated with the results of bacterial cultures, enabling early formulation of a specific antimicrobial regimen before the culture results are available. In a study of 94 mechanically ventilated patients with suspected VAP who underwent FOB with BAL and PSB, direct BAL fluid examination results were available within 2 hours, BAL and PSB culture results were available after 24 hours, and antibiotic susceptibility was available after 48 hours.[71] At each step in the strategy, the senior physician and the resident in charge of the patient were asked their diagnoses and their therapeutic plans based on the available data. Using a threshold of 1% infected cells, direct BAL examination discriminated well between patients with and without VAP (sensitivity 94%, specificity 92%, area under the receiver operating characteristic curve 0.95). In contrast, the senior clinical judgment before FOB was correct for only 71% of the patients compared with the definitive diagnosis and final antibiotic susceptibility test results. In addition, the therapeutic prediction was correct for 65% using clinical judgment (15 untreated patients, 3 ineffective treatments, and 15 unnecessary treatments), 66% using airway visualization (14 untreated VAP patients, 4 ineffective treatments, and 14 unnecessary treatments), and 88% using direct BAL examination results (1 untreated patient, 6 ineffective treatments, and 4 unnecessary treatments). Therefore, a strategy based on bronchoscopy and direct examination of BAL fluid may lead to more rapid and appropriate treatment of VAP than a strategy based only on clinical evaluation.

INTRINSIC ANTIBACTERIAL ACTIVITIES OF ANTIMICROBIAL AGENTS

Intrinsic antibacterial activities of antimicrobial agents used for the treatment of nosocomial pneumonia, based on frequently reported pathogens associated with this type of infection, are indicated in Table 43-7. Effective antibiotic treatment of bacterial pneumonia depends on adequate delivery of antibacterial agents to the infection site, and therefore, scrupulous attention must be given to optimal doses, route of administration, and pharmacodynamic characteristics of each agent used to treat this infection. Owing to major methodologic problems, published data concerning the penetration of most antibiotics into the lung probably should be viewed with caution, and only general trends concerning concentrations

TABLE 43-7 Intrinsic Antibacterial Activities of Antimicrobial Agents Used for Treatment of Nosocomial Pneumonia

achievable at the infected site in lung tissue can be derived from those studies.[177]

For penicillins and cephalosporins, the bronchial secretion-to-serum-drug-concentration ratios range between 0.05 and 0.25. Fluoroquinolones have better penetration characteristics, and bronchial secretion concentrations are between 0.8 and 2 times those in serum. Aminoglycosides and tetracyclines have ratios of 0.2 to 0.6. Host-related as well as drug-related factors may, however, influence the penetration of antimicrobial drugs across the blood-bronchus and alveolar-capillary barriers. Thus, for those drugs, such as the β-lactams and the glycopeptides, which do not cross membranes readily, penetration may increase in the presence of inflammation because of enhanced membrane permeability.[178]

Several published reports have demonstrated a relationship among serum concentrations of β-lactams or other antibiotics, the in vitro minimal inhibitory concentration (MIC) of the infecting organism, and the rate of bacterial eradication from respiratory secretions in patients with lung infection, thereby emphasizing that clinical and bacteriologic outcomes can be improved by optimizing the therapeutic regimen according to pharmacokinetic properties of the agent(s) selected for treatment.[179–182] Most investigators distinguish between antimicrobial agents that kill by a concentration-dependent mechanism (e.g., aminoglycosides and fluoroquinolones) and those that kill by a time-dependent mechanism (e.g., β-lactams and vancomycin).

Development of a priori dosing algorithms based on MIC, patient creatinine clearance and weight, and a clinician-specified pharmacokinetic-pharmacodynamic variable, such as the 24-hour area under the concentration-time curve divided by the MIC (AUIC), therefore may be a valid way to improve treatment of these patients, leading to a more precise approach than current guidelines for optimal use of antimicrobial agents.

DE-ESCALATION

Once the microbiologic data become available, it is necessary to de-escalate therapy to avoid prolonged use of a broader spectrum of antibiotic therapy than is justified by the available information.[183] For many patients, including those with late-onset infection, the culture data will not show the presence of highly resistant pathogens, and in these individuals, therapy can be narrowed or even reduced to a single agent in light of the susceptibility pattern of the causative pathogens without risking inappropriate treatment. While a de-escalating approach to antibiotic therapy (i.e., culture-guided treatment) may not help individual patients, it could benefit the ICU as a whole by reducing the selection pressure for resistance. Every possible effort therefore should be made to obtain, before new antibiotics are administered, reliable pulmonary specimens for direct microscope examination and cultures from each patient clinically suspected of having developed VAP.

MONOTHERAPY VERSUS COMBINATION THERAPY

Several studies have examined the use of a single antibiotic, e.g., a third-generation cephalosporin, imipenem-cilastatin, or a fluoroquinolone, to treat VAP.[27,184] In general, monotherapy has proven to be a useful alternative to combination therapy, with the same success rate and no more superinfections or colonizations by multiresistant pathogens.[185] Because these studies included nonhomogeneous populations of patients with different types of infections, and given the potential inaccuracy of using only clinical criteria to diagnose lung infection, further trials are needed to clarify all these uncertainties. Furthermore, for patients with severe infection due to *P. aeruginosa* or other multiresistant bacteria, such as *Klebsiella* spp. or *Acinetobacter* spp., combining an antipseudomonal β-lactam with an aminoglycoside or ciprofloxacin is likely to obtain a much better outcome than monotherapy, as shown previously. In a prospective clinical study of 200 patients with *P. aeruginosa* bacteremia, mortality rates for patients with pneumonia receiving monotherapy or combination therapy as the initial empirical treatment were 88% (7 of 8 patients) and 35% (7 of 20 patients), respectively ($p = 0.03$).[186] Similarly, for the subgroup of 55 patients who experienced hypotension within 72 hours prior to or on the day of the positive blood culture in a prospective observational study on 230 *Klebsiella* bacteremias, the mortality rate was significantly lower for patients who received combination therapy (24%) than for those given monotherapy (50%).[187] It should be noted, however, that the β-lactam agents used in these studies were older agents with less potent activity than the advanced cephalosporins or carbapenems available today.

Based on these data, it is probably safer to use a β-lactam antibiotic in combination with an aminoglycoside or a quinolone for patients with severe VAP, at least for the first days of therapy while culture results of pulmonary secretions are pending. It may be that monodrug therapies for nosocomial pneumonia would best be reserved for infections in which *P. aeruginosa* or other multiresistant microorganisms, such as *Klebsiella, Enterobacter, Citrobacter, Serratia,* or *Acinetobacter* spp. have been excluded as the etiologic agents.

DURATION OF ANTIMICROBIAL THERAPY

The optimal antimicrobial regimen and duration of therapy for patients who develop pneumonia have not been established. Most experts recommend that the duration be adapted to the severity of the disease, the time to clinical response, and the microorganism(s) responsible.[26] A "long" treatment, i.e., a minimum of 14 to 21 days, is prescribed for the following situations: multilobular involvement, malnutrition, cavitation, gram-negative necrotizing pneumonia, and isolation of *P. aeruginosa* or *Acinetobacter* spp., which correspond to the majority of pulmonary infections occurring in patients requiring mechanical ventilation. This duration is essentially justified by the high theoretical risk of relapse, especially in case of infection caused with *P. aeruginosa,* which is particularly difficult to eradicate from the respiratory tract.[188] Thus, at present, a short-term regimen is rarely prescribed in patients who develop VAP, despite the potential major advantages it could have in terms of bacterial ecology and the prevention of emergence of multiresistant bacteria. Lowering the amount of antibiotics administered to patients hospitalized in ICUs is indeed a primary objective of every strategy aimed at reducing the emergence and dissemination of such bacteria.[189]

Prevention

Because VAP has been associated with increased morbidity, longer hospital stays, increased health care costs, and higher mortality rates, prevention of this infection is a major

challenge for intensive care medicine. A number of preventive strategies have been tested, and a number of recommendations have been published.[120,190–194] However, evaluation of the impact of such interventions is a complex issue. Three methodologic difficulties make the measurement of potential efficacy of prevention strategies for VAP of limited value: (1) the difficulty of obtaining an accurate diagnosis of VAP (in fact, only patients who develop true VAP are likely to benefit from preventive measures), (2) the difficulty of precisely determining the impact of prophylactic measures on the overall mortality of a general ICU population (i.e., to identify preventable deaths directly attributable to VAP among all deaths occurring in a population of ventilated ICU patients), and (3) the difficulty of assessing the consequences of a preventive measure on a potentially pathogenic mechanism—a surrogate outcome (e.g., to determine the exact role played by prevention or reduction or modulation of tracheal colonization in modifying the development of VAP).

CONVENTIONAL INFECTION CONTROL APPROACHES

These measures should be the first step taken in any prevention program.[195] The design of the ICU has a direct effect on the potential for nosocomial infections. Adequate space and lighting, proper functioning of ventilation systems, and adequate facilities for hand washing lead to lower infection rates.[196] However, it should be kept in mind that physical upgrading of the environment does not per se reduce the infection rate unless personnel attitude and practices are improved. In any ICU, one of the most important factors is probably the team that staffs it: the number, quality, and motivation of its medical, nursing, and ancillary members. The team should include a sufficient number of nurses to avoid having them move from one patient to another and to avoid working under constant pressure.[197] The importance of personal cleanliness (education and awareness programs) and attention to aseptic procedures (simple barrier isolation methods based on the use of disposable gowns and nonsterile gloves) must be emphasized at every possible opportunity. It is clear that careful monitoring, decontamination, and compliance with the usage guidelines of respiratory equipment decrease the incidence of nosocomial pneumonia.[198] In any case, hand washing or hand rubbing with alcohol-based solutions remains uncontested as the most important infection control practice.[197,199]

A bacterial monitoring policy facilitates the early recognition of colonization and infection and has been associated with statistically significant reductions in nosocomial infection rates.[200] The focal point for infection control activities in the ICU is a surveillance system designed to establish and maintain a database that describes endemic rates of nosocomial infection. Awareness of the endemic rates enables recognition of the onset of an epidemic when infection rates rise above a calculated threshold.

Preventing infection by modifying host risk has focused on treatment of underlying diseases and complications and control of antibiotic use. Adoption of an antibiotic policy restricting the prescription of broad-spectrum agents and useless antibiotics is of major importance.[201] Simple, safe, inexpensive, logical, but unproven measures, including the use of physiotherapy,[202] the judicious use and prompt removal of nasogastric tubes,[43] and removal of tubing condensate, may have tremendous impact on the frequency of nosocomial pneumonia in mechanically ventilated patients.[124]

SPECIFIC PROPHYLAXIS AGAINST VAP

Since invasive MV is a risk factor for VAP, strategies that reduce its duration may reduce its incidence. Optimization of weaning protocols is a first way to reduce the duration of exposure to risk.[203,204] Noninvasive ventilation is an alternative approach to the use of artificial airways to avoid infectious complications and injury of the trachea in patients with acute respiratory failure. Many observations and studies, unfortunately small and not blinded, suggest that patients who tolerate noninvasive ventilation have a lower incidence of pneumonia than those intubated tracheally, whatever the possible explanations: noninvasive ventilation itself or differences in disease severity, in the distribution of risk factors for VAP, or in the duration of exposure to each of the two ventilation methods.[205–208] However, although seven randomized trials have compared noninvasive ventilation with conventional MV for prevention of pneumonia, only one could demonstrate a statistically significant benefit in favor of noninvasive ventilation.[204,209–214]

Apart from these protocols aiming at reducing the duration of mechanical ventilation, seven prophylactic approaches have been studied: semirecumbent positioning, oscillating and rotating beds, continuous or intermittent aspiration of subglottic secretions, ventilator circuits management, methods of enteral feeding, stress ulcer prophylaxis, and antibiotic use, including selective digestive decontamination.

SEMIRECUMBENT POSITIONING

Supine patient positioning has been shown to be independently associated with the development of VAP.[37] Placing ventilated patients in a semirecumbent position to minimize reflux and aspiration of gastric contents is a simple measure, although some practical problems can occur in unstable patients. Three trials have evaluated the potential efficacy of semirecumbent positioning,[122,215,216] but only one measured the incidence of VAP.[215] This trial, which included 86 intubated and mechanically ventilated patients, was stopped after the planned interim analysis because the frequency and risk of VAP were significantly lower for the semirecumbent group. These findings were confirmed indirectly by demonstration that the head position of the supine patient during the first 24 hours of MV was an independent risk factor for acquiring VAP.[215] No adverse effects were observed in patients assigned to semirecumbent positioning.

Semirecumbent positioning is a low-cost, low-risk preventive approach that merits being considered in all ventilated patients, whenever feasible.

OSCILLATING AND ROTATING BEDS

Immobility in critically ill patients treated with MV results in atelectasis and impaired secretions drainage and potentially predisposes to pulmonary complications, including VAP. Oscillating and rotating beds may help in preventing pneumonia.[217–224] Six randomized trials, including mostly surgical and trauma patients, ventilated or not, summarized in a meta-analysis by Choi and Nelson[225] have compared continuous lateral rotational therapy with standard beds for

the prevention of nosocomial pneumonia. The meta-analysis found a statistically significant reduction in the risk for pneumonia, principally concerning early-onset (<5 days) pneumonia, and a decreased duration of ICU stay. However, five of these studies were limited to surgical patients or those with neurologic impairment. The sixth study, which included primarily medical patients, found no significant benefit.[219] A recent randomized, controlled trial of medical and surgical patients not included in the meta-analysis also found no benefit to oscillating beds.[226] Some adverse events have been described with these beds, including disconnection of catheters or pressure ulceration; in addition, nursing care potentially is complicated with oscillating beds. Despite the cost of such beds, cost-benefit analyses performed in those studies seem favorable, mainly due to the shorter duration of the ICU stay.

Although oscillating or rotating beds have no apparent benefit in general populations of medical patients, there is reasonably good evidence that this practice may be effective in surgical patients or patients with neurologic problems. Use of these beds in these select patient populations therefore should be considered.

ASPIRATION OF SUBGLOTTIC SECRETIONS

Continuous or intermittent aspiration of oropharyngeal secretions has been proposed to avoid chronic aspiration of secretions through the tracheal cuff of intubated patients. Aspiration of subglottic secretions requires the use of a specially designed endotracheal tube with a separate lumen that opens into the subglottic region. Three randomized, controlled trials have studied aspiration of subglottic secretions for the prevention of VAP.[227–229] Mahul and colleagues[227] found that pneumonia was significantly less frequent in patients with endotracheal tubes having a separate dorsal lumen for hourly suctioning of stagnant secretions above the cuff than in others and that VAP development was delayed. Similarly, in a 3-year prospective, randomized, controlled study, Valles and colleagues[228] documented a lower VAP rate when continuous subglottic aspiration was performed. However, this difference was fully explained by the VAP occurring during the first week, whereas late-onset pneumonias were more frequent in the aspiration group. Furthermore, detailed microbiologic analysis demonstrated that this reduction concerned only pneumonia due to *H. influenzae* or gram-positive cocci. The incidence of VAP due to *P. aeruginosa* or Enterobacteriaceae did not differ between the two groups.[228] Kollef and colleagues[229] performed a randomized trial on 343 post–cardiac surgery patients to compare continuous subglottic aspiration and standard postoperative medical care. Although those authors found similar rates of VAP in both groups, VAP episodes occurred significantly later in patients receiving subglottic aspiration than in those treated conventionally. No difference in mortality rates was observed in these three studies. Whereas no adverse events were reported with aspiration of subglottic secretions in the three studies just reported, experimental data have suggested the possibility of tracheal damage in sheeps intubated with this type of tube.[230]

Aspiration of subglottic secretions is a promising strategy for the prevention of early-onset VAP but cannot be recommended for general use because of the mixed results in the literature. Further study of this approach is warranted.

VENTILATOR CIRCUIT MANAGEMENT

Decreased frequency of ventilator circuit changes, replacement of heated humidifiers by heat and moisture exchangers, decreased frequency of heat and moisture exchanger changes, and closed suctioning systems all have been tested for preventing VAP. Four randomized trials of decreased frequency of ventilator circuit changes have been published[231–234] comparing changes every 2 days, 7 days, and no scheduled change and did not find any significant differences in the rate of VAP, as summarized in a recent meta-analysis.[235] One meta-analysis summarized the results of five randomized, controlled trials that compared the effects of heated humidifiers and heat and moisture exchangers on the risk of VAP.[194] Only one out of these five studies found a significant reduction of VAP rate with the use of heat and moisture exchangers.[236] The efficacy of both humidification strategies seems comparable; however, two studies reported increased rates of endotracheal tube occlusion with the use of heat and moisture exchangers.[194] Another potential caveat of these devices includes an increased resistive load resulting in difficulties in the ventilation and weaning process of patients with severe ARDS.[237] Finally, one study evaluated the impact of less frequent changes (daily versus every 5 days) of heat and moisture exchangers on the development of VAP.[238] No differences in the VAP rates were observed.

A policy of no circuit changes or infrequent circuit changes is simple to implement, does not lead to increased development of VAP, and costs less than frequent, regular circuit changes. Such a policy should be considered in all mechanically ventilated patients. The favorable impact of the use of heat and moisture exchangers on the risk of VAP has to be confirmed before being recommended for general use.

To avoid hypoxia, hypotension, and contamination of suction catheters entering the tracheal tube, investigators have examined closed suctioning systems.[239–241] While some found a nonsignificantly lower prevalence rate of VAP for patients managed with the closed system compared with those with the open system,[241] others not only failed to show a statistically significant protective effect of the closed system on the incidence of VAP but also observed an increased frequency of endotracheal colonization associated with the closed device.[239] At the present time, use of theses devices cannot be recommended for preventing VAP.

METHODS OF ENTERAL FEEDING

Nearly all patients receiving mechanical ventilation have a nasogastric tube inserted to manage gastric and enteral secretions, prevent gastric distention, or provide nutritional support. The nasogastric tube may increase the risk for gastroesophageal reflux, aspiration, and VAP.[43] Four randomized, controlled trials have evaluated various methods of enteral feeding aimed at preventing VAP: postpyloric or jejunal feeding (versus gastric feeding), the use of motility agents (metoclopramide versus placebo), acidification of feeding (with addition of hydrochloric acid), and intermittent (versus continuous) feeding.[242–245] These studies did not find differences in the incidence of VAP and/or mortality rates. Potentially serious adverse effects have been observed in patients receiving acidified feeding (gastrointestinal bleeding) or intermittent enteral feeding (increased gastric volume and lower volumes of feeding). Thus, to date, methods of enteral feeding aimed

to reduce the incidence of VAP cannot be recommended for routine use.

STRESS ULCER PROPHYLAXIS

Gastric colonization by potentially pathogenic organisms has been shown to increase with decreasing gastric acidity.[246] Thus medications that decrease gastric acidity (antacids, H_2 blockers) may increase organism counts and increase the risk for VAP. In contrast, medications that do not affect gastric acidity, such as sucralfate, may not increase this risk.

Seven meta-analyses of more than 20 randomized trials have evaluated the risk for VAP associated with the methods used to prevent gastrointestinal bleeding in critically ill patients.[97,98,100,105,106,247,248] Four of these seven meta-analyses reported a significant reduction in VAP incidence with sucralfate therapy compared with H_2 blockers[97,100,106] and three a statistically significant mortality benefit.[98,100,105]

However, the relationships between prophylaxis of stress ulcer and prophylaxis of VAP are complex: (1) VAP is a possible indirect consequence of the use of drugs that raise the stomach pH, (2) gastrointestinal bleeding is a serious complication in critically ill patients at high risk for stress ulcer (e.g., patients with coagulopathy or the need for prolonged mechanical ventilation) but is extremely rare in patients at low to moderate risk, (3) the largest randomized trial comparing ranitidine with sucralfate showed that ranitidine was superior in preventing gastrointestinal bleeding and did not increase the risk of VAP,[107] and (4) the risk of VAP is unknown when accurate methods of enteral feeding or other preventive measures are used in combination with stress ulcer prophylaxis.

Clinicians must weigh the potential benefit of sucralfate (with potentially less VAP and more gastrointestinal bleeding) versus H_2 blockers (with potentially more VAP and less gastrointestinal bleeding) and probably limit stress ulcer prophylaxis to high-risk patients.

SELECTIVE DIGESTIVE DECONTAMINATION

There is theoretical interest in using topical antibiotics to sterilize the oropharynx and stomach in mechanically ventilated patients, with the goal of reducing the incidence of VAP.[249] Several groups have used topical prophylactic antibiotics for selective decontamination of the oropharynx and digestive tract (SDD) in patients at high risk for nosocomial pneumonia. The SDD regimen usually includes a short course of systemic antibiotic therapy, such as cefotaxime, trimethoprim, or a fluoroquinolone, and nonabsorbable local antibiotic prophylaxis consisting of a combination of an aminoglycoside, polymyxin B, and amphotericin.[249] Since the original studies published by Stoutenbeck and colleagues[250,251] in 1984, which demonstrated a decrease of the overall infection rate in patients receiving the SDD regimen, more than 40 randomized, controlled trials and 7 meta-analyses have been published.[91,252–258] All seven meta-analyses reported a significant reduction in the risk of VAP, and four reported a significant reduction in mortality.[91,254,255,257] No mortality benefit occurred with topical prophylaxis alone.[91,252,254,257] However, a clear consensus as to the effectiveness of SDD has not been established owing to limitations and methodologic deficiencies of the studies analyzed.[104,259] Furthermore, the impact of SDD on the emergence of resistant organisms is currently unknown but potentially important.[260,261]

Conclusions drawn based on meta-analyses of SDD studies may be summarized as follows: (1) SDD reduces the incidence of VAP and, when a combined topical and systemic regimen is used, may reduce mortality, (2) an inverse relationship has been described between methodologic quality of the studies and benefit, questioning the overall value of results reported in the meta-analyses, (3) the long-term effects of SDD on emergence of resistance and risk of superinfections currently are unknown, and finally, (4) the impact of SDD on the duration of MV, ICU stay, and hospital stay appears to be limited. Thus, at present, this approach cannot be recommended for overall populations of ICU patients treated with MV, although SDD may be effective for specific populations, particularly surgical or trauma patients.

Early attempts at systemic prophylaxis with parenteral antibiotics alone against pneumonia clearly were unsuccessful.[262,263] In contrast, recent studies showed that a short-course antibiotic regimen in patients with structural coma or severe burns was an effective prophylactic strategy to decrease the VAP rate.[92] The influence of rotating of antibiotics (generally associated with restrictive use) in the ICU on VAP prevalence was investigated recently by comparing successive periods during which one antibiotic was used in place of another for the empirical treatment of suspected gram-negative bacterial infections. Some investigators found that VAP occurred significantly less frequently during the after period compared with the before period.[264–266]

Chapter 44

LIBERATION FROM MECHANICAL VENTILATION

CONSTANTINE A. MANTHOUS
GREGORY A. SCHMIDT
JESSE B. HALL

KEY POINTS

- *Patients are candidates for liberation from mechanical ventilation when gas exchange or circulatory disturbances that precipitated respiratory failure have been reversed.*
- *More than half of all critically ill patients can be liberated successfully from mechanical ventilation after a brief trial of spontaneous breathing on the first day that reversal of precipitating factors is recognized. Gradual reduction of mechanical support, termed* weaning, *frequently is unnecessary and can prolong the duration of mechanical ventilation.*
- *Once a patient has been liberated from the ventilator, extubation should follow if mechanisms of airway maintenance (e.g., cough, gag, and swallow) are sufficient to protect the airway from secretions. Whether to extubate is a decision that follows successful liberation from the ventilator.*
- *In patients who fail their first trial of spontaneous breathing, attention should turn to defining and treating the pathophysiologic processes underlying failure.*
- *Weaning regimens that use ventilator modes with the goal of improving respiratory muscle endurance have not been proved to expedite liberation, but data from animal models suggest that "exercise" may be beneficial. Approaches attempting to exercise the respiratory muscles should not substitute for daily interrogation of readiness for spontaneous breathing.*
- *One weaning regimen, the gradual reduction of intermittent mandatory breaths, prolongs patients' time on mechanical ventilation.*
- *Liberation from mechanical ventilation is achieved most expeditiously if patients with a stable circulation (not on pressors or with evolving myocardial infarction) and adequate oxygenation are given a trial of spontaneous breathing (T piece or pressure support $\leq$ 7 cm H_2O) each day. Patients remain on ventilators unnecessarily when clinicians do not put this simple plan in place.*
- *Patients who have had most correctable factors addressed and remain marginal with regard to ventilatory capacity in most circumstances should undergo a trial extubation rather than remain intubated for protracted periods. Noninvasive positive-pressure ventilation is extremely useful in these patients to transition them to fully spontaneous breathing following extubation.*

Respiratory failure occurs when the lungs and respiratory pump fail to exchange oxygen and carbon dioxide adequately (see Chap. 31). Hypoxemic (type 1) respiratory failure usually results from flooding or collapse of the distal airspaces leading to intrapulmonary shunt and inadequate arterial oxygenation despite generous concentrations of inspired oxygen (see Chap. 38). Hypercapnic (type 2) respiratory failure results from inability to sustain sufficient alveolar ventilation to eliminate the CO_2 produced from aerobic metabolism. Perioperative respiratory failure, a special case of types 1 and 2, results when postoperative pain and recumbency result in atelectasis and hypoxemia or when medications to alleviate pain reduce respiratory drive, leading to hypercapnia. Shock-related respiratory failure is another special case in which the underperfused respiratory muscles are unable to compensate for the acidosis resulting from inadequate global tissue perfusion. Mechanical ventilation substitutes for the respiratory pump until these disturbances have been reversed adequately to allow resumption of spontaneous breathing and gas exchange.

Institution of positive-pressure ventilation can be lifesaving for the disorders just described but is also associated with many complications (Table 44-1), and if this form of life support is extended beyond the point at which it is absolutely necessary, it may result in unnecessary morbidity and mortality for the patient. Most studies have demonstrated that earlier withdrawal of mechanical ventilatory support, when feasible, is associated with better outcomes for the patient. We will discuss the cardiopulmonary effects of positive-pressure ventilation and then outline principles and approaches to the withdrawal of mechanical ventilation in a way to achieve this milestone of critical care management at the earliest possible time and in the safest possible fashion.

Cardiopulmonary Effects of Positive-Pressure Ventilation and Its Cessation

PULMONARY EFFECTS

Positive-pressure ventilation (PPV) is the most common mode of mechanical ventilation used in critically ill patients. PPV can deliver an inspiratory volume or pressure to the lungs and can provide positive end-expiratory pressure (PEEP). PEEP reduces the likelihood of end-expiratory alveolar collapse, thus preserving functional residual capacity.[1,2] When used properly, PPV and PEEP can achieve and maintain alveolar recruitment and improve oxygenation. Excessive PPV or PEEP levels also can have adverse effects on gas exchange by reducing cardiac output or by increasing physiologic dead space.[2,3]

The discontinuation of mechanical ventilation increases the propensity for atelectasis, especially in patients with respiratory muscle weakness, restrictive physiology (e.g., obesity), or respiratory depression. In patients with lung injury, surfactant depletion and ultrastructural lung changes increase the likelihood of alveolar collapse (see Chap. 38). Thus cessation of PPV or PEEP may lead to atelectasis and hypoxemia (Table 44-2). In addition, the transition to spontaneous ventilation frequently is associated with increased venous return, which can precipitate pulmonary edema and hypoxemia. Finally, for patients with unrepaired imbalance between respiratory system load and neuromuscular competence, discontinuation of mechanical ventilation will precipitate

TABLE 44-1 Complications Associated with Endotracheal Intubation and Mechanical Ventilation

COMPLICATIONS RELATED TO THE ENDOTRACHEAL TUBE
Endotracheal tube malfunction—mucus plug, cuff leak
Endotracheal tube malposition
Self-extubation
Nasal or oral necrosis
Pneumonia
Laryngeal edema
Tracheal erosion
Sinusitis
COMPLICATIONS RELATED TO THE VENTILATOR
Alveolar hypoventilation/hyperventilation
Atelectasis
Hypotension
Pneumothorax
Diffuse alveolar damage
EFFECTS ON OTHER ORGAN SYSTEMS
Gastrointestinal hypomotility
Pneumoperitoneum
Stress gastropathy and gastrointestinal hemorrhage
Arrhythmias
Salt and water retention
Malnutrition

the symptoms and signs of recurrent ventilatory failure (Fig. 44-1).

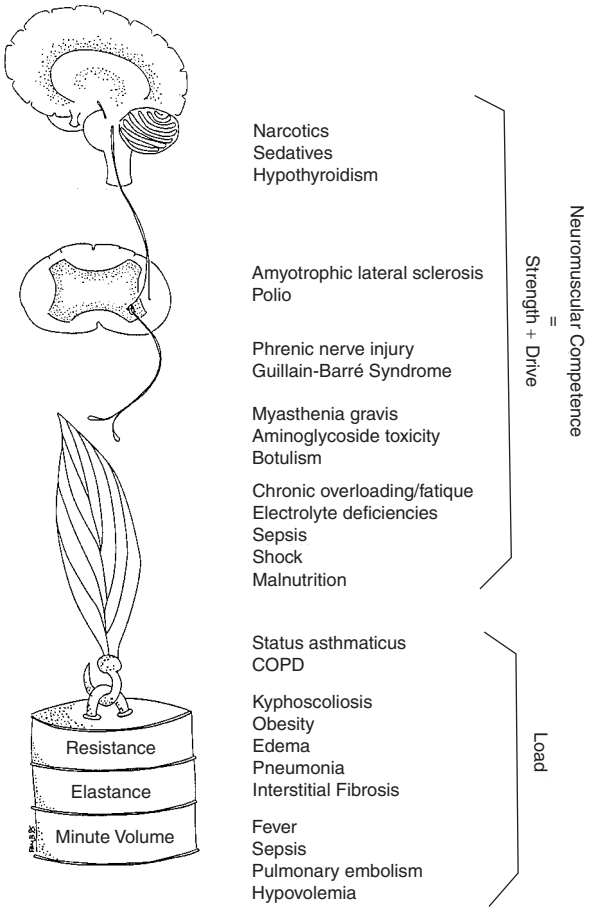

FIGURE 44-1 The neuromuscular circuit. This diagram summarizes the components of neuromuscular competence and respiratory muscle load and illustrates processes that can affect the strength-load balance leading to ventilatory failure. ***(Reproduced with permission from Manthous CA, Siegel M: Ventilatory failure, in Matthay et al (eds): Pulmonary and Critical Care Yearbook, vol 3. St. Louis, Mosby, 1996, Chap 2.)***

CARDIOVASCULAR EFFECTS

The principal circulatory effects of PPV and PEEP are to reduce biventricular preload[4–9]and left ventricular afterload.[4,10–13] PPV and PEEP also may increase right ventricular afterload by increasing lung volumes.[14] When patients begin to breathe spontaneously, intrathoracic pressures that were positive on inspiration during PPV and PEEP become negative. Accordingly, the transition from PPV and PEEP to

TABLE 44-2 Pathogenesis of Hypoxemia and Hypercapnia with Cessation of Mechanical Ventilation

FACTORS CONTRIBUTING TO HYPOXEMIA
Pulmonary edema due to mobilization of peripheral edema
Atelectasis due to recumbency, old age, obesity, residual sedatives, surfactant depletion (in patients with diffuse alveolar damage)
Hypoventilation
Withdrawal of PEEP
Increased $\dot{V}_{O_2}$ due to the work of breathing
Congestive heart failure precipitated by increased work of breathing
FACTORS CONTRIBUTING TO HYPERCAPNIA
Hypercapnia due to strength-load imbalance = ventilatory failure (see Table 44-3)
Reduced respiratory muscle strength
Sepsis, malnutrition, electrolyte derangements, prolonged mechanical ventilation, dyssynchronous mechanical ventilation, corticosteroids, postparalytic syndrome
Increased respiratory muscle loads
Resistance—bronchospasm, excessive secretions, endotracheal tube
Elastance—pulmonary edema, dynamic hyperinflation, obesity
Minute volume—hypermetabolism, increased dead space, fever, overfeeding
Other hypercapnia—does not necessarily signal ventilatory failure
Compensation for metabolic alkalosis
Acute return to premorbid P_{CO_2} after iatrogenic hyperventilation
Hyperoxic hypercapnia (in chronic hypercapnic respiratory failure patients)
Residual sedatives/narcotics

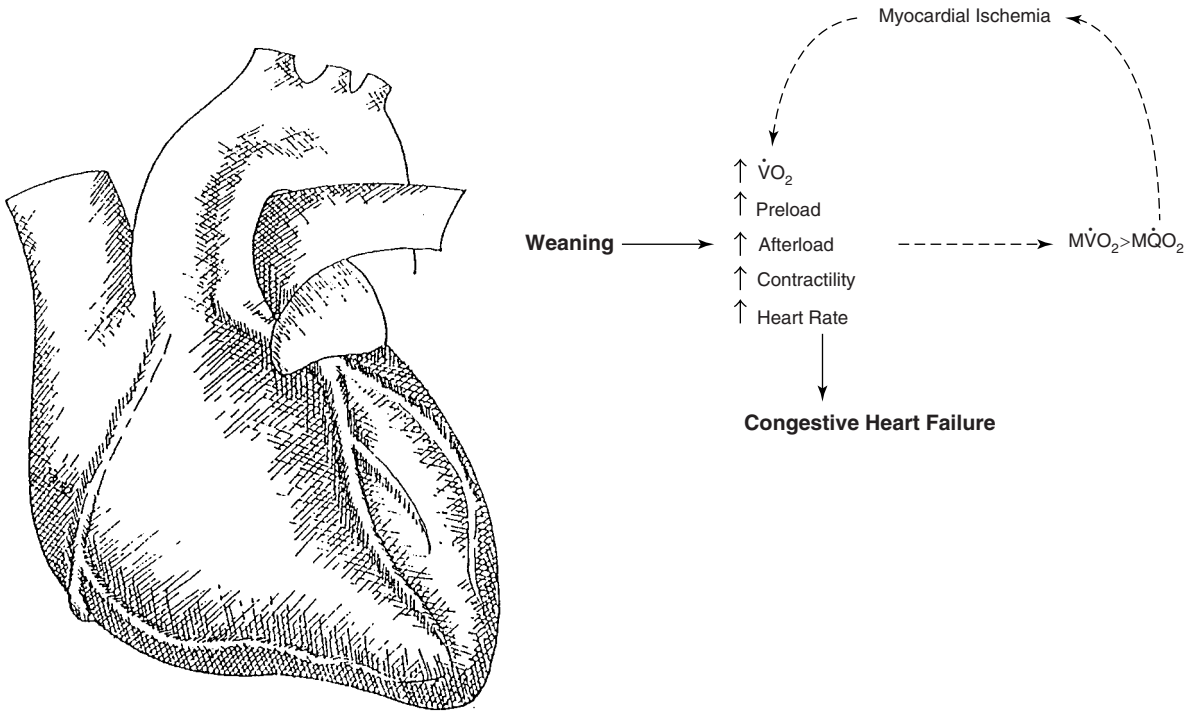

FIGURE 44-2 Pathophysiologic mechanisms of weaning-related ischemia and congestive heart failure. $\dot{V}O_2$, global oxygen consumption; $M\dot{V}O_2$, myocardial oxygen consumption; $M\dot{Q}O_2$, myocardial oxygen supply.

unassisted breathing causes acute increases in venous return and left ventricular afterload. In patients with normal hearts, these circulatory changes usually are well tolerated. However, in patients with left ventricular dysfunction, augmentation of venous return and increased left ventricular afterload increase left heart transmural pressures substantially. In addition, increased cardiac loads during weaning may precipitate ischemia in patients with coronary artery disease. Thus the transition from PPV to spontaneous breathing is accompanied by multiple events that can contribute to left ventricular failure and cardiogenic pulmonary edema (Fig. 44-2).

Expediting Liberation from Mechanical Ventilation

In order to minimize the duration of ventilator dependence, the clinician must:

1. Identify the pathogenesis of respiratory failure in each patient and institute appropriate treatment based on this pathophysiology.
2. Prevent iatrogenic complications associated with mechanical ventilation.
3. Detect when the patient is ready to breathe without the machine.

Since mechanical ventilation has numerous risks, including infection and barotrauma[15–17] (see Table 44-1), it is appropriate to work aggressively to repair the "broken" patient and determine each day whether the patient still requires the ventilator. In this section we delineate the physiologic changes that occur during and the impact of underlying diseases on the transition to spontaneous breathing. We highlight methods used to expedite readying the patient for liberation and to identify patients who are appropriate candidates for liberation from mechanical ventilation. We also describe an approach to patients who do not succeed rapidly at being liberated from mechanical ventilation.

ITEM 1: FIX THE PATIENT

Although it may seem intuitive that an organized systematic approach aimed at remedying the pathogenesis of disease should expedite liberation from mechanical ventilation, only recently has a study examined the efficacy of such an approach. Smyrnios and colleagues[18] examined the utility of a combined protocol to identify and repair pathophysiology that binds patients to ventilators *and* recognize readiness to breathe spontaneously. This approach resulted in a substantial reduction in ventilator days and costs and expedited patient throughput. However, it is not possible to determine the degree to which the specific systematic approach of fixing the patient versus the liberation protocol contributed to the observed improvements. While from this study or the available literature it is not possible to determine the relative importance of each of these arms of treatment of respiratory failure, it is certain that both are crucial. Accordingly, from the very first day a patient requires intubation, it is worthwhile to define the mechanisms causing the need for initiation of mechanical ventilation. This can be approached through the following questions:

1. Did the patient need the ventilator, an artificial airway, or both? A significant number of patients are intubated for airway incompetence in the absence of significant hypoxemia or causes of hypercapneic respiratory failure. Disorders leading to an incompetent airway include primary neurologic diseases that attenuate airway protective reflexes

or primary mechanical airway problems such as airway obstruction or insufficient cough to expectorate secretions.

2. If the patient needed the ventilator, was the mechanism of respiratory failure acute hypoxemia, hypercapnia (ventilatory failure), or a combination of these abnormalities? This is usually apparent from the clinical presentation combined with data obtained shortly after intubation. Patients whose initial presentation is poor oxygenation despite high concentrations of inspired oxygen (i.e., 100% facemask) most often have shunt physiology with atelectasis and/or alveolar flooding with blood, pus, or edema. Patients with acute hypercapnia can be separated into two categories: those with diminished drive to breathe (e.g., narcotic/sedative overdose) manifesting as a relatively comfortable patient with diminished level of consciousness and no respiratory distress *or* those who are uncomfortable and tachypneic, suggesting an imbalance between respiratory muscle strength and endurance and the load on the respiratory system. Some patients present with elements of both elevated work of breathing *and* hypoxemia, such as a patient with pneumonia with both a large intrapulmonary shunt producing hypoxemia and the consolidated lung increasing lung elastance and the work of breathing.

Hypotheses regarding pathogenesis can be confirmed shortly after intubation by evaluation of the chest radiograph and by using the mechanical ventilator as a pulmonary function machine. Lobar atelectasis usually is seen as an abnormal opacity, but subsegmental atelectasis can cause a shunt that is not obvious on a chest radiograph. Atelectasis often improves with PPV unless caused by airway obstruction. Patients with hypoxemia requiring high F_{IO_2} and PEEP levels and lung opacities generally have alveolar flooding processes. Other clinical data are then used to confirm the mechanism of flooding. Appropriate history, purulent endotracheal secretions, and leukocytosis point to pneumonia. A dropping hematocrit with or without bloody endotracheal secretions suggests alveolar hemorrhage. Four-quadrant, relatively homogeneous airspace filling on chest radiograph suggests pulmonary edema (in the absence of hemorrhage), and attention turns to determining whether left ventricular dysfunction and/or hypervolemia are responsible or if capillary leak has resulted in hypoxemia (i.e., acute lung injury, acute respiratory distress syndrome). Clinicians should define the pathophysiology and treat underlying causes as appropriate.

In patients with hypercapnic respiratory failure, attention turns to examination of the elements of neuromuscular capacity and respiratory load. Although *primary* respiratory "pump" failure occurs occasionally (requiring one to consider a series of neurologic disorders, including CNS depression, polio or ALS, Guillain-Barré syndrome, phrenic nerve dysfunction, myasthenia gravis, and muscle dysfunction due to electrolyte deficiencies, medications, or sepsis; see Fig. 44-1), most commonly hypercapnic failure results from overloading of the neuromuscular apparatus. The three respiratory muscle loads are

1. *Flow-resistive pressure cost of breathing.* This is a function of the magnitude of flow and the resistance of the conducting airways, where Pr = flow × resistance. When the patient is on the ventilator and flow is delivered in a constant (square-wave) regime, Pr = (peak airway pressure – plateau airway pressure)/flow. If measured with a constant flow of 60 L/min (1 L/s), Pr = peak – plateau pressure yields resistance in centimeters of water per liter per second. These are the units used in the pulmonary function laboratory; since a 6- to 8-mm endotracheal tube and ventilator tubing contribute 5 to 10 cm H_2O/L per second and normal airway resistance is less than 5 cm H_2O/L per second, total resistance that is greater than 10 to 15 cm H_2O/L per second after the patient is intubated is abnormal. Removal of airway secretions and administration of bronchodilators and, if required, corticosteroids are used to treat elevated airway resistance related to airway disease. Left-sided heart dysfunction also may contribute to increased airway resistance (cardiac asthma) and should be considered in patients with known or suspected cardiac disease.
2. *Elastic pressure cost of breathing.* This refers to the pressure required to expand the lung and chest wall from functional residual capacity to a given tidal volume; Pel = Ers × VT, where Ers = elastance of the respiratory system and VT = tidal volume. The elastic (plateau) pressure can be measured on the ventilator with an inspiratory pause of 0.5 to 1.0 second. The inverse of the elastance—the compliance—can be computed as VT/plateau pressure – PEEP, normal being 50 mL/cm H_2O. If compliance is decreased (elastance increased), one must determine whether the lung or chest wall is responsible. Chest wall noncompliance, which arises from conditions such as abdominal distention, obesity, and kyphoscoliosis, is usually readily apparent by clinical examination. Lung noncompliance usually is associated with lung infiltrates, large pleural effusions, or dynamic hyperinflation (due to increased airway resistance and/or hyperventilation).
3. *Minute volume.* This is not a *mechanical* load of breathing, but insofar as a higher minute volume requires more resistive and elastic pressure work of breathing (more breaths per minute), a higher minute volume loads the neuromuscular apparatus. Since minute volume equals alveolar ventilation plus dead space, any process that increases these will increase minute volume requirements. Alveolar ventilation can be increased by excess CO_2 production, such as occurs in sepsis/systemic inflammatory responses and overfeeding, or by inefficient elimination (high dead space), such as occurs in late-stage acute respiratory distress syndrome (ARDS), chronic obstructive pulmonary disease (COPD), and pulmonary embolism.

After stabilizing patients on a ventilator, the three loads are measured easily, and if they are elevated, they likely contributed to respiratory muscle failure and hypercapnia. If they are completely normal, one reconsiders the possibility of either diminished drive to breathe or a cause of neuromuscular weakness that includes the respiratory muscles.

Hypercapnic respiratory failure occurs clinically in one of three ways: acute, chronic, and acute on chronic. In *acute hypercapnic respiratory failure,* a sudden mismatch of respiratory load to neuromuscular competence places the patient in acute respiratory failure over minutes to hours. There is an abrupt increase in Pa_{CO_2} with no metabolic correction and a blood pH

consistent with an acute respiratory acidosis. In *chronic hypercapnic respiratory failure,* the mismatch of respiratory load to neuromuscular competence has been long-standing and usually gradual in evolution—over days to weeks or even years. Pa_{CO_2} elevation exists, but metabolic correction is near complete. Typically, pH is 7.30 to 7.36. These patients are particularly vulnerable to acute increments of load or decrements of capacity, termed *acute-on-chronic hypercapnic respiratory failure.* The respiratory muscles are unable to respond to the new insult, and Pa_{CO_2} rises too fast for immediate renal compensation. pH is usually less than 7.30, Pa_{CO_2} is much greater than 40 mm Hg, and bicarbonate is elevated (>24 mEq/L), the "footprint of chronicity." In such cases, clinicians should seek to understand the pathogenesis of the chronic component and to define which loads and/or decrements of capacity have contributed to the acute component.

ITEM 2: PREVENT IATROGENIC COMPLICATIONS OF MECHANICAL VENTILATION

Although not emphasized in most discussions of weaning from mechanical ventilation, strategies that avoid further lung injury during mechanical support are extremely important to returning the patient to spontaneous breathing. *Ventilator-induced lung injury* (VILI) (see Chap. 37) refers to a number of mechanisms by which lung injury can occur in patients with acute lung injury and ARDS.[17] Patients with severe airflow obstruction are at risk for dynamic hyperinflation and adverse consequences such as hypotension and diminished venous return[20] (see Chap. 40). In both cases, ventilation with plateau airway pressures of less than 30 to 35 cm H_2O appears to be associated with improved outcomes. Some patients with excessive chest wall stiffness (e.g., severe obesity) may require higher plateau airway pressures to maintain alveolar recruitment, but we seldom use tidal volumes that yield plateau airway pressures in excess of 35 cm H_2O. A common misconception is that the peak airway pressure is the primary marker for risk of lung injury—indeed, this is an alarm parameter usually followed during mechanical ventilation. Very high peak airway pressures are well tolerated by the patient if plateau (i.e., end-inspiratory) alveolar pressures are maintained at less than 35 cm H_2O, a circumstance encountered commonly in patients with status asthmaticus undergoing mechanical ventilation (see Chap. 40).

Aspiration should be prevented by maintaining the head of the bed of all ventilated patients at 30 degrees unless contraindicated.[21] Ventilated patients usually are sedentary and therefore at risk of deep venous thrombosis, justifying universal prophylaxis with subcutaneous heparin or pneumatic compression boots.[22] Gastric mucosal protection also should be provided for ventilated patients.[23] Proton pump inhibitors, H_2 receptor blockers, carafate, and antacids have been used to protect the stomach. Whether continuous feeding of the gut, which usually neutralizes pH, obviates the need for prophylaxis remains unclear. Ventilated patients often require sedatives and narcotics to maintain their comfort and synchrony with the ventilator. However, these medications have a cost. If overused, they delay patients' return to consciousness and full respiratory drive, thereby prolonging the duration of mechanical ventilation. One method of reducing the amount of sedative is to titrate ventilator volumes/flows/rates/modes to patient comfort before resorting to large doses of sedatives and narcotics. When these medications are used, they should be used on an "as needed" basis,[24] or when a continuous infusion is used, a period of daily awakening should be encouraged.[25]

ITEM 3: RECOGNIZE READINESS—THE LOGISTICS OF LIBERATION

Weaning implies gradual, rather than rapid, withdrawal of ventilatory assistance. This word suggests that the mechanism for separating the patient and the ventilator successfully resides in the machine next to the patient rather than in the patient himself or herself. The remainder of this chapter will emphasize a very simple truism that "many patients do not require repetitive measurements or involved plans for discontinuation of mechanical ventilation—if intercurrent problems causing respiratory muscle weakness or abnormal lung mechanics have not arisen, the most easily effected plan for discontinuation of mechanical ventilation is to wheel the machine out of the room."[26] Thus *liberation* more accurately describes the process by which most patients are freed from the ventilator. In patients who cannot breathe independently, liberation will be possible only after the patient is treated and recovers.

Weaning Parameters

Historically, weaning parameters have been used to *predict* patients' ability to breathe without the ventilator. However, despite decades of research, no weaning parameter has predictive accuracy sufficient to be used exclusively to make liberation decisions.[27,28] Moreover, it seems wasted effort to spend time trying to predict whether a patient can breathe without the ventilator when the question can be answered directly with a trial of spontaneous breathing. Accordingly, we do not use weaning parameters routinely to make liberation decisions. In the last edition of this book we dedicated a great deal of space to discussing weaning parameters. Now we provide instead references to demonstrate why clinicians simply should perform spontaneous breathing trials (SBTs) in most of their patients to determine their candidacy for extubation.[29–46]

To consider a patient for an SBT, he or she should be stable hemodynamically, without evidence of myocardial ischemia and, preferably, not excessively tachycardic. Oxygenation must be adequate,[47] and the Pa_{O_2}/FI_{O_2} should be greater than 120 (i.e., Pa_{O_2} > 60 mm Hg on a concentration of oxygen less than or equal to 50%) at nominal levels of PEEP (PEEP $\leq$ 5.0 cm H_2O). If these two criteria are met, then attention turns to determining whether the patient can ventilate and oxygenate *without* the machine (Fig. 44-3).

Can the Patient Breathe without the Ventilator?

PREPARATION

Sedatives and narcotics should be discontinued several hours before a breathing trial to reduce the likelihood of inadequate drive to breathe. Indeed, while several studies have

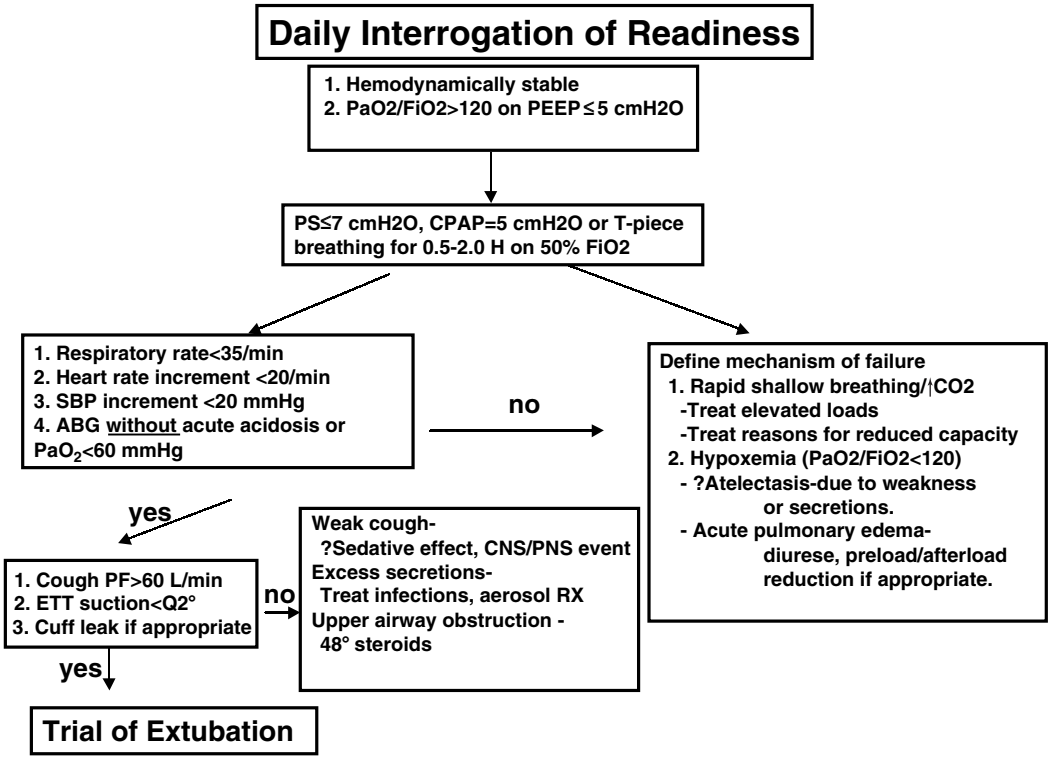

FIGURE 44-3 A simple bedside algorithm for liberating patients from mechanical ventilation and performing a trial of extubation.

indicated that protocol-driven approaches to weaning have identified patients earlier for extubation than routine care by clinicians on a day-to-day basis, other investigations protocolizing a daily interruption of sedatives have been associated with a decreased time of mechanical ventilation and diminished time in the ICU.[25] It is likely that these are two tightly linked ICU activities—sedation and mechanical ventilatory support—and that clinicians are not extremely adept at identifying prospectively when patients do not need one or the other. A simple approach to this problem is to discontinue sedatives frequently and, in those patients awakening in a stable condition, to perform an SBT.

VENTILATOR MODE AND DURATION OF THE SBT

Pressure support, continuous positive airway pressure (CPAP), and T-piece trials are the most common methods used to test readiness for liberation from mechanical ventilation. The choice of whether to use pressure support or to allow the patient to breathe without inspiratory assistance through the endotracheal tube remains a point of physician style. Some data suggest that the endotracheal tube can increase resistive load significantly,[48] which theoretically could contribute to failure. Consequently, many investigators have suggested that a pressure support of 5 to 8 cm H_2O can be used to counter this tube-related load. Recent studies have suggested, however, that pressure support intended to overcome tube resistance unloads the respiratory muscles compared with extubated breathing. These data suggest that T-piece breathing most closely approximates the work of unassisted breathing after extubation.[49,50] Nonetheless, one study suggested that the rate of extubation failure following successful trials of pressure support equal to 8 cm H_2O was not greater than following successful T-piece trials.[51] Another study found similar rates of successful extubation following trials of pressure support of 7 cm H_2O versus T piece.[52]

The first SBT need be only 30 minutes[53] because extending the trial longer does not enhance the clinician's ability to assess the patient's readiness for extubation. The proper duration of subsequent SBTs in those who fail has not been studied (30 to 120 minutes generally are used). Thus the available data suggest that patients should be considered for a trial of extubation after a successful trial (30 to 120 minutes) of either T piece, CPAP, or pressure support of 5 to 8 cm H_2O.

THE PATIENT WHO FAILS INITIAL SBTs

Failure of an SBT is most often a clinical diagnosis. The clinical signs of failure include rapid-shallow breathing, tachycardia (>110 beats per minute), hypertension (increment of more than 20 mm Hg), mental status changes, and subjective distress. These signs result from (1) decrements in gas exchange, (2) cardiovascular events, and/or (3) other (noncardiopulmonary) issues. When a patient fails an SBT, clinicians frequently focus on specific ventilator regimes aimed at improving respiratory muscle function. Although some studies in animal models have suggested that respiratory muscle exercise may be helpful,[54] to date no study has suggested that the ventilator can be used to expedite the recovery from respiratory failure. If "exercise" is attempted, all attempts should be made to avoid exhausting the patient (generally accomplished if respiratory rates stay below 30/min). However, instead of concentrating on the ventilator, the clinician should turn attention to treatable factors underlying the patient's

respiratory failure (Table 44-3). Some traditional weaning parameters are helpful in making this determination. For example, a markedly reduced maximum negative inspired pressure suggests respiratory muscle weakness. An elevated rapid-shallow breathing index (the respiratory rate per minute divided by the tidal volume in liters) suggests imbalance of respiratory muscle load and capacity. Reasons for abnormalities then can be examined by systematic diagnostic and therapeutic interventions.

ANALYZING FAILURE OF AN SBT

Acute hypercapnia during weaning frequently results from an imbalance between respiratory pump capacity and load. Normal individuals who are subjected to resistance loading exhibit rapid-shallow breathing as a sign of impending respiratory failure.[55,56] When the patient is clearly failing an SBT, it should be discontinued (even before a blood gas analysis demonstrates gas exchange abnormalities) because patients who are "weaned" to exhaustion frequently take several days to recover adequately to resume trials.

Many factors may reduce respiratory muscle strength or increase respiratory muscle loads in critically ill patients. In patients who fail due to strength-load imbalance, we quantify neuromuscular function and the three elements of respiratory muscle load (resistance, elastance, and minute volume; see above) each day so as to define/treat reversible elements. Critical illness frequently is associated with a catabolic state, malnutrition, and electrolyte deficiencies that can contribute to respiratory muscle weakness. Some patients recovering from severe illness develop a polyneuropathy[57–60] that has been hypothesized to contribute to reduced respiratory pump function and prolonged need for mechanical ventilation.[58,59] Sepsis occurs frequently in critically ill patients and is a relatively common reason for weaning failure. Numerous studies suggest that sepsis has a negative impact on respiratory muscle function,[61–65] and this effect is mediated by cytokines.[63,64] In addition, treatments that are used commonly in critically ill patients, such as administration of corticosteroids[66–68] and neuromuscular blockers,[69–71] also negatively affect respiratory muscle function. Mechanical ventilation itself may contribute to disuse atrophy of the respiratory muscles, thus contributing to the pathogenesis of prolonged ventilator dependence.[54,72] Bronchospasm and increased airway secretions frequently contribute to resistive loading of the respiratory muscles. Elevated airway resistance greater than 15 cm H_2O/L per second frequently can be reversed by removing excessive airway secretions[73] or treating with aerosolized bronchodilators.[74] If resistance remains greater than 15 cm H_2O/L per second despite bronchodilators in a patient who repeatedly fails to wean, a therapeutic trial of corticosteroids may be helpful.

Finally, numerous factors contribute to increased respiratory system elastance, ranging from acute lung injury to abdominal distention. Pulmonary edema and pneumonia are common reversible causes of increased lung elastance. Occult PEEP also increases elastic load[75] and can contribute to respiratory muscle fatigue by increasing the work of assisted[76] and unassisted breathing. Increased minute volumes associated with lung injury, hypermetabolic states of critical illness (e.g., sepsis), pulmonary embolism, and overfeeding could contribute to dynamic hyperinflation during the recovery process, thus increasing mechanical loads on the recovering respiratory muscles.

Acute hypercapnia does not necessarily connote weaning failure. In three relatively common situations, hypercapnia during an SBT trial is not accompanied by physiologic decompensation and does not signal ventilatory failure. First, occasional patients with chronic hypercapnia are hyperventilated iatrogenically to a normal P_{CO_2}, and over the course of days in the ICU, the bicarbonate concentration also decreases to normal. When these patients resume spontaneous breathing, their P_{CO_2} rises to their baseline level, leading to an acute respiratory acidosis. The clinician must decipher whether the acute acidosis is arising from strength-load imbalance, in which case the patient usually shows other signs of failure, or from preceding iatrogenic hyperventilation. Similarly, when some patients with chronic hypercapnic respiratory failure are given a high fraction of inspired oxygen, they acutely retain CO_2 in the absence of strength-load imbalance.[77–79] Reduction in the supplemental oxygen to yield a saturation of 90% to 92% may reverse this iatrogenic cause of hypercapnia. Finally, some patients who have primary metabolic alkalosis will have compensatory hypoventilation and hypercapnia.

Hypoxemia (Pa_{O_2} <60 mm Hg or saturation less than 90% on 50% inspired oxygen) can occur during weaning for several reasons. Old age, obesity, and recumbency predispose to a lower functional residual capacity (FRC), which can contribute to atelectasis and subsequent hypoxemia during the transition to unassisted breathing. Thus patients should be sitting at greater than a 30-degree angle during spontaneous breathing. Respiratory muscle weakness and sedatives or narcotics may lead to shallow breathing and atelectasis. Lung injury, a common complication of critical illness, is associated with surfactant depletion and an increased propensity for atelectasis during the withdrawal of positive-pressure ventilation. Thus many pulmonary factors can contribute to hypoxemia during SBTs. Hypoxemia also can result from cardiovascular changes during weaning.

The transition to unassisted breathing is associated with centralization of blood and increased left heart afterload, which may predispose patients with baseline left ventricular dysfunction to develop cardiogenic pulmonary edema.[6–15] SBTs also may increase the level of circulating catechols,[80] which could induce increases in heart rate, blood pressure, and arrhythmias. Tachycardia during weaning frequently is a sign of inadequate cardiopulmonary reserve and subsequent weaning failure. Moreover, in patients with coronary artery disease, if mechanical loads and catechol-induced changes are sufficient, weaning can trigger cardiac ischemia that could contribute to the clinical signs of weaning failure[81–84] (see Fig. 44-2). In a study of 93 medical patients being weaned from mechanical ventilation, ST-segment changes were noted in 6% of all patients and in 10% of those with a preceding history of coronary artery disease. Moreover, weaning-related ischemia tended to increase the risk of weaning failure.[84]

In patients who are clinically hypervolemic or who have left ventricular dysfunction, pre-emptive diuresis and nitrate therapy can be helpful in attenuating acute increases in preload during SBTs. Continuous monitoring of ST segments and treatment with additional nitrates also may be helpful in patients who experience ischemia during weaning.[84]

OTHER REASONS FOR SBT FAILURE

Even though most weaning failures are of cardiopulmonary etiology, other exogenous factors also may contribute to failure.

VENTILATOR AND CIRCUIT ELEMENTS

The ventilator and its circuitry can contribute to weaning failure by two mechanisms: (1) by increasing respiratory loads enough during an SBT to fatigue the respiratory muscles and (2) by imposing significant respiratory muscle work during "rest" periods. The resistance of the endotracheal tube increases with time, and this increase occasionally can be of sufficient magnitude to impede weaning. The ventilator circuit provides increased dead space and in some modes (for older ventilators) can require excessive work to trigger a "sticky" demand valve. Some studies suggest that flow triggering may reduce the ventilator-imposed work of breathing compared with pressure-triggered modalities.[85,86] Thus the ventilator circuit can load[87,88] and covertly fatigue the respiratory muscles when patients are presumed to be "resting," as well as when they are weaning. Patient-ventilator synchrony during "rest" periods reduces the likelihood that the ventilator is contributing to weaning failure.[87,89,90] Irregular pressure-volume curves or frequent, large esophageal or intravascular pressure fluctuations during assisted ventilation may help to identify patients who are working hard on the ventilator.[91] Empirical manipulation of inspiratory flow rates, waveforms, and triggering mechanisms may aid in improving patient-ventilator synchrony.[86] Finally, in patients with obstructive lung disease, intrinsic PEEP may increase significantly the work required to trigger ventilator-supported breaths (so-called trigger asynchrony). In selected patients, addition of applied PEEP to nearly match intrinsic PEEP can reduce this ventilator-induced load.[76]

PSYCHOLOGICAL AND HOUSEKEEPING ISSUES

Subjective distress, including anxious appearance and sweating, are nonspecific signs of weaning failure. Anxiety during breathing trials may manifest as rapid-shallow breathing, tachycardia, and hypertension that are interpreted as weaning failure by caregivers. Bedside personnel should explain the weaning process; so-called verbal anesthesia is effective in some patients. The use of sedatives to treat anxiety must be undertaken with caution because most of these drugs also depress respiratory function. Haloperidol or very low doses of benzodiazepines can be used to facilitate comfort in these exceptional patients. However, subjective distress most frequently signals that the cardiopulmonary system requires additional repair before resuming unassisted breathing.

The effect of re-establishing patient day-night cycles remains to be well studied.[92–94] In patients who fail initial trials of breathing, we are careful to ensure sleep at night and wakefulness, if not exercise, during the day.

LIBERATION STRATEGIES

Many intensivists have reasoned that by reducing ventilatory support gradually, the respiratory muscles exercise at subfatiguing loads, leading to gradual improvement in function. Some studies have suggested that respiratory exercises (repetitions of low-load resistive breathing) can lead to successful extubation in patients who have failed previously.[95] However, there are as yet no studies proving that respiratory muscle training, through the use of graded withdrawal of ventilatory support, hastens the recovery to unassisted breathing.

Two recent studies have assessed the role of "weaning" strategies in expediting *liberation of the subset of those who fail initial SBTs.* Brochard and colleagues[51] studied 456 medical-surgical patients being considered for weaning, of whom 347 (76%) were extubated successfully on the first day of weaning. One hundred and nine patients who failed an initial SBT were randomized to be weaned by one of three strategies: (1) T-piece trials of increasing length until 2 hours could be tolerated, (2) intermittent mandatory ventilation with attempted reductions of 2 to 4 breaths per minute twice a day until 4 breaths per minute could be tolerated, and (3) pressure-support ventilation (PSV) with attempted reductions of 2 to 4 cm H_2O twice a day until 8 cm H_2O could be tolerated. Patients randomized to the three strategies were similar with regard to disease severity and duration of ventilation before weaning. Patients assigned to T-piece were placed on assist control overnight, whereas synchronized intermittent mandatory ventilation (SIMV) patients remained on an unspecified SIMV rate, and PSV patients remained at an unspecified level of pressure support. There was no difference in the duration of weaning between the T-piece and SIMV groups, but PSV led to significantly shorter weaning compared with the combined T-piece and SIMV cohorts. Interestingly, PSV and T-piece were not compared directly. These authors concluded that "the outcome of weaning from mechanical ventilation was influenced by the ventilatory strategy chosen, and the use of PSV resulted in significant improvement compared with other strictly defined weaning protocols using T-piece or SIMV."

Esteban and colleagues[96] performed a similar study of 546 medical-surgical patients, 416 (76%) of whom were extubated successfully on their first day of weaning. The 130 patients who failed were randomized to undergo weaning by (1) once-a-day T-piece trial, (2) two or more T-piece or CPAP trials each day as tolerated, (3) PSV with attempts at reduction of 2 to 4 cm H_2O at least twice a day, and (4) SIMV with attempts at reducing 2 to 4 breaths per minute at least twice a day. Patients assigned to the four groups were similar with regard to demographic characteristics, acuity of illness, and a number of cardiopulmonary variables. Duration of ventilation before weaning was shorter in the SIMV group than in other groups. The mode of ventilation at night was not specified. The weaning success rate was significantly better with once-daily T-piece trials than for PSV and SIMV. Twice-daily T-piece trials were not significantly better, and PSV was not superior to SIMV. The median duration of weaning was 5 days for SIMV, 4 days for PSV, and 3 days for the T-piece regimens. These authors concluded that "a once-daily trial of spontaneous breathing led to extubation about three times more quickly than intermittent mandatory ventilation and about twice as quickly as pressure-support ventilation."

The statistical methods used in these studies warrant some comment. The first study[51] asserts the superiority of pressure-support weaning to T-piece but does not compare these directly. The second study[96] presents "adjusted" rates of successful weaning—the nature of the adjustments and their impact on the results are unclear because raw data were not presented. However, several important conclusions can be drawn from these relatively large studies. First, and most

important, most patients can be extubated successfully on the first day that physicians recognize readiness after a brief trial (30 to 120 minutes) of breathing through a T-piece. *Weaning is not necessary for most patients.* Second, both studies suggest that in patients who have failed an initial T-piece trial, SIMV weaning prolongs the duration of mechanical ventilation. These conclusions depend on the precise algorithms used in the studies—it is possible that if a more "aggressive" SIMV algorithm were used, no difference would be noted. However, if one considers the results of these studies together, *choices of ventilator mode do not appear to have a major impact in speeding the recovery to unassisted breathing.* Clinicians frequently use SIMV or PSV as the initial approach before attempting a T-piece trial. Since most patients are extubated successfully after a brief T-piece trial, such an approach is likely to prolong mechanical ventilation for many patients. PSV weaning may be equivalent to T-piece weaning in carefully controlled protocols. However, in our experience, in busy ICUs, respiratory therapists and nurses frequently are unable to "keep up" with the demands of such protocols—so pressure-support withdrawal protocols have the risk of prolonging ventilation unless followed strictly.

Extubation

There is an important distinction between liberation from mechanical ventilation and extubation. Once a patient has been liberated, i.e., has passed the SBT, he or she does not need the ventilator. The endotracheal tube, aside from providing the avenue for PPV, allows removal of secretions for patients whose airway protective mechanisms have been altered by disease. Accordingly, after a patient has performed a successful trial of unassisted breathing (is liberated from the ventilator), the physician must determine whether the patient still needs the artificial airway.

One consideration is whether the patient has an upper airway lesion that would collapse to a critically small size after extubation. Patients at risk of this problem include those who were initially intubated for upper airway stenosis and stridor and those who have had a traumatic or prolonged intubation.[97] A number of studies have suggested that the ability to breathe around a deflated endotracheal tube cuff[98–100] or a cuff leak of greater than 110 mL during volume-cycled ventilation[100] reduces the likelihood of postextubation failure. However, lack of a cuff leak does not absolutely predict extubation failure.

The patient's mental status, airway protective mechanisms, ability to cough, and amount of secretions are also determinants of extubation outcome. Patients with cough peak flows of 60 L/min or less are five times as likely to fail a trial of extubation (TOE) compared with those with cough peak flows of more than 60 L/min. Those who cannot cough and wet a white card placed 1 to 2 cm from the end of the open endotracheal tube are three times as likely to fail a TOE. Those who require endotracheal suctioning more than every 2 hours are also at increased risk of extubation failure.[47,101] Thus, in general, we are disinclined to extubate patients if they have excessive or tenacious secretions and a weak cough or are not cooperative enough to aid in their own pulmonary toilet (deep breathing and expectoration of secretions). Patients with severe cerebral vascular accidents (CVAs) frequently present with this constellation. It remains unclear as to whether early elective tracheostomy to prevent aspiration and aid in pulmonary toilet is superior to a trial of extubation. When the cause of impaired airway protection is thought to be reversible, treating and attempting a TOE at a later time are reasonable. Recent data suggest that swallowing is abnormal in more than 30% of patients following extubation.[102] Accordingly, all patients, especially those with altered mentation or CVA, should be observed carefully after extubation, and formal swallowing assessment is advisable for many patients.

Postextubation stridor arising from upper airway edema is fairly common after extubation. Pulmonary edema can develop in some of these patients[103] because large negative intrathoracic pressures during inspiration can increase left ventricular afterload dramatically.[11] Nebulized racemic epinephrine and parenteral corticosteroids have been used for the treatment of airway edema but have not been studied systematically. Heliox or mask CPAP may be used to reduce upper airway resistance temporarily in selected patients who do not require immediate reintubation.[104]

Noninvasive face-mask positive-pressure ventilation (NIPPV) may prevent the need for reintubation in selected patients who appear to be failing immediately after extubation.[105–107] One study prospectively randomized 39 patients with COPD and normal sensorium who had failed a T-piece trial to pressure-support weaning or extubation to NIPPV. Patients assigned to NIPPV were more likely to be liberated from mechanical ventilation and succeeded 5 days sooner than those who were weaned using pressure support.[107] In a multicenter trial of 221 patients failing extubation (only 10% having COPD), NIV was ineffective in preventing reintubation and did not reduce mortality.[107a] Thus NIPPV remains unproved for extubation failure, but may be useful in cooperative patients who appear to be failing extubation and who do not require immediate reintubation for impending respiratory arrest.

Deep-breathing exercises and incentive spirometry after extubation may help to prevent atelectasis in at-risk patients. Intermittent positive-pressure breathing treatments may be helpful to reduce atelectasis in patients who have not recovered adequately to cough and deep breathe. Continuous ST-segment monitoring can identify some patients with myocardial ischemia; early recognition and treatment may reduce the likelihood of recurrent respiratory failure. There are few data to support these suggestions, but common sense may not require prospective validation.

Breaking the Rules

Most experienced clinicians have treated patients whose SBTs suggested that they would fail but who were liberated and extubated successfully nonetheless. When the numbers look bad but the patient looks good or there is concern that the presence of the endotracheal tube is responsible for weaning failure, it is reasonable to perform a careful TOE. The following are among the clinical situations that could prompt consideration for a TOE in such patients:

1. When an endotracheal tube has been in place for more than 7 days. Endotracheal tube resistance increases with time and can contribute to failed SBTs.

2. When the patient experiences repeated episodes of bronchospasm on awakening from sedation. The endotracheal tube can cause reflex bronchospasm in some individuals.
3. When patients become overwhelmingly anxious when awakened to breathe through the endotracheal tube and the amount of sedative required to make them comfortable causes hypoventilation. We are particularly careful to ensure that cardiopulmonary reasons for failure have been reversed in these patients.
4. When patients with restrictive chest wall disease (e.g., obesity) repeatedly desaturate every time PEEP is decreased to less than 10 cm H_2O. Some obese patients require more than 5 cm H_2O to prevent atelectasis while intubated yet maintain adequate oxygenation when extubated.
5. When patients with severe restrictive or obstructive lung disease breathe rapidly and shallowly (a rapid-shallow breathing index or frequency/V_T > 125 breaths per minute per liter). For some end-stage patients, rapid-shallow breathing is their chronic baseline.

In these relatively rare situations, extubation should *not* be performed casually. We consider breaking the rules outlined in this chapter only after numerous failed trials of unassisted breathing and after treating reversible causes of failure. The clinical risks associated with failure and reintubation must be weighed against those of continued mechanical ventilation. We extubate these unusual patients with personnel who are skilled at endotracheal intubation nearby, should reintubation be required. In addition, we ensure ready access to NIPPV, which may avert the need for reintubation in carefully selected patients.

TABLE 44-3 Reversible Factors Contributing to Ventilatory Failure—Daily Correction of Reversible Contributors to Ventilatory Failure Expedites Patient Recovery

Reduce Respiratory Load	Improve Respiratory Strength
Resistance	Replace K^+, Mg^{2+}, PO_4^{2-} to normal
Inhaled bronchodilators	Treat sepsis
Corticosteroids	Nutritional support without overfeeding (aim to achieve a normal prealbumin)
Removal of excess airway secretions	Consider stopping aminoglycosides
Treatment of upper airway obstructions	Rule out:
Elastance	Neurologic disease/occult seizures
Treat pneumonia	Hypothyroidism
Treat pulmonary edema	Oversedation
Reduce dynamic hyperinflation	Critical illness myopathy/polyneuropathy
Drain large pleural effusions	
Evacuate pneumothoraces	
Treat ileus	
Minute volume	
Detect intrinsic PEEP	
Bronchodilators	
Antipyretics	
Treat sepsis	
Therapy for pulmonary embolism	
Maintain least PEEP possible	
Correct metabolic acidoses	
Resuscitate shock	
Prevent hypovolemia	
Avoid overfeeding	

A Practical Approach

At many institutions, patients remain bound to ventilators for longer than necessary because clinicians either do not obtain weaning parameters in a timely manner or are hesitant to extubate even when parameters and breathing trials are favorable. Mechanical ventilation can cause complications.[15–17] Conversely, there is a small risk associated with extubation failure. The relative risks of each vary from patient to patient and from institution to institution. A simple approach can minimize both risks. Each day the clinician should ask: *Can my patient be liberated from the ventilator?* The use of interdisciplinary weaning teams[108–110] or respiratory therapist–driven protocols may expedite successful liberation by actively addressing this question each day.

Ely and colleagues studied 300 mechanically ventilated adult medical patients, of whom 149 were prospectively randomized to receive algorithm-guided *attention* to weaning, and the remaining 151 received "routine" care.[110] All patients were assessed daily to delineate recovery to adequate oxygenation (Pa_{O_2}/FI_{O_2} > 200 on PEEP ≤ 5 cm H_2O), hemodynamic stability, and a frequency/V_T of 105 breaths per minute per liter or less (measured on CPAP). When all these criteria were met, a note was left in the charts of patients assigned to the treatment group suggesting that they were ready for liberation. Overall, patients whose care was guided by these criteria were liberated 1.5 days more rapidly than patients in the control group. The median weaning time after satisfaction of the criteria was 2 days shorter in the treatment group. This reduction in ventilator days translated to a trend toward reduced ICU length of stay and a significant reduction (by $5000) in ICU costs of care. Interestingly, median weaning time from satisfaction of the screening criteria was 1 day in the treatment group, suggesting that further reductions could have been realized if the gentle "reminder" led to a prompt trial of unassisted breathing. Other studies[47] have suggested that the oxygenation criteria used in this study may be conservative (e.g., Pa_{O_2} ≥ 80 mm Hg on 40% oxygen). In addition, roughly 50% of patients with a frequency/V_T of 100 to 125 breaths per minute per liter can be extubated successfully.[32] Thus additional reductions in duration of mechanical ventilation can potentially be achieved using a more aggressive algorithm (Fig. 44-3). Note also that these results cannot necessarily be generalized to all institutions because "routine care" (the control group in this study) likely varies considerably among hospitals. However, this study strongly suggests that many patients are inappropriately retained on mechanical ventilators. Other studies have applied very different algorithms to achieve significant reductions in duration of ventilation.[18,111] However, they all have one thing in common: They substitute a program of daily systematic scrutiny of readiness for breathing for the individual variation occurring in unstructured care systems. Whether achieved by protocol or by individual clinician perseverance, we believe that patients can be liberated from mechanical ventilation more expeditiously if they are screened on a daily basis for this potential event.

Our approach can be summarized as follows: If the patient is hemodynamically stable, awake, and triggering the ventilator with a $Pa_{O_2}/F_{I_{O_2}}$ greater than 120 on PEEP of 5.0 cm H_2O or less, we perform an SBT. Alternatively, patients can be screened with a 1- 2-minute T-piece trial using the frequency/VT to guide whether to lengthen the trial (as in the Ely and colleagues study).[110] We prefer pressure support at a low level or T piece on 50% oxygen for 30 minutes (60 minutes after a first-day failure). If the patient remains comfortable, with an oxygen saturation greater than 90% and without tachycardia or hypertension, and the breathing rate remains less than 35/min at 30 minutes, we will obtain an arterial blood gas and consider a TOE using independent judgments to gauge the patient's ability to do without the endotracheal tube itself (see above). For patients who fail an initial SBT, we aggressively assess the pathogenesis of their failure and perform daily trials of either T piece or pressure support of less than 7 cm H_2O until the patients can tolerate a greater than 30-minute trial of unassisted breathing and then proceed to liberation from the ventilator and assessment for extubation.

Chapter 45

PRINCIPLES OF ANTIMICROBIAL THERAPY AND THE CLINICAL PHARMACOLOGY OF ANTIMICROBIAL DRUGS

FRED Y. AOKI

KEY POINTS

- *Rational antibiotic use requires the most specific diagnosis that can be made, knowledge of commonly used antimicrobial agents, and appropriate monitoring of therapy.*
- *Antimicrobial prophylaxis against bacterial infections is indicated in selected patients undergoing surgical procedures and in those with cardiac valvular disease.*
- *When suspected infection threatens life or major organ function, antimicrobial therapy should be directed at all infectious possibilities of more than trivial probability until the results of definitive investigations are available.*
- *Knowledge of the clinical pharmacology of antibiotics commonly prescribed in the intensive care unit is essential for the intensivist.*

Antimicrobial Use in Critically Ill Patients

The importance of antimicrobial drugs in the management of patients admitted to the intensive care unit (ICU) is beyond question. The prevention and treatment of infections in ICU patients pose formidable challenges despite advances in our understanding of the pathophysiology of specific infections, the availability of more rapid, sensitive, and specific diagnostic tests, and an array of potent antimicrobial agents.

PROPHYLAXIS OF INFECTIOUS DISEASES IN ICU PATIENTS

The efficacy of short-term systemic antibacterial administration to prevent operative site infections after surgery is well established. Effective prophylaxis requires that the antibacterial agent inhibit specific pathogenic agents that cause the infection and be present at therapeutic concentrations in the operative site at the time the incision is made. It is imperative that surgical wound prophylaxis be prescribed, when appropriate, in the management of ICU patients. Recommended drugs, doses, and duration of prophylaxis for some specific surgical procedures are listed in Table 45-1.[1]

Unlike perioperative antimicrobial prophylaxis for the prevention of wound infection, the efficacy of antibiotics to prevent bacterial endocarditis has not been established by controlled trials. Nevertheless, to prevent bacterial endocarditis, it is recommended that patients with valvulopathy (congenital or acquired) or prosthetic valves (bioprosthetic and homograft valves) be given antimicrobial prophylaxis.[2] Table 45-2 lists the cardiac conditions for which endocarditis prophylaxis is recommended, Table 45-3 presents the surgical procedures for which antibacterial prophylaxis is recommended, and Table 45-4 lists the recommended injectable drugs and doses, all of which were adapted with permission from Dajani and associates.[3]

In contrast, the usefulness of antimicrobial agents to prevent infections other than endocarditis and infections related to surgery remains limited or controversial. Two general approaches have been evaluated. In one, antibiotics are applied to sterile sites or clean skin wounds to prevent local infection; in the other, antibiotics are used to selectively eradicate the potentially pathogenic bacteria of the gastrointestinal tract and simultaneously preserve the anaerobic "nonpathogenic" flora. The former approach includes endotracheal administration of nonabsorbable antibacterial drugs, such as the aminoglycosides, instillation of antibiotics into the urinary bladder, and the covering of wounds by creams mixed with antibacterial agents. With the exception of topical use of sulfonamide creams in the management of burned patients, these methods have been associated with inconsistent prophylactic effects and a high incidence of relapse, resistance, and superinfection that renders this strategy unacceptable.

The second approach is referred to as *selective decontamination of the digestive tract* (SDD).[4] The strategy of SDD is based on the hypothesis that eradication of selected components of the bacterial and fungal flora of the oropharyngeal or gastrointestinal tract can decrease the risk of infection and maintain the natural defense of these mucosal surfaces conferred by the anaerobic flora. SDD studies include various systematic antimicrobial agents plus oral administration of nonabsorbable agents such as polymyxin E, tobramycin, plus amphotericin B, but other regimens use only nonadsorbable drugs. The antibiotics are administered for the entire duration of the critical illness; in this respect, SDD differs from short-term perioperative surgical prophylaxis. The technique has received intensive investigative attention over the past decade and evidence that SDD is effective in decreasing ICU mortality but the relative importance of antibiotic resistance varies among institutions so that SDD cannot be recommended for routine use.[5]

THERAPY OF INFECTIOUS DISEASES IN ICU PATIENTS

Rational antibiotic use requires a systematic approach to the assessment of suspected infection, knowledge of commonly used agents, and appropriate selection and monitoring of drugs.

Regardless of whether infection is suspected in an ICU patient because of the development of florid symptoms and signs of inflammation (rubor, calor, dolor, tumor, or functio laesa) or of subtle deterioration in the level of consciousness or gas exchange, the same thorough, systematic evaluation is recommended: The first question to be addressed is whether infection can be reasonably inferred to be present. Does the history show systemic or local symptoms of inflammation?

TABLE 45-1 Recommended Antibiotic Prophylaxis for Some Commonly Performed Surgical Procedures

Surgical Procedure	Recommended Prophylactic Regimen[a]
Gynecologic surgery	
Cesarean section	Cefazolin (1 g IV) after clamping the cord and 6 and 12 h later Prophylaxis is not indicated in uncomplicated elective procedures Uterine irrigation with antibiotics may be comparable to systemic therapy; if irrigating antibiotics are used, 2 g cefoxitin in 1 L normal saline is effective; in patients with β-lactam allergy, metronidazole (500 mg IV) after cord clamping is effective
Orthopedic surgery	
Open reduction of fracture or insertion of hardware[b]	Cefazolin (1 g IV) preoperatively and q 6 h (3 doses). Complex (open) fractures are considered contaminated and cefazolin therapy (1 g q 8 h for 10 d beginning at admission) is indicated
Laminectomy and spinal fusion	Prophylactic antimicrobials have not proved to be beneficial
Amputation of lower limb	Cefoxitin (2 g IV) preoperatively and q 6 h (4 doses)
General surgery	
Cholecystectomy	Cefazolin (2 g IV) preoperatively in "high-risk" patients, i.e., >60 y, previous biliary surgery, history of acute symptoms, or jaundice In patients with β-lactam allergy, gentamicin (80 mg IV) preoperatively and q 8 h (3 doses) is effective.
Colon surgery	Neomycin and erythromycin base, 1 g of each orally at 1, 2, and 11 PM on the day before surgery For emergency colon surgery or situations precluding preoperative oral prophylaxis, cefoxitin (2 g IV) preoperatively and q 4 h (3 doses) is effective In patients with β-lactam allergy, metronidazole (500 mg IV) and gentamicin (1.7 mg/kg IV) preoperatively and q 8 h postoperatively (3 doses) are effective
Primary appendectomy	Cefoxitin (2 g IV) preoperatively and q 6 h (3 doses) in nonperforated appendixes; in perforated appendixes, therapy is continued for 3–5 d Although combined aerobic and anaerobic coverage appears to be preferable, in patients with β-lactam allergy, metronidazole (500 mg IV) preoperatively is effective; with perforated appendixes, this is continued q 8 h (IV or oral administration) for 3–5 d
Gastric resection	Cefazolin (1 g) preoperatively in "high-risk" patients only, i.e., bleeding gastric or duodenal ulcer, obstructive duodenal ulcer, gastric ulcer, gastric cancer, or morbid obesity (prophylaxis is not indicated for cases of chronic uncomplicated duodenal ulcers) In patients with β-lactam allergy, 1 preoperative IV dose of gentamicin (120 mg) and clindamycin (600 mg) may be effective, but data are limited
Surgery for penetrating abdominal trauma	Cefoxitin (2 g IV) on admission to the hospital For patients with intestinal perforation, 2 g cefoxitin IV q 6 h for 2–5 d is effective
Surgery on nose, mouth, and pharynx	
Major head, neck, and oral surgery	In major surgical procedures involving an incision through oral or pharyngeal mucosa, a combination of gentamicin (1.7 mg/kg) and clindamycin (300 mg IV) preoperatively and q 8 h (2 doses) is recommended; cefazolin and third-generation cephalosporins also have demonstrated effectiveness when given over 24 h perioperatively
Rhinoplasty and repair of nose	Prophylactic antimicrobials have not proved to be effective
Cardiothoracic and vascular surgery	
Median sternotomy, coronary artery bypass grafting, and valve surgery	Cefazolin (1 g IV) preoperatively and q 6 h for 48 h In patients with β-lactam allergy, vancomycin (15 mg/kg IV) preoperatively, after initiation of bypass (10 mg/kg), and q 8 h postoperatively for 48 h may be effective
Pacemaker insertion	Cefazolin (1 g) as above; in patients with β-lactam allergy, no prophylaxis may be a reasonable alternative, given the low incidence of infection
Thoracic surgery procedure including lobectomy and pneumonectomy	Cefazolin (1 g) preoperatively and q 6 h postoperatively for 24 h; the optimal duration of postoperative prophylaxis has not been established In penetrating thoracic trauma and in the placement of chest tubes in trauma management, prophylactic antibiotics have not been effective
Peripheral vascular surgery	Cefazolin (1 g) preoperatively and q 6 h postoperatively for 24 h The usefulness of antibiotic prophylaxis in carotid artery surgery has not been established, but cefazolin should be used as described above when infection rates increase
Vascular surgery that involves the abdominal aorta or a groin incision	Cefazolin (1–2 g IV) preoperatively and q 4–8 h for the duration of the procedure[b]

TABLE 45-1 (Continued)

Surgical Procedure	Recommended Prophylactic Regimen[a]
Neurosurgical procedures	
Cerebrospinal fluid shunting procedures	Antibiotic prophylaxis is not indicated in institutions with low infection rates (<10%) Trimethoprim (160 mg) plus sulfamethoxazole (800 mg) IV preoperatively and q 12 h (3 doses) may be beneficial in institutions with high infection rates (>20%)
Craniotomy	For high-risk procedures (e.g., re-exploration and microsurgery), clindamycin (300 mg IV) preoperatively and q 4 h has been effective, as has vancomycin (1 g IV) plus gentamicin (80 IM) preoperatively

[a] Unless otherwise noted, the preoperative dose of intravenous antibiotic should be administered at about the time of the operative incision. Preoperative intramuscular antibiotic should be administered 30 minutes to 1 hour before the incision.
[b] From reference 2.
ABBREVIATIONS: IM, intramuscularly; IV, intravenously.
SOURCE: Reproduced with permission from Kaiser.[1]

Are signs of inflammation present? Can other causes of inflammation such as tissue injury due to drugs, immunologic diseases, and physical agents (thermal energy or electromagnetic irradiation) be excluded? Is there laboratory evidence of inflammation—visible pus or polymorphonuclear leukocytes in microscopic examinations of body fluids?

The second question for the intensivist is: What is the infectious disease that is occurring? Is this meningitis, pneumonitis, intraabdominal sepsis, intravascular, catheter-related bacteremia, or some other process? This question must be answered as specifically as possible, because an accurate diagnosis will logically lead to collection of the appropriate specimens for microbiologic testing before antibiotic therapy is initiated, and an appropriate working conclusion about the probable etiologic agents involved.

An outline of the investigation of particular infections is beyond the scope of this chapter and is detailed elsewhere in the text. Contemporary intensivists have access to a wide range of noninvasive radiologic imaging techniques that have been invaluable in confirming the diagnosis of deep visceral infections and assisting in their repeated evaluation during treatment. Occasionally, however, the patient will be too ill to tolerate the most appropriate diagnostic evaluation. This may limit the accuracy of the initial assessment, but the initiation of antimicrobial therapy must not be delayed. It is axiomatic in the critically ill patient that initial antimicrobial therapy be directed at all infectious possibilities of more than trivial probability until the results of definitive investigations are available.

TABLE 45-2 Endocarditis Prophylaxis Recommendations: Cardiac Conditions

Prophylaxis Recommended
Prosthetic cardiac valves, including bioprosthetic and homograft valves
Previous bacterial endocarditis, even in the absence of heart disease
Most congenital cardiac malformations
Rheumatic and other acquired valvular dysfunction, even after valvular surgery
Hypertrophic cardiomyopathy
Mitral valve prolapse with valvular regurgitation
Prophylaxis not recommended
Isolated secundum atrial septal defect
Surgical repair without residua beyond 6 months of secundum atrial septal defect, ventricular septal defect, or patent ductus arteriosus
Previous coronary artery bypass graft surgery
Mitral valve prolapse without valvular regurgitation
Physiologic, functional, or innocent heart murmurs
Previous Kawasaki disease without valvular dysfunction
Previous rheumatic fever without valvular dysfunction
Cardiac pacemakers and implanted defibrillators

TABLE 45-3 Endocarditis Prophylactic Recommendations: Surgical Procedures

Prophylaxis Recommended (clinically important risk of bacteremia)
Tonsillectomy and/or adenoidectomy
Surgical operations that involve intestinal or respiratory mucosa
Bronchoscopy with a rigid bronchoscope
Sclerotherapy for esophageal varices
Esophageal dilation
Gallbladder surgery
Cystoscopy
Urethral dilation
Urethral catheterization if urinary tract infection is present
Urinary tract surgery if urinary tract infection is present[a]
Prostatic surgery
Incision and drainage of infected tissue[a]
Vaginal hysterectomy
Vaginal delivery in the presence of infection[a]
Prophylaxis not recommended (risk of bacteremia considered to be negligible)[b]
Tympanostomy tube insertion
Endotracheal intubation
Bronchoscopy with a flexible bronchoscope, with or without biopsy
Cardiac catheterization
Endoscopy with or without gastrointestinal biopsy
Cesarean section
In the absence of infection for urethral catheterization, dilation and curettage, uncomplicated vaginal delivery, therapeutic abortion, sterilization procedures, or insertion or removal of intrauterine devices

[a] In addition to prophylactic regimen for genitourinary procedures, antibiotic therapy should be directed against the most likely bacterial pathogen.
[b] In patients who have prosthetic heart valves, history of endocarditis, or surgically constructed systemic-pulmonary shunts or conduits, physicians may choose to administer prophylactic antibiotics even for low-risk procedures that involve the lower respiratory, genitourinary, or gastrointestinal tracts.

TABLE 45-4 Endocarditis Prophylaxis Regimens

Drug	Dosing Regimen
	Oral and Upper Respiratory Tract Procedures
Ampicillin	IV or IM administration of ampicillin, 2.0 g, 30 min before procedure; then IV or IM administration of ampicillin, 1.0 g, or oral administration of amoxicillin, 1.5 g, 6 h after initial dose
	For patients allergic to ampicillin, amoxicillin, or penicillin
Clindamycin	IV administration of 300 mg 30 min before procedure and IV or oral administration of 150 mg 6 h after initial dose
	For patients considered high risk and not candidates for standard regimen
Ampicillin, gentamicin, and amoxicillin	IV or IM administration of ampicillin, 2.0 g, plus gentamicin, 1.5 mg/kg (not to exceed 80 mg), 30 min before procedure; followed by amoxicillin, 1.5 g, orally 6 h after initial dose; alternatively, the parenteral regimen may be repeated 8 h after initial dose
	For high-risk patients allergic to ampicillin, amoxicillin, or penicillin
Vancomycin	IV administration of 1.0 g over 1 h, starting 1 h before procedure; no repeated dose necessary
	Genitourinary and Gastrointestinal Procedures
	Standard regimen
Ampicillin, gentamicin, and amoxicillin	IV or IM administration of ampicillin, 2.0 g, plus gentamicin, 1.5 mg/kg (not to exceed 80 mg), 30 min before procedure; followed by amoxicillin, 1.5 g, orally 6 h after initial dose; alternatively, the parenteral regimen may be repeated once 8 h after initial dose
	For patients allergic to ampicillin, amoxicillin, or penicillin
Vancomycin and gentamicin	IV administration of vancomycin, 1.0 g, over 1 h plus IV or IM administration of gentamicin, 1.5 mg/kg (not to exceed 80 mg), 1 h before procedure; may be repeated once 8 h after initial dose
	Alternative regimen for low-risk patients
Amoxicillin	3.0 g orally 1 h before procedure, then 1.5 g 6 h after initial dose

ABBREVIATIONS: IM, intramuscular; IV, intravenous.

Ideally, the choice of antibiotic agent(s) for the treatment of a specific infectious disease in a given host in the ICU should be based on unequivocal results from rigorous, controlled clinical trials. With a few exceptions, such data do not exist. Therefore, the selection of the proper antimicrobial agent depends on careful consideration of the known or likely susceptibility patterns of the putative pathogen in this specific type of patient at this particular institution, the natural history of the infection, and the spectrum of agents likely or known to be effective for treatment of this type of infection. The two former areas are reviewed in other sections of this book and are not elaborated on here. This chapter emphasizes the importance of knowledge of the clinical pharmacology of antibiotics as one critical element in the rational use of drugs for treatment of infectious disease in the ICU patient.

The selection of the proper drug is essential to minimize toxicity and maximize efficacy. The following key steps relative to knowledge of the antimicrobial agents in humans should be systematically considered in the selection process. These steps are essential to the rational use of any drug.

A. *Individualize* the treatment by considering the following in choosing drugs and designing dosage regimens.
  1. Processes that alter the pharmacokinetics of the drug
    a. Physiologic
      - Extremes of age
      - Pregnancy
      - Barriers to drug penetration (e.g., blood-brain barrier, intraocular fluid)
    b. Disease induced
      - Barriers to drug penetration (avascular abscess wall, infarcts, burn eschar, wet gangrene, etc.)
      - Changes in drug clearance because of hepatic, renal, or other disease (e.g., enhanced aminoglycoside clearance in burned patients, penicillins in cystic fibrosis patients)
    c. Drugs administered concurrently
      - Chemical interaction (e.g., penicillins inactivate aminoglycosides in azotemic plasma)
      - Enhanced metabolism
      - Competitive inhibition of renal or metabolic clearance in the kidney or liver
      - Displacement of highly bound drug from plasma protein
  2. Processes that alter the pharmacodynamics of the drug
    a. Allergy to the drug
    b. Other (e.g., reduced seizure threshold)

B. *Select* and *monitor* therapeutic end points.
  1. Clinical symptoms and signs of infection
  2. Laboratory measures of
    a. Efficacy (e.g., leukocyte concentration, erythrocyte sedimentation rate, serial imaging results such as brain abscess shrinkage on serial computed tomographic scans)
    b. Toxicity (e.g., creatinine concentration and urinalysis in patients receiving aminoglycosides)
  3. Microbiologic (e.g., serial cultures, serum bactericidal titers)
  4. Pharmacologic—serum concentrations of drugs

Selecting the proper antimicrobial agent, skillfully individualizing the dose regimen, and choosing the appropriate parameters to monitor for beneficial and adverse effects of drugs are closely related to knowledge of the pharmacologic

effects of antimicrobial agents in humans. The remainder of this chapter reviews these aspects of many classes of antimicrobial agent from the intensivist's perspective.

Antibacterial Agents

This section reviews selected aspects of commonly used groups of antimicrobial agents likely to be prescribed by intensivists, with an emphasis on the clinical pharmacology of the drugs rather than on their molecular pharmacology and mechanisms of action.

PENICILLINS

MECHANISM OF ACTION The penicillins are natural and semisynthetic compounds that have in common a thiazolidine ring connected to a β-lactam ring to which is attached a side chain of variable composition. The composition of the side chain affects the antibacterial spectrum of the molecule. The integrity of the β-lactam ring is essential for the antibacterial activity of the penicillins. Hence, its enzymatic hydrolysis by β-lactamases is the most important mechanism of bacterial resistance to penicillins.

Penicillins are generally bactericidal. The antibacterial effect of penicillins involves binding to penicillin binding proteins (PBPs), which are peptidases in the cell wall of susceptible bacteria.[6] The types of PBPs found in different bacterial species vary. High activity of penicillins against susceptible bacteria correlates with high affinity binding to certain PBPs, especially PBPs 1, 2, and 4. Modifications in the penicillin side chain of some semisynthetic penicillins have enhanced their antibacterial activity against gram-negative bacteria by increasing their ability to pass through the lipopolysaccharide outer layer to reach PBP ligands in the peptidoglycan layer and, less importantly, by increasing their resistance to β-lactamase, which these organisms all contain in small amounts in the periplasmic space between the inner and outer membranes.

Penicillin binding to PBPs inhibits peptidoglycan assembly and cross-linking. Cell death is usually the result of activation of endogenous autolysins (peptidoglycan hydrolases), which cause structural defects, resulting in cell lysis. Occasionally, stable round forms develop that continue to grow for several generations before lysis ultimately occurs.[7] Hence, although different penicillins, carbapenems, and cephalosporins may have different molecular sites of action, combining two or more of these agents to achieve additive or synergistic antibacterial effects is of unproven value.

The antibacterial effect of the penicillins when susceptible organisms are exposed to intermittent doses of the drugs is determined by composite events occurring during three periods: the time during which the antibacterial drug exerts its maximal effect, the time during which the drug is present at concentrations that have a definite but lesser bactericidal effect, and the period after which concentrations have decreased to levels that are not bactericidal but during which some bacteria continue to die at a faster rate than the surviving cells can multiply (now known as the period of the *postantibiotic effect* [PAE]).[8]

Bacterial killing during exposure to penicillins in vitro occurs most rapidly when exposure occurs during the logarithmic phase of bacterial growth. The killing effect of penicillins during this phase shows little dependence on concentration in excess of minimal inhibitory levels. The PAE of the penicillins usually lasts 1 to 3 hours against gram-positive coccal bacteria and 1 hour against susceptible *Enterobacteriaceae* and other enteric gram-negative bacteria. The duration of the PAE is more closely related to the duration of exposure to inhibitory concentrations of penicillin than to concentration per se. Beyond these facts, the relation between penicillin concentration and bacterial killing is complex even in vitro and more so in patients in whom host factors contribute to the antibacterial effect. It has been difficult to use these observations to optimize the way we give penicillins to patients—by intermittent administration or continuous infusion.[9] Morever, because the concentrations at the site of infection cannot be predicted, it is conventional to administer penicillins in relatively large doses at frequent intervals, or else continuously, to ensure the maximal antibacterial effect.[10] The effectiveness of this strategy depends more on the duration that penicillin concentrations exceed the inhibitory level than on the absolute concentration of drug. Extremely high peak concentrations may only increase the frequency of concentration-related adverse effects of penicillins (see below).

MECHANISMS OF RESISTANCE Enzymatic hydrolysis of the β-lactam bond by β-lactamase is the most important mechanism of bacterial resistance to penicillins. Many gram-negative bacteria are inherently insusceptible to penicillins because the penicillins cannot diffuse through the lipopolysaccharide layer to interact with PBPs. In other bacteria, mutations in genes encoding PBPs may yield altered transpeptidases that no longer bind penicillins. Mutant streptococci have been described in which exposure to penicillins triggers synthesis of inhibitors of autolysins.

CLASSIFICATION The penicillins can be divided into five classes based on their clinically most important antibacterial activity, notwithstanding substantial degrees of overlap demonstrable in vitro.

Natural Penicillins

Penicillin G, the prototypical member of this group, is the drug of choice for infections caused by susceptible streptococci, staphylococci, *Clostridia* and *Neisseria* species, and oral anaerobes including *Bacteroides melaninogenicus.*

Aminopenicillins

Ampicillin is the only member of this group, which includes amoxicillin and bacampicillin among others, that can be administered parenterally. It is the drug of initial choice for the treatment of community-acquired meningitis in adults, in addition to a third-generation cephalosporin and, when combined with an aminoglycoside, for the therapy of subacute bacterial endocarditis in individuals with native valves and pyelonephritis suspected to be or caused by *E. faecalis*. Although ampicillin was widely used for treatment for *Haemophilus influenzae* infections, 19% to 24% of *H. influenzae* type B bacteria causing respiratory infection in adults are now resistant to ampicillin, usually by virtue of producing β-lactamase.[11] Accordingly, in the seriously ill patients in whom *H. influenzae* is a potential pathogen, it is prudent to use a drug other than ampicillin until the organism can be shown to lack β-lactamase by in vitro testing.

Penicillinase-Resistant Penicillins

These penicillins, such as cloxacillin and nafcillin, are the antibacterial drugs of choice for therapy of *Staphylococcus aureus* infection suspected or known to be susceptible (collectively referred to as methicillin-sensitive *S. aureus* [MSSA].

Antipseudomonal Penicillins

Ticarcillin has been superseded by the extended-spectrum penicillins (see below) for treatment of patients with suspected or proven infection caused by *Pseudomonas aeruginosa*. The activity of ticarcillin against *Proteus vulgaris*, *Proteus rettgeri*, and *Morganella morganii* exceeds that of ampicillin, but against other enteric aerobic gram-negative bacilli its potency is similar to that of ampicillin and inferior to the extended-spectrum penicillins. In addition, ticarcillin and carbenicillin may interfere more with platelet function, an undesirable side effect in critically ill patients with thrombocytopenia or other potential causes of hemorrhage (e.g., stress ulcers). Because development of resistance during therapy can be a problem, ticarcillin is generally used with an aminoglycoside when *P. aeruginosa* sepsis is suspected or diagnosed.

Extended-Spectrum Penicillins

Piperacillin and mezlocillin inhibit *P. aeruginosa* in a manner similar to the antipseudomonal penicillins but also have considerably more clinically useful activity against a number of other enteric gram-negative aerobic and anaerobic organisms. Mezlocillin is more active than ticarcillin against most *Enterobacteriaceae*, but many strains are resistant through production of β-lactamase. Mezlocillin is active against oropharyngeal gram-negative anaerobic bacilli, but *Bacteroides fragilis* group organisms are not uniformly susceptible. Mezlocillin is highly active against *H. influenzae*, meningococci and gonococci, *Streptococci* (including *S. faecalis*), and penicillin-sensitive *S. aureus* strains. Because of its greater potency against *P. aeruginosa* in vitro, piperacillin is the antipseudomonal penicillin of choice.

Combining piperacillin with the β-lacatamase inhibitor tazobactam (or ticarcillin with clavulanate) extends the spectrum of piperacillin to include a number of β-lactamase–producing bacteria, including *S. aureus*, and some gram-negative bacilli such as *Serratia* species, *Acinetobacter* species, and *B. fragilis*. Thus, piperacillin/tazobactam and ticarcillin/clavulanate have utility in the ICU as broad-spectrum antibiotics in patients in whom *P. aeruginosa* is also a significant concern as an etiologic agent (see section on β-lactamases).

CLINICAL PHARMACOLOGY The absorption of orally administered penicillins is sufficiently variable among even ambulatory patients that, for this reason alone, these drugs are administered only intravenously in the critically ill patient. The range of doses of some penicillins recommended for adult patients with moderate to severe infection, with normal or impaired renal function, and dialysis-dependent kidney disease are presented in Table 45-5.

In the circulation, penicillins are bound to plasma proteins, chiefly albumin, to different degrees, ranging from 18% for ampicillin to 96% for dicloxacillin. This affects the apparent volume of distribution (AVD), the theoretical calculated volume in which a drug must be uniformly distributed if present at the concentration measured in plasma[12] expressed as liters per kg of body weight. The AVD of penicillins is approximately inversely related to the degree of protein binding, ranging from 9% of body weight for dicloxacillin to 41% for ampicillin. Although protein-bound antibiotic is not pharmacologically active,[12a] serum protein binding of penicillins has not proved to be clinically important because the binding is loose and rapidly reversible in vivo, and the doses used in clinical practice greatly exceed the capacity of the plasma proteins to bind drug. The clinical relevance of coadministering

TABLE 45-5 Recommended Intravenous Doses of Selected Penicillins for Adult Patients with Moderate to Severe Infection and Normal or Impaired Renal Function or Undergoing Dialysis

	CREATININE CLEARANCE (mL/min)				DOSE WITH END-STAGE RENAL FAILURE	
	>60	40–49	10–39	<10	Peritoneal Dialysis	Hemodialysis
Natural						
Penicillin G	1–3 million U q 4 h	Up to 2 million U q 4 h	Up to 1 million U q 4 h	Up to 1 million U q 8 h	As for creatinine clearance <10 mL/min	500,000 U q 6 h during dialysis
Amino						
Ampicillin	1–3 g q 6 h	No change	No change	1–3 g q 12 h	As for creatinine clearance <10 mL/min	0.5 g q 6 h
Penicillinase resistant						
Cloxacillin	1.5–3 g q 6 h	No change	No change	1–2 g q 12 h	?	?
Nafcillin	1.5–3 g q 6 h	No change	No change	No change	No change	No change
Antipseudomonal						
Ticarcillin	2–3 g q 3 h	No change	3 g initial dose, then 2 g q 8 h	3 g initial dose, then 2 g q 12 h	As for creatinine clearance <10 mL/min	3 g after dialysis, then 2 g q 12 h
Extended spectrum						
Piperacillin	2–4 g q 4–6 h	No change	2–4 g q 8 h	4 g q 12 h	2 g after dialysis, then 2 g q 12 h	2–4 g after dialysis, then 4 g q 12 h
Mezlocillin	3–4 g q 6 h	5 g q 12 h	5 g q 24 h	5 g q 48 h	3 g q 12 h	Normal doses

drugs that compete for the same albumin binding sites as penicillins is unclear but unlikely, with an interaction due to altered protein becoming likely only when binding exceeds 90%.[13]

Penicillins are largely eliminated from the body as unchanged drug by renal proximal tubular secretion and glomerular filtration, but some metabolic transformation occurs and can compensate for diminished renal clearance of some penicillins. For example, in anuric patients, the plasma elimination half-life ($t_{1/2}$) of penicillin G is increased from 0.5 to 10.0 hours, and doses must be reduced to obviate dose-related toxic effects (see below). However, the serum elimination $t_{1/2}$ of cloxacillin increases only threefold, to 1.5 hours, and no dose reduction is required.

Probenecid, an organic acid like the penicillins, competitively inhibits renal tubular secretion of penicillins. Coadministration results in an array of pharmacokinetic effects including increased plasma concentrations (double in the case of penicillin G), higher concentrations in the cerebrospinal fluid (CSF) because of inhibition of penicillin secretion from CSF into blood by the choroid plexus, and higher free drug concentrations in plasma because of displacement from albumin. The magnitude of these effects is greatest for those penicillins primarily eliminated by renal proximal tubular secretion.

Various other organic acids also compete with penicillins for secretion by renal tubular cells and produce probenecid-like effects on penicillin disposition. These acids include aspirin, phenylbutazone, sulfonamides, indomethacin, thiazide diuretics, furosemide, and ethacrynic acid. The clinical importance of concurrent administration of these drugs on the antibacterial effects of penicillin is not known but is unlikely to be significant.

ADVERSE DRUG REACTIONS Adverse drug reactions (ADRs) include all unwanted effects of drugs. They are classified into those that are immunologically mediated (hypersensitivity or allergic reactions) and those that are dose or concentration related. For antibiotics, the latter class also includes all unwanted or undesired complications arising from perturbations in the normal microbiologic flora (e.g., pseudomembranous colitis and yeast vaginitis) and from superinfections caused by agents resistant to the antibiotics being administered to the patient. A third class comprises ADRs for which the mechanism is not understood. This includes anaphylactoid reactions (similar clinically to anaphylaxis but without a demonstrated immunologic basis) and idiosyncratic effects. ADRs to penicillins mostly are of the first two classes. Although they may rarely be fatal (1 per 100,000 cases treated), hypersensitivity reactions are much more important than dose-related penicillin ADR in the ICU, because such intolerance precludes the use of this useful class of drugs. Allergic reactions to penicillins are not uncommon.[14] The overall incidence in different studies ranges from 0.7% to 10.0%. In order of decreasing frequency, hypersensitivity reactions to penicillins include urticaria, fever, bronchospasm, vasculitis, serum sickness, exfoliative dermatitis, and anaphylaxis. Hypersensitivity reactions may be induced by any member of this group, and cross-reactions must be anticipated. Anaphylaxis has been reported more commonly with penicillin G than with other members of the penicillin group, but this probably reflects the frequency of its use. Anaphylaxis and accelerated urticarial reactions, rash, and serum sickness are triggered by immunobinding of penicillin antigens to immunoglobulin (Ig) E, IgM, and IgG antibodies, respectively.[15] Atopic individuals are not more prone to have allergic reactions to penicillins. Approximately 75% of persons without medical exposure to penicillins have IgM antibody to penicilloyl, the most important penicillin antigen produced by breakage of the β-lactam ring. It acts as a hapten by covalently binding to plasma proteins. The formation of two other antigens, penicilloic acid and penicillanic acid, are increased by high and low pH, respectively. Together, penicilloic and penicillanic acids are known as major determinants because 95% of tissue-bound penicillin is in the form of penicilloyl and penicillanic acid conjugates with body proteins. IgG and IgM antibodies to these moieties occur in most patients treated with penicillins, but the allergic reactions that occasionally result are generally limited to skin rash rather than accelerated, systemic reactions. The term *penicillin minor determinants*, however, refers to benzylpenicillin itself, sodium benzyl penicilloate, and penilloate. IgE-mediated reactions to minor determinants are responsible for most anaphylactic reactions due to penicillins.

Interstitial nephritis associated with methicillin may be a delayed-type hypersensitivity reaction in which the drug induces autoimmunity to renal tubular basement membranes. This unusual immunologically mediated ADR is most commonly seen in patients treated with methicillin for extended periods in large doses, but it has been reported after therapy with most other penicillins and some cephalosporins.

The most important aspect of management of patients with hypersensitivity to penicillins is avoidance. A reliable story of anaphylaxis or an accelerated reaction to any member of this group of drugs (or a cephalosporin or carbapenem) is an absolute contraindication to their use. A history of any other form of hypersensitivity reaction should be given appropriate weight in the therapeutic decision-making process and, in particular, should be balanced against the fact that, perhaps, apart from the treatment of syphilis in the pregnant woman, there are no infectious diseases for which penicillins are absolutely the only effective antibacterial available. If it is decided to administer penicillins to a person with a history of a hypersensitivity reaction, skin testing is advised to identify those with severe hypersensitivity. Testing should be done with major and minor determinant mixtures.[16,17] The reagents themselves appear safe: 1% of patients with a history of penicillin allergy developed reactions to the skin test reagents, mostly urticaria. Negative results of skin testing with both preparations have a high negative predictive value in individuals despite a history of penicillin allergy. Ninety-seven percent to 99% did not experience any reaction on administration of penicillin. However, two (22%) of nine patients with positive skin tests to major or minor determinant mixture given penicillin experienced reactions compatible with IgE-mediated or accelerated penicillin allergy, indicating the positive predictive value of such testing.

Even if no reaction to a skin test reagent is observed, it is prudent to administer the first dose with epinephrine and resuscitation equipment at hand and to inject only a fraction of the initial dose. If none occurs after 15 to 30 min, the remainder of the initial dose may be administered. If a reaction occurs during skin testing, penicillin should, in general, be avoided, although in selected cases consultation with a clinical immunologist to effect desensitization may be appropriate.

Rashes caused by ampicillin should be distinguished from those caused by other penicillins. The rashes occur in 7% to 8% of patients, an incidence three times greater than with all other penicillins, and are not considered to be immunologically mediated. Certain patients are more prone to experience ampicillin-induced skin reactions: females, hyperuricemic patients receiving allopurinol, individuals with acute mononucleosis caused by Epstein-Barr virus (EBV) or cytomegalovirus (CMV), and those with lymphocytic leukemia, reticulosarcoma, and other lymphomas. The rashes typically are morbilliform, appear 4 to 5 days after initiation of therapy, are not accompanied by other signs of allergy, and usually subside during continued therapy. Skin testing with ampicillin and major and minor penicillin determinants will be negative. Such rashes should not be considered a contraindication to subsequent therapy with one of the other penicillins.

A few adverse reactions to penicillins are neither immunologically mediated nor dose related. Neutropenia occurs in about 15% of patients treated with methicillin and somewhat less commonly with other penicillins. Neutropenia generally occurs 10 to 20 days after initiation of therapy and resolves rapidly on discontinuation of therapy. Reversible thrombocytopenia and bone marrow suppression have also been described in patients receiving penicillins. Hypokalemia has been described in up to 81% of patients without significant renal dysfunction who were treated with methicillin or carbenicillin. The mechanism of this ADR is unclear. Although these two penicillins likely behave like a nonabsorbable anion in the distal renal tubule, increasing passive potassium urinary excretion, some have proposed that the hypokalemia may instead be caused by an intracellular shift of potassium because of a membrane-altering effect.

Four dose-related side effects of the penicillins are uncommon but may be clinically important. First, undesirable augmentation of body sodium or potassium content can occur in patients with salt and water overload (e.g., congestive heart failure or renal failure) who are treated with large doses of penicillins because the penicillins are formulated for injection as salts of one of these cations (Table 45-6).

Second, penicillins may cause neurotoxic effects including seizures. This is related to an innate pharmacologic effect of the molecule and, hence, to the concentration of drug in the body. Penicillin G is the most inherently epileptogenic of the group. Seizures usually will be seen only in patients with impaired renal function given large doses. Impairment of the blood-brain barrier due to meningeal inflammation, uremia, and cardiopulmonary bypass may contribute to the effect, as may hyponatremia or concomitant probenecid therapy that blocks penicillin excretion from the CSF. Neurotoxicity will progress from muscular irritability with choreiform, involuntary twitching, or myoclonic jerking to a depressed level of consciousness and, ultimately, seizures, unless penicillin administration is halted. Penicillin concentrations in lumbar sac CSF in excess of 5 mg/L have been associated with seizures,[18] but the critical concentration in the CSF contiguous with cortical neurons has not been described. This toxic effect of penicillins will resolve with discontinuation of therapy and elimination of penicillin. Unfortunately, in those most predisposed to this ADR (patients with severe renal failure),[19] penicillin clearance will be slower than in those with normal renal function.

A third dose-related side effect of penicillins is impaired platelet aggregation that may lead to clinically important bleeding. Ticarcillin is the most potent in this regard, although piperacillin, mezlocillin, and penicillin G can induce this defect.[20] The effect is caused by a concentration-dependent blocking of receptor sites on platelet membranes, thereby interfering with adenosine-induced aggregation. The defect may persist for up to 12 days after drug discontinuation, suggesting an effect on megakaryocytes and circulating platelets. Impaired platelet aggregation can be avoided by limiting dose size and avoiding these agents in patients with conditions predisposing to hemorrhage, such as thrombocytopenia or severe hepatic dysfunction.

A fourth category of ADR caused by penicillin is that related to suppression of endogenous bacterial flora. The most important example is *Clostridium difficile* toxin-induced pseudomembranous colitis or diarrhea. As a group, the penicillins (and cephalosporins) rank close behind clindamycin as the most common antibacterials causing this undesirable and potentially life-threatening complication.

TABLE 45-6 Cation Content of Some Penicillins

	Sodium Content
Penicillin G[a]	2 mEq/million units
Ampicillin	2.6 mEq/g
Cloxacillin	2.3 mEq/g
Nafcillin	2.9 mEq/g
Ticarcillin	5.9 mEq/g
Piperacillin	2.0 mEq/g
Mezlocillin	1.9 mEq/g

[a] Potassium penicillin G has a sodium content of 1.7 mEq/million units.

CEPHALOSPORINS

The cephalosporins resemble the penicillins structurally and in their mode of action, versatility, and general lack of toxicity. They possess a β-lactam structure in which the thiazolidine ring characteristic of penicillins is replaced by a six-member dihydrothiazine ring. Modification in the side chains at the 3 and 7 positions of the nucleus has yielded molecules with different pharmacokinetic and pharmacodynamic characteristics, respectively.[21] Side chain modifications at position 7 alter and extend the spectrum of antibacterial activity but, in some cases, also cause unusual adverse pharmacologic effects such as inhibition of vitamin K–dependent hepatocyte synthesis of clotting factors II, VII, IX, and X and induction of reactions to disulfiram (Antabuse) in individuals ingesting or being treated with alcohol concurrently.

The potency of third-generation cephalosporins against a wide range of clinically important bacteria and a general lack of serious toxicity have led to an emerging consensus that certain members of this group are drugs of first choice for a number of severe bacterial infections, especially nosocomial ones, including meningitis, pneumonitis, bacteremia, and urinary tract infections.[22] This is particularly true for infection caused by increasingly resistant organisms and for initial, empirical therapy in the ICU setting. The first- and second-generation cephalosporins, however, are not drugs of first choice for any acute life-threatening infectious disease that might be seen in ICU patients, although they continue to be important first-line

drugs for a variety of less severe infections such as cellulitis and community-acquired pneumonia.

MECHANISM OF ACTION The mechanism of action of the cephalosporins is identical to that of the penicillins and involves binding to, and inactivation of, PBPs in the inner aspect of the cell wall of susceptible bacteria.

MECHANISM OF RESISTANCE Resistance to cephalosporin antibiotics is also mediated by mechanisms that confer resistance to penicillins. Cephalosporins may not penetrate through the lipopolysaccharide cell wall to the site of the PBPs. The cephalosporin may be inactivated by β-lactamase. Substantial evidence indicates that exposure to some third-generation cephalosporins may induce synthesis of large amounts of β-lactamase with high affinity for the cephalosporins. As a result, the antibiotic is avidly bound by the enzyme and unable to interact with PBPs.[23] This is hypothesized to be the mechanism of resistance observed in *Enterobacter*, *Serratia*, *Citrobacter*, and *Pseudomonas* species exposed to third-generation cephalosporins.

CLASSIFICATION Cephalosporins are arbitrarily classified as belonging to one of three generations. This classification is based solely on the spectrum of antibacterial activity. None of the cephalosporins is useful for infections caused by *Streptococcus faecalis* or methicillin-resistant *Staphylococcus epidermidis* and *S. aureus* (MRSA). However, cephalosporins are useful antibacterials for treatment of a wide range of infections and for surgical prophylaxis (Table 45-1).

The *first-generation cephalosporins* are potent inhibitors of aerobic gram-positive cocci such as *S. aureus* and *S. pneumoniae*, with moderate activity against a limited number of aerobic gram-negative bacilli including *Escherichia coli*, *Klebsiella pneumoniae*, and indole-negative proteus. They are active against some anaerobic gram-positive and gram-negative oropharyngeal organisms, as is penicillin G, but are not consistently effective against *B. fragilis* group and other fecal anaerobic organisms. Cefazolin is the prototypical agent of this group, which contains the most active cephalosporins against susceptible aerobic gram-positive cocci.

The *second-generation cephalosporins* as a group exhibit enhanced potency against *E. coli*, *K. pneumoniae*, and indole-negative proteus, compared with first-generation agents. Individual members of this class have clinically important antibacterial activity against β-lactamase–producing *H. influenzae* (cefamandole, cefuroxime, and cefotetan), *B. fragilis* group organisms (cefoxitin, cefotetan), *Neisseria meningitidis* and *N. gonorrhoeae*, and some species of enteric gram-negative bacilli. However, activity against the last group of organisms is sufficiently variable so that it is more appropriate to initially prescribe a third-generation cephalosporin, aminoglycoside, or perhaps fluoroquinolone. The extended spectrum of some of these second-generation agents has made them drugs of importance, albeit not first choice, in some serious infections: mixed aerobic and anaerobic pulmonary, gastrointestinal, genital tract, and skin and soft tissue infections, such as aspiration pneumonia, intra-abdominal and pelvic peritonitis, pelvic inflammatory disease, and diabetic foot infection (cefoxitin), respectively. For pneumonia caused by an exacerbation of chronic bronchitis, cefuroxime is commonly prescribed.

The *third-generation cephalosporins* are particularly noteworthy for their potency against aerobic gram-negative bacilli, which they inhibit in concentrations 10 to 100 times less than required for aminoglycosides. These cephalosporins inhibit a wide range of this group of bacteria that are resistant to first- and second-generation cephalosporins, extended-spectrum penicillins, and aminoglycosides. The lack of inherent toxicity of third-generation cephalosporins is another advantage in treating ICU patients with multisystem dysfunction, especially renal failure. Two of the third-generation cephalosporins, cefoperazone and, particularly, ceftazidime, have clinically useful activity against most strains of *P. aeruginosa,* although susceptibility may differ substantially across institutions. Third-generation cephalosporins are not more resistant to penicillinase produced by *S. aureus*, nor are they more active against this organism than are the penicillinase-resistant penicillins or first-generation cephalosporins, which are preferred for therapy of such infections.

Recommended intravenous doses of selected cephalosporins for adult patients with moderate to severe infection and normal or impaired renal function or undergoing dialysis are presented in Table 45-7.

CLINICAL PHARMACOLOGY Like the penicillins, the cephalosporins are variably bound to plasma proteins; the range is 15% (cephalexin) to 84% (cefazolin) with AVDs of 0.10 (cefoxitin) to 0.30 (cefuroxime) L/kg. These characteristics are independent of the generation to which the agent belongs. They differ from the penicillin group pharmacokinetically:

1. Hepatic biotransformation is a significant route of elimination for some members of this group. Moreover, cefotaxime hepatic biotransformation yields metabolites with antibacterial activity that contribute to the overall antibacterial effect, although their precise contribution is unclear.
2. Some have prolonged plasma $t_{1/2}$ in patients with normal renal function. For example, the extended plasma $t_{1/2}$ of 8 hours for ceftriaxone has made once- to twice-daily dosing feasible without a loss in efficacy.
3. The third-generation drugs readily cross the blood-brain barrier. Therefore, unlike the first- and second-generation cephalosporins, the third-generation ones predictably attain therapeutic concentrations in the CSF and are efficacious for treatment of meningitis. However, therapeutic concentrations of cephalosporins are attained in the vitreous and aqueous humors of the eye only by sub-Tenon or intraocular injection or topical administration of antibiotic, respectively.

Probenecid inhibits renal proximal tubule secretion of cephalosporins just as for penicillins. Moderate to severe renal dysfunction necessitates reduction in the doses of some of the cephalosporins (see Table 45-7). Hemodialysis or peritoneal dialysis may remove sufficient drug (see Table 45-7) to necessitate additional postdialysis doses. Only cefoperazone doses must be reduced in patients with moderate to severe hepatic dysfunction.

ADVERSE DRUG REACTIONS Hypersensitivity reactions to the cephalosporins qualitatively similar to those produced

TABLE 45-7 Recommended Intravenous Doses of Selected Cephalosporins for Adult Patients with Moderate to Severe Infection and Normal or Impaired Renal Function or Undergoing Dialysis

	CREATININE CLEARANCE (mL/min)				DOSE WITH END-STAGE RENAL FAILURE	
	>60	40–59	10–39	<10	Peritoneal Dialysis	Hemodialysis
First generation						
Cefazolin	0.5–2 g q 8 h	0.5 g initially, then 0.5–2 g q 12 h	0.5 g initially, then 0.25–1 g q 24 h	0.5 g initially, then 0.1–0.5 g q 24 h	As for creatinine clearance <10 mL/min	As for creatinine clearance <10 mL/min plus 0.25 g after dialysis
Second generation						
Cefuroxime	0.75–1.5 g q 8 h	No change	0.75–1.5 g q 12 h	0.75 g q 24 h	0.75 g q 24 h	0.75 g after each dialysis and each 24 h
Cefoxitin	1–2 g q 6–8 h	Same dose at interval of 8–12 h	Same dose at interval of 12–24 h	Same dose at interval of 24–36 h	As for creatinine clearance <10 mL/min	1–2 g after each dialysis and each 72 h
Third generation						
Ceftriaxone	1–4 g q 24 h	No change	No change	No change	No change	1 g q 24 h
Cefotaxime	0.5–2 g q 4–8 h	No change	0.5–2 g q 12–24 h	0.5–2 g q 24 h	As for creatinine clearance <10 mL/min	As for creatinine clearance <10 mL/min plus 0.5–2 g after each dialysis
Ceftazidime	0.5–2 g q 8 h	0.5–1.5 g q 12 h	0.5–1.5 g q 24 h	0.5–1 g q 48 h	0.5 g q 24 h	0.25–0.5 g q 24 h plus 0.5–1 g after dialysis
Cefoperazone	0.5–2 g q 6–12 h	No change	No change	No change	No change	No change

by penicillins are the most common adverse effects.[15] They are no more common with any single cephalosporin or generation of cephalosporins and likely are related to the shared bicyclic nuclear structure. However, cephalosporins lose both their ring structures when exposed to β-lactamases, in contrast to penicillin degradation. Thus, molecules unique to cephalosporins that may function as haptens are generated. This probably accounts for the lack of predictable cross-allergenicity between penicillins and cephalosporins. Haptenic activity of acyl side chains at position 7 of the β-lactam ring further complicates the predicting of reactions induced by cephalosporins in individuals with a history of penicillin intolerance. Cross-reactions do occur in penicillin-sensitive patients treated with cephalosporins.[24] However, the frequency of such cross-reactions is minimally, if at all, increased in patients with penicillin allergy. Nevertheless, a history of penicillin allergy of the immediate or accelerated type precludes use of cephalosporins. No established testing methods identify cephalosporin allergy.

Dose-related side effects of cephalosporins are generally less marked than those induced by penicillins. The likelihood of cation overloading even with large doses of cephalosporins is small. Although they are mostly sodium salts containing up to 3.6 mEq Na^1/g (Ceftriaxone), the total sodium load administered even with very large doses is unlikely to be clinically important except in rare patients with severe sodium and water overload. The epileptogenic potential of the cephalosporins is less than that of the penicillins. All cephalosporins in high concentration except cephaloridine are similar to penicillins in interfering with platelet aggregation.

Modifications induced by altering the side chain on the dihydrothiazine ring at position 3 have yielded cephalosporins with unusual pharmacologic side effects: cefamandole, cefoperazone, cefotetan, and moxalactam have a methyltetrazolethiol side chain that provokes a disulfiram-like reaction in patients ingesting or receiving ethanol. Inhibition of hepatic aldehyde dehydrogenase with accumulation of acetaldehyde during metabolism of alcohol is the presumed mechanism. These four agents may also predispose the patient to bleeding because of interference with synthesis of vitamin K–dependent clotting factors[25] in addition to their inhibition of platelet aggregation. Bleeding may only occur in patients whose oral intake of vitamin K and synthesis of endogenous vitamin K by colonic flora are impaired concomitantly. As a consequence, cefamandole, cefoperazone, and moxalactam are no longer widely used.

Superinfections are surprisingly uncommon given the wide antibacterial spectrum of third-generation cephalosporins, with occurrences from 1% of cefotaxime recipients up to 3% to 5% for cefoperazone-treated patients.[26] Superinfections in patients treated with moxalactam have been observed to frequently be caused by *S. faecalis*. Otherwise, superinfection caused by resistant aerobic enteric gram-negative bacilli, *Clostridia* species, and yeast has been the most common.

Adverse effects of cephalosporins on the kidney are rare with two exceptions: cephaloridine in doses of 4 to 6 g/d causes acute tubular necrosis, and cephalothin appears to enhance the nephrotoxic effect (but not vestibular or cochlear toxic effects) of gentamicin and tobramycin.

OTHER β-LACTAM DRUGS

Carbapenems and monobactams are two new classes of β-lactam antibiotics of importance to intensivists (Table 45-8).

TABLE 45-8 Recommended Intravenous Doses of Selected Carbapenems, Monobactams, and Combinations of a β-Lactam Antibiotic with a β-Lactam Inhibitor for Adult Patients with Moderate to Severe Infection and Normal or Impaired Renal Function or Requiring Dialysis

	CREATININE CLEARANCE (mL/min)				DOSE WITH END-STAGE RENAL FAILURE	
	>60	40–59	10–39	<10	Peritoneal Dialysis	Hemodialysis
Carbapenem						
Imipenem	0.25–1 g q 6 h	No change	0.5 q 8–12 h	0.25 g q 12 h	0.25 g q 12 h	As for creatinine clearance <10 mL/min plus 0.5 g after dialysis
Meropenem	1 g q 8 h	No change	0.5 g q 12 h	0.5 g q 24 h	0.5 g q 24 h	As for creatinine clearance <10 mL/min plus dose after dialysis
Ertapenem	1.0 g q 24 h	1.0 g q 24 h	0.5 g q 24 h	0.5 g q 24 h	?	0.5 g q 24 h; if dosed <6 h before dialysis, give 150 mg after dialysis
Monobactam						
Aztreonam	1–2 g q 6–12 h	0.75–1.5 g q 6–12 h	0.5–1 g q 6–12 h	0.25–0.5 g q 6–12 h	?	?
β-Lactamase inhibitor plus β-lactam antibiotic						
Ticarcillin clavulanate	3 g/0.1 g q 3–6 h	3 g/0.1 g q 6 h	3 g/0.1 g q 12 h	2.0 g/0.1 g q 24 h	3 g/0.1 g q 2 h	2 g/0.1 g q 24 h plus 3 g/0.1 g after dialysis
Piperacillin/tazobactam	3 g/0.375 g q 6 h	No change	3 g/0.375 g q 8 h	3 g/0.375 g q 12 h	?	As for creatinine clearance <10 ml/min plus 0.75 g/.094 g after dialysis

[a] Use the 3 g/10.1 g combination for kidney infection.

CARBAPENEMS

Carbapenems possess novel stereochemical characteristics that distinguish them from the other bicyclic β-lactams, the penicillins, and cephalosporins. Imipenem, meropenem, and ertapenem are currently licensed carbapenems.

Imipenem and meropenem have the widest spectrum of any β-lactam antibiotic studied to date. They are potent inhibitors of nearly all common bacterial pathogens, including those resistant to aminoglycosides and newer cephalosporins, in concentrations as low as, or lower than, any other β-lactams. Imipenem binds primarily to PBP-2 and is not hydrolyzed by most β-lactamases, penicillinases, or cephalosporinases. The wide spectrum of activity appears to be related to the ability of this relatively compact β-lactam molecule to diffuse readily through porin channels of gram-negative enteric bacilli, in addition to the β-lactamase resistance conferred on the molecule by the unusual transconformation related to the hydroxyethyl side chain. Tolerance is not observed when bacteria are exposed to imipenem (i.e., there is no major discrepancy between inhibitory and bactericidal concentrations), and, unique among β-lactams, imipenem exerts a marked PAE on gram-positive and gram-negative bacteria. Imipenem inhibits gram-positive cocci other than *E. faecium* and MRSA, most *Enterobacteriaceae*, and gram-negative bacilli including *P. aeruginosa* but excluding most *Pseudomonas cepacia* and *S. maltophilia* strains, and all oral and most fecal anaerobic bacteria. There is no cross-resistance between imipenem and other β-lactams.

Meropenem differs from imipenem in possessing slightly greater activity against gram-negative bacteria due to more rapid penetration through the cell wall. Thus, it inhibits some *P. aeruginosa* strains resistant to imipenem.[27]

Ertapenem has a narrower spectrum of activity than does imipenem or meropenem. It is more similar to meropenem than to imipenem against *Enterbacteriaceae* including most anaerobes. However, unlike imipenem and meropenem, it possesses no activity against *P. aeruginosa* or *Acinetobacter* species.[28]

The place of the carbapenems in the therapy of infection in ICU patients continues to evolve. Clinical experience suggests that meropenem and imipenem are therapeutically equivalent.[29] For treatment of lower respiratory tract infection in patients in the ICU, meropenem is more effective than ceftazidime.[30] Ertapenem has been demonstrated to be comparable to piperacillin/tazobactam in patients with intra-abdominal, skin and skin structure, and pelvic infections;[31] its efficacy compared with imipenem and meropenem has not been described. For treatment of patients with meningitis, meropenem is the carbapenem of choice (imipenem use is associated with a significant risk of seizures and ertapenem has not been studied in patients with meningitis).

Overall, imipenem and meropenem are appropriate as monotherapy for treatment of serious nosocomial and community-acquired infections due to aerobic and/or anaerobic bacteria. Ertapenem may be as efficacious, but data are not available to support that conclusion and ertapenem

should not be administered where *P. aeruginosa* is a probable or proven cause of infection. In general, they are appropriate for indications such as those for which extended-spectrum cephalosporins would be used. As monotherapy, they are probably as effective as clindamycin combined with an aminoglycoside for treatment of seriously ill patients with intra-abdominal infections.[32] Imipenem and meropenem should not be used as monotherapy of *P. aeruginosa* infections because of the risk of resistance, and ertapenem should not be used at all. The greatest value of the carbapenems may be that their broad spectrum permits their use conveniently in place of multiple-drug regimens for polymicrobial infections, with an attendant reduction in the risk of adverse reactions. Recommended intravenous doses of the carbapenems for adult patients with moderate to severe infections and variable renal function are listed in Table 45-8.

CLINICAL PHARMACOLOGY The carbapenems are not absorbed after oral administration and therefore are available only in parenteral formulations. Imipenem and meropenem are only 2% to 20% protein bound, whereas ertapenem is highly bound. They penetrate into a wide variety of tissues and brain cells but poorly into other cells. These characteristics make them unsuitable for treatment of infections caused by bacteria that are primarily intracellular pathogens and may account in part for the epileptogenic potential of imipenem in particular.

The carbapenems are eliminated from plasma by a first-order process primarily by glomerular filtration, with a mean $t_{1/2}$ of 1 hour for imipenem and meropenem; the $t_{1/2}$ for ertapenem is 4 hours, due in part to its high protein binding. Renal tubular secretion is minimal.

Renal handling of filtered carbapenems differs markedly. Imipenem is remarkably stable to bacterial β-lactamase but its β-lactam ring structure is susceptible to metabolic degradation in humans, primarily by peptidases in the brush border of renal tubular epithelial cells. Inhibition of these enzymes (by cilastatin, see below) increases urinary recovery of undegraded imipenem from 7% to 38% up to 70% to 85%. Meropenem and ertapenem are not degraded by renal tubular peptidase and, unlike imipenem, therefore are formulated without cilastatin.

Like cephaloridine, imipenem is toxic to proximal renal tubule epithelial cells. The toxic moiety appears to be a hydrolysis product, the formation of which can be safely blocked by coadministration of cilastatin, which inhibits the catalytic effect of dehydropeptidase I in the brush border and completely eliminates renal tubular damage without affecting the plasma $t_{1/2}$ of imipenem. A ratio of 1:1 for imipenem to cilastatin is optimal, and imipenem is marketed in this fixed combination.[33]

ADVERSE DRUG REACTIONS The carbapenems are generally well tolerated, like other β-lactams. Major adverse effects such as diarrhea, superinfection, or pseudomembranous colitis are infrequent. Allergic reactions, including rashes and drug fever, occur in 2% to 3% of subjects, and cross-allergenicity to penicillins has been observed. The relatively high incidence of seizures, 0.2% in series of patients treated with imipenem,[34] is unique among β-lactam antibiotics and also not seen with meropenem or ertapenem. Pre-existing central nervous system (CNS) disease, advanced age, and renal insufficiency predispose patients to this serious but reversible side effect. Seizures ought to be preventable by appropriate dose reductions in patients with renal disease, a maneuver of particular importance in patients with CNS disease.

MONOBACTAMS

Aztreonam is the first marketed member of a new completely synthetic class of monocyclic β-lactam antibiotics called *monobactams*. Aztreonam has no clinically important activity against gram-positive or anaerobic bacteria because of failure to bind to PBPs of these organisms. Aztreonam binds primarily to PBP 3 in *Enterbacteriaceae*, *P. aeruginosa*, and other gram-negative aerobic bacteria and, hence, has a bactericidal effect; its narrow spectrum of activity most resembles that of the aminoglycosides. When combined with other β-lactam antibiotics to treat gram-negative aerobic bacterial infections, the net effect is unpredictable. Aztreonam is more predictably synergistic, or at least additive, with aminoglycosides.[35] Lack of susceptibility is caused by failure of aztreonam to cross the outer cell wall and failure to bind to PBPs. Aztreonam is stable in the presence of a wide variety of β lactamases,[36] so inactivation by this process is less important as a mechanism of bacterial resistance than for other β-lactam antibacterial agents.

The exact niche of aztreonam in the treatment of gram-negative aerobic bacterial infections in ICU patients is unclear at present. The most logical, albeit rare, circumstance for which it could be used would be in treating patients with significant allergy to β-lactam antibiotics (see below) in whom its combination with another agent, such as an aminoglycoside to obtain a synergistic or additive effect, is deemed necessary. Aztreonam also may be used alone in such patients if an aminoglycoside is considered contraindicated, but its relative utility compared with aminoglycosides and other alternatives such as fluoroquinolones and trimethoprim-sulfamethoxazole (TMP-SMX) has not been evaluated in controlled trials.

CLINICAL PHARMACOLOGY Aztreonam is poorly absorbed after enteral administration because of intragastric hydrolysis and, hence, must be administered intramuscularly or intravenously. After such injection, aztreonam distributes widely and achieves therapeutic concentrations in all body tissues and fluids except perhaps the vitreous humor. Metabolism has a minimal effect on aztreonam clearance. Aztreonam is eliminated primarily by renal filtration and tubular secretion, but some excretion in bile into the gut occurs.[37] Elimination is a first-order process with a plasma $t_{1/2}$ of 1.7 hours that is inversely related to glomerular filtration rate and increases to 6 hours in anephric patients. The usual dose, 1 to 2 g every 6 to 12 hours (maximum, 8 g/d), should be reduced in patients with renal insufficiency. The drug is removed by hemodialysis and peritoneal dialysis, but alternative schedules for such patients (see Table 45-8) have not been established.

ADVERSE DRUG REACTIONS Aztreonam shares the general safety profile of other β-lactam antibiotics. Up to 7% of patients experience rash, diarrhea, nausea, or vomiting, and isolated elevations of serum transaminase concentrations. Aztreonam is unique among β-lactams in being weakly immunogenic and not cross-allergenic with other penicillins or cephalosporins.[15] Aztreonam has been administered safely to penicillin-allergic patients, including those with positive skin

test results. This unique property appears to result from the fact that aztreonam lacks the allergenic bicyclic nuclear structure of penicillins, cephalosporins, and carbapenem β-lactam antibiotics.

β-LACTAMASE INHIBITORS

Clavulanate, sulbactam, and tazobactam are β-lactam compounds that possess weak, insignificant antibacterial activity but are clinically useful because they extend the spectrum of activity of many β-lactam antibiotics by inhibiting β-lactamases. The three compounds differ in their potency and the range of lactamases they inhibit.[38] Tazobactam inhibits a wider range of plasmid- and chromosome-encoded lactamases than clavulanate and sulbactam. This fact and the greater intrinsic antibacterial effect of piperacillin in comparison with ticarcillin or amoxicillin/ampicillin account for the wider antibacterial spectrum and greater potency of piperacillin-tazobactam than the other two combinations of drugs. Thus, although injectable formulations of ampicillin-sulbactam and ticarcillin-clavulanate exist, piperacillin-tazobactam has largely supplanted the other two compounds. Moreover, the combination of tazobactam with piperacillin makes the combination an effective inhibitor of MSSA, thereby converting piperacillin into a broad-spectrum antimicrobial with attendant added utility for ICU patients.

The efficacy and safety of piperacillin-tazobactam compared with standard therapy has been demonstrated in controlled trials of patients with intra-abdominal infection, postpartum endometritis or pelvic inflammatory disease, community-acquired pneumonia, and skin and skin-structure infections.[39,40] The usual dose is 3 g piperacillin with 375 mg tazobactam every 6 hours, but for patients seriously ill with proven or suspected *Pseudomonas* species infection, 4 g plus 500 mg for every 4 hours with another drug is recommended. Studies suggest that piperacillin-tazobactam combined with amikacin is more efficacious (61% efficacy) than ceftazidime with amikacin (54%) for treatment for febrile episodes in neutropenic cancer patients.[41]

The value of piperacillin-tazobactam compared with piperacillin alone for treatment of serious infection caused by *Pseudomonas* species is unclear[39] because most lactamase-mediated resistance of *Pseudomonas* species is a result of the production of inhibitor-insusceptible enzymes. Therefore, for the treatment of serious *Pseudomonas* infections, Sanders and Sanders recommend piperacillin-tazobactam (4 g/0.5 g) every 4 hours with an additional agent such as an aminoglycoside.[39]

CLINICAL PHARMACOLOGY Clavulanate, sulbactam, and tazobactam share many clinical pharmacologic characteristics common to β-lactam antibiotics. Only the characteristics of tazobactam combined with piperacillin are discussed here; the characteristics of amoxicillin-clavulanate,[42] ampicillin-sulbactam,[43] and ticarcillin-clavulanate[44] have been reviewed elsewhere.

When piperacillin and tazobactam are administered together in a ratio of 8:1, the pharmacokinetic activities of piperacillin are unaffected. However, the pharmacokinetic characteristics of tazobactam are significantly affected, largely owing to competitive inhibition of renal proximal tubular secretion of tazobactam by the much larger quantity of piperacillin. When the peak plasma concentration of tazobactam was increased by about 30% and the plasma $t_{1/2}$ by about 100% from a mean of 0.45 to 0.94 hours, renal clearance was reduced approximately 25%.[45]

Piperacillin and tazobactam are eliminated primarily into urine by glomerular filtration and tubular secretion. Less than 1% of piperacillin and no tazobactam are secreted into bile. In patients with renal impairment, the renal clearances of piperacillin and tazobactam are proportionately reduced. Dose reductions are recommended for patients with creatinine clearances lower than 40 mL/min (see Table 45-8). Hemodialysis removes approximately 35% of piperacillin-tazobactam and peritoneal dialysis removes approximately 20% of piperacillin-tazobactam. Hence, the supplementary doses recommended after the two types of dialysis are different (see Table 45-8).

In patients with hepatic cirrhosis, the elimination $t_{1/2}$ of piperacillin and tazobactam increases by about 20%, but no dose reductions are recommended in such patients.

ADVERSE DRUG REACTIONS Adverse effects of piperacillin-tazobactam have been generally mild to moderate in severity.[34] Gastrointestinal complaints, mostly diarrhea, were noted in 4.6% of patients, but with a range from 0% to 32%; skin rash occurred in 0% to 12% of subjects. In their review, Sanders and Sanders concluded that, overall, the rates and character of adverse reactions are comparable to, or less than, those reported for piperacillin alone, ticarcillin-clavulanate, ampicillin-sulbactam, and imipenem-cilastin.[39]

AMINOGLYCOSIDE ANTIBIOTICS

One or more of the aminoglycoside antibiotics (streptomycin, kanamycin, gentamicin, tobramycin, netilmicin, amikacin, and neomycin) has been a mainstay of our antibacterial armamentarium since the discovery of streptomycin in 1943. Streptomycin currently is limited to use in the combination therapy of tuberculosis and for treatment of *Francisella*, *Yersinia pestis* infection, and brucellosis. Neomycin is too toxic for systemic use but is still administered orally for the treatment of portosystemic encephalopathy (see Chaps. 83 and 84). The remaining agents—kanamycin, gentamicin, tobramycin, netilmicin, and amikacin—are first-line drugs for the treatment of serious infection caused by *Enterobacteriaceae* and *Pseudomonas* and *Serratia* species. The importance of these bacterial species as causes of nosocomial infection has progressively increased in the antibacterial era, and the importance of the aminoglycosides has increased in parallel. Kanamycin utility has been limited by widespread resistance among many *Enterobacteriaceae* and innate inefficacy against *P. aeruginosa*. Gentamicin, tobramycin, amikacin, and netilmicin share similar spectra of activity with the following caveats. Tobramycin is twice as potent as gentamicin or netilmicin in inhibiting *P. aeruginosa* in vitro, although the clinical relevance of this superiority is not clear. Netilmicin is the most potent inhibitor of *S. epidermidis*. Amikacin is the most resistant to aminoglycoside-inactivating enzymes. As a result, many enteric bacilli resistant to kanamycin, gentamicin, and netilmicin remain susceptible to amikacin.

Unfortunately, the utility of these agents in the therapy of patients with significant infection in the ICU has been limited by their inherent toxic effects on the proximal tubule epithelial

cells of the kidney and the hair cells of the cochlea, saccule, and utricle and by the emergence of resistance.

MECHANISMS OF ACTION The aminoglycosides are rapidly bactericidal in contrast to β-lactam antibacterial drugs, which cause bacterial cell death only after a lag period.[9] Although their mode of action has been extensively studied,[46] the precise mechanism(s) of their lethal effect remains unclear. It is generally accepted that aminoglycosides interfere with bacterial protein synthesis by binding to the 30S subunit of bacterial ribosomes, resulting in misreading of mRNA codons and synthesis of faulty bacterial proteins, but the resulting alterations in protein molecules are not considered sufficient by themselves to cause cell death. Aminoglycoside uptake by bacteria depends in part on energy derived from aerobic metabolism. Thus, all of these agents are inactive under anaerobic conditions. In vitro, aminoglycosides cause bacterial cell death in a concentration-dependent manner,[47] and this effect is little affected by inoculum size.[48] This pharmacologic effect underlies, in part, the attractiveness of once-daily aminoglycoside dosing to attain greater efficacy (and less toxicity) than is achieved with multiple doses each day. Moreover, these agents consistently produce a concentration- and time-dependent PAE on gram-positive and gram-negative aerobic bacteria.[49] The PAE persists longer (usually longer than 3 hours) for gram-negative aerobic bacilli than for gram-positive aerobic bacteria (usually less than 2 hours). The mechanism of the PAE of aminoglycosides is likely related to the time required for organisms to resynthesize proteins essential for replication.

MECHANISMS OF RESISTANCE Aminoglycoside resistance of aerobic organisms is mediated primarily by aminoglycoside-inactivating enzymes.[50] Less commonly, ribosomal mutation and diminished permeability of bacterial cells to aminoglycoside molecules account for resistance. Different enzymes may acetylate, adenylate, or phosphorylate aminoglycosides and, by these changes, preclude binding of the drug to ribosomes. The aminoglycosides differ considerably in their susceptibility to enzymatic modification. For example, gentamicin is susceptible to modification by at least five different enzymes elaborated by gram-negative bacilli, but amikacin is susceptible only to an acetyltransferase found in some *P. aeruginosa* and *Acinetobacter* species strains. The genes encoding aminoglycoside-modifying enzymes are most commonly acquired on plasmids. This usually occurs in the setting of heavy and widespread use of these agents (antibiotic selection pressure).[50] As a result, gentamicin resistance emerging under antibiotic selection pressure in institutions is more common than resistance of bacteria to amikacin; resistance of bacteria to tobramycin, netilmicin, and kanamycin is of intermediate prevalence. Although aminoglycoside resistance is to some extent a function of use, this association is not entirely predictable because other factors are probably involved.[52]

CLINICAL PHARMACOLOGY The aminoglycosides are polycations whose polarity is responsible in part for many of their shared clinical pharmacokinetic characteristics. They are poorly absorbed after oral administration, have an AVD that is mathematically similar to the extracellular fluid volume, are excluded from the normal subarachnoid space, vitreous humor, and prostatic fluid, and are eliminated almost exclusively by the kidney.[53]

After intramuscular administration, the aminoglycosides are rapidly and completely absorbed. Their AVD is equal to 25% to 30% of ideal body weight. The AVD is approximately 25% less in obese than in nonobese individuals and approximately 20% greater in patients with protein-calorie malnutrition. This information must be used to calculate the initial dose, which is a function of the desired plasma concentration multiplied by the AVD. For gentamicin, tobramycin, and netilmicin, the minimal inhibitory concentration (MIC) of most susceptible aerobic enteric gram-negative bacilli is 2 to 4 mg/L, and toxicity has been shown to increase at peak concentrations in excess of 10 mg/L. It is therefore conventional to prescribe an initial dose to attain a serum concentration (Cs) of 7 mg/L, which for a 70-kg adult would be 7 mg/kg $\times$ 70 kg $\times$ 0.25, or approximately 120 mg. For kanamycin and amikacin, for which desired Cs values are 25 to 30 mg/L, the initial dose, similarly calculated, would be 500 mg.

Aminoglycosides are actively concentrated in the endolymph of the cochlea, saccule, and utricle and in epithelial cells of the proximal renal tubule, a fact important in the production of aminoglycoside toxicity[54] (see below). Less than 1% of an injected dose appears in the feces and none in saliva.

Aminoglycosides are eliminated exclusively by glomerular filtration. An inverse relation exists between plasma $t_{1/2}$ and creatinine clearance as a measure of glomerular filtration rate. At creatinine clearance rates of 100 mL/min, the plasma $t_{1/2}$ averages 2 hours.[55] As the creatinine clearance declines, the plasma $t_{1/2}$ increases. In the presence of renal disease, it is possible to prescribe maintenance doses by repeating the initial dose at intervals equal to three times the estimated $t_{1/2}$ of the drug. However, it has been found to be more practical to maintain the interval at the conventional 8 or 12 hours but to reduce the dose administered proportionate to renal function (e.g., if estimated remaining renal function is 50% of normal, one can administer 50% of the dose at 8-hour intervals[51]); such a dose regimen will result in a lower peak plasma aminoglycoside concentration but in trough plasma concentrations comparable to those achieved by maintaining the dose (milligrams per kilogram) constant and increasing the dose interval. The efficacy and safety of these two approaches has not been compared in patients with renal insufficiency. Maderazo and colleagues confirmed the utility of the following formulas for adjusting the dosing regimen for aminoglycosides (and other drugs eliminated almost wholly by glomerular filtration).[56]

A. To reduce the dose and maintain the same interval as in a person with normal renal function, use this formula:

$$\text{reduced dose} = \frac{\text{creatine clearance}}{100} \times \text{n, and}$$

B. To maintain the dose but decrease the dose frequency, use this formula:

$$\text{new dose interval} = \frac{100}{\text{creatine clearance}} \times \text{u}$$

where the creatinine clearance (milliliters per minute) is calculated from the formula of Cockcroft and Gault[57] and

n represents dose (milligrams) and u represents the dose interval (hours) in a person with normal renal function.

If possible, it is preferable to use antibiotics other than aminoglycosides in patients with significant renal insufficiency. If aminoglycosides must be used, serum aminoglycoside measurements should be used to maximize efficacy and minimize toxicity (see below). The importance of serum aminoglycoside measurements is greater when renal function is fluctuating or when disease or other drugs may be affecting aminoglycoside disposition. For example, in burned and febrile patients, aminoglycoside pharmacokinetic characteristics are altered, and larger doses will be required. In patients with renal failure given aminoglycosides and penicillins in large doses, aminoglycosides are inactivated. The rate and extent of the inactivation depend on the concentration of the penicillin. Kanamycin, gentamicin, and tobramycin are most susceptible to inactivation in this manner, and amikacin the least with netilmicin of intermediate susceptibility.

The concentration in plasma (Cp)-versus-time curve after intravenous administration of an aminoglycoside dose is affected by the pre-existing Cp, the dose administered, and the method of administration (intramuscular or intravenous injection, bolus, or infusion and the rate of infusion). These variables particularly affect the time and magnitude of peak Cp. Trough Cp is less affected by these factors. This variability has made it more difficult to define the relation between post-dose aminoglycoside concentration and therapeutic effect than that between trough Cp and toxic effects. Although incontrovertible data do not exist, some data demonstrate that Cp measured 60 minutes after intramuscular or 15 minutes after an intravenous infusion of the aminoglycoside is related to efficacy. For gentamicin, a post-dose Cp of 8 mg/L or larger is associated with a better outcome than lower Cp in patients being treated for gram-negative aerobic bacillary pneumonia, whereas concentrations of at least 5 mg/L are associated with a better outcome in patients being treated for non-pneumonia, non-CNS, gram-negative aerobic bacillary infections.[58] It is assumed that the same relation holds for netilmicin and tobramycin. For amikacin and kanamycin, post-dose Cp values of 20 to 40 mg/L are desirable.

A direct relation between predose or trough aminoglycosides Cp and toxicity was first demonstrated in 1950 for streptomycin.[59] Trough Cp higher than 3 mg/L during once-daily intramuscular administration of streptomycin for therapy of tuberculosis was associated with an increased risk of dizziness, presumably owing to vestibulotoxicity. Old age was also a factor. At other times Cp values were much more variable, and often higher, but did not correlate with this toxic effect. Subsequent studies have suggested an increased risk of gentamicin nephrotoxicity, demonstrated by a rise in serum creatinine concentration, when trough gentamicin Cp exceeds 2 mg/L.[60] This interpretation is supported by studies in animals.

Compelling in vitro and correlative in vivo data provide strong support for the current practice of administering aminoglycosides intermittently rather than by constant infusion to optimize efficacy and minimize toxicity. Extrapolating further, some have argued for once-daily dosing in individuals with normal renal function.[49] These expectations are based on in vitro observations including a concentration-dependent aminoglycoside antibacterial effect over a wide range of concentrations beginning at the MIC and extending beyond tolerable serum concentrations in patients, and concentration-dependent PAE. Moreover, these observations have been supported by studies in animals with experimental infection and provide the rationale for dosing to achieve high aminoglycoside concentrations in plasma and at the site of infection. However, clinical trials comparing conventional multiple-daily doses with once-daily administration of aminoglycosides have demonstrated little or no advantage of this practice over traditional 8- or 12-hour administration in terms of efficacy or safety.[61,62] It may only be more convenient than dosing two or three times daily.

The methodologically best-designed controlled trials included almost exclusively immunocompetent adults with normal renal function; a few had mildly impaired renal function (serum creatinine <300 mmol/L).[63] Controversy exists concerning virtually all other aspects of the practice. This includes the question of whether it is appropriate to prescribe aminoglycosides once daily to infected patients with neutropenia, sepsis syndrome, and moderate to severe renal insufficiency.[64] Additional subgroups for whom few or no data are available to support once-daily aminoglycoside use include pediatric patients and patients with severe burns, endocarditis, pregnancy, or ascites. Moreover, uncertainty exists about optimal dose size[65] and the rationale for, and specifics of, serum aminoglycoside concentration measurement for monitoring.[66] Despite these limitations of the available data, as early as 1993, 19% of a random sample of 336 acute care hospitals in the United States reported that aminoglycosides were being prescribed once daily in their institutions, albeit with the anticipated variability in practice expected given the incomplete database.[67]

Until definitive data become available to guide the practice of once-daily administration of aminoglycosides, the following guidelines are recommended:

1. Restrict the practice to the prescription of netilmicin, gentamicin, tobramycin, and amikacin.
2. Once-daily administration is acceptable to treat adult patients with normal or mildly impaired renal function (serum creatinine <300 mmol/L or estimated creatinine clearance >30 mL/min). Patients should not be pregnant; endocarditis, neutropenia, severe burns, or sepsis and moderate or severe renal impairment are relative contraindications.
3. Doses: netilmicin 6 mg/kg; gentamicin and tobramycin 4 mg/kg; and amikacin 15 mg/kg.
4. Infuse the drug over 60 min, preferably by a pump, to permit interpretation of the peak serum concentration result as described by Moore and colleagues.[68]
5. Measure aminoglycoside Cp:
   - **A.** To enhance efficacy, measure the Cp 60 minutes after the end of the infusion "peak."[68] If the peak Cp is below 5 mg/L for netilmicin, gentamicin, or tobramycin, increase the dose proportionately (e.g., if Cp = 4 mg/L, increase the dose by at least 20%).
   - **B.** To minimize toxicity, measure the Cp just before the dose. If the Cp is above 2 mg/L for netilmicin, gentamicin, or tobramycin or above 10 mg/L for amikacin, reduce the dose proportionately.

6. Measure aminoglycoside Cp at the peak and trough every 3 days if renal function (serum creatinine concentration) is stable and more frequently if it is not.

ADVERSE DRUG REACTIONS All aminoglycosides share three dose-related, largely reversible toxic effects, although quantitative differences exist among members of this family. These are neuromuscular paralysis, nephrotoxicity, and cochleovestibular toxicity. The mechanisms of the unwanted effects are not well characterized, but an interaction of the cationic aminoglycoside molecule with calcium, magnesium, and membrane phospholipids[69] may be common to all. These effects of aminoglycosides are a result of their inherent pharmacologic properties occurring at doses close to those required for treatment. As such, the effects are not likely completely avoidable.

Neuromuscular paralysis of clinical consequence is likely to be seen only in patients receiving neuromuscular blocking drugs or with diseases such as botulism or myasthenia gravis. Aminoglycoside-induced skeletal muscle paralysis involves inhibition of acetylcholine release and blockage of acetylcholine receptors. The postsynaptic inhibitory effect is directly related to high concentrations of aminoglycoside at the neuromuscular end plate as seen when the antibiotic is injected rapidly as a bolus or when large quantities of aminoglycoside are administered and absorbed (e.g., by injection in the pleural or peritoneal cavity). The effect can be avoided by slow intravenous administration over 30 to 60 minutes or intramuscular injection and mitigated by calcium injection.

Aminoglycoside nephrotoxicity spans a wide spectrum, ranging from asymptomatic increased urinary excretion of renal tubular epithelial cell brush border enzymes to renal failure necessitating dialysis. In between is diminished creatinine clearance demonstrated by elevated serum creatinine concentration. Enzymuria is almost universally demonstrable in patients receiving therapeutic doses of aminoglycosides, whereas oliguric renal failure is rare. Elevated serum creatinine concentration is observed in 5% to 25% of treated patients.

The nephrotoxic effect is associated with accumulation of aminoglycoside in renal proximal tubule epithelial cells with resultant cell damage and, possibly, inhibition of synthesis of vasodilatory prostaglandins resulting in renal afferent arteriolar vasoconstriction and diminished glomerular filtration. Renal injury manifest as elevations in serum creatinine concentration usually occurs several days after initiation of therapy and is largely reversible because of epithelial cell regeneration. Animal and clinical studies have indicated that neomycin is the most nephrotoxic and amikacin the least nephrotoxic of currently used aminoglycosides. Gentamicin is more nephrotoxic than tobramycin.[70]

The nephrotoxic effect of aminoglycosides in animal studies is related directly to the height of the trough serum aminoglycoside concentration and the area under the serum concentration-time curve, which in turn are the important determinants of aminoglycoside uptake and sequestration in proximal tubule epithelial cells. This leads to the recommendation that trough serum aminoglycoside concentrations should be as low as possible.[61] For gentamicin, levels below 3 mg/L at trough are recommended.[62] Intuitively, the same level would seem to be appropriate for tobramycin and netilmicin, which have similar pharmacokinetic properties and antibacterial potency to gentamicin. The appropriate trough Cp for amikacin is 5 to 10 mg/L.

Additional risk factors for nephrotoxicity include older age, female sex, concomitant liver disease, hypotension, and concomitant drug therapy with cephalothin, cisplatin, amphotericin B, and cyclosporine.

Ototoxic effects of aminoglycosides include hearing loss caused by cochlear injury and vertigo caused by vestibular damage. Neither has been as well studied as nephrotoxicity because of difficulties in assessing cochlear and vestibular functions in critically ill patients. Nevertheless, available data suggest that all the injected aminoglycosides can cause both types of injury. Tobramycin is more ototoxic than netilmicin.[71]

The incidence of clinically detectable hearing loss ranges from 0.5% to 5.0% and that of vestibular dysfunction causing vertigo or nystagmus ranges from 0.4% to 4.0%. Auditory toxicity is caused by selective destruction of the outer hair cells of the organ of Corti, especially at the basal turn, with subsequent retrograde degeneration of the associated fibers of the auditory nerve. The vestibular toxicity is caused by similar injury to hair cells of the ampullae cristae. Because these are highly differentiated cells that do not regenerate if destroyed, ototoxicity is irreversible. Animal and some clinical data suggest that ototoxic effects are related to selective concentration and trapping of the cation aminoglycoside molecules in the perilymph and endolymph of the cochlea and vestibular apparatus and this in turn to high trough serum aminoglycoside concentrations,[59,72] although other data show no relation.[73] Renal insufficiency is the most important risk factor,[73] but dose is important in patients with normal renal function; duration of therapy and older age are of variable pertinence. Concomitant ethacrynic acid, but not furosemide therapy, increases the risk of ototoxicity.

Other adverse effects of aminoglycosides are uncommon.These include pseudomembranous colitis due to *C. difficile* toxin and hypersensitivity reactions such as rash, fever, Stevens-Johnson syndrome, and delirium.

Although dose-related toxic effects of aminoglycosides may be unavoidable despite assiduous attention to dose selection plus monitoring of serum concentrations, the small risk of toxic effects that are generally reversible should not engender use of small, potentially inefficacious doses of these drugs in critically ill ICU patients.

POLYMYXINS B AND E (COLISTIN)

The polymyxins are a group of basic polypeptide antibiotics that inhibit only aerobic gram-negative bacteria. Their antimicrobial action is mediated by binding to phospholipids in the cytoplasmic membrane, with disruption of membrane permeability, macromolecular and ion disequilibria, and cell lysis. Intrinsic resistance is caused in part by inability of the drug to gain access to the cytoplasmic membrane; acquired resistance is rarely observed. The potency and spectrum of activity of polymyxin are similar to those of the aminoglycosides. However, because of more marked nephrotoxicity, only polymyxins B and E (colistin) are used clinically. Polymyxin B continues to be used in topical or oral formulations from which it cannot be absorbed. Thus, polymyxin B has been administered orally to suppress aerobic gram-negative bacterial intestinal flora in immunocompromised patients. Polymyxin E (colistin) alone, or combined with another antibiotic, has

a limited role as a parenteral agent for the treatment of infection caused by multiply resistant, nosocomial pathogens for which no alternative agents are available. Polymyxin E has been administered with rifampicin to treat multiresistant nosocomial *S. marcesens* infection[74] and with cotrimoxazole, to treat *P. cepacia* and *S. marcescens* infections.[75,76] It is unaffected by enzymes that degrade β-lactam and aminoglycoside antibiotics.

CLINICAL PHARMACOLOGY Like aminoglycosides, polymyxins are eliminated unchanged by glomerular filtration. The plasma elimination $t_{1/2}$ of colistin is 1.6 to 3.0 hours. No reliable data exist on the relation between serum concentrations and therapeutic or toxic effects. Accordingly, when polymyxin E is administered parenterally, avoidance of drug toxicity depends solely on clinical evaluation, urinalysis, and measurement of changes in glomerular filtration rate. In the critically ill ICU patient, the confounding effect of concurrent changes owing to disease and other drugs makes this more difficult than usual.

The usual dose of polymyxin E is 2.5 to 5.0 mg/kg per day as two or four divided intramuscular or intravenous doses or a continuous intravenous infusion at a rate of 5 to 6 mg/h. Polymyxin E accumulates in patients with renal failure so that the total daily dose should be reduced:

Creatine Clearance (mL/min)	Dose
>20	Standard dose
5–19	25.0% of standard dose every 12 h
<5 and hemodialysis and peritoneal dialysis	15% of standard dose every 12 h

ADVERSE DRUG REACTIONS Adverse reactions after topical or oral administration are uncommon, although nausea, vomiting, and diarrhea are caused by administration of large doses ($\geq$600 mg) by mouth. After parenteral administration, side effects are similar to those caused by aminoglycosides. Reversible dizziness, paresthesias especially affecting the face, incoordination caused by vestibulotoxicity and proteinuria, microscopic hematuria, and progressive azotemia or acute tubular necrosis may occur. Respiratory paralysis owing to neuromuscular blockade occurs rarely; unlike that owing to aminoglycosides, respiratory paralysis cannot be reversed by neostigmine.

A recent report described the nephrotoxicity of polymyxin B in 80 patients with nosocomial multidrug-resistant gram-negative bacterial infections.[77] Mortality rate was 20%; the organism was cleared in 88% of patients. Nephrotoxicity, defined as a doubling in serum creatinine occurred in 14% of patients, all of whom had normal baseline creatinine levels. Older age was the only predictor of nephrotoxicity; neither total dose nor duration of polymyxin B therapy was a significant predictive factor. This study is encouraging in demonstrating that this drug, which is often active against multidrug-resistant gram-negative nosocomial bacteria, can be used, if necessary, with a reasonable therapeutic-to-toxic index.

GLYCOPEPTIDE ANTIBIOTICS

Vancomycin and teicoplanin are structurally and functionally related members of the glycopeptide family of antibacterial drugs.

VANCOMYCIN

The antibacterial activity of vancomycin is essentially restricted to gram-positive bacteria. It is the drug of first choice for initial therapy of MRSA and *S. epidermidis* infection.[22] It is a significant alternative agent for treatment of enterococcal infection as ampicillin resistance continues to increase. *Staphylococcus aureus*, *S. epidermidis*, streptococci, and *Corynebacterium* and *Clostridium* species are almost uniformly sensitive to vancomycin. However, strains of vancomycin-resistant *S. aureus* (MIC >32 mg/L) are being reported.[78] Fortunately, their prevalence has not yet significantly compromised the utility of vancomycin as initial therapy for infections suspected to be caused by these organisms. In combination with gentamicin or tobramycin, vancomycin synergically inhibits *S. aureus* strains, including those resistant to methicillin and nearly all strains of *S. faecalis.* A major crisis in antimicrobial therapeutics is looming with the emergence of vancomycin-resistant enterococci (VRE), which are often resistant to all other available antibiotics.

MECHANISMS OF ACTION AND RESISTANCE Vancomycin is bactericidal by inhibiting an early stage in the formation of the peptidoglycan of the cell wall. Resistance to it, at least in enterococci, is associated with synthesis of a plasmid-encoded ligase that results in synthesis of cell wall precursors that will not bind vancomycin but can still be cross-linked by enterococcal transpeptidases to form a normal cell wall. Concern is increasing that this vancomycin resistance may be transferred to MRSA, because this can be effected readily in vitro. This appears to have occurred in a case of vancomycin-resistant *S. aureus*[78] in which vancomycin resistance was mediated by acquisition of the *Van A* gene.

CLINICAL PHARMACOLOGY Vancomycin is poorly absorbed after oral administration. For systemic therapy, it must be injected intravenously because intramuscular injection causes marked discomfort and possibly tissue necrosis. It is 30% to 55% protein bound and distributes widely into inflamed tissues and spaces in effective concentrations, including the subarachnoid space in patients with meningitis and the peritoneal cavity in patients with renal failure and peritonitis complicating chronic peritoneal dialysis. The AVD is approximately 40% of total body weight. It may be 50% less on average in morbidly obese patients, but the implication of this for dose calculation is unclear. The drug is eliminated primarily unchanged by glomerular filtration. The plasma elimination $t_{1/2}$ varies widely, with a range of 3 to 13 hours (average, 6 hours) even in patients with normal renal function. Plasma $t_{1/2}$ is prolonged with renal insufficiency and may be as long as 17 days in anuric patients. In patients with liver disease without concomitant renal dysfunction, plasma $t_{1/2}$ is also increased and has been reported to be as long as 37 hours. This observation and the incomplete recovery of injected vancomycin in urine collections from healthy volunteers indicate that vancomycin is partly eliminated by a nonrenal, presumably hepatic, route.

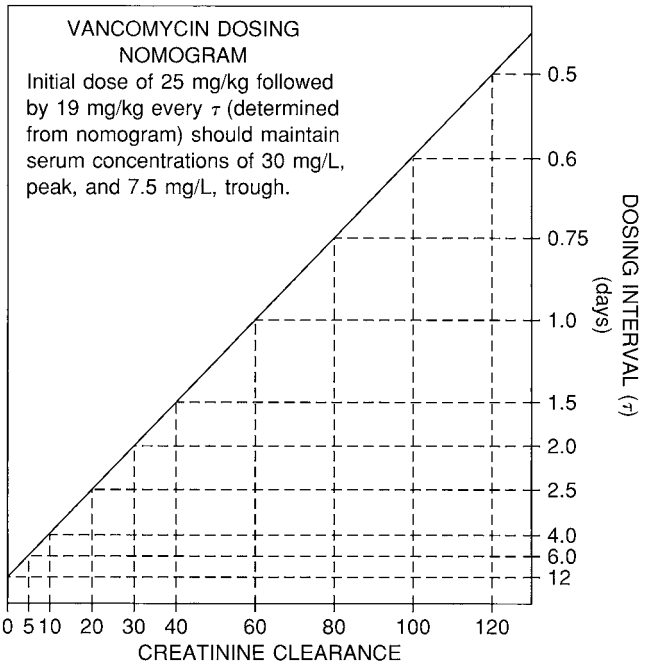

FIGURE 45-1 Dosage nomogram for vancomycin in patients with various degrees of renal function. The creatinine clearance can be estimated by a formula using the patient's age, sex, and serum creatinine as follows. In males, creatinine clearance (mL/min) = {wt(kg) [140 − age (years)]}/0.81 [serum creatinine (mL/L)]. In females, multiply the above value by 0.85. ***(Reproduced, with permission, from Matzke GR, et al.[79])***

Vancomycin Cp is directly proportional to dose. The Cp 2 hours after infusion of 0.5, 1.0, and 2.0 g in adult volunteers averages 2 to 10, 25, and 45 mg/L, respectively. The mean Cp 6 hours after infusion of 0.5 g is 6 mg/L and that 12 hours after infusion of 1.0 g is 5 mg/L.

The usual adult dose of vancomycin is 6.5 to 8.0 mg/kg administered every 6 hours or 15 mg/kg every 12 hours, given in a relatively dilute solution infused over 60 min. More rapid infusion is frequently associated with the occurrence of the *red-man syndrome*, an important adverse reaction (see below). In adults with impaired renal function, dose reductions are recommended to avoid ototoxic and, purportedly, nephrotoxic side effects (see below). One nomogram that permits calculation of the appropriate dose interval is shown in Fig. 45-1.[79]

In patients with fluctuating renal function and those with clinically important liver disease, dose intervals should be based on vancomycin concentrations in serum after the usual initial dose. Although the data demonstrating a relation between vancomycin Cp and beneficial or toxic effects are not robust[80] and lack consensus in some countries,[81] avoiding maximum concentrations of 30 mg/L is conventional after the distribution phase is complete (30 minutes after the end of infusion) to obviate ototoxicity and perhaps the red-man syndrome, as is avoiding trough concentrations above 10 mg/L, to minimize nephrotoxicity. However, in patients with gram-positive bacteremia receiving vancomycin alone, peak serum vancomycin above 20 mg/L and trough concentrations above 10 mg/L were associated with an "improved outcome."[82] If a continuous infusion of vancomycin is administered, the target Cp should be 15 mg/L.

In functionally anephric patients who are being dialyzed, 1 g vancomycin infused weekly yields maximum Cp values of 40 to 50 mg/L that are usually well tolerated and remain therapeutic after 7 days (Cp 5 to 7 mg/L). Thus, once-weekly vancomycin infusions are a practical and convenient method for treating serious infection in patients requiring dialysis. Hemodialysis does not remove significant amounts of vancomycin so that no supplemental doses need be administered after completion of dialysis.

Vancomycin administered by mouth is effective for therapy of pseudomembranous colitis.[83] It is considered the drug of choice for severe cases, whereas metronidazole is no less effective for mild to moderately severe disease.[84] The recommended dose is 125 mg administered four times per day; the maximum dose is 500 mg administered four times per day. In patients with adynamic ileus, the optimal therapy for pseudomembranous colitis is unknown. Some experts recommend vancomycin administration intravenously and by nasogastric tube. When cholestyramine is administered by mouth for treatment of pseudomembranous colitis, coadministration of vancomycin should be avoided because it will be inactivated by binding to the resin. In patients with severe pseudomembranous colitis and moderate to severe renal dysfunction treated with vancomycin by mouth, vancomycin Cp values have been reported to reach peak concentrations as high as 13 mg/L depending on the dose given.[85] It was estimated that only an average of 4.0% of oral doses were absorbed and that the accumulation of vancomycin in serum was primarily a function of concurrent renal insufficiency in those patients. Monitoring of vancomycin Cp values has been recommended if such therapy is prolonged (>28 days) or involves higher than conventional doses (>2 g/d).

Vancomycin administered intraperitoneally in dialysis fluid is the preferred mode for treatment of gram-positive coccal peritonitis complicating peritoneal dialysis. This choice is predicated on the knowledge that peritonitis in such patients is a superficial and localized infection of the serosal surface of the peritoneum. Absence of fever in 80% to 90% of milder cases and the rarity of bacteremia support this view. Vancomycin moves readily bidirectionally across the inflamed peritoneal lining into the blood stream, and vice versa. Accordingly, the Cp ultimately attained approaches that in the peritoneal fluid. One vancomycin treatment schedule for peritonitis begins with a dose of 1 g in the initial dialysate, followed by 50-mg maintenance doses in subsequent exchanges. On such therapy, mean vancomycin Cp rises to 9 mg/L at 5 hours and averages 6 to 9 mg/L during subsequent dwell periods. In patients with severe peritonitis, it is not certain that concomitant intravenous therapy alters the outcome, but vancomycin may be administered by both routes. In such patients, the need for frequent measurement of vancomycin Cp to avoid excessively high levels becomes more acute.

ADVERSE DRUG REACTIONS The red man syndrome is the most important immediate adverse effect of vancomycin infusion. It appears to be caused by histamine release. The reaction may begin within minutes of starting the infusion or shortly after its completion and definitely occurs more

commonly with rapid infusions. In general, tingling and flushing of the neck, face, and thorax develop during the course of a rapid infusion, sometimes with progression to hypotension and shock. The flushed appearance usually resolves over several hours. Antihistamines can prevent vancomycin-induced hypotension in humans,[86] but the value of antihistamines for treating hypotension after the onset of the reaction is unclear. Nevertheless, treatment with fluid administration, antihistamines, and steroids has been advocated for severe reactions. Many, but not all, occurrences of the syndrome can be prevented by following the manufacturer's strong recommendation that vancomycin be infused over at least 60 min. A maximum rate of administration of 10 mg/min may further reduce the risk of hypotension, as demonstrated in a study in volunteers.[87]

A maculopapular rash (sometimes accompanied by pruritus, fever, and rigors), not dissimilar to the cutaneous flushing seen as a component of the red man syndrome, may occur in up to 3% of patients treated with vancomycin. This adverse effect appears to be an allergic reaction, so intensivists may have to decide whether to risk readministration of the antibiotic in such patients. In those in whom the reaction is part of a typical red man syndrome, continued therapy with cautious, slower administration has been advocated; however, if allergy is diagnosed, use of alternative agents is more prudent.

Ototoxicity owing to vancomycin does not appear to be common, but definitive data are lacking.[88] In one prospective study, reversible tinnitus and dizziness occurred in 2 of 34 patients.[89] However, tinnitus may herald high-frequency hearing loss and deafness that will progress despite discontinuation of vancomycin therapy. Ototoxicity is probably caused by injury to the hair cells of the cochlea, a toxic effect identical to that caused by aminoglycoside antibiotics. It is therefore not surprising that vancomycin ototoxicity is more likely when aminoglycosides are administered concomitantly. Ototoxicity is also more frequent in elderly patients and those with renal failure. It is associated with peak vancomycin Cp above 80 mg/L but is infrequent if drug is administered so the peak and trough Cp values are below 30 mg/L and below 10 mg/L, respectively.

The nephrotoxic potential of vancomycin administered alone or in combination with an aminoglycoside is not clear despite several careful prospective observational studies. Nephrotoxicity demonstrated by a rise in creatinine Cp values has been reported in 5% to 75% of patients treated with vancomycin alone and in 0% to 22% of patients treated with vancomycin plus an aminoglycoside. In one study, trough vancomycin Cp values above 30 mg/L were associated with nephrotoxicity,[80] but others could not identify such an association.[80] Renal dysfunction developing during vancomycin therapy is usually mild and reversible, but as many as 9% of patients may have persisting evidence of diminished renal function.[89]

Even though the nephrotoxicity of vancomycin and the relevance of monitoring serum vancomycin concentration are debated, until the issue is clarified serum creatinine levels should be monitored in patients being treated with vancomycin and doses should be adjusted to obtain peak and trough Cp values below 30 mg/L and below 10 mg/L, respectively. Combination therapy with an aminoglycoside plus vancomycin requires even more careful attention to these measures.[90]

TEICOPLANIN

Teicoplanin is, like vancomycin, a glycopeptide antibiotic. It is produced by *Actinoplanes teichomyceticus* and is formulated as a complex mixture of six closely related molecules.[91]

Teicoplanin, like vancomycin, inhibits a wide range of gram-positive aerobic and anaerobic bacteria ranging from MRSA to *Clostridia* species. It is indicated for treatment of infections caused by susceptible gram-positive bacteria including MRSA and VRE. In the ICU, it probably represents an alternative to vancomycin. Administered orally, teicoplanin may be an alternative to metronidazole or vancomycin for the treatment of *C. difficile* toxin diarrhea and colitis.

The usual dose is 400 mg infused intravenously over 30 minutes or by intramuscular injection (unlike vancomycin) once daily or as often as every 12 hours for treatment of more severe infection.

MECHANISM OF ACTION Teicoplanin is bactericidal like vancomycin, presumably through its inhibition of peptidoglycan synthesis and, hence, the cell wall of daughter cells. It binds to the alanine residue of the terminal portion of the muramyl pentapeptide, resulting in inhibition of the transglycosylation reaction and cell wall biosynthesis.

Compared with vancomycin, it contains more fatty acid chains that, it is hypothesized, facilitate penetration through the bacterial cell wall and result in greater potency and a longer biological $t_{1/2}$. These fatty acids also may account for its solubility at pH 7.4, which permits good local tolerance and rapid absorption after intramuscular injection.

MECHANISM OF RESISTANCE Some bacteria are inherently insensitive to glycopeptide antibiotics; these include *Leuconostic*, *Pediococcus*, *Lactobacillus*, and *Erysipelothrix* species. Of greater clinical importance are strains that are differentially inhibited by teicoplanin and vancomycin. *Enterococcus faecalis* and *E. faecium* strains expressing the *Van A* gene exhibit high-level resistance to both drugs. Resistance is transferable by conjugation and inducible by the glycopeptides. *Enterococcus faecium* strains with the Van B phenotype exhibit susceptibility to teicoplanin but moderate resistance to vancomycin. Differential susceptibility of *S. epidermidis* or *S. haemolyticus* to the two glycopeptides has been observed. In vitro selection of stepwise resistance to teicoplanin has been observed in coagulase-negative staphylococci and *S. aureus* strains with heterogeneous patterns of β-lactam susceptibility.

Overall, these data suggest that teicoplanin may be an alternative to vancomycin for some vancomycin-resistant infections.

CLINICAL PHARMACOLOGY Absorption after intramuscular injection is equivalent in extent to intravenous injection. The AVD is 0.8 to 1.62 L/kg body weight. The drug does not penetrate into the CSF. Elimination from plasma is almost wholly by renal mechanisms; only 3% of teicoplanin is metabolized. The elimination $t_{1/2}$ is 155 to 168 hours.

Renal and total body clearance correlate with creatinine clearance, and doses must be reduced in patients with impaired renal function. Dose reductions are recommended to begin after the fourth day of treatment. For patients with creatinine clearance 40 to 60 ml/min, maintenance

doses should be halved by administering one-half the dose daily or the usual dose every 2 days. For those with creatinine clearance slower than 40 mL/min and in patients on hemodialysis (teicoplanin is not removed by dialysis), the maintenance dose should be one-third the usual dose by administering one-third the usual dose daily or the full dose every 3 days.

For treatment of peritonitis due to susceptible patients on continuous ambulatory peritoneal dialysis (CAPD), a loading dose of 400 mg intravenously or intramuscularly should be accompanied by addition of teicoplanin to yield 20 mg/mL in the dialysate for the first week and then 20 mg/mL on alternate days in the second week and then in each bag in the third week.

ADVERSE DRUG REACTIONS Teicoplanin is generally well tolerated. In a large trial in Europe, 10.3% of 3377 patients treated with teicoplanin had an adverse reaction: allergic-type reactions in 2.6%, local intolerance in 1.7%, fever in 6.8%, and ototoxicity in 0.3%. Abnormal liver and renal function tests developed in 1.7% and 0.6% of patients, respectively.

Anaphylactoid reactions to vancomycin, described as "red man syndrome," have seldom been reported in patients treated with teicoplanin. The extent of cross-allergenicity to teicoplanin in patients allergic to vancomycin is uncertain, but some reactions have been reported.

Nephrotoxicity due to teicoplanin appears to be very uncommon, including a lesser propensity than with vancomycin to increase creatinine concentration when administered with an aminoglycoside.

Overall, based on a lesser likelihood than vancomycin of causing nephrotoxicity when coadministered with an aminoglycoside and greater ease of administration intravenously or intramuscularly once daily, with probable equal efficacy, teicoplanin may be a preferred alternative to vancomycin for initial broad-spectrum therapy of nosocomial infection, especially when the prevalence of MRSA and VRE is of any concern. Conversely, the lack of availability of a serum teicoplanin assay and knowledge of levels associated with safety and efficacy makes it more complicated to administer teicoplanin than vancomycin. More data from head-to-head comparative trials are needed.

SULFONAMIDES

The discovery of the antibacterial action of sulfonamides in the 1930s and the administration of these agents systemically to prevent and cure bacterial infections represented a revolutionary breakthrough in medicine and opened the chemotherapeutic era. When first introduced for general use, this group of antibiotics was effective against a wide range of infections caused by aerobic gram-positive and gram-negative bacteria, actinomycetes (*Nocardia* and *Actinomyces*), protozoa (*Pneumocystis carinii*, *Toxoplasma gondii*, and malarial parasites), and *Chlamydia trachomatis*. Since that time, their usefulness has declined markedly because of a number of factors: the advent of a wide range of alternative agents, the frequent emergence of resistance to sulfonamides in many formerly susceptible microorganisms, an awareness of the frequency and severity of ADR caused by some sulfonamides, and the relative unavailability of parenteral formulations.

CLASSIFICATION Sulfonamides may be classified as follows:

1. *Sulfonamides rapidly absorbed and eliminated after oral administration.* Sulfisoxazole is the prototypical agent; sulfamethoxazole and sulfadiazine are other widely used members of this class.
2. *Poor absorption of orally administered sulfonamide.* Sulfasalazine is used to treat ulcerative colitis and Crohn's disease. About 20% of an oral dose is absorbed in the small intestine, a small portion (~10%) of which is excreted into urine, and the rest is secreted in bile and enters the enterohepatic circulation.[92] This portion plus unabsorbed drug passes into the colon, where it is split into two metabolites, sulfapyridine and 5-aminosalicylic acid, which accounts for the therapeutic effect of sulfasalazine in inflammatory bowel disease.
3. *Sulfonamides for topical use.* Sulfacetamide is approximately 90 times more soluble in aqueous solution than is sulfadiazine at neutral pH and is nonirritating to the eye. It is formulated as 30% and 10% ophthalmic solutions and a 10% ointment. Ocular fluids and tissues are thus exposed to high concentrations of antibiotic during topical ophthalmic application. However, topical ophthalmic use is associated with a risk of sensitization, and this consideration plus the insensitivity of most nosocomial bacteria to sulfonamides limit the usefulness of sulfacetamide for treatment of bacterial conjunctivitis and keratitis.

   Two sulfonamides have an established place in the ICU for the topical therapy of patients with second- and third-degree burns. Silver sulfadiazine is relatively insoluble. It reacts with chloride and protein components of tissue exudate to form silver chloride, silver protein complexes, and sodium sulfadiazine. The relative contributions of each of these products to the potent inhibitory effect of silver sulfadiazine on the growth of a broad spectrum of microorganisms is unclear, but inhibition of growth of bacteria, including some species resistant to sulfonamides and fungi,[93] is observed. This suggests that inhibition other than by interference with folate synthesis (see below) contributes to the antibiotic effect.

   Mafenide is a sulfonamide marketed as 8.5% cream. Like silver sulfadiazine, it is effective for the prevention of colonization of burns by a large variety of gram-negative and gram-positive bacteria, including some anaerobes. However, *Candida* species are not inhibited as they are by silver sulfadiazine. Mafenide is rapidly absorbed and converted to a nontoxic metabolite, *p*-carboxy-benzene-sulfonamide, which is excreted in urine. Unlike all other sulfonamides, mafenide is active in the presence of blood, pus, and serum.
4. *Long-acting sulfonamides.* Sulfadoxine has a singularly long $t_{1/2}$ of 7 to 9 days. This has made it an attractive choice for malaria prophylaxis in combination with pyrimethamine (Fansidar) for the prevention and treatment of illness owing to chloroquine-resistant strains of *Plasmodium falciparum*. It has no uses as an antibacterial agent.

MECHANISM OF ACTION Sulfonamides are structural analogues of para-aminobenzoic acid. They exert a bacteriostatic effect by competitively inhibiting dihydropteroate synthetase. This enzyme catalyzes the synthesis of dihydropteroic acid, the immediate precursor of folic acid, from para-aminobenzoic acid. Folic acid is required for 1-carbon

transfer reactions for purine synthesis. Most bacterial cells are impermeable to folic acid, in contrast to mammalian cells. These facts concerning the mechanism of action of sulfonamides on susceptible cells account for the selective toxicity of sulfonamides for bacterial but not for mammalian cells, the mechanism of bacterial resistance to sulfonamides, inhibition of sulfonamide action in sites of tissue necrosis, and, as will be discussed later, synergistic inhibition of some bacteria by combination with dihydrofolate reductase inhibitors such as trimethoprim (TMP) or pyrimethamine.

Because mammalian cells are permeable to folic acid, sulfonamides do not cause dose-related or concentration-related adverse effects on cellular metabolism in humans. Side effects are predominantly idiosyncratic or allergic (see below).

MECHANISMS OF RESISTANCE Acquired bacterial resistance to sulfonamides arises by random mutation and selection or by transfer of resistance by plasmids. Such resistance is a stable characteristic whose cumulative prevalence currently limits the use of sulfonamides as initial therapy to a few infections such as brucellosis and nocardiosis. Sulfonamide resistance may be mediated by an alteration in the affinity of dihydrofolate reductase for sulfonamide, use of alternative pathways for purine and pyrimidine synthesis, and compensatory overproduction of the natural substrate, paraaminobenzoic acid. Acquired resistance to silver sulfadiazine cream in burn units has been reported and necessitated use of alternative therapy such as silver nitrate and chlorhexidine cream.[94]

CLINICAL PHARMACOLOGY Most orally administered sulfonamides are rapidly absorbed from the stomach and small intestine, but the efficiency of this process in acutely ill patients has not been described. Absorbed sulfonamides bind to serum proteins, in particular albumin, from 20% to more than 90% and affect disposition. High protein binding of sulfadoxine (97%) accounts in part for its long disappearance $t_{1/2}$ from plasma. High protein binding of other sulfonamides administered to neonates can contribute to the development of kernicterus. This is hypothesized to be due to displacement of bilirubin from albumin binding sites, although this is disputed.[95] The lipid-soluble sulfonamides diffuse readily into inflamed and noninflamed tissues and body fluids including pleural, peritoneal, and ocular fluids, and the CSF. They readily cross the placenta and enter the fetal circulation in sufficient concentration to exert antibacterial and toxic effects.

A varying proportion of sulfonamide is acetylated in the liver or inactivated by other metabolic pathways. The rate of acetylation is genetically determined, and slow acetylators are more likely to experience certain side effects than are rapid acetylators (see below). Unchanged non–protein-bound sulfonamides and metabolites are excreted mainly by glomerular filtration into urine. Different agents are reabsorbed to different degrees in the renal tubules. In the case of sulfadoxine, resorption is so extensive and efficient that this contributes to its long $t_{1/2}$ of 7 to 9 days.

The pH of the urine influences urinary excretion of sulfonamides because they are weak acids. Thus, their clearance is enhanced in the presence of alkaline urine. In general, however, sufficient free drug reaches the urine to make sulfonamides effective agents for therapy of urinary tract infections caused by susceptible organisms. In patients with significant renal insufficiency, too little sulfonamide reaches the urine to be effective. Doses must be reduced if they are used to treat nonrenal or nonurinary infection. In burned patients with renal failure, mafenide should be used with caution (see below).

ADVERSE DRUG REACTIONS Overall, sulfonamides cause ADR in about 5% of recipients. The types and severity of ADR are quite varied. They are due largely to allergy and only occasionally to direct dose-related toxic effects.

The best understood dose-related toxic effects include renal colic, urethral pain, hematuria and obstruction due to crystalluria, and hemolysis in patients (and fetuses) with glucose-6-phosphate dehydrogenase deficient erythrocytes. Pseudocyanosis owing to methemoglobinemia or sulfhemoglobinemia was seen with earlier sulfonamide formulations; it is rarely seen now. Mafenide causes a unique dose-related toxic effect. Mafenide and its metabolite inhibit carbonic anhydrase, which results in a metabolic acidosis usually compensated for by hyperventilation. In patients with significant renal dysfunction, high concentrations of mafenide and its metabolite will accumulate and exaggerate this effect. The absorption of silver from silver sulfadiazine and its deposition in different organs has recently been identified as a possible cause of ocular injury and of leucopenia and renal, hepatic, and neurologic toxicities.[96,97]

The slow acetylator phenotype is associated with severe, delayed hypersensitivity reactions to sulfonamides in patients with[98] and without[99] the human immunodeficiency virus. These reactions occur much less commonly than do typical exanthematous or urticarial rashes caused by sulfonamides, which resolve rapidly on discontinuation of therapy. The reactions occur late in the course of sulfonamide therapy and are typically heralded by the onset of high fever followed by development of a skin rash such as erythema multiforme. Patients with the slow acetylator phenotype are postulated to have more parent sulfonamide available for oxidative metabolism to intermediates that have been shown to mediate those adverse reactions.[100] The slow acetylator phenotype is also associated with the common side effects of sulfasalazine therapy: nausea, vomiting, anorexia, and headache are related to serum sulfapyridine concentrations above 20 mg/L,[92] which are more commonly observed in slow acetylators given the standard dose of sulfasalazine.

Sulfonamides may also cause ADR because of interactions with other drugs being administered concurrently. Sulfadiazine, sulfamethizole, and sulfaphenazole may impair hepatic metabolism of phenytoin and warfarin. Cotrimoxazole may cause an exaggerated hypoprothrombinemic effect in patients taking warfarin if their warfarin dose requirements are high and the plasma albumin level is low (see below).

Allergic and idiosyncratic reactions to sulfonamides are relatively common, occasionally may be severe, and rarely are fatal. Skin rashes are fairly frequent, usually occur after treatment of approximately 1 week, and may be maculopapular or urticarial. Erythema nodosum, erythema multiforme, and, rarely, Stevens-Johnson syndrome may occur. The risk of developing Stevens-Johnson syndrome is increased by prior sulfonamide therapy (because of the risk of sensitization) and administration of long-acting sulfonamides. Cross-allergy between sulfonamides makes it unwise to administer another agent from this group. Moreover,

cross-allergy with other non-antibacterial sulfonamide drugs may occur: diuretics (acetazolamide, thiazides, bumetanide, and furosemide), oral sulfonylurea hypoglycemic agents, and antithyroid drugs (propylthiouracil). There is no skin test for sulfonamide allergy.

Idiosyncratic reactions include acute agranulocytosis. This rare reaction may be reversible on cessation of administration. However, leukopenia is seen in as many as 3% to 5% of burned patients treated with silver sulfadiazine, usually within 2 to 4 days of initiation of therapy. It is usually self-limiting even with continued use of the drug. Fatal aplastic anemia has been described with sulfonamides but less commonly than with chloramphenicol; megaloblastic anemia responsive to folic acid in patients with inflammatory bowel disease treated with sulfasalazine and thrombocytopenia has been reported.

Hepatotoxicity is a rare idiosyncratic hypersensitivity reaction to sulfasalazine administration. The toxic effect appears to be caused by sulfapyridine, the major absorbed metabolite of sulfasalazine breakdown by colonic bacteria. That this reaction is a result of hypersensitivity is suggested by additional features such as rash, lymphadenopathy, arthralgia, and eosinophilia often observed concurrently 2 to 4 weeks after initiation of therapy.

Drug interactions involving sulfonamides may cause ADR because of interference with hepatic metabolism of the concomitantly administered drug by sulfonamide and displacement of drug from plasma protein by highly bound sulfonamides. For example, tolbutamide, phenytoin, and warfarin metabolism is inhibited by usual therapeutic doses of sulfaphenazole, sulfadiazine, and sulfamethizole. Sulfamethoxazole may displace warfarin from plasma albumin and predispose the patient to an exaggerated anticoagulant effect (however, interference with hepatic metabolism of warfarin is more important).

TRIMETHOPRIM COMBINED WITH SULFAMETHOXAZOLE

TMP is marketed commercially alone and in combination with SMX in oral and parenteral formulations in a fixed ratio of 1:5. Due to its greater lipid solubility, TMP distributes more rapidly and widely than the sulfonamide, yielding a plasma TMP:SMX ratio of approximately 1:20 throughout the dose interval, the optimal ratio for in vitro synergistic antibacterial effects. This ratio is maintained relatively constant because the two agents have similar elimination $t_{1/2}$ values of about 10 hours in persons with normal renal function.

MECHANISM OF ACTION TMP inhibits dihydrofolate reductase of bacteria about 50,000 times more efficiently than that of mammalian cells. It interferes with purine synthesis in the same pathway that sulfonamides act. The combination, therefore, produces synergistic inhibition of replication in certain bacteria.

TMP is more active than sulfonamide against many bacterial species except *Nocardia*, *Neisseria*, and *Brucella* species. The net inhibitory effect of the combination of TMP-SMX against bacteria is not consistently predictable. However, a synergistic effect is likely when a bacterium is sensitive to both agents. Moreover, when synergy is demonstrable in vitro, the net antibacterial effect may be bactericidal, although the component agents alone are only bacteriostatic.

The clinical advantage of prescribing TMP-SMX together to achieve a synergistic therapeutic effect or to minimize the emergence of resistant isolates during therapy is not well supported by clinical studies. For example, in urinary tract infection, the activity of TMP greatly exceeds that of SMX, and the potential synergy expected is not observed.[101] Resistance to TMP is increased by TMP use, but its administration with SMX has not been shown to substantially decrease this occurrence.[102]

TMP enhances the antibacterial activity of antibiotics other than sulfonamides. It enhances the inhibitory effect of rifampin against *H. influenzae* and *Brucella* species. In combination with carbenicillin and rifampicin, TMP is often synergistic against *S. maltophilia*, a frequently multiply-resistant nosocomial pathogen.[103] The potential utility of these combination therapies in critically ill patients with resistant infections should not be overlooked, but appropriate in vitro testing will be necessary to permit confident administration of these combinations.

MECHANISMS OF RESISTANCE Resistance to TMP is most commonly associated with acquisition of a plasmid that codes for an altered dihydrofolate reductase enzyme. Some species have acquired resistance as a result of the selection of mutants that do not use the tetrahydrofolate pathway to synthesize thymidine. It is not uncommon for 30% to 40% of aerobic gram-negative enteric bacteria in hospitals to be resistant to TMP and, usually, also SMX.

CLINICAL PHARMACOLOGY TMP is a lipid-soluble, weak base. Its AVD, 1.8 L/kg body weight, greatly exceeds that of SMX, 0.24 L/kg body weight. It diffuses freely into most tissues and body fluids and concentrates in prostatic and vaginal fluids, which are more acidic than plasma. TMP is eliminated primarily by glomerular filtration as unchanged drug, with a small amount eliminated with bile. Approximately 10% of drug in the urine is inactive metabolites formed in the liver. The elimination $t_{1/2}$ of TMP from plasma is approximately 10 hours in patients with normal renal function but increases with diminished renal function. In severe renal failure, the serum $t_{1/2}$ of SMX is increased slightly more than that of TMP, to ranges of 22 to 50 hours and 14 to 46 hours, respectively. This is attributable to the more efficient clearance of TMP than of SMX by nonrenal mechanisms.

The usual adult doses for those with normal renal function are 160 to 240 mg of TMP and 800 to 1200 mg of SMX infused intravenously every 6, 8, or 12 hours, depending on the severity of the infection. The dose should be diluted to minimize phlebitis: each 5-mL ampule (TMP 80 mg and SMX 400 mg) should be diluted in a minimum of 75 mL of 5% dextrose, 0.15 M NaCl, or Ringer solution. Extravasation causes local irritation and inflammation. In patients with renal dysfunction, a modified dose is advised: for patients with creatinine clearance faster than 25 mL/min, there is no reduction in the standard dose; for those with creatinine clearance of 15 to 24 mL/min, one-half the usual dose is given; for those with creatinine clearance slower than 15 mL/min, use is not recommended.

For *P. carinii* infection, it has been recommended that TMP-SMX doses should be adjusted to achieve TMP concentrations 1.5 to 2 hours after administration of 3 to 10 mg/L (or SMX concentrations of 100 to 150 mg/L).[104] These concentrations

are usually achieved with oral or intravenous doses of TMP and SMX of 20 and 100 mg/kg per day in three to four divided doses, respectively, using the fixed-dose formulation of TMP with SMX. However, in one trial, only 32% of SMX levels were in the desired range after dose adjustments.[104] Thus, although no beneficial clinical effect on the therapeutic outcome or side effects was observed, this trial was not able to answer the question of whether sustained maintenance of SMX levels in the target range would be beneficial.

ADVERSE DRUG REACTIONS In many cases, it is difficult to separate side effects caused by the components of TMP-SMX. TMP causes fewer reactions than the combination, but it is not known whether the combination causes a "synergistic" increase in adverse effects.

Although interference with folic acid metabolism and, hence, erythropoiesis can be demonstrated with high TMP concentrations in normal human bone marrow cells cultured in vitro, concentrations observed during therapy in humans do not attain these levels and do not produce such impairment, and this is corroborated by clinical experience. However, in individuals with pre-existing megaloblastic anemia, TMP can aggravate neutropenia and thrombocytopenia and interfere with the therapeutic response to vitamin B_{12} or folic acid. Therefore, the drug is relatively contraindicated in patients with megaloblastic anemia or in those who may be predisposed to it: pregnant women, patients on anticonvulsant drugs (phenytoin, primidone, or barbiturates), and those with macrocytic erythrocytes. For these individuals, regular blood cell counts are advised if prolonged therapy is prescribed.

Combination TMP-SMX may cause an apparent dose-related impairment of renal function in renal transplant patients or individuals with pre-existing renal insufficiency, especially if inappropriately high doses of TMP-SMX are used. TMP-SMX should be prescribed cautiously to such patients. TMP-SMX administration may cause a temporary rise in serum creatinine concentration not due to a reduction in glomerular filtration rate. This has been attributed to TMP competitive inhibition of creatinine secretion by the renal tubular cation transport system.

Gastrointestinal reactions are the most common side effects of oral TMP-SMX therapy: 3% of recipients experience nausea, vomiting, and anorexia and approximately 0.5% experience diarrhea. *Clostridium difficile* toxin-induced diarrhea and pseudomembranous colitis have been reported in patients treated with these agents.

Skin rashes occur in 1.6% to 8% of patients treated with TMP-SMX. Most of these are probably caused by the sulfonamide, but TMP occasionally causes rashes when administered alone. The rashes usually present as morbilliform eruptions and less frequently as urticarial or vasculitic processes.

QUINOLONES

The quinolone antibiotics comprise three relatively distinct generations of drugs.[105,106] The first-generation quinolones, nalidixic acid, oxolinic acid, and cinoxacin, achieve effective concentrations only in urine, thus limiting their usefulness to the oral therapy of uncomplicated urinary tract infection and, hence, are not discussed further. The second-generation quinolones are 4-fluorinated analogues of nalidixic acid: norfloxacin, ciprofloxacin, pefloxacin, ofloxacin, and enoxacin. They have enhanced potency against enteric bacteria compared with the first-generation agents but have inconsistent inhibitory activity against gram-positive cocci including streptococci of groups A, B, C, and G, *S. pneumoniae*, *viridans* group *streptococci*, *Streptococci*, or *E. faecalis*. Ciprofloxacin is distinguished by its potency against *P. aeruginosa*, for which it is the most useful fluoroquinolone for systemic therapy, although, for *P. aeruginosa* urine infection, some of the other members of this group achieve therapeutic concentrations in urine. All members of this group, apart from norfloxacin, exhibit sufficient oral bioavailability to make them useful to treat systemic infection. Only 26% to 32% of a norfloxacin dose is recovered in the urine over 24 hours compared with 75% to 95% for the other agents.

A third generation of fluoroquinolones consists of levofloxacin, moxifloxacin, and gatifloxacin. This group is characterized by clinically useful antibacterial activity against *Chlamydia*, *Legionella*, and *Mycoplasma* species and by streptococcal and staphylococcal pathogens and, hence, is also referred to as respiratory fluoroquinolones; they possess variable activity against *E. faecalis*. They inhibit penicillin-sensitive and penicillin-resistant pneumococci. Moxifloxacin and gatifloxacin are the only fluoroquinolones that inhibit *B. fragilis* species.

In the ICU setting, ciprofloxacin is particularly useful as therapy for systemic *P. aeruginosa* infection. All the second- and third-generation fluoroquinolones are effective for most enteric bacterial infections, especially as less toxic alternatives to aminoglycosides, as are third-generation cephalosporins, carbapenems, and extended-spectrum β-lactams. The respiratory quinolones are alternatives to the macrolide agents for treatment of atypical pneumonia caused by *Chlamydia*, *Mycoplasma*, and *Legionella* species. Thus, the third-generation fluoroquinolones can be administered as broad-spectrum agents for nosocomial infection and for a wide range of community-acquired respiratory and genitourinary infections.

MECHANISMS OF ACTION The quinolones exert a bactericidal effect by selectively inhibiting two type II DNA topoisomerase enzymes, DNA gyrase and topoisomerase IV, but not the analogous cellular enzyme, topoisomerase; both normally cut segments of replicating bacterial DNA strands to prevent tangling.

MECHANISMS OF RESISTANCE Resistance among gram-negative enteric bacteria including *P. aeruginosa* and *S. aureus*, although varying in prevalence in different countries, has emerged since widespread use of ciprofloxacin began in 1984.[107] Such strains are usually completely cross-resistant to other quinolones. Resistance arises due to chromosomal mutations in the DNA gyrase and topoisomerase IV and, to a lesser extent, to reduced drug accumulation in the bacterial cell due to active efflux of the agents by antibiotic efflux pumps.[108]

CLINICAL PHARMACOLOGY The oral bioavailability of the fluoroquinolones, apart from norfloxacin, exceeds 75%; however, for the ill patient in the ICU, intravenous administration is recommended. Ciprofloxacin, levofloxacin, and gatifloxacin are formulated for intravenous and oral

administrations, and the plasma $t_{1/2}$ values in patients with normal renal function are 4.0, 6.0, and 8.4 hours, respectively; therefore, for levofloxacin and gatifloxacin, once-daily dosing is adequate. The usual doses are 400 mg every 12 hours and 500 and 400 mg once daily, respectively. Renal elimination accounts for 60%, 95%, and 90% of the drug clearance, so $t_{1/2}$ is not unexpectedly inversely related to creatinine clearance. When creatinine clearance declines to 50 mL/min, doses should be halved. Hemodialysis patients should receive 50% of the standard dose supplemented by 200 mg every 12 hours, no extra doses, and 200 mg every 24 hours after dialysis for the three drugs, respectively.

Dose reductions are generally unnecessary for healthy elderly patients or patients with mild to moderately severe hepatic disease (Child-Pugh class B).

ADVERSE DRUG EFFECTS Quinolones and fluorinated quinolones are generally well tolerated. Gastrointestinal symptoms including nausea, anorexia, vomiting, and diarrhea occur in fewer than 5% of patients. First- and second-generation quinolones on the market cause neurologic symptoms whose pathogenesis is unclear. Dizziness and headache are the most common, being reported in 2% of patients. Giddiness, excitation or depression, visual disturbances, lethargy, agitation, somnolence, syncope, and, rarely, convulsions and acute psychosis have been reported with the first-generation quinolones and norfloxacin but not with ciprofloxacin. These effects may be more common in patients given larger doses in the presence of renal dysfunction. Some quinolones interfere with the inhibitory neurotransmitter γ-aminobutyric acid, but no clear relation exists between this characteristic of the quinolones and their propensity to cause neurotoxic symptoms. Nevertheless, the quinolones should be used with caution in patients with CNS disease or renal impairment.

Hypersensitivity reactions are uncommon; urticarial rash with eosinophilia has been reported in 0.5% to 1.0% of patients.

Rare side effects observed with nalidixic acid that may occur with second-generation quinolones include intracranial hypertension, lactic acidosis, and hemolytic anemia.

Quinolones interfere with cartilage formation in young animals and are therefore relatively contraindicated in prepubertal patients. In addition, fluoroquinolones appear to double the risk of tendinopathy compared with other antibiotics.[109] This appears to be a class effect, although pefloxacin is the most commonly associated agent (up to 68% of cases). Achilles tendon rupture is the most common and dramatic manifestation and can manifest after only 1 to 2 days of fluoroquinolone therapy. The mechanism is unknown, and the pathology is nonspecific. Concomitant renal dysfunction may predispose the patient to this adverse effect.

Drug interactions include enhancement of warfarin activity because of displacement from albumin by nalidixic acid, elevated plasma theophylline concentrations caused by impairment of metabolism by ciprofloxacin, and increased risk of CNS toxic effects in patients given nonsteroidal anti-inflammatory drugs and ciprofloxacin concurrently.

Fluoroquinolones as a class effect can increase QTc intervals. QTc prolongation can result in *torsade de pointes*, which can lead to ventricular fibrillation and sudden death. Thus, ciprofloxacin, levofloxacin, and gatifloxacin should not be given in excess of recommended doses and should be avoided in patients with known QTc prolongation and hypokalemia and those receiving class Ia (e.g., quinidine and procainamide) or class III (e.g., amiodarone, sotalol) antiarrhythmic drugs. These fluoroquinolones also should be given with caution concurrently with other drugs that prolong QTc intervals including cisapride, erythromycin, cotrimoxazole, astemizole, terfenadine, haloperidol, phenothiazine, tricyclic antidepressants, and vasopressin.[106]

Anaphylactoid reactions reported after administration of ciprofloxacin, pefloxacin, and norfloxacin may be another adverse class effect of the fluoroquinolones.[110] Hypotension, shock, asthma, laryngeal edema and urticaria, and angioedema have been reported as manifestations of these reactions. Having the acquired immunodeficiency syndrome (AIDS) may predispose to the reaction. It has been reported within 5 minutes after a first dose in individuals previously unexposed to fluoroquinolones. Although life-threatening, no deaths have been reported. The exact incidence is not known, but the adverse reaction is one with which intensivists need to be aware.

Hypoglycemia has been reported in diabetic patients receiving insulin or glyburide plus fluoroquinolone, so their coadministration must be undertaken with care.

METRONIDAZOLE

Metronidazole is one of a group of 5-nitroimidazoles, including tinidazole, nimorazole, carnidazole, and sulnidazole, that possesses a broad spectrum of antiprotozoal and antibacterial activities. Only metronidazole is available in North America. The following comments pertain to metronidazole only and its antibacterial action.

The clinically important antibacterial activity of metronidazole is restricted to obligate anaerobic bacteria. In vitro, metronidazole is a potent bactericidal antimicrobial against anaerobic gram-negative and gram-positive organisms. More than 99% of 341 blood culture isolates of *B. fragilis* from U.S. patients collected from 1987 to 1999 were susceptible to metronidazole, whereas 22% were not susceptible to clindamycin. Thus, metronidazole continues to be a potentially, uniformly efficacious, antimicrobial agent for initial treatment of *B. fragilis* infection before susceptibility test results can be available.[111] Resistant anaerobic organisms include *Proprionobacterium* species, many strains of *Bifidobacterium*, *Actinomyces*, and *Arachnia*. *Lactobacillus* species and aerobic and microaerophilic streptococci are also resistant.

Oral metronidazole is the drug of choice for *C. difficile* toxin-associated diarrhea and colitis.[84] When administered with penicillin, metronidazole is the drug of choice for the treatment of brain abscess complicating paranasal sinusitis, caused primarily by aerobic streptococci, in particular *Streptococcus milleri*, together with β-lactamase–producing *Bacteroides* species. Metronidazole is used similarly in the combined therapy of temporal lobe brain abscesses of otitic origin commonly caused by anaerobic bacteria, in particular *B. fragilis* and aerobic enteric bacilli. Metronidazole combined with an aminoglycoside is efficacious therapy for mixed aerobic and anaerobic bacterial infections of the peritoneal cavity and female genital tract. In general, this combination is not different in efficacy from clindamycin, ticarcillin, cefoxitin, or chloramphenicol combined with the aminoglycoside.[32]

Advantages arise from differences in the frequency, nature, and severity of adverse effects.

MECHANISM OF ACTION Metronidazole is rapidly bactericidal by an immediate inhibition of DNA synthesis, but the mechanism of this action has not been fully elucidated.

MECHANISM OF RESISTANCE Acquired resistance to metronidazole occurs extremely rarely.[111] Isolated reports have documented resistance to metronidazole associated with clinical failure in *B. fragilis* strains. Resistance appeared to be related to a decreased rate of metronidazole uptake and to an insufficiently low intracellular redox potential to reduce metronidazole to its active form.

CLINICAL PHARMACOLOGY The clinical pharmacology of metronidazole and its two principal metabolites has been studied extensively.[112] It can be administered intravenously, orally, and rectally as a suppository to treat bacterial infection. The absolute bioavailability of orally administered metronidazole approaches 100%. After intravenous administration of 500 mg over 20 min, the mean metronidazole Cp 30 minutes after the completion of infusion was 27 mg/L and the trough concentration was 16 mg/L.[112] After rectal administration of a 500-mg suppository, mean peak Cs after about 3 hours was 19 mg/L, with the level remaining at approximately 10 mg/L over the next 8 hours.[113] These data suggest that rectal administration may be effective in those who cannot take the drug orally. The drug diffuses widely throughout the body: concentrations in saliva and breast milk are comparable to those in the serum; CSF concentrations in normal volunteers average 43% of the simultaneous Cp and are therapeutic; urine concentrations range from 76 to 115 mg/L after a 500-mg dose. Only about 14% of an oral dose of metronidazole is excreted in the feces, but concentrations attained in feces are much greater than the MIC of metronidazole for *C. difficile*, which is 4 mg/L or lower.

Metronidazole undergoes extensive metabolism, probably in the liver, to two oxidation products, an "alcohol" metabolite and a "hydroxy" metabolite.[112] The latter is produced in larger amounts, can be readily detected in the plasma of patients with normal renal function, and accumulates in the plasma of those with renal insufficiency. The metabolites possess 5% and 30%, respectively, of the antibacterial activity of the parent compound, so that they probably contribute in part to the therapeutic effect of metronidazole, particularly in patients with renal failure. Of 500 mg of metronidazole administered intravenously to healthy volunteers, 44% was recovered in the urine, consisting of parent drug (8%) and the hydroxy (24%) and alcohol (12%) metabolites. The mean plasma $t_{1/2}$ of metronidazole is 8.5 hours.

In patients with renal insufficiency, metabolites accumulate, but the parent compound does not. It is conventional not to reduce the dose of metronidazole for such patients, including those undergoing peritoneal dialysis or hemodialysis. Severe hepatic disease would be expected to reduce the metabolism of metronidazole, but its disposition in such patients and a need for dose reduction have not been described.

Interactions of metronidazole have been described in adults ingesting phenytoin and barbiturates, which induce its metabolism. Phenobarbital decreased the plasma $t_{1/2}$ of metronidazole to 3.5 hours.

ADVERSE DRUG EFFECTS In experimental nonhuman systems, metronidazole is teratogenic, mutagenic, and carcinogenic. Comparable effects have not been demonstrated in humans, but avoiding its use during the period of organogenesis in the first trimester of pregnancy is considered prudent. Metronidazole is generally well tolerated. Gastrointestinal side effects occur occasionally. These include a metallic taste, furred tongue, and nausea. Paradoxically, two confirmed reports of pseudomembranous colitis have been described in patients receiving only metronidazole. In one, this side effect appeared to be caused by a metronidazole-resistant strain of *C. difficile*,[114] but in the other, the organism was susceptible. Transient reversible leukopenia occurs infrequently, but it is the most common hematologic side effect. Peripheral sensory neuropathy has been described in patients receiving large doses for prolonged periods. The cause is not known. One child developed seizures during metronidazole therapy that ultimately resolved completely.

Interactions of metronidazole with a few other drugs are well documented; it can produce an Antabuse-like reaction after alcohol ingestion. This is probably caused by inhibition of hepatic alcohol metabolism resulting in accumulation of acetaldehyde, which causes the adverse symptoms. Metronidazole augments the hypoprothrombinemic effect of warfarin sodium (Coumadin) owing to a stereoselective inhibition of the S(2)-moiety (levo warfarin).

MACROLIDES, LINCOSAMIDES, AND KETOLIDES

ERYTHROMYCIN, CLARITHROMYCIN, AZITHROMYCIN, CLINDAMYCIN, LINCOMYCIN, AND TELITHROMYCIN

These six antibiotics are considered together because they share similar mechanisms of action and resistance spectra of antibacterial activity, and clinical pharmacologic properties. Structurally, they comprise three groups, macrolides (erythromycin, clarithromycin, and azithromycin), lincosamides (lincomycin and clindamycin), and ketolides (telithromycin).

Erythromycin

Erythromycin is produced by *Streptomyces erythreus*. It is a member of the macrolide group of antibacterial compounds, which also includes spiramycin (used in Europe to treat *T. gondii* infection), azithromycin, and clarithromycin.

Erythromycin base is poorly soluble in water, has a pKa of 8.8, and is rapidly inactivated by gastric acid. Many alternative oral formulations have therefore been developed to enhance oral bioavailability over that of the base. Two water-soluble salts, erythromycin-gluceptate and erythromycin-lactobionate, have been developed for intravenous administration. In ICU patients, only the intravenous formulation can ensure adequate systemic delivery of drug, so this discussion does not include the characteristics of the oral products.

In vitro, erythromycin has a broad spectrum of antimicrobial activity that includes bacteria (including chlamydia), mycoplasma, spirochetes (*Treponema pallidum*), *Ureaplasma*, and some strains of rickettsias. Its useful antibacterial activity includes gram-positive organisms (*S. aureus*, *S. pyogenes*, *S. pneumoniae*, and viridans group streptococci, *Cornyebacterium diphtheriae*, *Clostridium perfringens*, and *Listeria monocytogenes*). Unfortunately, increased use of macrolides over a long duration has resulted in the emergence of substantial levels of

resistance to macrolides in *S. pneumoniae*. Macrolide resistance increased from 13% to 23%, from 9% to 11%, from 15% to 25%, and from 34% to 41%, between 1997 and 1999 in the United States, Canada, Europe, and the Asia-Pacific region, respectively.[115] Some gram-negative organisms (*B. pertussis*, *H. influenzae*, *N. gonorrhoeae*, *N. meningitidis*, and *B. catarrhalis*), *Legionella pneumophila*, *Mycoplasma pneumoniae*, *Ureaplasma urealyticum*, and *C. trachomatis* are susceptible.

Clinically, erythromycin is used to treat *M. pneumoniae* and *L. pneumophila* infections. It is the alternative drug of choice for *C. trachomatis* infection of pregnant women and children who cannot be treated with tetracycline and for *C. diphtheriae* infection in penicillin-allergic patients. Although formerly used as the alternative to penicillin in allergic patients with *T. pallidum*, *M. catarrhalis*, and *L. monocytogenes* infections, erythromycin use in these infections has been largely superseded by other agents.

MECHANISM OF ACTION Erythromycin and the other macrolide antibiotics inhibit bacterial growth by interfering with protein synthesis. Erythromycin binds specifically to the 50S subunit of the ribosome. The precise molecular mechanism is not known but is hypothesized to interfere with the translocation reaction. This reaction, catalyzed by the enzyme translocase, involves the movement of the growing peptide chain, with its tRNA, from the acceptor to the donor site on the ribosome. Erythromycin is thought to bind to the donor site and thereby interfere with translocation of the peptide chain from the acceptor to the donor site. In humans, erythromycin is likely only bacteriostatic.

MECHANISM OF RESISTANCE Gram-negative enteric bacilli are uniformly resistant to erythromycin. This is probably a result of the inability of the drug to penetrate the cell wall to reach the ribosomal site of action. In certain other resistant bacteria, a plasmid-mediated mutational change in the 50S subunit, resulting in methylation of the tRNA erythromycin receptor, precludes erythromycin binding. Two other plasmid-mediated mechanisms confer erythromycin resistance: diminished permeability of the cell envelope of gram-positive bacteria as occurs with *S. epidermidis* and production of an esterase that hydrolyzes erythromycin in some *Enterobacteriaceae*.

Overall, the prevalence of erythromycin resistance among important pathogens such as *S. pneumoniae* currently limits the utility of these agents as first-line antimicrobials for some serious infections such as community-acquired pneumonia.

CLINICAL PHARMACOLOGY Therapeutic concentrations are attained in all sites except the brain and subarachnoid space. Although inflammation enhances erythromycin penetration into brain tissue and CSF, this effect is unpredictable, and erythromycin is thus relatively contraindicated for therapy of brain abscess and meningitis. Disappearance from plasma is first order with $t_{1/2}$ of 1.6 hours. Approximately 15% of an injected dose appears as unchanged drug in the urine; high concentrations of drug are observed in bile, but the overall contribution of this route of drug clearance to erythromycin elimination is not known. A large proportion of injected erythromycin cannot be accounted for by drug in urine or bile, so extensive biotransformation, probably in the liver, is hypothesized.

The normal plasma $t_{1/2}$ of 1.6 hours is prolonged to 4.8 to 5.8 hours in anuric patients. In patients with alcoholic liver disease and ascites, plasma $t_{1/2}$ was increased to an average of 1.6 hours as opposed to 1.3 hours in concurrently studied healthy controls.[116] In both groups, no dose reduction was necessary in view of the low risk of dose-related ADR. In patients with more severe liver disease, dose reduction would appear prudent. However, no explicit guidelines for such patients have been proposed or validated.

ADVERSE DRUG EFFECTS Erythromycin is one of the safest antibacterial agents in clinical use, but tolerance is limited by the frequent occurrence of irritating side effects. First, abdominal cramps, dyspepsia, nausea, vomiting, and diarrhea occur, which result, in part, from a direct smooth muscle–stimulating effect of erythromycin.[117] They are observed after oral and intravenous administrations. Although the smooth muscle–stimulating effect can be inhibited in vitro by the antimuscarinic agent atropine, this strategy has not been studied in humans. Second, intravenous administration predictably causes phlebitis, which can be ameliorated only partly by slow infusion of drug diluted in large volumes of intravenous fluid.

Tinnitus and reversible severe deafness occur after large intravenous doses of erythromycin.[118] Old age, renal failure, and hepatic insufficiency appear to predispose to this unusual adverse effect. The mechanism of this reaction is not known. Pseudomembranous colitis has been reported. Hypersensitivity reactions such as skin rash, fever, and eosinophilia are rare.

Cholestatic jaundice caused by erythromycin estolate (and rarely by the stearate) appears to be specifically related to the propionyl ester linkage of the 29 position so that cross-sensitivity is said not to occur.[119] Thus, a history of cholestatic jaundice during therapy with oral erythromycin estolate is not an absolute contraindication to intravenous therapy with erythromycin gluceptate or lactobionate.

In some individuals, erythromycin can inhibit elimination of astemizole, terfenadine, methylprednisolone, theophylline, carbamazepine, warfarin, and cyclosporine, with significant clinical consequences.

Clarithromycin and Azithromycin

Clarithromycin and azithromycin are recently approved analogues of erythromycin.[120,121] They differ in several respects, but few of these differences are clinically important, particularly for the intensivist.

In vitro, both drugs differ qualitatively from erythromycin in their potent inhibitory effect on *Mycobacterium avium* intracellulare. They differ quantitatively from erythromycin in being up to 10-fold more potent against *C. trachomatis*, *H. pylori*, *M. catarrhalis*, *N. gonorrhoeae*, and *H. ducreyi.*

Bacteria resistant to erythromycin are cross-resistant to clarithromycin and azithromycin.

CLINICAL PHARMACOLOGY Only azithromycin is available in a parenteral formulation. Clarithromycin and azithromycin are well absorbed after oral administration, although bioavailability has not been assessed in critically ill patients. Their good oral bioavailability is attributable in part to the changes in the lactone ring that prevent acid degradation. Reduced acid degradation, moreover, decreases the

formation of ketal products that have prokinetic effects on the gastrointestinal smooth muscle, thereby decreasing the frequency of adverse gastrointestinal effects of clarithromycin and azithromycin compared with erythromycin (see Adverse Effects, below). Clarithromycin undergoes first-pass hepatic metabolism, with 20% of an oral dose being converted to a 14-hydroxymetabolite that possesses antibacterial properties similar to those of the parent molecule. Like erythromycin, these two newer macrolides have a low degree of ionization at physiologic pH and are lipid soluble, so they distribute extensively in body fluids and tissues. The AVD of clarithromycin is 2 to 3 L/kg versus 0.6 L/kg for erythromycin. Azithromycin is distributed even more widely, with an AVD of 23 L/kg.

Clarithromycin is primarily eliminated by hepatic oxidation and hydrolysis. Metabolism is characterized by a disproportionate 13-fold increase in clearance when the dose is increased from 150 to 1200 mg. Elimination $t_{1/2}$ increases from 4.4 to 11.3 hours over the same dose range. Unchanged clarithromycin increases from 18% to 30% of the dose over the 250- to 1200-mg dose range. Doses should be reduced by one-half when creatinine clearance is less than 30 mL/min; dose adjustments in the presence of hepatic disease are likely necessary but as yet remain undefined.

Azithromycin kinetic characteristics are distinguished by low Cp values and a prolonged elimination $t_{1/2}$ that reflects extensive tissue sequestration. The liposomal phospholipid complex of azithromycin is mainly excreted unchanged in the feces, with a polyphasic serum $t_{1/2}$ of 10 to 57 hours, depending on the dose and the sampling intervals. Azithromycin doses need not be adjusted in the elderly or in the presence of mild renal or mild to moderate hepatic impairment.

Clarithromycin, unlike erythromycin or azithromycin, is embryolethal and has induced congenital anomalies (cardiovascular) in preclinical studies. Its use in pregnant patients is relatively contraindicated because of uncertainty about the relevance of these data to humans.

Azithromycin appears less likely than clarithromycin or erythromycin to interact with drugs that are metabolized by hepatic cytochrome P450 enzymes. Elevated theophylline, carbamazepine, and terfenadine plasma concentrations have been demonstrated during concurrent administration of clarithromycin. These have not been observed during concomitant administration with azithromycin, but careful observation during combined therapy is recommended by the manufacturer.

The following agents interact adversely with erythromycin and warrant prudence during coadministration with clarithromycin and azithromycin: cyclosporin, valproic acid, and phenytoin.

ADVERSE DRUG EFFECTS Like erythromycin, clarithromycin and azithromycin are well tolerated. Overall, side effects are observed in 20% to 10% of recipients of clarithromycin and azithromycin, respectively; 80% to 90% of these adverse symptoms are mild to moderate in severity. Gastrointestinal side effects are the most common adverse symptoms with both drugs but occur half as often as with erythromycin. Like erythromycin, azithromycin administration has been associated with transient deafness.[122]

A uniquely prolonged adverse effect observed with azithromycin is noteworthy: rare patients have developed serious allergic reactions including angioedema and anaphylaxis. Despite successful initial symptomatic therapy, allergic symptoms reappeared when therapy was discontinued, even without further azithromycin exposure, presumably owing to the slow clearance of azithromycin from the body. Thus, intensivists should be aware of the possible risk of protracted serious allergic reactions even after discontinuation of azithromycin therapy.

In summary, clarithromycin and azithromycin are new macrolide antibiotics that broaden the therapeutic spectrum of this class of drugs and decrease the incidence of gastrointestinal side effects but may not offer any solution to the problem observed with the prototype, erythromycin, of adverse interactions with other drugs given concomitantly.[123] The usual dose of clarithromycin for serious infection is 250 to 500 mg twice daily. A loading dose of 500 mg azithromycin is recommended, followed by 250 mg once daily; for single-dose therapy of *C. trachomatis* infection, a 1-g dose is administered.

Clindamycin and Lincomycin

Lincomycin was marketed only for oral administration. Chemical modification of lincomycin led to the development of clindamycin, which is superior in activity to lincomycin and is available for oral administration as the hydrochloride salt and for intravenous injection as the phosphate ester. This characteristic has led to the exclusive use of clindamycin in critically ill patients. Accordingly, only clindamycin is reviewed here.

In vitro, the antibacterial spectrum of clindamycin exceeds that of erythromycin as follows: resistance of *S. aureus* to clindamycin tends to be less common than to erythromycin, but resistance levels can range from 5% to 20% depending on the region. Many of these clindamycin-resistant *S. aureus* strains are also resistant to multiple other antibiotics, including methicillin. Clindamycin is much more potent than erythromycin against species of the *B. fragilis* group, although up to 22% of *B. fragilis* strains[111] and up to 15% of *Bacteroides vulgatus* strains are relatively resistant to clindamycin. Nevertheless, this degree of activity against enteric gram-negative anaerobic bacilli is exceeded only by metronidazole. *Clostridium difficile* strains are resistant, but other species such as *Clostridium welchii* and *Clostridium tetani* are sensitive. *Mycoplasma pneumoniae*, *H. influenzae*, and *N. meningitidis* are resistant.

Clindamycin in combination with an aminoglycoside is arguably the antibiotic of first choice for the therapy of serious mixed aerobic and anaerobic enteric bacterial infection of the abdomen and pelvis.[32] A meta-analysis has suggested that the dose of 900 mg every 8 hours may be more efficacious than 600 mg every 8 hours for treatment of intra-abdominal infection (although results of treating female pelvic infection with either dose are similar).[125] In similar infections of the soft tissues and skin of the feet of diabetic patients, this combination is also highly efficacious. Clindamycin alone is superior to penicillin as a single agent for treatment of serious anaerobic lung infection,[124] but their combined use for treatment of such infections is currently recommended. Clindamycin is also considered to be as effective as penicillins for the therapy of non-endocarditis infections caused by *S. aureus*, *S. pyogenes*, and *S. pneumoniae* and as effective as a single injection of benzathine penicillin in eradicating *C. diphtheriae* from the nasopharynx of asymptomatic carriers. Clindamycin is an acceptable alternative to penicillin for treatment of cervicofacial

actinomycosis. Incidentally, clindamycin and quinine sulfate are effective for treatment of *Falciparum malaria* infection.

In summary, clindamycin is a valuable alternative to penicillin in patients who are allergic to the β-lactam agents and is a first-line agent, when combined with an aminoglycoside, for intra-abdominal and pelvic infections, and with penicillin, for mixed anaerobic and aerobic lung infection.

MECHANISM OF ACTION The mechanism of action of clindamycin is identical to that of erythromycin, and both are bacteriostatic.

MECHANISM OF RESISTANCE Resistance is caused by modification of the ribosomal target of clindamycin. Clindamycin-resistant *S. aureus* strains are usually resistant to erythromycin. Clindamycin resistance in *B. fragilis* group organisms is caused by at least two different mechanisms, one of which is plasmid mediated.

CLINICAL PHARMACOLOGY After intravenous injection, clindamycin distribution is analogous to that of erythromycin. Clindamycin does not predictably attain therapeutic concentrations in the fluids of the eye, the cavity or wall of brain abscess, or the CSF even in patients with meningitis. High concentrations are demonstrable in bone, but the relevance of this observation to treatment of osteomyelitis is not clear. High concentrations are attained in polymorphonuclear leukocytes, which may contribute to enhanced killing of phagocytosed bacteria.

The elimination of clindamycin is incompletely understood but probably similar to that of lincomycin, which has been more extensively documented. After intravenous injection, approximately 30% appears in urine and 5% to 15% in feces as unchanged drug and metabolites (N-dimethyl clindamycin, clindamycin sulfoxide, and others). The remainder is hypothesized to be metabolized to inactive compounds. The mean plasma $t_{1/2}$ is normally 3 hours. Severe renal failure is associated with a doubling of peak Cp, and, on this basis, halving of the usual dose is recommended. Neither hemodialysis nor peritoneal dialysis enhances its clearance from plasma. The effect of liver disease on the clinical pharmacokinetics of clindamycin is not clear; increases in plasma $t_{1/2}$ from 40% to 500% have been described. It would seem reasonable to reduce clindamycin doses in patients with severe liver disease, but no clear guidelines have been tested or validated. The usual dose for adults with moderate to severe infection is 900 to 2400 mg/d in two or three divided equal intravenous doses.[125]

ADVERSE DRUG EFFECTS Intravenous clindamycin commonly causes local phlebitis, which can be reduced by slow infusion of dilute solutions. The manufacturer recommends dilution to a concentration of 12 mg/L or lower and infusion longer than 10 minutes (preferably >25 min).

The most important adverse effect of clindamycin administration is diarrhea. This occurs in 2% to 20% of patients treated intravenously or by mouth and varies in severity. Clindamycin is the most common antibiotic cause of diarrhea. The precise pathogenesis of diarrhea associated with clindamycin is not known. However, in that subgroup of patients in whom diarrhea and, in florid cases, pseudomembranous colitis is associated with production of enterotoxin by *C. difficile* in the colon, a direct toxic effect on the colonic mucosa is responsible. Continuation of clindamycin will intensify the severity of the colitis. When clindamycin cannot be discontinued, concomitant oral administration of metronidazole or vancomycin may permit safe continuation of the clindamycin.

Hypersensitivity reactions caused by clindamycin occur occasionally. In one study, rash occurred in 10% of patients. Drug fever and eosinophilia have also been reported.

It is worth reiterating that no cross-allergenicity exists between clindamycin and penicillin.

Unlike erythromycin, clindamycin does not cause clinically important interactions with other drugs.

Telithromycin

Telithromycin is the first ketolide antibiotic to be licensed. Ketolides are analogues of the macrolide class, molecularly modified specifically to inhibit respiratory tract bacterial pathogens that have acquired resistance to the macrolide agents.[126]

In vitro, the spectrum of activity of telithromycin is comparable to that of other macrolides except it is a potent inhibitor of *S. pneumoniae* and *S. pyogenes* strains that are resistant to macrolides by virtue of the *erm* B–resistance genotype. It does not inhibit erythromycin-resistant *S. aureus* strains.

It is available only for oral administration. The usual dose is 800 mg once daily. Clinical trials comparing telithromycin with conventional treatments for community-acquired pneumonia and exacerbations of chronic obstructive airway disease and acute sinusitis have generally demonstrated comparable efficacy and good tolerance. Limited data suggest very good efficacy in patients with macrolide-resistant *S. pneumoniae* infection. Based on the limited published data, the availability of other antibiotics to treat macrolide-resistant *S. pneumoniae* infection, and the lack of a parenteral formulation, a role for telithromycin in the ICU remains undefined.

MECHANISM OF ACTION Like erythromycin from which it is synthesized, telithromycin is bacteriostatic by inhibiting protein synthesis by binding near the peptidyl transfer site on the bacterial 50S ribosomal subunit.

MECHANISM OF RESISTANCE Resistance to macrolides is mediated most commonly by *mef*-encoded efflux and *erm* A- and B-encoded methylation of 23srRNA. Bacterial strains possessing *mef* and *erm* A genotypes are susceptible to telithromycin (see above). In vitro and in vivo experiments have demonstrated that streptococci exposed to ketolides are less likely to develop such resistance genotypes than are those exposed to macrolides.

CLINICAL PHARMACOLOGY The oral bioavailability is approximately 60% under controlled conditions in healthy volunteers; fractional absorption in ill ICU patients is not known and may be less. Telithromycin distributes widely throughout the body; of note is active transport into polymorphonuclear cells, which may contribute to its clinical efficacy in infections caused by intracellular pathogens such as *Chlamydia*. Approximately 70% of a telithromycin dose is metabolized (33% presystemic and 37% systemic) primarily by cytochrome P450, specifically CYP 3A4, hepatic enzymes. Elimination is a first-order process with $t_{1/2}$ of 9.5 hours, mediated by hepatic biotransformation and biliary and renal excretion.

The doses should be halved in patients with severe renal insufficiency. No dose adjustment is recommended in the presence of mild, moderate, or severe hepatic impairment.

ADVERSE DRUG EFFECTS Available data suggest that telithromycin is well tolerated, with a tolerance profile similar to those of clarithromycin and azithromycin. Gastrointestinal symptoms were the most common adverse symptoms (diarrhea in 13%, nausea in 8%, and vomiting in 2%). Most (69%) of these symptoms were mild in severity.

Less common (0.4%) but more severe side effects included hepatitis, pseudomembranous colitis, and erythema multiforme.

Laboratory abnormality, specifically elevated liver enzymes in comparative trials, occurred with similar frequency in groups treated with other conventional antibiotics. Fewer than 1.0% of telithromycin recipients had elevated liver enzymes.

Telithromycin may prolong the QT interval when large doses are administered (see below).

Drug interactions due to competitive metabolism of telithromycin by CYP 3A4 and other drugs administered concurrently have demonstrated inhibition of simvastatin, cisapride, itraconazole, ketoconazole, and theophylline. No interaction with concomitant warfarin has been demonstrated.

STREPTOGRAMINS

Quinupristin and dalfopristin are streptogramin antibacterial drugs recently licensed for the treatment of vancomycin-resistant *E. faecium* infection and complicated skin and skin-structure infection caused by *S. pyogenes* and MSSA. The drugs are formulated as a 30:70 mixture for intravenous injection. The standard dose is 7.5 mg/kg infused over 60 minutes every 8 to 12 hours in 5% dextrose in water; it is incompatible with saline.[127]

MECHANISM OF ACTION Quinupristin and dalfopristin inhibit susceptible gram-positive bacteria including *E. faecium*, MSSA, MRSA, *S. pyogenes*, and *S. pneumoniae* by binding to the 50S ribosome. The two streptogramins produce a synergistic effect. Against *Staphylococcus*, including MRSA, quinupristin and dalfopristin are bactericidal; against *E. faecium*, the effect is generally bacteriostatic. The locus of ribosomal binding is near to, but different from that of, the macrolides.

A prolonged PAE of 9 to 10 hours from *S. aureus* and *S. pneumoniae* permits dosing every 8 or 12 hours despite a short elimination $t_{1/2}$.

MECHANISM OF RESISTANCE The macrolide antibiotics, lincosamide, and streptogramin antimicrobial agents have a common mechanism of action so that shared resistance is common. However, quinupristin and dalfopristin bind to a proximate but different locus on the 70S ribosome, so that cross-resistance with the aforementioned agent is uncommon as is resistance to quinupristin or dalfopristin.

CLINICAL PHARMACOLOGY Only a parenteral formulation is available. Dose and peak plasma concentrations are linearly related over the dose range of 1.4 to 29.4 mg/kg, suggesting indirectly that the apparent volume of distribution is constant. The mean plasma $t_{1/2}$ is similar for both drugs and ranges from 30 to 50 min. Protein bindings range from 11% to 26% for dalfopristin and from 55% to 78% for quinupristin.

Quinupristin and dalfopristin are eliminated primarily (about 75%) by hepatic biotransformation, followed by secretion into the bile and elimination in feces; 15% to 20% is eliminated as metabolite into urine.

Plasma concentrations are significantly increased in patients with hepatic insufficiency (Child-Pugh classes A and B). Dose reduction in such patients is appropriate, but precise regimens have not been formulated or validated.

Severe renal dysfunction (creatinine clearance 6 to 28 mL/min) did not significantly alter quinupristin and dalfopristin kinetics.

Pharmacokinetic studies in elderly (69 to 74 years) adults or obese patients did not yield clinically important differences from values in healthy male volunteers.

Quinupristin and dalfopristin inhibit CYP 3A4 and, at doses in excess of 10 mg/kg, prolong QT intervals. Thus, this combination must be given with care to patients receiving other drugs primarily metabolized by the CYP 3A4 P450 isozyme and with a narrow therapeutic window, particularly those that can prolong the QT interval (cisapride, lidocaine, quinidine, and disopyramide), and other drugs such as cyclosporine and tacrolimus, some antiretroviral drugs (delavirdine, neviapine, indinavir, and ritonavir), antineoplastic agents (vinca alkaloids, docetaxel, and paclitaxel), benzodiazepines (midazolam and diazepam), calcium channel blockers (dihydropyrines, verapamil, and diltiazem), antiepileptics (carbamazepine), and cholesterol-lowering drugs (statins).

ADVERSE DRUG EFFECTS Local pain and inflammation with edema and phlebitis are common during quinupristin or dalfopristin intravenous infusion, being observed in almost 50% of treated patients. Arthralgia, myalgia, and/or nausea resulted in treatment discontinuation in 22% of 90 treated patients with MRSA infection.

The major adverse effect of quinupristin and dalfopristin is phlebitis. This may be ameliorated by increasing the volume of the diluent, slowing the infusion rate even more, and delivering the drugs through a central venous catheter rather than a peripheral one.

Conjugated hyperbilirubinemia has been reported in 9% of treated patients, possibly related to competition for hepatocyte biliary secretion.

OXAZOLIDINONE

Linezolid is a synthetic, recently licensed member of a new class of antibiotics, the oxazolidinones.[128] It has a unique mechanism of action on susceptible bacterial ribosomes that differs from that of the macrolides, aminoglycosides, streptogramins, and lincosamides, making cross-resistance unlikely.

Linezolid is indicated for a wide range of gram-positive coccal infections in adult patients: VRE *faecium* infection; nosocomial pneumonia caused by MSSA, MRSA, and *S. pneumoniae* (penicillin-susceptible strains only); complicated skin and skin-structure infection due to MSSA, MRSA, *S. pyogenes*, or *S. agalactiae*; and uncomplicated skin and soft tissue infection caused by MSSA or *S. pyogenes*; and community-acquired pneumonia (CAP) due to penicillin-susceptible *S. pneumoniae* or MSSA.

Linezolid is formulated as oral tablets or for intravenous injection. The usual adult dose is 600 mg every 12 hours (400 mg every 12 hours for uncomplicated skin infection).

MECHANISM OF ACTION The precise molecular mechanism of action is not known, but linezolid inhibits bacterial protein synthesis. It is hypothesized to do so by interfering with the interaction of tRNA with the 50S ribosomal subunit during the initiation phase.

MECHANISM OF RESISTANCE Resistance of *S. aureus* and *S. epidermidis*, including methicillin-resistant strains, has been difficult to induce during serial passage in vitro in the presence of linezolid. A few *E. faecium* clinical isolates resistant to linezolid have been observed in a compassionate-use treatment program.[129]

CLINICAL PHARMACOLOGY Linezolid is 100% orally bioavailable in volunteers, but it is not known whether the same completeness of absorption can be confidently expected in critically ill patients; for such patients, intravenous administration is preferable. It is metabolized principally by oxidation to a biologically inactive form and excreted in urine as metabolites (70%) and unchanged drug (30%). The plasma $t_{1/2}$ is 4.6 to 5.4 hours.

Pharmacokinetic studies in volunteers with different degrees of renal dysfunction have indicated that linezolid doses need not be adjusted in persons with creatinine clearance faster than 10 mL/min. However, hemodialysis removes 38% of a dose, so the drug should be given after a hemodialysis treatment or an additional 200-mg dose can be given at the end of dialysis.

Linezolid pharmacokinetic characteristics in subjects with mild to moderate hepatic dysfunction did not differ from those in controls.

ADVERSE DRUG REACTIONS Linezolid can cause two unusual, clinically important adverse effects, myelosuppression and drug–drug interactions with adrenergic and serotonergic drugs.

Linezolid causes dose- and time-dependent myelosuppressions in 2% to 10% of patients at therapeutic doses; most commonly, thrombocytopenia is observed. The effect appears to be generally reversible on discontinuation of therapy; no irreversible blood dyscrasias have been reported. Complete blood counts at weekly intervals are recommended during therapy to facilitate early detection of this adverse effect.

Linezolid is a mild, reversible, competitive inhibitor of monoamine oxidase; therefore, in patients in the ICU, concomitant administration of linezolid with indirectly acting adrenergic or dopaminergic drugs including serotonin reuptake inhibitors may cause exaggerated sympathomimetic effects and occasionally signs and symptoms of the serotonin syndrome (e.g., hyperpyrexia and cognitive dysfunction). This adverse effect was expected but not observed in controlled clinical trials of linezolid in part because patients treated concurrently with dopaminergic and adrenergic drugs were excluded and because the monoamine oxidase inhibitory effect of linezolid is a relatively weak one.

In comparative clinical trials, linezolid was more likely than control comparator antibiotics to cause diarrhea (8.3% vs. 6.3% for comparators), nausea (6.2% vs. 4.6%), vomiting (3.7% vs. 2.0%), and insomnia (2.5% vs. 1.7%). Linezolid caused thrombopenia in 2.4% of recipients of linezolid versus 1.5% in recipients of comparative antibiotics. Bleeding effects were not observed in those randomized trials but were observed during open-label compassionate use.

Overall, in the ICU, linezolid may become a valuable niche agent with particular utility for treatment of infection caused by nosocomial drug-resistant pathogens such as MRSA and VRE *faecium*.

Antiviral Drugs

Community-acquired and nosocomial viral infections may cause acute organ dysfunction or failure that necessitates admission of adult patients to the ICU or may complicate their management. A moderate number of different drugs are currently available that specifically and selectively inhibit virus replication and have an established role in the management of selected, serious, acute infections caused by DNA and RNA viruses in immunocompetent and immunocompromised hosts. The following agents are discussed in more detail: acyclovir, valacyclovir, famciclovir, foscarnet, ganciclovir, amantadine, rimantadine, zanamivir, oseltamivir, ribavirin, and some of the 16 currently licensed HIV-1 inhibitor drugs.

All these agents are virustatic only, which partly explains their limited value or failure in patients with defective immune responses.

VIDARABINE

Vidarabine (ara-A) was the first antiviral drug administered parenterally to humans whose efficacy was demonstrated unequivocally in a controlled trial (in patients with *Herpes simplex virus* [HSV] encephalitis).[130]

Ara-A has been approved for the treatment of HSV-1 encephalitis. Controlled trials have demonstrated that it is efficacious for the therapy of otherwise healthy neonates with HSV infection (mostly HSV-2) and immunocompromised patients with chickenpox, mucocutaneous HSV infection, and localized herpes zoster with a duration shorter than 72 hours. Acyclovir has replaced it for these indications, owing to greater ease of administration and better tolerance.[131] Ara-A is no longer marketed and is not further discussed.

ACYCLOVIR

Acyclovir is a synthetic, acyclic, purine nucleoside analogue of guanine in which the deoxyribose moiety has been replaced by a hydroxy-ethoxy-methyl substituent. In vitro, acyclovir inhibits HSV-1 and HSV-2 equally in concentrations 10 to 100 times less than are required with ara-A. Varicella zoster virus (VSV) is 10 times less sensitive than HSV, and the susceptibility of VZV to ara-A and acyclovir is similar. EBV is 10 to 20 times less sensitive than VZV, and CMV is 10 times less sensitive than EBV, to acyclovir.

Acyclovir is approved for the treatment of initial and recurrent mucocutaneous HSV infections in immunocompromised children and adults and for initial episodes of genital herpes in the normal host. It is the drug of choice for treatment of HSV encephalitis[131] and perinatal HSV infection.[131a] In neonates, it is no more effective than ara-A, but it is more acceptable because it can be administered in smaller volumes

of intravenous fluid. It is also the drug of choice for the treatment of chickenpox[132] in normal and immunocompromised hosts and for recurrent VZV skin infections[133] in immunocompromised patients. In these patients, acyclovir accelerates resolution of the cutaneous eruption and prevents cutaneous and visceral dissemination. Acyclovir efficacy for other serious, non-neurologic HSV infections such as esophagitis and hepatitis in normal and immunodeficient hosts has been suggested in case reports.

CMV infections do not respond in a predictable manner to acyclovir because of the relative insusceptibility of CMV to acyclovir and the host immunodeficiency commonly present. To treat CMV infection, ganciclovir is currently recommended (see below). However, therapeutic and limited antiviral effects with acyclovir treatment were observed in renal transplant recipients with CMV pneumonia, enteritis, hepatitis, nephritis, and retinitis,[134] bone marrow transplant recipients with CMV pneumonitis,[135] and children with congenital CMV infection.

Infectious mononucleosis in normal hosts is favorably affected by acyclovir,[136] but steroids are more likely to be useful to treat oropharyngeal airway obstruction owing to lymphatic hyperplasia and hypertrophy. The usefulness of intravenous acyclovir to treat life-threatening EBV complications such as hepatitis or polyclonal B-cell lymphoproliferative disease in immunodeficient individuals (X-linked lymphoproliferative syndrome, renal transplantation, severe combined immunodeficiency, and ataxia telangiectasia) is unclear, although some favorable effects have been observed.

Herpesvirus simiae, also called *herpes B virus*, commonly causes infection in Old World monkeys. In rare instances, infection has been transmitted to monkey handlers and laboratory workers manipulating simian tissue. Infection usually results in severe, fatal encephalomyelitis. If an animal handler is scratched or bitten by a monkey suspected or known to be carrying B virus, an experimental study has suggested that intravenous, but not topical, acyclovir can prevent infection.[137] Its value in patients with established neurologic infection is less clear, but its use would seem reasonable.[138]

MECHANISM OF ACTION Acyclovir inhibits HSV with low toxicity for uninfected host cells. Its therapeutic:toxic ratio in vitro is 30 to 300:1. Acyclovir acts as a prodrug that diffuses freely into and out of host cells. In HSV-infected cells, viral thymidine kinase phosphorylates acyclovir to a monophosphate nucleotide. This conversion selectively traps the drug and contributes to its lack of toxicity for uninfected cells. Cellular enzymes convert the monophosphate form to di- and triphosphate nucleotides. Acyclovir triphosphate mediates the antiviral effect by inhibiting viral DNA polymerase and by inserting into DNA, precluding further addition of bases to the DNA strand, a process known as *chain termination.*

Because EBV possesses little thymidine kinase and CMV possesses none, acyclovir lacks a similar potent inhibitory effect on these two herpesvirus strains.

MECHANISM OF RESISTANCE Strains of HSV relatively resistant to acyclovir exist in nature and may comprise up to 10% of HSV viruses.[139] In addition, acyclovir-resistant strains of HSV and VZV may be selected in vitro and in patients during therapy. In patients, acyclovir inefficacy associated with emergence of resistant strains is almost exclusively observed in immunocompromised hosts.[139] Acyclovir-resistant strains of HSV and VZV remain susceptible to ara-A and foscarnet in vitro, and these agents have been reported to be effective when acyclovir is not.[140]

Acyclovir resistance in HSV and VZV is mediated by genetic alterations that result in production of thymidine kinase–defective mutants (mostly) and DNA polymerase-insusceptible mutants (less commonly).[141]

CLINICAL PHARMACOLOGY[142] Acyclovir is available in topical, oral, and intravenous formulations. Although it is freely soluble in water, solutions have a high pH of 9 to 11, so it is not recommended for intramuscular or subcutaneous injection because it causes tissue inflammation and pain. After intravenous injection, concentrations in CSF and aqueous humor are 35% to 50% of those in the plasma. Binding to plasma proteins is relatively low (9% to 22%), so adverse interactions owing to displacement by other drugs have not been described.

The elimination $t_{1/2}$ of acyclovir from plasma is directly related to renal function because acyclovir is eliminated by glomerular filtration and renal tubular secretion. The latter mechanism is dominant as demonstrated by a mean acyclovir clearance rate that is four to six times greater than the creatinine clearance rate and by elevated Cp and prolonged $t_{1/2}$ values in patients given probenecid concurrently. The plasma elimination $t_{1/2}$ ranges from 2.5 hours in adults with normal renal function to 18 hours in those who are anuric. Nonrenal elimination of acyclovir contributes minimally to acyclovir clearance except in the presence of severe renal insufficiency. Up to 14% of a dose is eliminated as a glucuronide metabolite in urine, and less than 2% appears in feces.

Mean acyclovir plasma $t_{1/2}$ during hemodialysis is approximately 5 hours, which reflects removal of about 50% of drug during 6 hours of dialysis.

The usual doses of acyclovir are 5 mg/kg for patients with mucocutaneous HSV infection and 10 mg/kg for patients with HSV encephalitis or VZV infection. The dose is repeated at intervals inversely related to creatinine clearance:

Creatine Clearance (mL/min)	Dose Interval (h)
>50	8
25–50	12
10–25	24
0–10	24–48

Hemodialysis patients should be given a standard initial dose that is repeated every 48 hours and after each dialysis.

ADVERSE DRUG REACTIONS Acyclovir is relatively free of serious toxicity. Crystalluria with renal tubular obstruction and elevated serum creatinine concentration can be avoided by not exceeding the recommended doses and by not administering a dose in less than 60 min. Phlebitis can be avoided by infusing acyclovir in concentrations below 10 mg/mL. Tissue inflammation will develop if drug extravasates during infusion.

Neurotoxic symptoms of lethargy, agitation, tremor, disorientation, or transient paraesthesias have been observed in bone marrow transplant recipients during prolonged intravenous acyclovir therapy.[143] These symptoms resolved on withdrawal of therapy, but their relation to acyclovir dose,

duration of therapy, or plasma or CSF concentrations remains unknown. Psychiatric side effects including hallucinations and depression have been observed in patients with renal failure given doses in excess of those currently recommended, suggesting a dose-related effect. Delirium has been reported as a side effect of acyclovir in a hemodialysis patient receiving appropriately reduced doses,[144] and coma has been reported, beginning 24 to 48 hours after development of peak acyclovir serum concentration after a severe overdose.[145] Based on pharmacokinetic calculations, a loading oral dose of 400 mg followed by 200 mg twice daily with a supplemental oral dose of 400 mg has been proposed for oral doses to minimize neurotoxicity.[146] However, the utility of these calculated doses has not been validated prospectively.

Serious neurotoxic effects of acyclovir are likely to occur primarily in individuals with renal insufficiency in whom these effects can largely be avoided by careful attention to dose, frequency, and rate of administration; it has been suggested that the adverse effects can be treated by hemodialysis.[146]

VALACYCLOVIR AND FAMCICLOVIR

Valacyclovir is the ester oral prodrug of acyclovir.[147] Esterification increases oral bioavailability of acyclovir approximately twofold, from 15% to 30% to 55%. Famciclovir is a well-absorbed (77% oral bioavailability) analogue of acyclovir.[148]

Neither of these oral agents offers any unique advantage over intravenous acyclovir for treatment of ICU patients and they are not discussed further.

GANCICLOVIR[149]

Ganciclovir is a synthetic, acyclic, nucleoside analogue of guanine that differs from acyclovir in possessing a hydroxymethyl group on the ribose remnant. This modest structural alteration nevertheless profoundly affects its antiviral potency and its cellular toxicity. Compared with acyclovir, ganciclovir in vitro is on average three times less potent against HSV-1 and HSV-2, 10 times less potent against VZV, similarly potent against EBV, and 10 to 100 times more potent against CMV (0.2 to 2.8 mg/L is inhibitory). Ganciclovir concentrations of approximately 0.6 mg/L are toxic to human bone marrow progenitor cells compared with concentrations in excess of 20 mg/L for acyclovir. The clinically important feature of ganciclovir is its antiviral effect against CMV, but its therapeutic:toxic ratio is 1 or less.

In addition to its low therapeutic:toxic ratio, ganciclovir is mutagenic, teratogenic, and carcinogenic in laboratory animals. Accordingly, its use is limited to patients with serious CMV infections, almost all of whom are immunoincompetent owing to iatrogenic factors, such as immunosuppressive drug therapy in transplant recipients, or disease, such as HIV infection. Controlled clinical trials have demonstrated ganciclovir efficacy for treatment of CMV retinitis in HIV-infected individuals.[150] Less substantive data suggest that ganciclovir produces improvement in 65% of HIV-infected patients with CMV enteritis, esophagitis, wasting illness, and, possibly, pneumonitis.[151] Ganciclovir for 3 weeks is effective to suppress CMV-emia in allogeneic bone marrow recipients.[152] However, controlled trials in bone marrow transplant recipients with CMV pneumonitis have demonstrated that ganciclovir is inefficacious when administered alone or in combination with corticosteroids but decreases mortality rate when administered with CMV hyperimmune globulin.[153]

Intravitreal ganciclovir appears to be effective for treatment of CMV retinitis in HIV-infected patients and to obviate the toxicity observed with intravenous therapy.

MECHANISMS OF ACTION Ganciclovir inhibits viral DNA replication after intracellular conversion to the triphosphate nucleotide form. Phosphorylation is catalyzed by the virus-encoded enzyme UL97. Ganciclovir triphosphate acts like acyclovir triphosphate in selectively inhibiting viral DNA polymerase; its incorporation into viral DNA causes a slowing of DNA chain elongation and ultimately effects chain termination of the viral DNA strand. However, because it possesses two hydroxyl groups on the acyclic side chain, ganciclovir can be incorporated into host and viral DNA without abruptly interfering with chain elongation the way acyclovir triphosphate does.

MECHANISM OF RESISTANCE Ganciclovir-resistant CMV strains have been selected during serial passage of virus in the laboratory in the presence of the drug. Resistance associated with failure of ganciclovir therapy has been reported in immunocompromised patients. Foscarnet was effective in two such patients. Resistance was associated with reduced intracellular accumulation of ganciclovir in infected cells mediated by one or more specific point mutations in the UL97 gene.[154] The presence of the mutation can be demonstrated by direct sequencing of CMV DNA in the patient's plasma.

CLINICAL PHARMACOLOGY Oral and intravenous formulations of ganciclovir are available. There are two oral formulations, ganciclovir in capsules, which is 3% to 6% bioavailable, and valganciclovir in tablets, a prodrug that increases systemic ganciclovir availability to 61% of injected drug.[155] Valganciclovir increases ganciclovir oral bioavailability 10-fold, likely due to recognition of valganciclovir as a substrate by intestinal peptide transporters.

Oral ganciclovir capsules in large doses (3000 mg/d) deliver sufficient ganciclovir systemically to maintain CMV suppression achieved initially by intravenous drug. Thus, it is efficacious for suppressing CMV retinitis in HIV patients. Oral valganciclovir will replace oral ganciclovir capsules because of its more favorable bioavailability. It also likely will be a stepdown alternative to intravenous ganciclovir, which remains the recommended mode of administration for ill patients.

Ganciclovir diffuses readily into lungs, liver, aqueous and vitreous humors, and CSF. Elimination from plasma is by a first-order process with a $t_{1/2}$ of 2.5 to 3.6 hours that is inversely related to creatinine clearance. Ganciclovir is excreted into urine as unaltered drug.

The recommended dose of intravenous ganciclovir for adults with normal renal function is 5 mg/kg infused intravenously over 1 hour every 12 hours. Oral valganciclovir, 900 mg in a single dose, yields a serum area under the plasma-concentration versus time curve (AUC) of 0 to 24 hours similar to that observed after a single ganciclovir intravenous infusion of 5 mg/kg (41.7 vs. 48.2 mg/L per hour). For patients with impaired renal function, the dose or interval for

intravenous ganciclovir scheduling should be adjusted as follows:

Creatine Clearance (mL/min)	Ganciclovir Dose (mg/kg)	Dose Interval (h)
>80	5.0	12
59–79	2.5	12
25–49	2.5	12
<25	1.25	24

Hemodialysis for 4 hours removes an average of 53% of the body load of ganciclovir; one-half (2.5 mg/kg body weight) the standard dose should be administered after each dialysis.

ADVERSE DRUG REACTIONS Primarily because of incorporation in replicating host DNA, ganciclovir causes significant toxic effects in rapidly proliferating tissues and organs. Thus, in laboratory animals, ganciclovir causes hematopoietic, gonadal, and gastrointestinal toxicities.

In humans, hematopoietic toxicity has been the most common adverse side effect observed. Neutropenia and thrombocytopenia have been observed in 40% and 20%, respectively, of HIV-infected patients, and anemia has been noted less frequently. Concomitant administration of zidovudine and ganciclovir increases the frequency of neutropenia. Neutropenia and thrombocytopenia are almost always promptly reversible when ganciclovir is discontinued. In up to 15% of patients, ganciclovir, similar to the antiviral nucleosides acyclovir and ara-A, causes CNS toxicity, with manifestations ranging from headaches to behavioral changes, psychosis, convulsions, and coma. The mechanism is not known. Ganciclovir CNS toxicity may be difficult to differentiate from CNS dysfunction owing to concurrent disease and other drug therapy in seriously ill patients.

Oral ganciclovir capsules, oral valganciclovir, and intravenous ganciclovir in clinically equivalent doses caused diarrhea in 13%, 42%, and 7%, respectively, of patients; nausea in 7%, 28%, and 13%, respectively; anemia in 7%, 25%, and 14%, respectively; and leucopenia in 22%, 36%, and 25%, respectively.

FOSCARNET[156]

Foscarnet (trisodium phosphonoformate hexahydrate) is a relatively insoluble (aqueous solubility 5% [wt/wt]) antiviral drug. In vitro, foscarnet inhibits several DNA and RNA viruses at concentrations from 6 to 120 mg/L, but cellular cytotoxicity is observed at concentrations of 150 to 300 mg/L, yielding toxic:therapeutic ratios ranging from 1 to 7:1.

Intravenous foscarnet is licensed only for treatment of CMV retinitis in AIDS patients. However, studies have suggested that foscarnet may have value for a wider range of CMV infections (pneumonitis and encephalitis) in immunocompromised patients (HIV-infected patients and renal and bone marrow transplant recipients). Foscarnet is effective for therapy of acyclovir-resistant HSV or VZV and ganciclovir-resistant CMV infections. Six patients with fulminant hepatitis caused by hepatitis B or concomitant Delta virus infection survived in association with intravenous foscarnet therapy. Although the number of patients studied was small and historical controls were used to analyze therapeutic benefit, foscarnet may have a role in fulminant hepatitis B infection because no other specific treatment for this infection is currently available.

Foscarnet is the drug of choice for the treatment of CMV infections in individuals unable to tolerate ganciclovir, for patients with acyclovir-resistant HSV and VZV infection, and for those with ganciclovir-resistant CMV infections.

MECHANISM OF ACTION Foscarnet is an analogue of pyrophosphate, a metabolite of nucleic acid synthesis. Foscarnet acts by inhibiting DNA and RNA polymerases, including HIV reverse transcriptase. Foscarnet inhibits DNA polymerase activity noncompetitively by binding at the pyrophosphate binding site.

MECHANISMS OF RESISTANCE Naturally occurring foscarnet-resistant HSV strains seem uncommon (1 of 41 HSV isolates in one study). Foscarnet-resistant mutants of HSV-1 and HSV-2 and non-HIV retroviruses can be cultivated in in vitro experimental systems. These mutants possess DNA polymerase resistant to foscarnet. However, resistance development has not been observed during foscarnet therapy of experimental HSV infection in laboratory animals or during clinical trials in patients with HSV or CMV infection.

Resistance appears to be mediated by a mutation in the foscarnet binding site on the DNA polymerase. Some, but not all, of these foscarnet-resistant strains exhibit diminished susceptibility to nucleoside analogues such as ara-A, suggesting that the mutational alteration affected a binding site on the enzyme common to both drugs. In addition, an acyclovir-resistant HSV-1 strain with intact thymidine kinase but mutated DNA polymerase exhibited increased sensitivity to foscarnet and ara-A, suggesting that a change in the acyclovir triphosphate binding site affects the interaction of foscarnet and the ara-A triphosphate metabolite with the polymerase.

CLINICAL PHARMACOLOGY[156] Foscarnet oral bioavailability is low, with only 12% to 22% of oral doses being absorbed. The combination of poor oral bioavailability and the large doses required (100 to 200 mg/kg per day) even when foscarnet is given intravenously make oral therapy impractical. Intravenous regimens used to treat CMV infections consist of an initial dose of 20 mg/kg over 30 minutes followed by continuous infusion of 230 mg/kg per day or 60 mg/kg three times per day to achieve a target Cp of 45 to 135 mg/L. Infusion requires several hours because the maximum concentration of drug recommended for intravenous administration is 2000 mg/L. Steady-state plasma foscarnet concentrations range from 40 to 400 mg/L (mean, 100) with a peak Cp of approximately 150 mg/L.

After intravenous administration, the drug disappears from plasma in a tri-exponential manner, with $t_{1/2}$ values of 0.5, 3, and 18 hours. The long terminal $t_{1/2}$ probably reflects the slow release of foscarnet from bone. The kinetic AVD is about 0.6 to 0.7 L/kg. Plasma protein binding is 17%. CSF concentrations average 43% (range, 13% to 68%) of simultaneous Cp. Penetration into the retina seems sufficient to inhibit CMV replication and ameliorate retinitis. Knowledge of foscarnet distribution in humans is otherwise incomplete. In animals, foscarnet, being a phosphate analogue, is incorporated into the mineral matrix of bone. Foscarnet does not undergo metabolic transformation. It is eliminated unchanged into the

urine. Renal clearance averages 130 to 175 mL/min per 1.73 m^2 of surface area, suggesting that renal tubular secretion and glomerular filtration contribute to foscarnet elimination.

The kinetic characteristics of foscarnet in patients undergoing dialysis require further study. Available data indicate that the Cp of foscarnet declines rapidly during hemodialysis. This is consistent with the knowledge that foscarnet is a small molecule (molecular weight, 300 kd) that is minimally protein bound. Tissue binding of foscarnet likely will preclude extensive removal by dialysis. This facet of foscarnet disposition and its implications for dosing require further study. However, one recommendation suggests reducing the foscarnet dose by 30 mg/kg per day for each 20 mmol/L increase in creatinine concentration above 70 mmol/L.[157]

ADVERSE DRUG EFFECTS Although foscarnet commonly causes biochemical evidence of toxicity (anemia, leukopenia, thrombocytopenia, and elevation in serum creatinine, etc.), symptomatic toxicity is uncommon. Hallucinations and a flapping tremor, temporally directly related to foscarnet therapy, were associated with a relatively high Cp of 449 mg/L for foscarnet and disappeared when foscarnet was discontinued; these were therefore considered to represent direct toxic effects of the drug.

Anemia without alterations in white blood cell count or platelet concentration and mild elevations in the serum creatinine level occurs in 15% to 50% of patients, but the contributions of concurrent other drugs (e.g., cyclosporine) and underlying disease have been difficult to exclude. Hypercalcemia occurs in about 20% of patients and abnormal transaminase in 5% to 10%. Local phlebitis is uncommon. Adverse interactions of foscarnet with other drugs have not been described.

AMANTADINE

Amantadine is a synthetic, tricyclic, basic amine antiviral agent with antimicrobial utility limited to the prevention and treatment of *influenza A virus* infection.

In vitro, amantadine inhibits influenza A viruses in low concentrations of 0.2 to 0.4 mg/L. This effect has been uniformly demonstrable against all three major pandemic strains of influenza A virus and their subtypes.

Amantadine is approved for the prevention and treatment of influenza A virus infection. It has been demonstrated to be efficacious in preventing nosocomial influenza A infection in patients in acute general hospital wards, and it should be similarly effective in ICU patients, although no data exist on this issue.[158] Treatment of otherwise healthy, young adults with uncomplicated influenza illness accelerates resolution of systemic symptoms and some respiratory tract symptoms by 50% and hastens the resolution of increased peripheral airways resistance that is presumably related to inflammatory narrowing of small and medium bronchioles. In addition, treatment decreases the frequency and duration of virus shedding. Unfortunately, no data demonstrate that similar beneficial effects can be achieved by amantadine therapy in ICU patients with influenza A infection complicating severe obstructive airways disease or other severe underlying parenchymal lung disease, or with primary influenza A pneumonia in the absence of pre-existing lung disease.

For outbreak control, amantadine should be administered to all patients if epidemic influenza A infection is suspected or documented in the institution. When amantadine is used for outbreak control, it should be administered to all patients regardless of whether they received influenza vaccine recently and to unvaccinated staff. All unimmunized staff and patients given prophylactic amantadine should be offered immunization with the current vaccine simultaneously if the epidemic strain(s) is identical to, or closely related to, the vaccine strain(s). Amantadine prophylaxis should be continued until the outbreak is over, that is, until an interval equivalent to two incubation periods, 48 and 72 hours, after the period of communicability of the last case in the institution (about 5 to 6 days after onset) has passed.

MECHANISM OF ACTION Amantadine inhibits replication of influenza A virus by interfering with uncoating of the virus and release of the RNA genome in lysosomes. This effect requires that drug be present continuously in the extracellular milieu. Thus, the prophylactic or therapeutic effect is rapidly lost as drug is excreted from the body after discontinuation of drug administration.

MECHANISM OF RESISTANCE Susceptibility to the antiviral effect of amantadine is influenced by the virion M2 protein in the influenza virion envelope. Even single changes of amino acid in M2 decrease susceptibility to amantadine. Resistance to amantadine is readily selected for in vitro, during passage in mice experimentally infected with influenza A virus, and during amantadine treatment in patients. More studies are required to define the precise clinical relevance of these observations.

CLINICAL PHARMACOLOGY[159] Amantadine is highly water soluble with a pKa of 11. Its utility in the ICU setting is limited by its availability only in enteral forms as capsules of 100 mg or a syrup containing 10 mg/mL. Although data from studies in experimentally infected mice and patients with severe natural infection suggest that inhalation of amantadine as an aerosol may be more effective for influenza therapy than administration enterally, no formulation suitable for aerosol administration is available. For healthy adults 65 years of age, the recommended amantadine dose is 200 mg/d; for those older than 65 years, the dose is 100 mg/d.

In healthy adults including the elderly, amantadine is slowly (time to peak Cp, 6 to 12 hours after ingestion) but virtually completely absorbed, but no data have confirmed that similar results occur in acutely ill ICU patients. It is widely distributed with a mean AVD of 6.6L/kg that probably decreases with advanced age. As expected, there are two consequences of this pharmacokinetic characteristic. First, Cp values are low, averaging 0.5 to 0.8 mg/L at peak and 0.3 mg/L at trough at steady state, in young, healthy adults ingesting 200 mg/d and elderly men with normal creatinine Cp ingesting 100 mg/d. Second, negligible amounts are removed by hemodialysis. Amantadine is found in highest concentration in the brain, liver, lung, and kidneys in treated animals; a similar localization in humans may explain the propensity of this drug to cause CNS side effects (and, in part, ameliorate symptoms of Parkinson disease). Nasal mucus concentrations of amantadine only approximate concurrent Cp. This may explain the superiority of administration of amantadine as an aerosol for therapy of influenza A in experimentally infected mice and volunteers because aerosol administration of

amantadine resulted in a mean nasal washing fluid (and presumably mucus and respiratory epithelial cell) concentration of 66,658 mg/L after long-term oral ingestion of 200 mg/d and 30,300 to 111,300 mg/L after inhalation of aerosol generated from a reservoir containing 10 g/L amantadine in volunteers.

Elimination is a first-order process, with a plasma $t_{1/2}$ averaging 14 hours in healthy, young adults and 28 hours in healthy, elderly men (and, presumably, women). Renal clearance exceeds creatinine clearance by approximately three times, implying significant renal tubular secretion of amantadine in addition to elimination by glomerular filtration. The plasma $t_{1/2}$ is inversely related to creatinine clearance, and this fact led to the following recommendation for dose modification in patients with stable renal dysfunction:

Creatine Clearance (mL/min per 1.73 m^2 surface area)	Amantadine Dosage
>80	200 mg/d
60–80	200–100 mg on alternate days
40–60	100 mg/d
30–40	200 mg twice weekly
20–30	100 mg thrice weekly
10–20	200–100 mg at alternate weeks

In patients on hemodialysis, a single 200-mg loading dose should be sufficient. The plasma $t_{1/2}$ of amantadine may be as long as 30 days in such individuals.

ADVERSE DRUG REACTIONS Amantadine is generally well tolerated. Mild, amphetamine-like adverse symptoms occur in 1% to 10% of young adults, manifesting as insomnia, difficulty concentrating, nightmares, jitteriness, and depression. These symptoms are rapidly reversible on discontinuation of drug administration. Rarely, severe neurotoxic adverse symptoms ranging from seizures (in those with underlying convulsive disorders), psychosis, to convulsions occur. These generally occur in patients given excessive doses or with renal insufficiency. Amantadine Cp values are usually above 1 mg/L in these individuals.

Isolated instances of congestive heart failure, vision loss, and urinary retention have been reported. Livedo reticularis and peripheral edema during chronic therapy have been described.

Anticholinergic and antihistamine drugs may increase adverse effects caused by amantadine. A diuretic containing triamterene and hydrochlorothiazide was associated with neurotoxicity and increased amantadine Cp owing to reduced renal clearance. Because amantadine is a cationic drug, its renal tubular secretion would be expected to be decreased by concurrent administration of other basic drugs such as quinidine, nicotine, and trimethoprim. The possibility of such concomitant therapy increasing the frequency or severity of amantadine side effects requires further study.

RIMANTADINE

Rimantadine, a methylated analogue of amantadine, is approved in the United States as an oral agent for prophylaxis of influenza A infection in children and adults and for the treatment of influenza A infection in adults. Rimantadine thus may be used to prevent infection in ICU patients and personnel during an outbreak. Rimantadine was better tolerated than amantadine in a comparative trial in young adults but no more efficacious than amantadine at the same dose, 200 mg/d. An experimental formulation of rimantadine was administered as aerosol to volunteers with influenza A infection. Aerosolized rimantadine caused mild nasal irritation but was as effective as a small oral dose (150 mg/d) of rimantadine and more effective than placebo. The value of such treatment in intubated, ventilated patients with severe influenzal illness in the ICU has not been described. No injectable formulation is available.

MECHANISMS OF ACTION AND RESISTANCE See mechanism of action of amantadine (above). Rimantadine is more potent in vitro than amantadine, with 50% inhibitory concentrations being two to eight times less than for amantadine; the clinical importance of this difference is uncertain.

MECHANISM OF RESISTANCE Resistance emerges as readily during therapy with rimantadine as during therapy with amantadine, being demonstrable in 30% of recipients after 2 to 3 days of treatment. The mechanism of rimantadine resistance is identical to that for amantadine resistance. Cross-resistance is complete.

CLINICAL PHARMACOLOGY[160] Rimantadine is available only as tablets or syrup for oral administration. Some clinical pharmacokinetic characteristics of rimantadine differ substantially from those of amantadine. Rimantadine is absorbed as well and completely (>90%) as amantadine. The AVD is similar to that of amantadine, about 10 L/kg. Greater than 75% of a rimantadine dose is metabolized compared with less than 10% of an amantadine dose. Rimantadine undergoes hydroxylation, conjugation, and glucuronidation. A 2-OH metabolite has 10% the activity of the parent compound; the others are devoid of antiviral activity. The metabolites are eliminated into urine. Rimantadine clearance, averaging 350 mL/min, is not affected by age in otherwise healthy adults. The elimination serum $t_{1/2}$ of rimantadine averages 25 to 37 hours, approximately twice as long as that of amantadine. The recommended dose for healthy adults younger than 65 years is 200 mg/d. Based on the incomplete pharmacokinetic data, a reduced dose of 100 mg/d is recommended for prophylaxis and treatment of adults with severe renal dysfunction (creatinine clearance < 10 mL/min) or hepatic dysfunction and of elderly nursing home patients. In patients with mild or moderate renal insufficiency, the standard dose should be administered and patients closely observed for adverse reactions. In patients with end-stage renal failure, mean elimination $t_{1/2}$ is 44 hours. A 50% reduction in dose is recommended. Rimantadine is not removed by hemodialysis. In patients with mild or moderate liver disease (no ascites, normal albumin, total bilirubin <46 mmol), rimantadine kinetics were not different from those in normal subjects.

ADVERSE DRUG REACTIONS Comparative trials have demonstrated that rimantadine, like amantadine, is generally well tolerated. It causes a lower incidence of adverse symptoms than does amantadine, and, unlike that drug, it causes predominantly gastrointestinal ADR (nausea, anorexia, dry mouth, abdominal pain, and diarrhea). Rimantadine enters

the brain, but CNS toxic symptoms are less commonly seen with it than with amantadine.

No clinically important interactions of rimantadine with other drugs have been reported.

There are no trials comparing the efficacy or safety of amantadine or rimantadine used to treat patients in the ICU, but the differences in pharmacokinetic characteristics are important to note in selecting one or the other in patients with severe renal or hepatic insufficiency.

ZANAMIVIR AND OSELTAMIVIR

These drugs have recently been approved for the prevention and treatment of influenza A and B infections.[161,162] Zanamivir is administered as an orally inhaled powder, whereas oseltamivir is administered as oral capsules; no intravenous formulations are available commercially, although intravenous zanamivir was well tolerated and effective in preventing experimental influenza A infection in volunteers.

These agents differ from the M2 ion channel inhibitors, amantadine and rimantadine, in three characteristics. First, zanamivir and oseltamivir inhibit influenza A and B viruses, whereas the M2 ion channel inhibitors only inhibit influenza A strains. Second, these agents do not cause dose-related side effects of consequence (oseltamivir causes mild nausea and/or vomiting after initial doses in 10% to 15% of subjects vs. 5% to 8% of placebo recipients and zanamivir rarely causes bronchospasm in those with underlying obstructive airways disease). Third, these agents do not seem to share the propensity of amantadine and rimantadine to engender the emergence of drug-resistant virus. Amantadine- and rimantadine-resistant influenza A viruses would be expected to be susceptible to zanamivir and oseltamivir.

Zanamivir and oseltamivir are effective for the prevention of influenza A and B, and the treatment of uncomplicated influenzal illness. Neither drug appears more efficacious than the other or more efficacious than amantadine or rimantadine. No available data demonstrate that either of these agents is effective for treatment of established primary influenza pneumonia.

MECHANISM OF ACTION Zanamivir and oseltamivir inhibit influenza virus replication by inhibiting the virus-encoded enzyme neuraminidase, which is essential for release of daughter virions from infected cells. Human neuraminidase is 10^6 to 10^7 times less susceptible to inhibition by these drugs.[163]

MECHANISM OF RESISTANCE Resistance evolves in two steps. Initially, mutational changes in the viral hemagglutinin enzymatic pocket result in diminished affinity of the hemagglutinin for sialic acid, resulting in decreased dependency on the neuraminidase for virus elution. Such viruses would be less susceptible to the inhibitory effect of these drugs. Subsequently, resistance arises due to mutations in the enzymatic pocket of the neuraminidase itself, which impairs the ability of the drugs to interfere with the neuraminidase-mediated catalytic function.

CLINICAL PHARMACOLOGY Orally inhaled zanamivir is administered in a dose of two puffs (10 mg) once (for prophylaxis) or twice (for treatment) each day. The recommended dose of oseltamivir is 75 mg once or twice a day for prevention or treatment of influenza, respectively. From 4% to 17% of a zanamivir dose is absorbed, mostly through the lungs. Oseltamivir is 80% orally bioavailable, although this has not been confirmed in seriously ill patients in the ICU.

Both drugs exhibit low levels of protein binding (<5%). Inhaled zanamivir distributes through the upper and lower airways, whereas oseltamivir distributes throughout the body, with an AVD equivalent to about 36% of total body weight; the anatomic correlate is not known.

Both drugs are eliminated from the body largely unchanged by glomerular filtration and by renal tubular secretion by a first-order process, with a serum $t_{1/2}$ of 1.8 hours in persons with normal renal function. Renal clearance is decreased by renal dysfunction and dose reductions by half are recommended for oseltamivir in patients with creatinine clearance slower than 30 mL/min. Systemic exposure to zanamivir after oral inhalation is so low and the tolerance of zanamivir sufficiently high that dose reduction of zanamivir is not needed in patients with renal dysfunction.

DRUG INTERACTIONS In both cases, low protein binding and systemic clearance as unchanged drug without significant metabolism suggest that drug interactions due to alterations in binding or competitive inhibition of metabolism will not affect other drugs administered concurrently. Animal studies and limited human studies have confirmed these predictions. Oseltamivir, which is secreted by a renal tubular anionic transporter, might interfere with the renal secretion of other anionic drugs such as probenecid. A clinical study confirmed that such an interaction could occur; probenecid clearance was reduced 50%.

ADVERSE DRUG REACTIONS Zanamivir rarely can cause worsening of airway obstruction in patients with severe or decompensated chronic pulmonary or airway disease or asthma, and the manufacturer recommends against its use in these patients.

Oseltamivir causes nausea and/or vomiting, usually after only the initial dose, in 5% to 10% of oseltamivir recipients in excess of rates in concurrent placebo recipients. No serious or fatal drug-related adverse events have been observed in oseltamivir recipients.

In conclusion, these two new anti-influenza drugs have substantial advantages over amantadine and rimantadine as agents for preventing and treating influenza A and B infections in the ICU. Unfortunately and of primary concern, no studies have demonstrated their efficacy for treating patients with influenza pneumonia.

RIBAVIRIN

Ribavirin is a synthetic analogue of guanosine. In vitro, it inhibits the replication of a wide range of RNA and DNA viruses. Clinically, its value in the management of ICU patients is limited to the treatment of individuals with influenza A or B or respiratory syncytial virus respiratory tract infection with aerosolized drug and the intravenous therapy of patients with Lassa fever, an enzootic infection of rodents in West Africa that may be imported in returning travelers and be transmitted from patients to health care workers.

In clinical trials, ribavirin has been efficacious when administered as an aerosol to children and adults with respiratory syncytial virus infection and otherwise healthy adults with

uncomplicated influenza A or B virus infection. Intravenous ribavirin decreases mortality rate in patients with Lassa fever and it is likely effective, although incompletely studied, for some other viral hemorrhagic fevers.[164] A rigorous evaluation failed to demonstrate any beneficial effect of intravenous plus intracerebroventricular ribavirin in an adult with symptomatic rabies encephalomyelopathy. An uncontrolled study suggested efficacy when given intravenously to three patients with severe lower respiratory tract infection with influenza or parainfluenza viruses.[165] The utility of ribavirin for therapy of alphavirus encephalitides caused by Eastern, Western, or Venezuelan equine encephalitis viruses that are susceptible in vitro has not been reported.

Recently, ribavirin combined with pegylated interferon α_{2b} has been licensed for the treatment of chronic hepatitis C infection. The recommended dose is 200 mg, or five capsules per day for patients weighing less than 75 kg or six capsules per day for those weighing more than 75 kg, plus 3 million U interferon α_{2b} injected subcutaneously three times per week, for 24 to 48 weeks.

MECHANISM OF ACTION The precise molecular basis of the antiviral effects of ribavirin is not known. Multiple mechanisms probably are involved with differences between RNA and DNA viruses and virus-specific differences within each of these two groups.

Within cells, ribavirin behaves in part like an adenosine analogue, being phosphorylated to its mono-, di-, and triphosphate nucleotide forms by cellular adenosine kinase. Ribavirin-5′-phosphate seems to be the principal metabolite mediating the antiviral effect of ribavirin on influenza replication by inhibition of cellular inosine monophosphate dehydrogenase resulting in guanosine depletion and inhibition of viral RNA synthesis. This antiviral effect can be reversed by exogenous guanosine. However, ribavirin-5′-triphosphate also selectively inhibits influenza RNA polymerase, suggesting another locus for the antiviral effect of ribavirin on influenza replication. The multiple modes of action of ribavirin may account for the absence of reports of ribavirin resistance in clinical isolates.

CLINICAL PHARMACOLOGY Ribavirin is a water-soluble agent that has been administered to patients by aerosol, mouth, and intravenous injection.

For aerosol administration to patients with viral pulmonary infection, the drug has been prepared as a solution containing 20 g/L, which must be aerosolized in a special generator to yield particles of about 1.4 μm in diameter that will reach terminal airways and alveoli. Oral ribavirin is approximately 45% bioavailable due to substantial first-pass metabolism. Intravenous administration yields Cp values of 17 and 24 mg/L after doses of 500 and 1000 mg, respectively. These are approximately 10-fold higher than after comparable oral doses. Ribavirin distributes widely throughout the body. It accumulates within erythrocytes owing to trapping by phosphorylation. CSF concentrations average 50% to 65% of concurrent plasma levels. The drug undergoes extensive hepatic biotransformation as demonstrated by recovery of only 24% of an intravenous dose as unchanged drug in urine. Elimination from plasma is a triphasic process, with $t_{1/2}$ values of 0.2, 2, and 36 hours. Attainment of plateau concentrations in plasma will take 1 to 2 weeks.

The effect of concomitant hepatic or renal disease or other drugs on ribavirin disposition remains largely unstudied.

ADVERSE DRUG REACTIONS After administration by aerosol, ribavirin is generally well tolerated except for mild conjunctival irritation. Wheezing and cough have been observed in patients with asthma or mild chronic obstructive airway disease. These adverse effects were reversible by discontinuation of aerosol therapy or administration of aerosolized β agonist.[166] When administered to intubated patients by mechanical ventilator, ribavirin aerosol droplets deposit on the tubing and hoses, absorb water owing to their hygroscopic nature, and thereby interfere with efficient ventilation. The use of in-line filters, modified circuitry, and careful attention to pressure build-up can minimize deleterious effects on pulmonary gas exchange.

Ribavirin given intravenously for Lassa fever therapy only caused reversible anemia, which did not require transfusion, as a side effect.

Chronic oral ribavirin therapy causes CNS and gastrointestinal complaints including headache, lethargy, fatigue, insomnia, and anorexia. A dose-dependent macrocytic hemolytic anemia with a contribution from myelosuppression in those receiving larger doses commonly occurs. During treatment of chronic active hepatitis C infection, 10% of patients developed hemolysis resulting in hemoglobin levels below 10 g/dL.

Adverse interactions of ribavirin with other drugs or diseases have not been described.

In view of possible ribavirin teratogenic and embryotoxic effects in humans, like those observed in small laboratory animals, pregnant members of the nursing staff are advised to avoid protracted exposure to ribavirin aerosol.

NUCLEOSIDE REVERSE TRANSCRIPTASE INHIBITORS

Nucleoside reverse transcriptase inhibitors (NRTIs) are antiretroviral inhibitors comprising seven agents that are analogues of purines and pyrimidines used in the transcription of the HIV genome. The drugs require intracellular activation to a triphosphate nucleotide form, which is the active antiviral molecule. That is, they are in effect prodrugs. All NRTIs share a dual mechanism of action, namely as competitive inhibitors of reverse transcriptase (RT) and as chain terminators of HIV-DNA elongation, when they are incorporated into the elongating chain in place of the natural nucleotide. Mutation in the RT gene leads to viruses that are variably cross-resistant to other NRTIs. Genotypic resistance testing is needed to determine which NRTI will inhibit resistant mutants.

Collectively, NRTIs have a relatively short plasma $t_{1/2}$ of one to several hours but their intracellular half-life is longer, at least 3 hours, thereby permitting their administration one to three times per day. As a class, they have low affinity for hepatic cytochrome P450 drug-metabolizing enzymes, so they do not cause important adverse drug interactions by this mechanism. In contrast, NRTIs as a class cause depletion of mitochondrial DNA by inhibiting human DNA polymerase γ and, hence, replication of mitochondrial DNA.[167] As a result, mitochondrial DNA is depleted and drug toxicity occurs. Adverse reactions due at least in part to mitochondrial toxicity include hepatic steatosis, skeletal muscle and cardiac myopathies,

peripheral neuropathy, and pancreatitis. Asymptomatic elevated serum lactate levels and fatal lactic acidosis also have been described as probable additional manifestations of NRTI mitochondrial toxicity. Mitochondrial toxicity is reversible on discontinuation of NRTI therapy.

All NRTI drugs are approved for use in combination therapy even though there are robust data supporting the use of azidothymidine (AZT) alone for peripartum prophylaxis to prevent transmission of HIV to the neonate.

These drugs competitively inhibit the use of different purines or pyrimidines by HIV RT. They also differ in the nature of the adverse reactions they cause.

The NRTIs and their analogous natural nucleosides are:

Azidothymidine (AZT)	Thymidine
Lamivudine (3TC)	Cytidine
Didanosine (ddI)	Adenosine
Stavudine (d4T)	Thymidine
Zalcitabine (ddC)	Cytidine
Abacavir	Guanosine
Tenofovir	Adenosine

The following discussion aims to highlight noteworthy, clinically important aspects of these drugs because they might cause morbidity necessitating ICU admission or cause significant iatrogenic disease when administered to ICU patients.

ZIDOVUDINE

CLINICAL PHARMACOLOGY[168] From 63% to 95% (mean, 90%) of an oral dose of AZT is absorbed. However, because of first-pass metabolism, the average oral bioavailability is 65% (range, 52% to 75%).[169] Absorption is rapid, with peak Cp appearing within 30 to 90 minutes after ingestion. The effect of gastrointestinal disease, including HIV enteropathy, on AZT absorption has not been described. The drug distributes widely throughout the body. Concentrations in CSF average 15% to 64% of concurrent Cp. Hepatic glucuronidation yields an inactive, nontoxic metabolite. The plasma elimination $t_{1/2}$ of AZT is approximately 1 hour. AZT and its glucuronide metabolite are eliminated primarily through the kidneys, contributing 14% and 74%, respectively, to urinary recovery. Renal elimination is by glomerular filtration and renal tubular secretion. Probenecid interferes with glucuronidation of AZT and inhibits renal excretion of the nontoxic glucuronide. In anuric patients, the plasma $t_{1/2}$ of AZT increased to only 1.4 hours compared with 1 hour for controls with normal renal function. However, the plasma $t_{1/2}$ of the principal metabolite (glucuronyl AZT) increased from 1 to 8 hours, with as yet incompletely understood clinical consequences. Hemodialysis has a negligible effect on AZT removal but accelerates clearance of the metabolite. Thus, AZT dose need not be adjusted for patients with renal disease, including those undergoing dialysis.

The effect of hepatic disease on AZT disposition has not been described. AZT accumulation to levels higher than that seen in subjects with normal liver function would be expected. Until more data permit development of validated dose schedules for patients with hepatic disease, one might try the following strategies for minimizing dose-related toxicity: use of smaller doses (e.g., 300 mg/d) and frequent assessment of reticulocytes, hemoglobin, and neutrophil concentrations, because these appear to be the most sensitive to toxic effects caused by AZT. Measuring Cp of AZT has no established place in this setting and is impractical.

ADVERSE DRUG REACTIONS In adults with HIV disease, AZT ADRs were more common in those with more advanced HIV disease and in those receiving larger doses.[170] In all placebo-controlled studies, anemia and granulocytopenia were the most common ADRs observed: Anemia (hemoglobin <75 g/L) was observed in 9% and 5% of volunteers with asymptomatic and advanced HIV disease, respectively, treated with placebo and 1% (500 mg/d) or 6% (1500 mg/d) up to 29% (1500 mg/d) in AZT recipients in the two respective groups. Similarly, granulocytopenia (<750 cells/mm^3, or $<0.75 \times 10^9$/L) was observed in 2% and 10% of subjects in the two groups treated with placebo and 2% (500 mg/d) or 6% (1500 mg/d) up to 47% (1500 mg/d) in the two groups, respectively, treated with AZT. These hematologic toxic effects generally appeared after 4 to 6 weeks of therapy and reversed with reduction of AZT doses or temporary discontinuation.

Other reactions intensivists may see include severe headache (42% of AZT recipients and 37% of placebo-treated subjects), nausea (46% to 61% and 18% to 41%, respectively, in severe and asymptomatic HIV infection), vomiting (25% and 13%, respectively), insomnia (5% of AZT recipients and 1% of placebo-treated subjects), and myalgia (8% and 2%, respectively).

Considering the number of drugs administered concomitantly to HIV-infected patients receiving AZT, a paucity of clinically important interactions has been described. Ganciclovir and AZT produce additive suppression of myeloid precursors with granulocytopenia, acetaminophen may inhibit AZT metabolism and increase its Cp, and dapsone plus AZT increases the risk of anemia. Ribavirin antagonizes the anti-HIV effect of AZT by inhibiting its phosphorylation to AZT phosphate.

LAMIVUDINE

Lamivudine (3TC), a dideoxy analogue of cytidine, is a potent, selective inhibitor of HIV-1 and HIV-2 replications in vitro.

CLINICAL PHARMACOLOGY[171] Absolute oral bioavailability is 85%. The Cp rises linearly over the dose range of 0.25 to 20 mg/kg (usual oral dose is 150 mg twice daily or ~2 mg/kg per dose). Mean elimination $t_{1/2}$ is 2 to 4 hours. Mean ratio of CSF to serum in HIV-infected patients without clinical CNS disease is 0.06, similar to, or better than, that for ddC and ddI (0.0 to 0.2) but less than that for AZT (0.25 to 0.75). Metabolism of 3TC is a minor route of elimination. The majority of 3TC is eliminated unchanged in urine. 3TC clearance is markedly affected by renal functional impairment, with mean $t_{1/2}$ values of 11.5, 14.1, and 20.7 hours in subjects with normal renal function, moderate renal impairment (creatinine clearance 10 to 40 mL/min), and severe dysfunction (creatinine clearance <10 mL/min), respectively. TMP decreases 3TC renal elimination, causing a 40% increase in 3TC Cp, probably by interfering with renal tubular secretion. This is not clinically important because 3TC has no dose-related toxic effects. 3TC dose reduction is recommended in patients with renal insufficiency; the dose should be halved for those with creatinine clearance of 30 to 49 mL/min; for patients with creatinine

clearance of 15 to 29 mL/min, an initial dose of 150 mg followed by 100 mg/d is recommended; for patients with creatinine clearance of 5 to 14 mL/min, a 150-mg initial dose followed by 50 mg/d is recommended; for patients with creatinine clearance lower than 5 mL/min, a 50-mg initial dose is recommended followed by 25 mg/d. Dose adjustments for patients on dialysis are not available.

ADVERSE DRUG REACTIONS 3TC causes no dose-related adverse effects. Unlike the other marketed nucleoside RT inhibitors (AZT, d4T, ddC, and ddI), 3TC is noteworthy for causing few ADRs. The exception is a risk of pancreatitis in pediatric patients treated with 3TC combined with AZT. In one trial in which adult subjects ingested AZT 600 mg/d, 3TC 600 mg/d, or 3TC 300 or 600 mg/d plus AZT 600 mg/d, the 3TC groups reported no more adverse effects than the AZT-only group.

DIDANOSINE

CLINICAL PHARMACOLOGY[171,172] Didanosine (ddI) was initially licensed in 1991 in the United States. It is rapidly degraded at acid pH, so oral formulations contain buffers to decrease gastric pH and facilitate absorption as chewable or water-dispersible tablets administered twice daily.

Oral bioavailability has ranged from 20% to 40%, likely due to variations in gastric degradation by acid, motility, and transit time. As of 2002, a convenient new enteric-coated tablet has been licensed that provides oral bioavailability equivalent to the buffered tablets without the need to chew them or disperse them in water before ingestion. More recently, it has been demonstrated that tenofovir administered concurrently increases ddI oral bioavailability in 44% to 60% of subjects.

Didanosine undergoes extensive intracellular metabolism in the purine pool, resulting in formation of hypoxanthine and uric acid. From 35% to 60% of a dose is recovered unchanged in urine.

In patients weighing more than 60 kg with renal impairment, doses should be reduced: for creatinine clearance of 30 to 59 mL/min, the daily dose should be 200 mg; for creatinine clearance lower than 29 mL/min, the daily dose should be 125 mg. For patients on dialysis, the daily dose should be administered after dialysis. There is no need to give supplementary doses after dialysis because ddI is not dialyzable.

In patients with hepatic impairment, the risk of ddI toxicity may be increased but no specific recommendations for reducing doses are available.

ADVERSE DRUG REACTIONS Important serious adverse drug reactions include diarrhea, pancreatitis, peripheral neuropathy, lactic acid with hepatic steatosis, fulminant hepatic necrosis, and retinal depigmentation and vision loss. The risk of pancreatitis is 1% to 10%.

Allopurinol given concurrently appears to increase ddI AUC fourfold and thereby increases the risk of pancreatitis. Coadministration of ddI and allopurinol is not recommended.

Didanosine does not interact with other HIV-inhibitor drugs.

STAVUDINE

CLINICAL PHARMACOLOGY[173] Only an oral capsule formulation of stavudine (d4T) is currently available. Oral bioavailability is 82% to 99%, but absorption in critically ill patients in the ICU is not known. AVD is 47.3 to 70 L in adults. Peak CSF concentrations are 16% to 72% of the concurrent plasma concentration. Plasma elimination $t_{1/2}$ is 1.6 hours in HIV-infected patients, but the intracellular $t_{1/2}$ is 3.5 hours, thus permitting twice-daily dosing.

About 40% of a dose is eliminated unchanged into urine. Renal clearance of d4T is about twice the creatinine clearance, indicating that net tubular secretion and glomerular filtration contribute to its renal elimination. Nonrenal clearance is hypothesized to involve intracellular metabolism and entry of metabolites into the pyrimidine pool. Less than 1% enters the bile.

Twice-daily doses are recommended to be reduced in adults with renal impairment: with creatinine clearance faster than 50 mL/min, doses are 40 mg twice daily for patients weighing at least 60 kg and 30 mg twice daily for those weighing less than 60 kg; with creatinine clearance of 26 to 50 mL/min, doses are 20 and 15 mg twice daily, respectively, for the two weight groups; with creatinine clearance of 10 to 25 mL/min, doses are 20 and 15 mg once daily, respectively, for the two weight groups.

No adjustment for patients with stable hepatic impairment is recommended.

ADVERSE DRUG REACTIONS Peripheral neuropathy is the most important ADR. It has occurred in 15% to 24% of patients in controlled trials, is dose related, requires drug discontinuation or reduction, and is generally reversible.

Elevated levels of lactic acid of long duration due to mitochondrial toxicity associated with NRTI have been observed particularly during therapy with d4T. Symptoms include fatigue, shortness of breath, weight loss, and lipid abnormalities.[174] This syndrome is distinct from rare, potentially fatal lactic acidosis seen during NRTI therapy.

ZALCITABINE

CLINICAL PHARMACOLOGY[175] Oral bioavailability of zalcitabine (ddC) in adults is approximately 85%. AVD is 0.6 L/kg. Plasma $t_{1/2}$ is 1.5 hours (range, 1.1 to 1.8 hours), and elimination is a first-order process. Urinary excretion of unchanged drug is the principal route of elimination, accounting for 62% to 75% of a dose. Approximately 10% of a dose is excreted unchanged in feces.

Renal clearance is decreased in the presence of renal dysfunction, suggesting a need for dose reduction in such patients. Doses of ddC should be reduced from 0.75 mg three times daily to 0.75 mg twice daily in adult patients with creatinine clearance of 10 to 40 mL/min and 0.75 mg once daily in those with creatinine clearance lower than 10 mL/min.

Apart from 25% reduced bioavailability when given with aluminum and magnesium hydroxide, no important drug interaction has been described.

ADVERSE DRUG REACTIONS Peripheral neuropathy occurs with a frequency up to 12%, pancreatitis in 1%, and ulcerative stomatitis in 0.2%. Anemia and neutropenia occurred in 6% to 8% of ddC recipients versus 6% to 9% of ddI recipients in one study.

The peripheral neuropathy is dose related and generally reversible with discontinuation of treatment.

TENOFOVIR

Tenofovir disoproxil fumarate is an acyclic nucleotide analogue of adenosine monophosphate that acts as an HIV RT inhibitor.[176,177]

MECHANISM OF ACTION Unlike NRTIs such as AZT, tenofovir only undergoes two catalytic steps to convert it to its active antiviral molecule, tenofovir. Tenofovir inhibits RT and causes DNA chain termination on being incorporated into the elongating chain.

CLINICAL PHARMACOLOGY Only an oral formulation is available. A high-fat meal increases oral bioavailability from 25% to 39%; tenofovir $t_{1/2}$ in HIV patients averages 12 hours. Elimination is a first-order process. Drug is eliminated largely (75% of a dose) unchanged into urine. Renal clearance exceeds creatinine clearance, suggesting that glomerular filtration and tubular secretion contribute to tenofovir renal elimination.

As expected, renal impairment decreases tenofovir clearance. In the United States, tenofovir is relatively contraindicated in patients with moderate renal impairment (creatinine clearance <60 mL/min). In Europe, it is considered relatively contraindicated for patients with severe renal dysfunction (creatinine clearance not specified).

Tenofovir is efficiently removed by dialysis; median extraction is 54%. It can be inferred that one-half the dose should be administered after dialysis, but the validity of this inference has not been examined. Tenofovir is relatively contraindicated in patients with creatinine clearance lower than 60 mL/min.

Like the NRTIs, tenofovir is not metabolized by cytochrome P450 isozymes, so no interactions with drugs biotransformed by the isozyme are expected.

The most important drug interaction is a 28% to 44% increase in ddI AUC during concurrent administration. Tenofovir AUC is not affected. The effect is believed to be due to enhanced ddI bioavailability, although the molecular mechanism is unclear.

ADVERSE DRUG REACTIONS Tenofovir is generally well tolerated. Adverse symptoms are primarily gastrointestinal, but placebo-controlled trials showed few differences between treatments in the incidence of adverse symptoms: nausea 11% and 10%, diarrhea 9% and 8%, and vomiting 5% and 2% in tenofovir recipients and placebo recipients, respectively, and abdominal pain 3% in both groups. Severe biochemical abnormalities were similarly not different between the tenofovir and placebo groups.

Postmarketing studies have described pancreatitis, lactic acidosis, and several other ADRs during tenofovir therapy.

Overall, tenofovir appears to be a potent, useful addition to the NRTI group of antiretroviral drugs due to its potency and tolerability.

ABACAVIR

CLINICAL PHARMACOLOGY[178] Absolute oral bioavailability at 83% is excellent. Abacavir kinetics are nonlinear at doses smaller than 600 mg/d; however, because the recommended doses exceed this level, nonindependence of kinetics at smaller doses may not be clinically important.

Abacavir undergoes extensive hepatic metabolism, with less than 2% of a dose appearing in urine as parent drug. Metabolism in the liver yields two principal metabolites that are biologically inactive. They are eliminated (83%) into the urine. Plasma $t_{1/2}$ is shorter than 2 hours, whereas intracellular $t_{1/2}$ of the antiviral metabolite is 3.3 hours, thereby supporting administration two or three times daily.

Abacavir does not undergo substantial metabolism by cytochrome P450 enzymes and no important interactions with other retroviral inhibitors or other drugs have been described.

ADVERSE DRUG REACTIONS Hypersensitivity reactions occur in 4% (range, 0% to 7%) of patients given this agent. Manifestations include respiratory symptoms (pharyngitis, dyspnea, or cough), gastrointestinal complaints (nausea, vomiting, diarrhea, or abdominal pain), and skin rash. The reactions usually occur in the first 6 weeks after initiation of therapy (median, 11 days) and can appear within hours of reintroduction of abacavir in patients who interrupted therapy after an uneventful initial course of treatment. The cause is not known, but the scenario fits with the generalized propensity of HIV patients to develop hypersensitivity reactions to sulfonamides and fluoroquinolones. This reaction may be fatal, so abacavir is absolutely contraindicated in a patient diagnosed with a hypersensitivity reaction to it.

Overall, abacavir is a useful NRTI for combination therapy. Intensivists restarting abacavir in patients in the ICU must be aware of the small but definite risk of the hypersensitivity reaction.

NON-NUCLEOSIDE REVERSE TRANSCRIPTASE INHIBITORS

Three non-nucleoside RT inhibitor (NNRTI) drugs are currently marketed: delavirdine, nevirapine, and efavirenz. All NNRTI, unlike NRTI, agents act directly to inhibit RT. They do not require intracellular phosphorylation, as do NRTIs, to generate antiviral molecules. The NNRTIs bind at a hydrophobic site close to the RT catalytic site and cause conformational change in the enzyme, whereas NRTIs bind to the catalytic site. The NNRTIs are noncompetitive inhibitors of RT, whereas NRTIs are competitive inhibitors. NNRTIs also inhibit HIV replication by inactivating RT, whereas NRTIs cause chain termination as their second antiviral mechanism of action.

NNRTIs differ structurally, so cross-allergenicity does not occur. Nonetheless, rash is a common adverse effect of all currently licensed members of the class and represents the major adverse effect of the NNRTI drugs. Most cases are mild and not life-threatening. Although the mechanism of rash is not known, "... most experts do not recommend use of any NNRTI in a patient who has had a severe hypersensitivity reaction to one of the drugs."[179,180]

All NNRTIs are approved for treatment of HIV infection in combination with other HIV-inhibitor drugs. Although nevirapine monotherapy was reported to be more effective than AZT to prevent HIV transmission from infected pregnant women to their neonates, it is not approved for that indication. A mutation in the RT gene at amino acid 103 can cause 20-fold decreased susceptibility to all NNRTIs.

From the point of view of their clinical pharmacology, they demonstrate different capacities to interact with a host of other compounds catabolized by hepatic cytochrome P450 isozymes and cause clinically important interactions. As a

class, all NNRTIs are cleared primarily by the hepatic cytochrome P450 isozyme CYP 3A4, although other isozymes may contribute (efavirenz is also cleared by CYP 2B6 and delavirdine, possibly by CYP 2D6). Concomitant administration of other drugs has resulted in a range of interactions extending from asymptomatic reduction in clearance (demonstrated as increased AUC) to fatal adverse effects. Accordingly, caution always must be exercised in co-prescribing other drugs cleared by the liver and in some cases should be avoided. The following drugs are contraindicated in patients receiving delavirdine or efavirenz:

Drug Class	Agent	Potentially Fatal ADR
Gastrointestinal prokinetic	Cisapride	Cardiac arrhythmia
Antiarrhythmic	Amiodarone, quinidine	Cardiac arrhythmia
Sedative-hypnotic	Midazolam, triazolam	Prolonged sedation and respiratory depression
Neuroleptic	Pimozide	Cardiac arrhythmia
Ergot alkaloid derivatives	Dihydroergotamine, ergonovine, methylergonovine	Peripheral vasospasm and ischemic, injury
Antihistamine	Astemizole, terfenadine	Cardiac arrhythmia

The clearance of many other drugs that are also metabolized by hepatic CYP 3A4 and other isozymes may be altered during concomitant therapy with NNRTI agents. Effects of the interactions are less predictably serious than those for the agents listed above, so they are considered to be only relatively contraindicated.[180]

The following review focuses on clinical pharmacologic characteristics and adverse reactions that are deemed important for intensivists to be aware of as they consider prescribing these drugs to ICU patients.

DELAVIRDINE

CLINICAL PHARMACOLOGY[180,181] Only an oral formulation is available. Oral bioavailability is 85%. Antacids and gastric hypoacidity due to inhibition of gastric acid secretion or disease decrease oral bioavailability by approximately 50%. The AVD is about 65 L. Delavirdine is highly protein bound (~98%), mainly to albumin, so drug–drug interactions due to displacement of other highly bound drugs such as warfarin or phenytoin can occur. It is almost completely metabolized by hepatic cytochrome P450 isozymes CYP 3A (major) and CYP 2D6 (minor). Less than 5% of a dose is eliminated into urine. Half the metabolites appear in urine and half in feces, presumably with bile.

Delavirdine elimination is dose dependent and not first order as demonstrated by an increase in plasma $t_{1/2}$ from 2.4 to 4.1 hours as dose is increased from 200 to 400 mg three times daily.

Due to its extensive biotransformation by cytochrome P450 isozymes, delavirdine interacts with a wide range of drugs given concurrently because similar biotransformation is a common route of elimination for many agents.

ADVERSE DRUG REACTIONS Delavirdine is generally well tolerated in combination therapy for HIV. The most common adverse effects are skin rash (38% vs. 5% for AZT or ddI), headache (24% vs. 15%), nausea (15% vs. 5%), and pruritus (10% vs. 7%).

Skin rash is usually a pruritic erythematous maculopapular eruption that appears 7 to 15 days after initiation of therapy. Rash does not resolve more rapidly with discontinuation of delavirdine. Severe or life-threatening rash (e.g., Stevens-Johnson syndrome) has rarely been reported (1 case per 1000).

Clinical and biomedical hepatotoxicities have not been observed more frequently in delavirdine-treated patients than in recipients of control HIV treatment.

NEVIRAPINE

CLINICAL PHARMACOLOGY Nevirapine is currently available as an oral formulation, and its bioavailability exceeds 90%.[182,183] It is lipophilic and thus distributes widely. AVD is 1.4 to 1.5 L/kg body weight in adults. The ratio of CSF to plasma is 29%.

The principal route of elimination is by hepatic biotransformation followed by renal excretion. Only 3% is excreted as the parent compound in urine. Nevirapine hydroxylation and glucuronidation of metabolites are catalyzed by cytochrome P450 isozymes, primarily CYP 3A4 and CYP 2B6. The elimination $t_{1/2}$ decreases over 2 weeks due to autoinduction of metabolism: plasma $t_{1/2}$ after initial doses averages 40 hours and then 20 to 30 hours 2 weeks later. This well-described phenomenon underlies the strategy of giving 200 mg daily for 2 weeks followed thereafter by 200 mg twice daily in adults.

When administered to pregnant women to prevent neonatal HIV infection, its pharmacokinetic characteristics in women in the third trimester are not different from those in nonpregnant women. However, if initiated in labor, its kinetic characteristics are significantly altered. Systemic clearance increases on average by 30%, AVD doubles on average, AUC decreases by 15%, and $t_{1/2}$ increases by 70%. The drug readily crosses the placenta as demonstrated by high concentrations in cord blood. Breast milk concentrations average 61% of maternal blood concentrations, but the total amount of drug delivered to the baby is small if given to the woman during labor.

Nevirapine not only induces its own metabolism but also has the potential to interact with a wide range of other drugs also catabolized by CYP 3A4 and CYP 2B6 isozymes (see above).

Nevirapine pharmacokinetic features have not been described in patients with renal or hepatic impairment. However, because less than 5% of the drug is excreted into urine as the active parent compound, it is unlikely that nevirapine disposition is significantly affected by renal impairment or that dose reductions are required to minimize toxicity. Pre-existing hepatic impairment is likely to affect nevirapine clearance, so caution is recommended when nevirapine is administered to patients with moderate to severe hepatic dysfunction; no specific dose recommendations have been provided by the manufacturer.

ADVERSE DRUG REACTIONS The most common ADR is rash, observed in approximately 17% of adults, usually within 6 weeks of initiation of therapy. The rash is usually an erythematous maculopapular eruption of mild to moderate severity.

It may be treated with antihistamines or topical glucocorticoids.

In 6% of patients, the rash is severe enough to necessitate discontinuation of therapy. In 0.5%, it progresses to Stevens-Johnson syndrome.

Uncommonly (<5% of patients), nausea and elevated hepatic enzymes are observed. Although uncommon, hepatitis and fatal hepatic necrosis have been associated with nevirapine use. The manufacturer therefore recommends intensive monitoring in the first 8 to 12 weeks of nevirapine therapy to detect the earliest manifestation of severe and life-threatening skin rash or hepatitis. "Intensive" monitoring of liver function tests during this period is recommended without specification of an exact frequency. In the ICU setting, once-weekly testing seems reasonable.

EFAVIRENZ

CLINICAL PHARMACOLOGY[184] Efavirenz is administered orally once daily. Absorption increases with increasing doses from 100 to 1600 mg but not proportionately, suggesting a saturable mechanism or process. A fatty meal increases AUC by 50%. Most of a dose (16% to 61%) is eliminated in feces as unchanged drug, 14% to 34% in urine as metabolites, and less than 1% in urine as unchanged drug. The drug is 99.5% bound to human plasma protein, so interaction due to displacement of other highly bound drugs with a narrow therapeutic:toxic ratio may cause clinically significant effects (e.g., warfarin and phenytoin).

Efavirenz crosses the blood-brain barrier, but CSF concentrations are 0.26% to 1.19% of plasma levels, suggesting minimal diffusion. It is metabolized in the liver, predominantly by cytochrome P450 CYP 3A4 and 2B6 isozymes, as is the case for nevirapine. The $t_{1/2}$ is 40 to 55 hours at steady state.

Efavirenz pharmacokinetic features have not been rigorously studied in patients with renal or hepatic impairment. However, because less than 5% of efavirenz is excreted unchanged into urine, it is unlikely that renal dysfunction would cause significant accumulation of the pharmacologically active parent molecule. Conversely, efavirenz probably should be decreased in patients with significant hepatic dysfunction. However, no validated dose recommendations are available and therapeutic drug monitoring is not practicable. Caution in this circumstance is recommended.

ADVERSE DRUG REACTIONS Neurologic symptoms are the most common side effect. Headache, dizziness, insomnia, and fatigue were reported by 48% and 54% of patients receiving efavirenz plus indinavir or AZT plus 3TC, respectively. Rash was the second most common side effect, being reported by 10% and 15% of subjects receiving efavirenz plus AZT and 3TC or indinavir, respectively. Neurologic and dermatologic ADRs with efavirenz tend to be mild to moderate in severity. Rashes may respond to antihistamines and topical corticosteroids, and neurologic symptoms may be decreased by drug administration at bedtime.

PROTEASE INHIBITORS OF HIV

Six protease inhibitors of HIV have recently been licensed for combination therapy of HIV-1 infection: saquinavir, ritonavir, indinavir, amprenavir, nelfinavir, and lopinavir. These agents inhibit HIV replication by preventing cleavage of polyprotein precursors essential for synthesis of progeny virions. Protease inhibitors used in combination with other retrovirus inhibitors have produced the most marked and sustained reductions in HIV plasma concentrations observed to date. They are generally active against strains sensitive and resistant to NRTI and NNRTI, and cross-resistance is not uniform. The durability of this effect and the effectiveness of these drugs in patients measured by clinical and laboratory end points, and their efficacy in patients with advanced HIV-1 disease are substantial.

The protease inhibitor drugs, like the NNRTIs, are cleared primarily by transformation to inactive metabolites by the hepatic cytochrome P450 CYP 3AP isozyme. In addition, they may be substrates for one or more isozymes: lopinavir is also catabolized by CYP 2D6, whereas ritonavir also is a substrate for CYPs 2C9, 2C19, 2A6, 1A2, and 2E6. Not surprisingly, ritonavir interacts with a wide variety of other drugs administered concurrently. As noted for the NNRIs, the same list of drugs considered contraindicated in patients receiving one of those three agents should be considered contraindicated in patients receiving a protease inhibitor agent.

The protease inhibitor agents cause a variety of adverse effects, of which one collection of metabolic or endocrine effects appears to be a common class effect: hyperglycemia with a diabetogenic effect, adipogenic effects, hyperlipidemia and hypercholesterolemia, and spontaneous bleeding episodes.[191]

SAQUINAVIR[185]

MECHANISM OF RESISTANCE Decreased sensitivity to saquinavir does not occur readily in vitro or in treated patients. In vitro, saquinavir resistance is associated with mutations at amino acid 90 (more common; leucine to methionine) or at amino acid 48 (less common; glycine to valine). In patients treated with saquinavir alone, 45% had saquinavir-resistant phenotypes at 1 year, which did not differ from the incidence in patients treated with saquinavir plus AZT or ddC. However, the three-drug combination of saquinavir with ddC and AZT seemed to restrict emergence of resistance to AZT and saquinavir (to 22%).

Saquinavir-resistant HIV strains do not appear to be cross-resistant to indinavir or ritonavir.

CLINICAL PHARMACOLOGY Saquinavir is poorly bioavailable, with less than 1% of oral doses being absorbed under fasting conditions. Food enhances saquinavir absorption to about 30%, but only 4% reaches the systemic circulation owing to extensive first-pass metabolism. Saquinavir partitions extensively into tissues as demonstrated by an AVD of 10 L/kg body weight.

Saquinavir is extensively metabolized by the hepatic microsomal cytochrome P450 system into a number of inactive hydroxylated compounds. These are secreted into the bile and, hence, into the feces. Less than 5% is excreted into urine. Mean residence time is 7 hours. Doses need not be adjusted for patients with mild to moderate renal or hepatic insufficiency; in those with severe hepatic or renal disease, the drug should be prescribed with caution.

ADVERSE DRUG REACTIONS Saquinavir is well tolerated. Diarrhea, abdominal discomfort, nausea, and dyspepsia occur in 2% to 4% of saquinavir recipients and in 2% to 3% of recipients of saquinavir plus ddC or AZT. Nervous system side

effects such as headache, dizziness, and myalgias occur with low (1% to 3%) frequency at similar rates in saquinavir recipients and recipients of saquinavir plus ddC or AZT. Adverse symptoms are generally mild. Studies have indicated that saquinavir does not alter the rate or severity of adverse effects from AZT or ddC; this finding correlates with studies finding no pharmacokinetic interactions during combination therapy.

RITONAVIR[186,187]

MECHANISM OF RESISTANCE Decreased HIV sensitivity to ritonavir appears to develop at a rate similar to that of saquinavir, although only limited data are available. Genotypically, ritonavir-resistant HIV-1 strains have changes at amino acids 54, 71, and 84. These alterations are distinct from those associated with saquinavir resistance. Clinically, waning of the antiviral effect of ritonavir monotherapy was observed beginning at 4 weeks and was inversely related to dose. In those receiving the largest dose, 600 mg twice daily, mean reductions in plasma HIV-1 RNA concentration were 15-fold at 4 weeks (maximal) and sixfold at 32 weeks. In recipients of 300 or 400 mg twice daily, mean concentrations at 32 weeks did not differ from pretreatment levels. Ritonavir potency when used alone appears to be similar to that of indinavir or AZT combined with 3TC and greater than that observed with saquinavir alone.

Ritonavir-resistant strains are not uniformly cross-resistant to indinavir and saquinavir.

CLINICAL PHARMACOLOGY Ritonavir is well absorbed and produces high concentrations in serum that exceed the minimum inhibitory concentration despite 90% serum protein binding. The serum $t_{1/2}$ is 3 to 4 hours. Elimination is primarily by hepatic metabolism.

ADVERSE DRUG REACTIONS Given alone, ritonavir caused adverse effects including nausea, vomiting, diarrhea, asthenia, and circumoral and peripheral paresthesias and altered taste in 5% to 26% of subjects compared with 1% to 6% in placebo recipients. Greater than twofold increases in serum concentrations of triglycerides, creatinine phosphokinase, and transaminases were observed in 6% to 15% of ritonavir recipients and in 1% to 7% in placebo recipients. These appear to be independent of dose, being observed in more than 85% of recipients receiving ritonavir 600 to 1200 mg/d. The mechanism of the elevated triglyceride level is not clear but does not appear to be caused by pancreatitis.

Many drugs interact with ritonavir because of metabolism by the same common pathway involving hepatic cytochrome P450 isozymes. At least 25 drugs are considered to be contraindicated in patients receiving ritonavir.[188] Ritonavir should be administered with caution and appropriate monitoring due to pharmacokinetic interactions: ritonavir causes a large increase in the AUC of the coadministered drug (AUC increase greater than three- to fourfold; 33 drugs), a moderate increase (1.5-fold to threefold increase; 39 drugs), a moderate increase or decrease (17 drugs), or a possible decrease in AUC (19 drugs).[188]

INDINAVIR SULFATE[189]

MECHANISM OF RESISTANCE Resistance to indinavir was observed in 43% of individuals receiving the recommended dose of 2.4 g/d after 24 weeks of therapy compared with 65% receiving only AZT and 18% receiving indinavir plus AZT. These initial data suggest that resistance to indinavir appears at a slightly slower rate than resistance to ritonavir during monotherapy and that combined therapy with AZT decreases the rate of emergence of indinavir resistance. Indinavir resistance is directly associated with cumulative amino acid mutations in as many as 11 RT sites.

Indinavir-resistant HIV-1 strains are cross-resistant to ritonavir and variably resistant to saquinavir.

CLINICAL PHARMACOLOGY Indinavir is readily absorbed, although large meals reduce absorption by 75% judging by reduction in AUC. Less than 10% of a dose is excreted unchanged in urine. The majority of the drug undergoes metabolism before elimination in feces and urine. The serum $t_{1/2}$ is 1.8 hours in subjects with normal renal and hepatic functions. In patients with mild to moderate hepatic insufficiency, the $t_{1/2}$ almost doubles. The effects of severe hepatic disease or renal insufficiency have not been studied. Penetration into CSF has not been described.

ADVERSE DRUG REACTIONS Indinavir is generally tolerated as well as, or better than, AZT or ritonavir. Nephrolithiasis with flank pain and hematuria occurs in 4% of patients, and asymptomatic indirect hyperbilirubinemia occurs in 10%. Other ADRs include abdominal pain (9% vs. 5% AZT alone), fatigue (4% vs. 8% AZT alone), diarrhea (5% vs. 2% AZT alone), and insomnia (3% vs. 0% AZT alone).

Phlebitis owing to the alkaline pH of the solution also has been reported.

NELFINAVIR

CLINICAL PHARMACOLOGY[190] Oral nelfinavir is 70% to 80% bioavailable when administered with food. Bioavailability is 50% to 73% less when administered in a fasting state. AVD is 2 to 7 L/kg. Plasma protein binding is high at 98%, primarily to α_1-acid glycoprotein.

Nelfinavir is metabolized in the liver by cytochrome P450 isozymes CYP 3A4, 2C9, 2C19, and 2D6. Elimination is primarily by fecal (biliary) excretion of a hydroxylated metabolite (78%); 22% of drug excreted in feces is unchanged drug, and 1% to 2% of nelfinavir is excreted in urine as unchanged drug. Plasma $t_{1/2}$ is 3.5 to 5 hours.

The pharmacokinetic characteristics of nelfinavir have not been described in patients with renal or hepatic impairment. Less than 2% of nelfinavir is excreted into urine as unchanged drug, so renal dysfunction is unlikely to significantly affect the pharmacodynamics of the active parent compound. Because the drug is primarily inactivated in the liver, caution is recommended when it is administered to patients with hepatic impairment, but the manufacturer provides no specific dose recommendations.

ADVERSE DRUG REACTIONS Nelfinavir is generally well tolerated, but ADRs were severe enough to necessitate treatment discontinuation in 1.5% to 4% of 690 subjects in controlled trials. A retrospective comparison suggested nelfinavir tolerability exceeds that of indinavir, saquinavir, or amprenavir.

Diarrhea is the commonest ADR but is generally mild to moderate in severity and usually can be controlled with drugs that decrease gastrointestinal motility (e.g., loperamide).

Diarrhea of moderate to severe intensity was reported by 20% of recipients of nelfinavir with AZT and 3TC compared with 3% in recipients of AZT and 3TC alone. A comparison of ADRs concluded that nelfinavir has better gastrointestinal tolerability than indinavir, saquinavir soft gel capsules, or ritonavir in causing only diarrhea (26% incidence) and nausea (5% incidence) but no vomiting, dyspepsia, abdominal pain, or taste perversion.[191]

AMPRENAVIR

CLINICAL PHARMACOLOGY[192,193] From 35% to 90% of an oral dose of amprenavir is absorbed. AUC increases proportionally to dose over the range of 300 to 1600 mg (the therapeutic adult dose is 1200 mg twice daily). The drug is 90% bound to plasma proteins; α_1-acid glycoprotein is the principal amprenavir binding protein. AVD is said to be 430 L in adults, suggesting sequestration in tissues outside the plasma compartment.

Elimination is by hepatic cytochrome P450 isozymes, primarily CYP 3A4. The plasma elimination $t_{1/2}$ is 7 to 11 hours, which is the longest for any of the licensed protease inhibitors. Amprenavir is excreted predominantly as metabolites into feces (75%) and urine (14%). Hence, amprenavir pharmacokinetics would not be expected to be affected by renal impairment. Clearance is decreased as the severity of cirrhosis increases (Child-Pugh score). The manufacturer recommends caution in the use of amprenavir in such patients, without recommending specific dose reductions.

ADVERSE DRUG REACTIONS The most common adverse reactions observed in two controlled trials involving 358 patients who received highly active antiretroviral therapy (HAART) including amprenavir were nausea (15%), diarrhea (14%), rash (11%), and vomiting (5%). In a controlled trial in which all subjects received AZT plus 3TC with amprenavir or its placebo, the incidence of all the aforementioned complaints was 20% to 100% less in the placebo recipients. Grade 3 or 4 increases in alanine aminotransferase and/or aspartate aminotransferase and neutropenia also were more common in amprenavir than placebo recipients (5% vs. 3% and 5% vs. 0%, respectively).

LOPINAVIR

CLINICAL PHARMACOLOGY[194,195] Lopinavir is marketed as a soft gel capsule containing 133.3 mg lopinavir and 33.3 mg ritonavir. The absolute bioavailability of lopinavir-ritonavir has not been established. Compared with ingestion in a fasting state, administration of lopinavir-ritonavir capsules with a moderately fat meal (23% to 25% fat) or high fat meal (56% fat) increased lopinavir AUC by 48% or 97%, respectively.

Lopinavir is 98% to 99% protein bound in human plasma, more to α_1-acid glycoprotein than to albumin. AVD has not been described.

Lopinavir is catabolized by hepatic cytochrome P450 isozymes, primarily CYP 3A4. This process yields metabolites with relatively little antimicrobial activity. Ritonavir is a potent inhibitor of CYP 3A4, which inhibits lopinavir metabolism and thereby increases lopinavir AUC. A study using isotope-labeled lopinavir reported that 89% of the plasma radioactivity after a single oral dose of isotope-labeled lopinavir with unlabeled ritonavir (400/100 mg) was parent lopinavir compound. The AUC of lopinavir (100 to 800 mg) increases greater than 100-fold when coadministered with ritonavir 50 to 200 mg. Lopinavir plasma $t_{1/2}$ was 5.8 hours at steady state during treatment with lopinavir-ritonavir 400 and 100 mg twice daily. After a single dose of the same mixture, 10% and 83% of isotope-labeled lopinavir was recovered in urine and feces, respectively, over 8 days. Unchanged lopinavir accounted for about 2% and 20% of drug in urine and feces, respectively.

Lopinavir pharmacokinetics have not been studied in patients with renal impairment, but no or perhaps trivial effect of renal insufficiency is anticipated.

Lopinavir-ritonavir disposition has not been studied in patients with hepatic impairment, but decreased clearance of both would be expected. In such patients the manufacturer recommends caution in the administration of lopinavir-ritonavir but has provided no specific dose guidelines.

Other drug interactions due to lopinavir and/or ritonavir inhibition on CYP 3A4 are to be expected during concurrent therapy. A list of drugs that could be affected has been published.[188]

ADVERSE DRUG REACTIONS In controlled trials involving 612 patients receiving HAART and including lopinavir-ritonavir or nelfinavir, the drug was generally well tolerated. ADRs necessitated discontinuation of lopinavir-ritonavir in 3% of patients in the groups treated with lopinavir-ritonavir and nelfinavir.

The most common ADR in lopinavir-ritonavir recipients was diarrhea (14%), which occurred with the same frequency in recipients receiving nelfinavir, d4T, and 3TC. In lopinavir-ritonavir recipients given therapy for another 48 weeks, diarrhea was reported by 24% of patients. Grade 3 or 4 increases in alanine aminotransferase and/or aspartate aminotransferase were observed in fewer than 1% of lopinavir-ritonavir recipients compared with 2% to 2.5% of subjects receiving nelfinavir, d4T, and 3TC. The rates of neutropenia at 24 weeks were 0.6% and 1.6% in the two groups, respectively.

Antifungals

Despite its inherent toxicity and the continuing development of new, potent, better tolerated imidazole antifungal drugs, amphotericin B administered alone or in combination with another antifungal agent remains the standard therapy for serious systemic mycoses. Although the arbitrary distinction between antifungal drugs used exclusively for topical therapy of superficial infection or for treatment of mycotic infections of viscera (deep mycoses) is becoming blurred with the development of the newer imidazoles, this discussion is limited to those agents that are licensed for therapy for deep mycoses:[196] amphotericin B, 5-fluorocytosine, some of the imidazoles (ketoconazole), structurally related N-substituted triazoles (fluconazole, itraconazole, and voriconazole), and an echinocandin (caspofungin).

AMPHOTERICIN B[197]

Amphotericin B is an antifungal antibiotic produced by *Streptomyces nodosus*. It exhibits amphoteric behavior, forming relatively soluble salts in basic or acid aqueous media, but is extremely insoluble in aqueous solutions at physiologic pH. Accordingly, for clinical use, amphotericin B is formulated for

intravenous administration as a colloidal suspension by using the bile salt deoxycholate and sodium phosphate buffer. Recently, interest was focused on the formulation of amphotericin B with lipids to decrease its toxic effects.[198] Three lipid-associated amphotericin B preparations are currently on the market.[199] AmBisome is a true liposomal suspension consisting of vesicles comprising a phospholipid bilayer stabilized with cholesterol resulting in an intravesicular hydrophilic and external hydrophobic environment. The amphipathic character of amphotericin B makes it ideal for entrapment in those liposomes. Abelcet consists of a suspension of 1600- to 11,000-nm ribbon-like bilayers in which the amphotericin B is trapped. Amphocil consists of a colloidal dispersion of amphotericin embedded in 120- to 140-nm disks of cholesteryl sulfate.

In vitro susceptibility testing of fungi and yeasts, as with viruses, remains an inexact science. Although improvements are being made in all facets of standardization of techniques and interpretation,[200] published data from different laboratories are difficult to compare. Notwithstanding this fact, there is general agreement that an inverse relation exists between concentrations of antifungal agents required to inhibit growth in vitro and their therapeutic efficacy. The following yeasts and fungi have MIC values below 1 mg/L to amphotericin B and are considered highly sensitive to this drug: *Cryptococcus neoformans*, *Blastomyces dermatitidis*, *Histoplasma capsulatum*, *Coccidioides immitis*, *Sporotrichum schenckii*, *Candida albicans*, *Paracoccidiodes brasiliensis*, and the zygomycoses (*Mucor*, *Rhizopus*, *Absidia*, and *Cunninghamella*). *Aspergillus* species are usually sensitive. The causative agents of chromomycosis (*Phialophora* species and *Cladosporidium carrionii*) are usually resistant to amphotericin B alone but can be effectively inhibited by amphotericin B in combination with 5-fluorocytosine. *Prototheca* species, which cause chronic persistent granulomatous skin and visceral infections, are usually sensitive to amphotericin B.

Combining amphotericin B with certain antibacterial drugs such as rifampicin and tetracycline in vitro yields additive or synergistic antifungal effects, owing to enhanced penetration of the fungal cell by these two inhibitors of protein synthesis, because of enhanced permeability caused by amphotericin B. However, data from studies of animals with experimental fungal infections do not suggest a consistent, predictable, additive or synergistic effect of the combinations sufficient to warrant their use in patients.

Studies of amphotericin B combined with other selected antifungal agents in vitro, in animals with experimental fungal infections and some patients, have demonstrated effects that are at least additive. Amphotericin B with 5-fluorocytosine is at least additive in vitro and in animals with experimental candida and cryptococcal infections. This has permitted the use of smaller doses of amphotericin B with lesser attendant toxicity in patients with cryptococcal meningitis and perhaps candidal meningitis and arthritis. In a murine model of systemic aspergillosis, these two drugs produced better results than either agent administered alone, and some clinicians recommend their combined use in patients with serious aspergillus infection, especially with significant immunosuppression.

Results have been conflicting when amphotericin B is combined with imidazole antifungal drugs. Indifference, synergy, and antagonism have been observed in studies in vitro and in vivo in animals with experimental mycoses. In view of the unpredictable effects of combining imidazoles and amphotericin, intensivists should be careful about the use of combined therapy in ICU patients.

Specific recommendations for the treatment of deep mycoses are found in Chaps. 46, 49, and 50. Amphotericin B alone is the drug of choice for some *C. albicans* infections (esophagitis, peritonitis complicating peritoneal dialysis, fungemia, and endophthalmitis), coccidioidomycosis (progressive pulmonary infection and meningitis), histoplasmosis, zygomycoses, and sporotrichosis (systemic, articular, or pulmonary). Amphotericin B combined with 5-fluorocytosine is recommended for therapy of cryptococcal meningitis or disseminated infection especially in the immunocompromised host, systemic candidiasis except as noted above, *Candida* (formerly *Torulopsis*) *glabrata* endocarditis, invasive aspergillosis, and chromomycosis.

To date, no unambiguous proof of consistently enhanced efficacy of any lipid-associated amphotericin B formulations compared with the standard colloidal suspension in desoxycholate solution has been reported. Overall, at this time, it appears that lipid-associated amphotericin B formulations require larger doses to achieve comparable therapeutic benefits and cause fewer of the significant adverse effects of colloidal amphotericin B, namely hypokalemia, nephrotoxicity, and infusion-related reactions.

MECHANISM OF ACTION The antifungal action of amphotericin B is complex and largely dependent on its interaction with sterols, primarily ergosterol, in the cytoplasmic membrane of sensitive fungi. The drug appears to form channels or pores that lead to leakage of essential metabolites and, eventually, lysis of the cell. In low concentrations, the effect is reversible and the result is inhibition of fungal cell growth. However, at higher concentrations, the effect is irreversible; hence, the drug is fungicidal.

Amphotericin B potentiates the antifungal effect of 5-fluorocytosine and other agents by enhancing their entry into fungal cells.

MECHANISM OF RESISTANCE[201] Natural and acquired resistances to amphotericin B during therapy with clinical failure have been considered to be uncommon and not a clinical problem. However, in one survey, 7% of 747 strains of *C. albicans*, *Candida tropicalis*, and *C. glabrata* were resistant to amphotericin B. Resistance was observed only in isolates obtained from oncology patients. These data suggest, contrary to general opinions, that resistance may not be uncommon and that selection pressure from extensive amphotericin B use in granulocytopenic oncology patients may contribute to resistance development. It is postulated that a major reason that *C. albicans* resistance to amphotericin B antibiotics is uncommon is because it lacks a haploid sexual stage in its life cycle. Thus, the frequency of mutational events that will alter the specific locus where amphotericin B acts will be low. This would also explain the higher frequency of resistance observed with *C. glabrata*, which is haploid.

CLINICAL PHARMACOLOGY Absorption of amphotericin B after oral administration is negligible. Amphotericin B may be administered intravenously, intrathecally, intra-articularly, instilled into the infected urinary bladder, and in dilute

solution into the peritoneal cavity of patients with fungal peritonitis.

After intravenous infusion, the drug dissociates from deoxycholate in the blood, binds extensively (90%) to plasma proteins (mostly β lipoprotein), and distributes widely throughout the body but not into CSF or the vitreous humor. Even in patients with cryptococcal meningitis, amphotericin B concentrations in CSF were less than 10% of serum values. The AVD is 4 L/kg but with wide variation. This is consistent with the observed, extensive binding of biologically active amphotericin B in tissues, particularly to sterols in hepatocytes and erythrocytes, in which the concentration is up to 30 times greater than in plasma. The Cp of amphotericin B declines in a biexponential manner after intravenous infusion. There is an initial phase of rapid decline, with $t_{1/2}$ of 24 to 48 hours and a slow terminal phase of 15 days. Kinetically, this biphasic pattern is consistent with amphotericin B infusion into a central compartment and its equilibration rapidly into two peripheral compartments. The rapid decline in plasma amphotericin B represents equilibration into the former, and the phase of slow decline represents the slow release of amphotericin B back into the central compartment from which it was eliminated.

Approximately 2% to 5% of a dose is recovered as unchanged drug in the urine. From 16% to 94% (median, 33%) of injected doses can be recovered unchanged by extraction of tissues. The remainder is assumed to be metabolized, but data are not available on this aspect of its disposition. Blood levels are unaffected by hepatic or renal failure. Dose modifications are not required in patients with renal failure to compensate for any effect of oliguria on amphotericin B disposition, but doses may be decreased to mitigate further nephrotoxic effects of the drug. Hemodialysis does not enhance amphotericin B clearance, so such patients do not require alterations in the standard dose. At steady state, plasma amphotericin B concentrations after infusion of 0.5 mg/kg are 1.0 to 1.5 mg/L, with reduction to 0.5 to 1.0 mg/L 24 hours later. Hyperlipidemic and dyslipidemic states, such as occur in animals with uncontrolled experimental diabetes, alter the distribution of amphotericin B, with reduced liver and kidney concentrations, diminished nephrotoxicity, and reduced clearance, associated paradoxically with a fourfold increase in apparent volume of distribution. The clinical implications of such altered disposition of amphotericin B remain to be elucidated.

The disposition of amphotericin B administered other than intravenously has not been extensively studied. Limited data on the decline in amphotericin B concentrations in CSF after instillation of drug into the lumbar sac or cerebral ventricle have been published. Intrathecally administered amphotericin B (0.3 mg) produces peak concentrations of 0.6 to 0.8 mg/L, which decline to 0.2 to 0.3 mg/L after 24 hours. Amphotericin B injected into a cerebral ventricle (0.5 mg) yielded mean ventricular CSF concentrations of 1.7, 0.27, and 0.16 mg/L at 4, 24, and 48 hours, respectively, after injection. For treatment of yeast peritonitis in renal failure patients undergoing chronic dialysis, amphotericin B is diluted to yield a final dialysate concentration of 1 mg/L. Between dialysis sessions, 25 mg amphotericin B is instilled in 250 mL 5% dextrose in water solution, with 25 mg hydrocortisone every 48 hours. With this regimen, peritoneal fluid predose concentration increased from 1.6 to 2.2 mg/L, and concentrations 4 hours after instillation increased from 2.5 to 3.6 mg/L. Concurrent serum amphotericin B concentrations were 15% to 33% as high. These data suggest amphotericin B is sequestered in the peritoneal cavity because the diluent solution is absorbed and that little diffuses into serum.

The clinical pharmacokinetic features of liposome-encapsulated amphotericin B also have not been well studied. In mice and rabbits, liposomal amphotericin B distribution was primarily to organs rich in reticuloendothelial cells, including liver, spleen, and bone marrow. A pharmacokinetic study in mice reported a reduced area under the serum concentration-time curve for liposomal compound compared with colloidal amphotericin B. It was suggested that liposomal amphotericin B is sequestered in tissues until the vesicles are removed from the circulation by phagocytic cells in the liver and other organs.

ADVERSE DRUG REACTIONS The inherent toxicity of amphotericin B is demonstrated by a high frequency of adverse effects whether the drug is administered intravenously or by any other route. This propensity to cause side effects is compounded by the need, in most patients, for prolonged therapy.

Some patients may tolerate full intravenous doses of amphotericin B without difficulty, but immediate and long-term side effects frequently necessitate dose reductions or interruptions in therapy. Acute intolerance manifested by fever, chills, malaise, muscle and joint pain, nausea, vomiting, and hypotension often begins within 1 to 2 hours after initiation of therapy and lasts 2 to 4 hours. The observation that liposomal encapsulation of amphotericin B decreases production of proinflammatory cytokines by phagocytic cells is consistent with the lesser propensity of lipid-associated amphotericin B to cause infusion-related toxicity. Antipyretic, antiemetic, and antihistaminic drugs may provide some symptomatic relief, but controlled trials have provided little support for these practices.

Therapy should be initiated with a test dose of 1 mg in 20 mL 5% dextrose in water infused over 20 to 30 min, followed by a dose of 0.3 mg/kg infused over 2 to 3 hours. Thereafter, to minimize infusion-associated adverse effects, the dose should be gradually increased, if the acuity and severity of the illness permits, to the usual dose of 0.5 mg/kg per day. The maximum recommended dose is 1.5 mg/d. However, there is no proof from controlled trials that this regimen decreases infusion-related adverse effects, at least one of which was observed in 71% of patients in one large survey.[202] No more effective in preventing infusion-related toxicity was intravenous administration of amphotericin B in 4 hours versus 1 hour, although toxic reactions occurred sooner with the latter (at approximately 2 to 3 hours vs. 1 to 2 hours, respectively).[203]

Some prophylactic measures have been demonstrated to be efficacious in controlled trials:

1. Ibuprofen, 10 mg/kg, a potent inhibitor of prostaglandin synthesis, administered orally 30 minutes before initiation of amphotericin B infusion decreased the frequency of chilling from 87% to 49% in placebo recipients.[204]
2. Hydrocortisone, 25 mg, injected directly into the intravenous tubing at the start of amphotericin B therapy decreased the frequency of fever and chills from 78% to 56% in placebo recipients. However, the severity of chills and

the level of fever was not less in the hydrocortisone-treated group. Hydrocortisone 50 mg was possibly more effective than 25 mg (reactions decreased from 36% to 22%). Hydrocortisone 50 mg was not different from pretreatment with 900 mg aspirin plus 50 mg diphenhydramine.[205]

3. Meperidine in an average intravenous dose of 45 mg (range, 25 to 60 mg) stopped shaking chills induced by amphotericin B in 11 minutes, whereas interruption of amphotericin B resulted in cessation of the reaction spontaneously in an average of 38 minutes (range, 8 to 95 minutes).[206]
4. In experiments in dogs and patients, pretreatment by infusion of 0.15 M NaCl aqueous solution decreased the nephrotoxic effect of amphotericin B. Administration of 1 L physiologic saline before administration of the daily dose of amphotericin B, where the patient's condition permits, was recommended.[207]

Nephrotoxicity is the most important adverse effect of amphotericin B therapy. Creatinine clearance decreases by about 40% soon after commencing therapy in all patients and usually stabilizes at 20% to 60% of normal thereafter during continued treatment. The appearance of red and white blood cells, albumin, and casts in the urine usually accompanies the decrease in glomerular filtration rate. Thus, no nonnephrotoxic therapeutic dose of amphotericin B exists. However, evidence indicates that the severity of the renal injury is increased by larger doses, so the manufacturer recommends an absolute limit of 1.5 mg/kg per day. The nephrotoxic effect of amphotericin B appears related to induction of renal vasoconstriction and cortical ischemia. In some patients, amphotericin B causes a syndrome similar to renal tubular acidosis with its attendant risk of nephrocalcinosis and renal failure. Early recognition and alkali therapy may help avert or minimize irreversible renal injury. In about 25% of patients being treated with amphotericin B, hypokalemia and mild to moderate hypomagnesemia from renal potassium and magnesium wasting, respectively, occur and require careful monitoring and replacement.

Amphotericin B administration can be made more convenient by giving 2 days' total dose on alternate days, provided the dose to be infused is less than 1.5 mg/kg. This strategy does not affect efficacy if the alternative dose is twice the daily dose and does not decrease the nephrotoxic ADR. Animal studies demonstrating that intravenous mannitol could attenuate amphotericin B nephrotoxicity were not borne out in a controlled study in patients. Other nephrotoxic drugs such as the aminoglycosides and cyclosporine can add to the adverse effect of amphotericin B on the kidney and should be avoided.

If the patient's serum creatinine level increases from the normal range to 170 mmol/L or higher, amphotericin B should be stopped until the creatinine concentration decreases below that level. However, the severity of the fungal infection may necessitate continuing therapy at a smaller dose despite evidence of mild to moderate renal dysfunction. This appears acceptable because the renal dysfunction usually resolves after completion of a full course treatment unless the total dose exceeds 4 to 5 g.

A reversible normochronic, normocytic anemia occurs in most patients during amphotericin B therapy; the hematocrit frequently declines to stable levels of 22% to 35%. Anemia appears to be due to a suppressive effect of amphotericin B on erythropoietin production. Leukopenia and thrombocytopenia are rarely observed.

Hepatic dysfunction is rare; anaphylaxis and hypersensitivity rashes are uncommon.

Extravasated drug may cause cellulitis. Whether this is caused by the polyene drug or the deoxycholate is unclear. A similar reaction probably accounts for the arachnoiditis commonly observed with intrathecal injection. This chemical meningitis can cause nerve palsies, manifest as difficulty in voiding, impaired vision, paraplegia, and convulsions.

An adverse interaction of amphotericin B with leukocyte transfusion, causing acute dyspnea, hypoxemia, and interstitial infiltrates has been described by one group but challenged by others. However, since amphotericin B can cause polymorphonuclear leukocytes to aggregate in vitro, such an adverse interaction is biologically plausible.

Liposomal amphotericin B has been demonstrated in animals with experimental fungal infections and small numbers of patients[208] to have a better therapeutic index than the colloidal formulation available commercially. Both acute infusion-related and chronic renal toxicity side effects were less frequent and severe and liposomal amphotericin B appeared to be effective in patients unresponsive to colloidal amphotericin B. This has been hypothesized to be due to specific, selective delivery of amphotericin B to fungal cells, often in the reticuloendothelial system. However, absence of data from controlled trials comparing results of therapy with liposomal and standard amphotericin B precludes conclusions about the advantages of the liposomal formulation.

CASPOFUNGIN

Caspofungin is the first marketed member of a new class of antifungals, the glucan synthesis inhibitors or echinocandins.[209]

It is approved for the treatment of invasive candidiasis, most commonly fungemic infection, esophageal candidiasis, and invasive aspergillosis in individuals who are refractory to or intolerant of other therapies. Caspofungin is as good as, or superior to, amphotericin B and fluconazole in controlled clinical trials. The usual dose is 50 mg/d infused over 60 minutes. A 70-mg loading dose is administered initially. Treatment is continued to the point of clinical and/or mycologic cure.

MECHANISM OF ACTION Caspofungin inhibits the synthesis of β(1,3)-D-glucan, an essential component of the cell wall of many filamentous fungi and yeast. β(1,3)-D-glucan is not a component of mammalian cells, so the drug has specificity limited to fungal cells, with a resultant paucity of adverse effects on the patient's tissues.

MECHANISM OF RESISTANCE Resistance to caspofungin is not readily induced in the laboratory. The prevalence of resistance in various clinical isolates has not been described. Experience with treatment of patients with invasive candidiasis or aspergillus continues to accumulate. However, as of July 2003, drug resistance in such patients has not been reported.

CLINICAL PHARMACOLOGY Only an injectable formulation is available. Caspofungin distributes slowly and widely. It is hydrolyzed and *N*-acetylated in the liver: 41% of the drug

is recovered as metabolites in urine and 34% is recovered in feces.

Mild hepatic insufficiency (Child-Pugh score 5 to 6) does not necessitate any dose reduction. For patients with moderately severe hepatic insufficiency (Child-Pugh score 7 to 9), 35 mg/d is recommended.

Caspofungin clearance was decreased 30% to 50% in patients with moderate to severe renal insufficiency. However, no dose reduction is required for patients with renal insufficiency, including end-stage renal impairment.

In patients on hemodialysis, caspofungin kinetic features are not affected, so no supplementary doses are required after dialysis.

ADVERSE DRUG REACTIONS Caspofungin is generally very well tolerated, as would be expected given its specificity for fungal cell metabolism.

A possible histamine-mediated adverse reaction with rash, facial swelling, itch, and bronchospasm has been reported. Anaphylaxis has been reported during caspofungin infusion.

Drug-related adverse reactions occurred much less frequently (28.9%) in caspofungin recipients than in patients receiving amphotericin B (58.4%). Infusion-related toxicity (chills and fever) also was much less common (20.2% vs. 48.8%) in patients treated with amphotericin B.

Caspofungin does not inhibit cytochrome P450 enzymes, making adverse interactions due to competitive inhibition or induction unlikely.

Overall, caspofungin will be a substantial improvement over amphotericin B for treatment of deep mycoses, if results from wider clinical use mirror results from comparative controlled trials.

5-FLUOROCYTOSINE

5-Fluorocytosine is a fluorinated analogue of cytosine. It is an oral, narrow-spectrum, synthetic antifungal drug usually used in combination with amphotericin B.[210]

In vitro, 5-fluorocytosine inhibits *C. neoformans*, *Candida* species such as *C. krusei*, *C. tropicalis*, and *C. parapsilosis*, *T. glabrata*, and the agents of chromomycosis. The MICs of susceptible fungi are usually 6.25 mg/L or less; resistant species have MICs greater than 25 mg/L. *Aspergillus* species are generally moderately to strongly resistant. Other causes of deep mycoses such as *B. dermatitidis* and *H. capsulatum* are resistant to 5-fluorocytosine in vitro and clinically.

Clinically, 5-fluorocytosine has a beneficial effect against cryptococcosis, candidiasis, and chromomycosis. However, as a single agent, it is the drug of choice only for the latter disease because its efficacy in the former two is inferior to that of amphotericin B, largely because of the rapid emergence of drug resistance.

MECHANISM OF ACTION 5-Fluorocytosine inhibits growth of susceptible fungi by at least two mechanisms. It is taken up by susceptible cells and rapidly converted by cytosine deaminase to 5-fluorouridine triphosphate, which is then incorporated in place of uracil into replicating fungal RNA, causing mistranslation and cessation of growth. Another metabolite of 5-fluorocytosine, 5-fluoro-deoxyuridine monophosphate, interferes with thymidylate synthesis and thereby inhibits DNA synthesis. The synergistic effect of 5-fluorocytosine with amphotericin B against some fungi results from enhanced penetration of 5-fluorocytosine because of alteration of cell membrane permeability caused by the amphotericin B.

MECHANISM OF RESISTANCE Naturally occurring resistance to 5-fluorocytosine is not uncommon. With *C. neoformans*, it is of the order of 1% to 2%. Resistance among *Candida* species is more variable, being demonstrable in 1% to 37% of isolates.

5-Fluorocytosine–resistant strains of *Candida* species and *C. neoformans* can be readily induced in vitro by serial passage in the presence of increasing concentrations of the drug. Such secondary resistance also has been demonstrated in patients with cryptococcal, candidal, and torulopsis infections being treated with this agent. In one study, two-thirds of isolates recovered from patients being treated with 5-fluorocytosine were resistant.

Resistance is associated with loss of the membrane permease that transports cytosine (and 5-fluorocytosine) into the cell, with diminished activity of cytosine deaminase or uridine monophosphate pyrophosphorylase that catalyzes conversion to 5-fluorodeoxyuridine. In most *C. albicans* strains resistant to 5-fluorocytosine, resistance results from a deficiency of uridine monophosphate pyrophosphorylase. The loss of the enzyme does not alter the pathogenicity of the resistant strains.

CLINICAL PHARMACOLOGY Only an oral formulation is available. In healthy volunteers, greater than 90% of an oral dose is absorbed, but absorption in critically ill ICU patients may be markedly less. Protein binding in plasma is negligible. 5-Fluorocytosine distributes widely throughout all organs and fluids. Concentrations in CSF are 71% to 85% of concomitant serum levels and those in the aqueous humor, 10 to 40 mg/L, which in one study was 20% of concomitant serum concentrations. The AVD approximates that of total body water. Elimination is a first-order process directly related to creatinine clearance and, by inference, glomerular filtration. The plasma $t_{1/2}$ is 3 to 6 hours in normal individuals and inversely related to creatinine clearance. In functionally anephric patients, plasma $t_{1/2}$ approaches 85 hours. A small amount of drug in the body is converted to 5-fluorouracil. This is hypothesized to be a result of conversion of drug in the bowel by bacteria. This metabolite may account for the hematologic and gut toxicities of 5-fluorocytosine.

The recommended daily dose is 50 to 150 mg/kg administered in four equal portions. In view of the unpredictable effects of altered gastrointestinal absorption and fluctuating renal function on 5-fluorocytosine kinetics in ICU patients, 5-fluorocytosine Cp values should be measured frequently to permit dose adjustments to maintain levels in the effective and nontoxic range. Effective Cp values range from 35 to 70 mg/L; Cp values higher than 100 mg/L are associated with an increased risk of toxicity.

The effect of urinary acidification and alkalinization on 5-fluorocytosine in humans has not been described; in other species, prolongation and shortening, respectively, of the plasma $t_{1/2}$ of 5-fluorocytosine have been observed. The effect of fluctuating pH in critically ill patients would further reinforce the need to monitor Cp values in ICU patients.

5-Fluorocytosine is cleared by dialysis; after hemodialysis, a supplemental dose of 37.5 mg/kg is recommended. Patients with creatinine Cp values higher than 150 mmol/L usually

require dose reduction. The following reduced doses should be administered every 6 hours: with creatinine clearance of 40 to 49 mL/min, the dose is 27.5 mg/kg; with creatinine clearance to 20 to 29 mL/min, the dose is 18.5 mg/kg; and with creatinine clearance slower than 10 mL/min, the dose is 9.5 mg/kg.

Abnormal liver function appears neither to alter 5-fluorocytosine disposition nor to necessitate dose adjustments.

ADVERSE DRUG REACTIONS 5-Fluorocytosine causes myelosuppression and enterocolitis. The myelosuppressive effect is mediated by direct cytotoxic effects of 5-fluorocytosine on granulocyte and erythroid progenitor cells, as demonstrated in culture systems ex vivo. However, 5-fluorouracil may contribute to the hematologic toxicity of 5-fluorocytosine. The risk of these side effects correlates with 5-fluorocytosine Cp values above 100 mg/L.

Hematologic side effects of 5-fluorocytosine occur more commonly in patients with diseases such as leukemia or drug or radiation therapy that has affected marrow reserves. In extreme instances, fatal bone marrow aplasia has been reported. More commonly observed are leukopenia and thrombocytopenia, which are reversible if 5-fluorocytosine can be removed rapidly. Accordingly, in anephric patients with 5-fluorocytosine Cs values of 100 to 150 mg/L in whom elimination will be prolonged, dialysis to remove drug may be warranted.

Gastrointestinal side effects (nausea and diarrhea) are uncommon. More severe symptoms, including vomiting, abdominal pain, and copious diarrhea warrant careful re-evaluation because they may reflect acute mucositis, resembling acute ulcerative colitis.

Hypersensitive rashes are rare. In 5% of patients, hepatotoxicity, as demonstrated by mild elevations of transaminase Cp values, occurs. These patients should be monitored closely and 5-fluorocytosine Cp values measured because the hepatotoxic effect may be related to dose and concentration.

IMIDAZOLES AND TRIAZOLES

Imidazoles and the structurally related N-substituted triazoles are considered together because they share similar broad spectra of antifungal activity and the same mechanism of action. Their potency and high therapeutic indexes suggest that they may ultimately displace amphotericin B as the standard therapy for many serious fungal infections.[211]

Ketoconazole is the prototypical imidazole for therapy of deep mycoses. It is of limited value because it is available only as an oral formulation with erratic bioavailability and it interferes with steroidogenesis and the metabolism of other drugs administered concurrently by inhibition of cytochrome P450.

N-substitution of the imidazole ring has given rise to a second generation of derivatives called *triazoles* that have an antifungal spectrum similar to that of ketoconazole but less effect on steroid metabolism. This discussion describes two triazoles that are licensed for use, fluconazole and itraconazole.

KETOCONAZOLE[212]

Ketoconazole is a weak dibasic synthetic compound soluble in aqueous solution only at a pH below 3. As a consequence, sufficient gastric acid is a prerequisite for adequate dissolution and absorption of this compound, a requirement commonly absent in ICU patients being treated with antacids of H_2-blocking drugs to prevent stress-induced gastric bleeding. Thus, although ketoconazole is currently the drug of choice to treat some uncomplicated deep mycoses in immunocompetent patients who are not gravely ill, it has a limited role in the therapy of fungal infections in ICU patients.

In vitro, ketoconazole is a potent inhibitor of a wide variety of fungi. Although MIC results from such studies do not correlate uniformly with susceptibility in humans, especially for some *C. albicans* strains, the following organisms are susceptible in vitro and in vivo: *Candida* species including *C. krusei*, *C. tropicalis*, *C. albicans*, *C. parapsilosis*, and *C. glabrata*; *Sporothrix schenckii*; *B. dermatitidis*; *C. immitis*; *H. capsulatum*; and *P. brasiliensis*. *Pseudallescheria boydii*, *C. neoformans*, *Aspergillus* species, and the agents of mucormycosis are variably susceptible to ketoconazole in vitro. Ketoconazole is not uniformly effective in infections caused by these agents.

Data are conflicting on the effects of ketoconazole combined with amphotericin B in vitro, and currently no evidence indicates a beneficial effect when these agents are combined.

Ketoconazole is the current drug of choice for treatment of mild to moderately severe nonmeningeal blastomycosis, histoplasmosis, coccidioidomycosis, pseudallescheriasis, and paracoccidioidomycosis in immunocompetent patients. Ketoconazole is also the drug of choice for therapy of oral and esophageal candidiasis and chronic mucocutaneous candidiasis.

MECHANISMS OF ACTION The molecular mechanisms of the antimycotic action of all imidazoles, including ketoconazole, are complex, with no single primary target responsible for all observed effects. However, at least two mechanisms of action have been described. At low concentrations, ketoconazole and the other imidazole agents exert a fungistatic effect on susceptible fungi. They inhibit 14-demethylation of lanosterol by binding to the cytochrome P450 enzyme C14 demethylase. This results in accumulation of 14-methylsterols and decreased concentrations of ergosterol, which is essential for normal fungal cytoplasmic membrane synthesis. At high concentrations in vitro, which probably can not be attained in human tissues, imidazoles are fungicidal to susceptible fungi. This effect is owing to direct cell membrane damage with leakage of essential components from the cells, an effect similar to that caused by amphotericin B.

MECHANISM OF RESISTANCE Acquired resistance to ketoconazole is increasingly being reported in *C. albicans* during chronic therapy in AIDS patients. Diminished susceptibility of some *C. albicans* strains isolated during chronic suppressive therapy in children with chronic mucocutaneous candidiasis has also been reported. Resistant strains are not uniformly resistant to other imidazole or triazole antifungal drugs. Resistance development in other susceptible fungi has been reported rarely. Resistance is associated with diminished uptake of ketoconazole at the cytoplasmic membrane.

CLINICAL PHARMACOLOGY After oral administration, in the presence of sufficient hydrochloric acid, ketoconazole is transformed into the hydrochloride salt, which is absorbed rapidly. Peak Cp after administration of 200 to 800 mg

increases as a function of dose, but the disproportionate prolongation of the time to maximal Cp at doses of 800 mg suggests saturation of enzymes responsible for presystemic elimination of ketoconazole. In dogs, the absolute bioavailability of oral ketoconazole was 50% to 57% compared with intravenous doses, but a comparable study has not been described in humans. Food does not affect the absorption of ketoconazole. If H_2-blocking drugs or antacids must be administered to patients receiving ketoconazole, the drugs or antacids should be given 2 hours after the antifungal agent. However, given the prolonged inhibition of gastric HCl secretion produced by H_2 blockers administered orally or intravenously, it is speculative whether this strategy will permit ketoconazole to be adequately absorbed.

After absorption into the circulation, ketoconazole is more than 95% bound to plasma proteins. Its Cp declines biexponentially. The mean $t_{1/2}$ of ketoconazole in the initial distribution phase is 1 to 2 hours. The mean elimination phase $t_{1/2}$ was dose dependent after single oral doses of 100, 200, or 400 mg, with times of 6.5, 8.1, and 9.6 hours, respectively. Ketoconazole, a lipophilic drug, distributes widely, with an average AVD of approximately 2.4 L/kg. Ketoconazole is detectable in almost all fluids and tissues, although CSF concentrations are low, consistent with the drug's inefficacy in fungal meningitis.

The major route of elimination of ketoconazole involves hepatic biotransformation and excretion via the biliary tract. The major metabolic pathways involve oxidation and degradation of the imidazole ring, *O*-dealkylation, and aromatic hydroxylation to inactive metabolite. Clearance of ketoconazole declines out of proportion to doses beyond the range of 200 to 800 mg, suggesting that ketoconazole undergoes first-pass metabolism.

Ketoconazole kinetic features are not affected by renal insufficiency, but, as expected, significant hepatic insufficiency affects its elimination. Strategies for adjusting ketoconazole doses in patients with liver disease have not been described.

ADVERSE DRUG REACTIONS Ketoconazole at small doses is a drug of comparatively low toxicity; at larger doses, significant side effects are observed. The usual dose is 200 mg once or twice daily, but doses of 800 mg/d have been used, albeit with a higher frequency of side effects.

The most common adverse effects are dose-dependent anorexia, nausea, and vomiting, which occur in about 20% of patients receiving 400 mg/d. Administration with food may improve tolerance without affecting bioavailability.

Hepatitis demonstrated by asymptomatic elevation of serum transaminases affects a small percentage of patients, with return to normal without interruption of therapy. More severe, occasionally fatal, hepatitis occurs in about 1 in 12,000 recipients. This appears to be an idiosyncratic, unpredictable reaction, although pre-existing liver disease may be a risk factor. Therefore, liver function should be assessed before initiation of ketoconazole therapy, and the potential benefits of pretreatment should be weighed carefully against the risk of further liver damage.

Ketoconazole at doses of 800 mg/d or larger significantly interferes with normal steroid metabolism. Testosterone synthesis is blocked with the possibility of gynecomastia, diminished libido, oligospermia, and hair loss; in women, menometrorrhagia has been observed, although the mechanism is not clear; cortisol secretion and the response to adrenocorticotropin may be suppressed. All these effects are reversible by stopping ketoconazole therapy or reducing the dose.

Interactions with other drugs are clinically important. Administration of ketoconazole with cyclosporine and the nonsedating antihistamines, terfenadine and astemizole, result in increased cyclosporine and antihistamine concentrations with an attendant risk of nephrotoxicity and cardiac dysrhythmias, respectively, because of interference with hepatic drug metabolism. Rifampin coadministration decreases serum ketoconazole levels, presumably by induction of cytochrome P450 metabolism of the antifungal drug.

Ketoconazole is not thought to potentiate the anticoagulant action of warfarin, as does miconazole, another imidazole drug, but this is debated. It seems prudent to monitor the prothrombin time frequently in patients receiving ketoconazole and warfarin until the data are more clear.

ITRACONAZOLE

Itraconazole is a triazole antifungal drug that differs from ketoconazole in several respects. It is more potent in vitro than ketoconazole and more lipophilic; therefore, it possesses significantly different clinical pharmacokinetic properties. However, the place of itraconazole in the armamentarium of antifungal drugs for therapy of deep mycoses appears similar to that of ketoconazole except that there is evidence to suggest it may also be useful to treat sporotrichosis and invasive aspergillosis.[196]

The mechanism of action of itraconazole is identical to that of ketoconazole. Primary and secondary resistances to itraconazole have undefined prevalence and clinical importance at this time.

CLINICAL PHARMACOLOGY[213] The clinical pharmacokinetic characteristics of itraconazole differ significantly from those of ketoconazole. Itraconazole is a weak base that is highly ionized and poorly absorbed at the pH of gastric juice. It is insoluble in water, and this has largely precluded the development of an injectable formulation. The absolute bioavailability of itraconazole is approximately 50% in dogs; the comparable kinetic parameter in humans is not known. The usual adult dose is 200 to 400 mg/d. Ingestion of itraconazole with food doubles its absorption, so it should be taken immediately after a meal to ensure optimal oral bioavailability. As with ketoconazole, oral bioavailability appears to be enhanced at larger doses (>500 mg). This augmented oral bioavailability at larger doses likely results from transient saturation of metabolic processes in the liver. Plasma protein binding of itraconazole is 99%, mainly to albumin. Itraconazole distributes widely and, as is characteristic of lipophilic drugs, possesses a large AVD, which is 20 times greater than that of ketoconazole, and reflects extensive tissue sequestration. However, itraconazole has negligible CSF penetration.

The metabolic fate of itraconazole has been studied in detail only in laboratory animals. However, its metabolic fate in humans is expected to be comparable to that in animals. Itraconazole undergoes extensive biotransformation, presumably in the liver. More than 30 metabolites have been identified, none of which has antifungal activity. About 54% of an oral dose is secreted through the bile into the feces and 35% into urine primarily as inactive metabolites. The mean

elimination $t_{1/2}$ from plasma ranges from 13 to 18 hours. Peak Cp of itraconazole attains steady state after about 2 weeks and averages 0.4 to 0.6 mg/L. In uremic patients with creatinine clearance slower than 12 mL/min who are not yet on maintenance hemodialysis and in volunteers with cirrhosis, itraconazole kinetics were not different from those in normal volunteers. Thus, dose alterations are not recommended for such patients.

Despite the high level of protein binding of itraconazole and its displacement from albumin by other drugs with similar high-level affinity, the clinical relevance of such interactions remains uncertain.

ADVERSE DRUG REACTIONS Like ketoconazole, itraconazole is reasonably well tolerated; 10% to 15% of patients experience nausea or vomiting, but the intensity does not usually require interruption of therapy. Unlike ketoconazole, itraconazole appears to neither cause hepatitis nor alter steroidogenesis.

No significant effect of itraconazole on the metabolism of warfarin has been reported. Concomitant itraconazole therapy reduces cyclosporine dose requirement by about 50%. Concurrent administration with terfenadine and astemizole inhibits their metabolism and increases the risk of cardiac dysrhythmias. Interaction with a single dose of rifampin, a potent inducer of hepatic drug-metabolizing enzymes, causes an initial inhibition of itraconazole metabolism followed by increased clearance (metabolism). The net effect of chronic dosing is hard to predict based on these limited data.

FLUCONAZOLE

Fluconazole is a novel, low-molecular-weight antifungal with two azole rings.[214,215] Its development provides intensivists with a potent, injectable, broad-spectrum antifungal of the imidazole and triazole class that is unique pharmacokinetically in penetrating readily into CSF across even uninflamed meninges and in being eliminated primarily as unchanged drug directly into the urine to yield high bioactive antifungal activity therein.

In vitro, the spectrum of action of fluconazole is comparable to that of ketoconazole, as is the scope of resistance (becoming more common) and its basis (diminished uptake by fungal cell membranes). It is efficacious in animal models of several deep fungal infections in normal and immunocompromised hosts. However, at this time, its relative usefulness compared with amphotericin B for serious visceral fungal infections is being evaluated.

Clinically, in addition to being injectable, fluconazole has two potential advantages over ketoconazole, which mirror the distinctive kinetic properties of fluconazole. First, fluconazole may be valuable for treatment and long-term suppression of fungal meningitis in immunocompetent and immunosuppressed patients such as those with AIDS; second, it may be effective for treatment of fungal urinary tract infection. Fluconazole shows great promise as a potent, safe agent for the treatment of fungal meningitis.[196] Its potential for management of this and other deep mycoses alone and in combination with amphotericin B remains to be elucidated in controlled trials.

CLINICAL PHARMACOLOGY Fluconazole is highly soluble in water; injectable and oral formulations are available. The usual daily adult dose in patients with normal renal function ranges from 100 to 400 mg. Peak Cp values average 4 to 8 mg/L after repetitive doses of 100 mg/d.

After oral administration, greater than 90% is absorbed, although whether this occurs in seriously ill ICU patients is unclear. Oral bioavailability is not affected by food or gastric pH. Fluconazole is 15% bound to plasma protein, so adverse interactions with other drugs because of displacement from plasma proteins are unlikely to be observed. CSF concentrations average 50% (range, 74% to 89%) of concurrent Cp in patients with normal and inflamed meninges. Elimination is primarily by glomerular filtration into urine as unchanged drug, so high, therapeutic antifungal concentrations are attained. The plasma $t_{1/2}$ in adults with normal renal function is approximately 30 hours, making once-daily dosing appropriate. In adults with creatinine clearance slower than 10 mL/min, fluconazole plasma $t_{1/2}$ is 48 hours, so a 50% reduction in dose is recommended. Hemodialysis for 3 hours decreases fluconazole Cp by 48%. A supplemental dose of 200 mg after dialysis is recommended. Fluconazole added to peritoneal fluid is almost completely bioavailable to the systemic circulation. Fluconazole administered orally yields peritoneal fluid concentrations 60% of corresponding Cp values. For patients requiring fluconazole and receiving peritoneal dialysis, dose reduction by 50% is recommended. *Candida* species peritonitis also can be treated by adding fluconazole 150 mg into the peritoneal dialysate every 2 days. The effect of dialysis or severe hepatic disease on fluconazole disposition and the details of associated dose adjustments needed in such patients remain to be defined.

ADVERSE DRUG REACTIONS Initial studies suggest that fluconazole shares the same safety profile as itraconazole: Gastrointestinal upset is the most common side effect. Transient elevations in serum transaminases have been described. No interference with steroid hormone synthesis has been observed.

Fluconazole administered concurrently with other drugs can affect their metabolism. Addition of fluconazole causes Cp values of terfenadine, astemizole, phenytoin, sulfonylureas, warfarin, and cyclosporine to increase, presumably by interference with their hepatic metabolism by the cytochrome P450 oxidation system.

It is expected that renal dysfunction will reduce fluconazole clearance and cause total body content and fluconazole Cp to rise if doses are not reduced. Although the clinical importance of these increased fluconazole Cp values has not yet been demonstrated, reducing fluconazole doses as renal function declines would seem prudent.

VORICONAZOLE

Voriconazole is a broad-spectrum triazole antifungal agent derived from fluconazole.[216,217] It is approved for the treatment of invasive aspergillosis in the United States and Europe for treatment of serious infections caused by *Fusarium*, *Scedosporium*, and azole-resistant *Candida* species.

In addition to caspofungin, the availability of voriconazole presents intensivists with an alternative to amphotericin B for

treating patients with invasive aspergillosis and off-label uses for other serious fungal infections.

Recommended doses are 6 mg/kg intravenously 12 hours apart for two doses, followed by 4 mg/kg every 12 hours; patients may be switched to 100 mg (≤40 kg body weight) or 200 mg (>40 kg) orally every 12 hours.

MECHANISM OF ACTION Like all azole antifungals, voriconazole inhibits 14-α-sterol demethylase, an enzyme involved in synthesis of sterols for the fungal cell membrane and wall. The effect is fungistatic. Voriconazole is as or more potent an inhibitor of *Aspergillus* species and other fungi than is itraconazole, fluconazole, or amphotericin B, although the exact clinical relevance of in vitro susceptibility tests for fungi remains uncertain.

MECHANISM OF RESISTANCE Voriconazole resistance has been observed in isolates recovered from HIV-infected pediatric patients with oropharyngeal candidiasis previously treated with azole antifungal drugs. This suggests that some cross-resistance between voriconazole and other azole antifungals is observed. However, voriconazole has been observed to inhibit fluconazole-resistant *C. albicans* from HIV patients with fluconazole-resistant esophageal candidiasis.

CLINICAL PHARMACOLOGY Oral and intravenous formulations are available. Oral bioavailability is 96% and is not affected by gastric pH. AVD is 4.6 L/kg body weight, implying wide distribution.

Voriconazole is eliminated from serum by hepatic metabolism by cytochrome P450 isoforms 2C19, 2C9, and 3A4. Less than 2% of a dose can be recovered unchanged in urine. Due to saturable metabolism, its kinetic features are nonlinear. However, at recommended doses, serum $t_{1/2}$ is approximately 6 hours.

Clearance is decreased by 50% in patients with moderate hepatic impairment (Child-Pugh class B). It has been suggested that the loading dose for such patients can be the same as in patients with normal hepatic function, but maintenance doses should be halved. Pharmacokinetic data on voriconazole in patients with severe hepatic impairment (Child-Pugh class C) are not available, and no specific validated dose recommendations are available for such individuals.

Renal impairment, including severe dysfunction, does not alter voriconazole kinetics. Although the carrier, cyclodextrin, may accumulate in such patients, it probably will not cause adverse effects.

ADVERSE DRUG REACTIONS Voriconazole is generally well tolerated, particularly in comparison with amphotericin B. However, it causes disturbances of vision (8% to 44% incidence), rash (5% to 6% incidence), and elevated liver function tests in about 10% of patients. In addition, because of its metabolism by hepatic CYP 3A4, a principal drug metabolizing enzyme, it has the potential to cause significant drug interactions during concurrent administration with a host of other drugs.

Vision changes consist of altered visual perception, blurring, color vision alterations, and photophobia. They were generally transient and did not necessitate interruption of treatment in published trials.

Skin rashes include Stevens-Johnson syndrome, toxic epidermal necrolysis, and erythema multiforme, although most rashes were only mild to moderate in severity.

Voriconazole markedly increases systemic exposure of concurrent warfarin, cyclosporine, phenytoin, omeprazole, sirolimus, and tacrolimus. It is predicted to increase systemic exposure of concurrent terfenadine, astemizole, cisapride, pimozide, or quinidine and potentially prolong QT intervals and cause dysrhythmias.

Concomitant treatment with nevirapine, rifampicin, rifabutin, or phenytoin decreases systemic exposure to voriconazole. Coadministration of voriconazole with erythromycin, delavirdine, and ritonavir increase voriconazole levels.

Clearly, voriconazole has the potential to cause significant drug interactions in patients, and vigilance will be required to anticipate and deal with adverse reactions arising from its use.

Chapter 46

SEPSIS WITH ACUTE ORGAN DYSFUNCTION

E. WESLEY ELY
RICHERT E. GOYETTE

KEY POINTS

- *Sepsis is the combination of a known or suspected infection and an accompanying systemic inflammatory response.*
- *Severe sepsis is sepsis with acute dysfunction of one or more organ systems; septic shock is a subset of severe sepsis.*
- *Severe sepsis is common, frequently fatal, and expensive. More than 750,000 cases occur annually in the United States.*
- *Effective management of patients with severe sepsis requires early identification, cardiopulmonary support, antibiotics, source control, and general supportive care.*
- *The prognosis of the patient with severe sepsis is related to the number of dysfunctional organs.*
- *Cardiopulmonary support consists of early and aggressive fluid resuscitation, maintenance of mean arterial pressure at 65 mm Hg or higher, and measures to maximize and maintain tissue oxygenation; judging the adequacy of tissue oxygenation is informed by measurement of the mixed venous oxygen saturation, and supportive therapy is most effective and beneficial when provided in the first hours of presentation.*
- *Patients should receive early intravenous empirical antibiotics directed at all possible sources of infection. Appropriate antibiotics decrease the mortality rate by 10% to 15% in patients with severe sepsis.*
- *Source control can be surgical or nonsurgical and is intended to remove or lessen the burden from the primary focus of infection.*
- *Despite appropriate antibiotics, source control, and organ support, the mortality rate in patients with severe sepsis remains at 28% to 50%.*
- *Specific antisepsis interventions have recently been introduced that target multiple pathophysiologic aspects of the sepsis cascade and can improve outcomes.*
- *To maximize outcomes, supportive measures must be introduced to ensure proper nutrition; maintain fluid, glucose, and electrolyte homeostasis; promote tissue oxygenation; and prevent complications.*

Sepsis with acute organ dysfunction (severe sepsis) is common and frequently fatal and represents a significant health care burden. The incidence and associated mortality and morbidity rates of severe sepsis are commonly underestimated. This is a function of a number of factors. Severe sepsis is not generally reported as a primary diagnosis. For example, although steps are underway to address this issue, the most recent edition of the *International Classification of Diseases, Ninth Revision, Clinical Modification* lacks a diagnostic code for severe sepsis. Instead, severe sepsis is often coded as a complication of another disorder (e.g., cancer or pneumonia). Several recent publications have evaluated the epidemiology of severe sepsis in the United States.[1,2] They have estimated that the annual incidence of severe sepsis in the United States is in the range of 240 to 300 cases per 100,000 population. Further, in 2003, there were approximately 750,000 cases of sepsis in the United States. In Europe, the incidence of severe sepsis exceeds 200,000 annually.[3] Reported mortality rates in patients with severe sepsis range from 28% to 50% or higher.[1,4] Thus, in the United States and Europe, at least 700 to 1300 patients die daily from severe sepsis. Patients with severe sepsis account for annual health care expenditures in excess of $16 billion in the United States and £5.2 billion in Europe.[1,3]

The incidence of severe sepsis peaks in children younger than 12 months, remains low until midlife, and then progressively increases.[1] In a study by Angus et al[1] of the patients who developed severe sepsis, nearly 66% were older than 65 years. This population also accounted for more than 75% of the overall health care costs of the disease. The incidence of severe sepsis is anticipated to increase approximately 1.5% per year until at least 2050.[1] This increase is due to a number of factors, including age shifts in the population, prevalence of more critically ill patients (e.g., transplant recipients), and increases in the numbers of invasive diagnostic procedures and monitoring techniques. This predicted increase has significant implications for the critical care community because it has been estimated that by 2020 there will be a 22% shortfall of available intensivists' hours to meet this demand.[5]

Definitions

In 1992, members of the American College of Chest Physicians (ACCP) and the Society of Critical Care Medicine (SCCM) developed a set of consensus definitions for sepsis and related disorders (Table 46-1).[6] The consensus committee believed that standardized terminology would improve the ability of clinicians to make an early diagnosis of sepsis, provide for more reliable reporting of the incidence and severity of sepsis, and facilitate early therapeutic interventions. In addition, they hoped that acceptance of the definitions would help to standardize research protocols and improve the dissemination and application of clinical information from subsequent studies. The consensus committee acknowledged that the clinical presentation of sepsis spanned a continuum of severity; however, they recognized certain common phases and provided specific definitions for them (Fig. 46-1). Sepsis was defined as the presence of at least two of the four systemic inflammatory response syndrome (SIRS) criteria developing in response to a documented or suspected infection. Severe sepsis was sepsis plus acute organ dysfunction (Table 46-2). Although these definitions have provided an important framework, they have been criticized as being too sensitive and not providing enough information for clinicians attempting to make a diagnosis.[7] In addition, the definitions lack a clear pathologic basis and fail to incorporate the hemostatic component of severe sepsis.[6]

However, the ACCP/SCCM definitions have endured the test of time. For example, the critical importance of organ dysfunction and outcomes first emphasized by the conferees was recently reaffirmed by a study of risk factors for hospital mortality rate in 3608 intensive care unit (ICU) patients included in the European Sepsis Study (Fig. 46-2).[8] In December 2001, representatives from the SCCM, the ACCP, the

TABLE 46-1 American College of Chest Physicians/Society of Critical Care Medicine Consensus Criteria for Sepsis and Related Disorders

Infection	Microbial phenomenon characterized by an inflammatory response to the presence of microorganisms or the invasion of normally sterile host tissue by those organisms
Bacteremia	The presence of viable bacteria in the blood
SIRS	SIRS represents the systemic response to several clinical insults; it is manifested by at least two of the following: (1) temperature >38°C or <36°C; (2) heart rate >90 beats/minute; (3) respiratory rate >20 breaths/minute or partial pressure of CO_2 <32 mm Hg; and (4) white blood cell count >12,000/μL, <4000 μL, or >10% immature (band) forms
Sepsis	Systemic response to infection, manifested by two or more SIRS criteria developing as the result of infection
Severe sepsis	Sepsis associated with acute organ dysfunction, hypoperfusion, or hypotension; hypoperfusion and perfusion abnormalities may include, but are not limited to, lactic acidosis, oliguria, or acute alterations in mental status (see Table 46-2)
Septic shock	Sepsis-induced hypotension despite fluid resuscitation in addition to the presence of perfusion abnormalities that may include, but are not limited to, lactic acidosis; oliguria, or an acute alteration in mental status; patients receiving inotropic or vasopressor agents may not be hypotensive at the time that perfusion abnormalities are measured
Sepsis-induced hypotension	Systolic blood pressure <90 mm Hg or a reduction ≥40 mm Hg from baseline without other causes for hypotension
Multiple organ dysfunction syndrome	Presence of altered organ function in an acutely ill patient such that homeostasis cannot be maintained without intervention

ABBREVIATION: SIRS, systemic inflammatory response syndrome.
SOURCE: Printed with permission from Bone et al.[6]

European Society of Intensive Care Medicine, the American Thoracic Society, and the Surgical Infection Society met to revisit the definitions of sepsis and related disorders.[9] After an intensive review, the group concluded that there was no evidence that would justify altering the definitions first proposed by the ACCP/SCCM. As part of the discussion, however, they expanded the lists of signs and symptoms of sepsis that are reflected by experience gained at the bedside that prompts a clinician to say that the patient "looks septic." Among these criteria, they included additional general (e.g., altered mental status, significant edema or positive fluid balance, or hyperglycemia), inflammatory (increased C-reactive protein [CRP] or pro-calcitonin [PCT]), hemodynamic (O_2 saturation in venous blood >70%, cardiac index >3.5 L/min per square meter), organ dysfunction (coagulation abnormalities, ileus, or hyperbilirubinemia), and tissue perfusion (decreased capillary refill or mottling) abnormalities. They also emphasized the need for a precise method to characterize and stage patients with sepsis. Creation and validation of such a system would bring an increased degree of precision to clinical trials and facilitate the ability of clinicians to more fully characterize the disease and to select appropriate therapies. As a subject for debate, they proposed the Predisposition, Insult/Infection, Response, Organ Dysfunction (PIRO) model, a staging process that uses concepts from the Tumor Nodes Metastases (TNM) system of clinical oncology.

FIGURE 46-1 Relation among systemic inflammatory response syndrome (SIRS), sepsis, and severe sepsis. ***(Reproduced with permission from Bone et al.[6])***

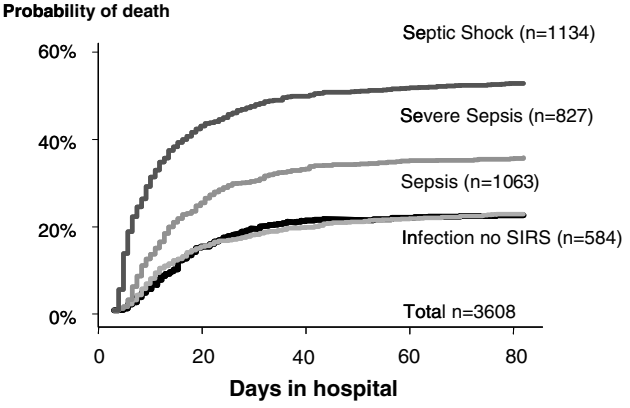
Pathogenesis

The pathogenesis of the septic response involves interaction of the host with a microbial invader. The outcome of the process depends on the capability of the immune system, endothelium and hemostatic mechanisms to contain and then eliminate the process, and the ability of the patient to restore homeostasis over time.

MICROBIAL FACTORS

Microbes possess several factors that facilitate their growth in a normally sterile environment (Fig. 46-3). These include properties of their capsule or envelope, cell wall, and metabolic factors such as the production of exotoxins. Some such factors are cited by way of example.

TABLE 46-2 Clinical Manifestations of Acute Organ Dysfunction



Cardiovascular system	Arterial systolic blood pressure ≤90 mm Hg or MAP ≤70 mm Hg for ≥1 h despite adequate fluid resuscitation, adequate intravascular volume status, or the use of vasopressors in an attempt to maintain a systolic blood pressure ≥90 mm Hg or MAP ≥65 mm Hg; tachycardia; arrhythmias; cardiac arrest
Respiratory system	Ratio of Pa_{O_2} to $F_{I_{O_2}}$ ≤250 in the presence of other dysfunctional organs or systems or ≤200 if the lung is the only dysfunctional organ; Pa_{O_2} <70 mm Hg; Sa_{O_2} <90%; tachypnea; mechanical ventilator dependence with or without PEEP
Renal	Urine output <0.5 mL/kg of body weight per hour for 1 h despite adequate fluid resuscitation; acute elevation of serum creatinine; oliguria; anuria; requirement for renal replacement therapy
Hematologic	Platelet count <80,000/μL or decreased by 50% in the preceding 3 d; leukocytosis/leukopenia; increased prothrombin time; elevated partial thromboplastin time; decreased protein C; increased D-dimer; impaired leukocyte function
Gastrointestinal	Elevated pancreatic enzymes (amylase, lipase), decreased gastric pHi; ileus; gastrointentinal bleeding or perforation; intestinal ischemia; acalculous cholecystitis, acute pancreatitis; intolerance of enteral nutrition
Hepatic	Hyperbilirubinemia; elevated aminotransferases; increased LDH; elevated alkaline phosphatase; hypoalbuminemia; elevated prothrombin time; jaundice; asterixis
Neurologic	Delirium; altered consciousness; impaired mentation; confusion; psychosis; abnormal bispectral EEG
Metabolic/endocrine	pH <7.30 or a base deficit ≥5.0 mmol/L in association with a plasma lactate level >1.5 times the upper limit of the normal value; hyperglycemia; hypertriglyceridemia; hypoalbuminemia

ABBREVIATIONS: EEG, electroencephalogram; $F_{I_{O_2}}$, fraction inspired O_2; LDH, lactate dehydrogenase; MAP, mean arterial pressure; Pa_{O_2}, arterial partial pressure of O_2; PEEP, positive end-expiratory pressure; Sa_{O_2}, arterial oxygen saturation.

SOURCES: Printed with permission from: Balk RA: Pathogenesis and management of multiple organ dysfunction or failure in severe sepsis and septic shock. *Crit Care Clin* 16:337, 2000; Balk RA, Ely EW, Goyette RE: *The Sepsis Handbook.* Nashville, TN: National Initiative in Sepsis Education, Vanderbilt University Medical Center, 2001; Bernard GR, Vincent J-L, Laterre P-F, et al: Efficacy and safety of recombinant human activated protein C for severe sepsis. *N Engl J Med* 344:699, 2001.

Pili of strains of *Escherichia coli* can enable the coliform bacillus to adhere to Tamm-Horsfall protein coating the epithelium of the lower urinary tract or P-blood group antigens expressed on the epithelium of the renal pelvis. Capsular polysaccharides of certain strains of *Streptococcus pneumoniae* render the organism resistant to phagocytosis. The cell wall of gram-negative bacteria consists of an inner phospholipid bilayer with embedded transport proteins and an outer layer composed of lipoproteins, lipopolysaccharides (LPS), outer membrane proteins, and capsular polysaccharides. Bacterial LPS is generally considered to be the principal element in the initiation of the septic response in patients with severe gram-negative infections. Whereas components of the cell wall of gram-positive bacteria may be able to elicit some of the effects of endotoxin, much of the pathogenicity of gram-positive organisms is the result of exotoxins. Some of these exotoxins can function as superantigens: chemical substances that simultaneously bind to common sequences on the major histocompatibility complex and the T-cell receptor. Superantigen binding and T-cell activation can produce a flood of cytokines and is independent of the antigenic specificity normally required for activation of various T-cell clones and the need for costimulatory molecules. Streptococcal and staphylococcal pyrogenic exotoxins acting as superantigens are believed to play a critical role in the pathogenesis of toxic shock syndrome. Hyaluronidase secreted by some bacteria can facilitate their spread along tissue planes.

FIGURE 46-2 Organ dysfunction as a major outcome parameter. This graph is from a study by Alberti et al on the relation among mortality, systemic inflammatory response syndrome (SIRS), infection, organ dysfunction, and shock. Observe that the mortality curves are virtually identical for infection and infection with SIRS (sepsis). The increase in mortality rate is related to the presence of sepsis with organ dysfunction (severe sepsis, septic shock). Risk of death increased from sepsis to severe sepsis (hazard ratio = 1.53, $p < 0.0001$) and septic shock (hazard ratio = 2.64, $p < 0.0001$). (*Adapted with premission from Alberti et al.*[8])

HOST FACTORS

The host has a spectrum of mechanisms that supports its ability to resist the invasive properties of some microorganisms (Table 46-3). The epithelium is the first line of defense against

FIGURE 46-3 Pathogenic microbial factors.

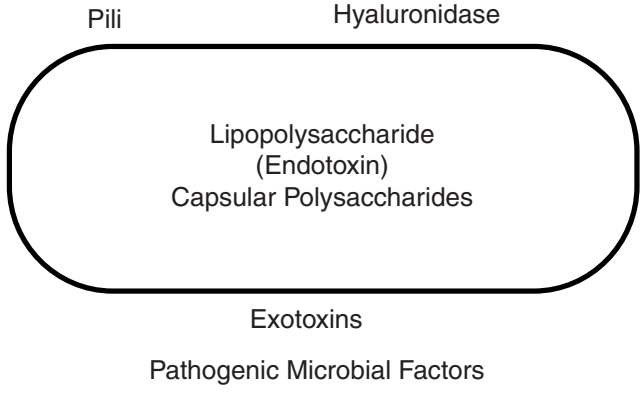


TABLE 46-3 Host Factors That Have Been Established to Contribute to an Increased Risk for Sepsis

Break in membrane integrity (surgery, toxic injury to epithelium)
Age (very young, elderly)
Gender (men > women)
Race (nonwhite > white)
Genetic polymorphisms (e.g., tumor necrosis factior promoter gene, toll-like receptors)
Comorbidities (e.g., diabetes mellitus, immunosuppression)

infection. It not only provides a mechanical barrier but also contributes other protective functions in a site-specific fashion (e.g., mucociliary flow in the respiratory tract and gastric pH). The immune status of the host is a function of inherited and acquired components. Genetic polymorphisms can be responsible for dissimilar responses to infection. For example, polymorphisms in *toll-like receptors* (TLRs) may govern an individual's response to endotoxin, whereas variants in the promoter region of the tumor necrosis factor (TNF) gene can help determine the risk for sepsis after trauma.[10] Age, disease, exposures, and interventions are acquired risk factors for sepsis. Young children and the elderly have an increased incidence of sepsis. Various morbidities can increase the risk of sepsis. Patients with diabetes mellitus are at increased risk of infection for a variety of reasons. Hyperglycemia appears to facilitate colonization and growth of organisms such as *Staphylococcus aureus* and *Candida* species. In addition, they have a variety of defects in cell-mediated immunity and phagocytosis. Genetic and acquired factors often interact to determine susceptibility to disease. For example, patients positive for the human immunodeficiency virus (HIV) who are heterozygous for a deletion in the gene for the macrophage CCR5 receptor or in the promoter region of the gene have slow progression of HIV disease compared with patients with the wild-type genotype.

INNATE IMMUNE SYSTEM

The human immune system is composed of adaptive and innate components. The adaptive elements are specialized B and T cells. Each of these cells has a structurally unique B- or T-cell antigen receptor that is generated randomly (i.e., not genomically encoded). When a lymphocyte bearing a useful receptor encounters a pathogen, it is selected for clonal expansion. Although adaptive immunity contributes significantly to the overall immune response and provides protection against future encounters with the organism, generation of a significant primary humoral or cellular immune response takes days to weeks, time that is unavailable to a patient with severe sepsis. Unlike the adaptive immune system, elements of the innate immune system can respond instantly to a challenge. This property helps explain the overwhelming systemic inflammatory response generated in patients with severe sepsis. Therefore, we focus the remainder of this section on innate immunity.

CELLULAR COMPONENTS OF INNATE IMMUNITY

In humans, cellular effectors of innate immunity are monocytes/macrophages, neutrophils, natural killer cells, and platelets. The monocyte/macrophage is the human analogue of the amebocyte, an innate immune cell present in invertebrates. Monocytes originate in the bone marrow and then transit the peripheral blood to lodge in tissues as macrophages, Kupffer cells, and other reticuloendothelial elements. Pathogen-associated molecular pattern receptors comprise a key component of the innate immune system.[11] Unlike the antigen receptors of B and T cells, these receptors are encoded in the germline, are functionally divided into three classes (secreted, endocytic, and signaling), and trigger an immediate effector function. Secreted pathogen-associated molecular pattern identification is discussed in the section on fluid-phase elements of innate immunity (below). Endocytic pattern recognition receptors such as the macrophage mannose or scavenger receptor recognize highly conserved molecular components of microbial cell walls and mediate their phagocytosis by monocytes/macrophages. Signaling receptors on monocytes/macrophages identify microbial molecular patterns and activate signal transduction pathways that upregulate a spectrum of immune response genes responsible for a variety of cellular functions, including cytokine release.

The *toll* gene, a transmembrane signaling protein present in organisms as primitive as the fruit fly, is believed to be very important to humans in the septic state. Humans possess at least 10 *toll* gene homologues known as TLRs. The TLR genes code for cell membrane molecular pattern receptors that play an integral role in the generation of local and systemic inflammatory responses. Natural ligands of the various TLRs include LPS (TLR4), peptidoglycan (TLR2), and flagellin (TLR5). The role of TLR proteins can be illustrated by the response of the innate immune system to LPS. LPS is an outer leaflet compound molecule that is unique to gram-negative bacteria; after infusion into humans, LPS reproduces many of the features of sepsis, including activation of the coagulation and complement systems.[12,13] After entering the plasma, LPS is recognized, bound, and transported to innate immune effector cells by LPS-binding protein. The cell membrane CD14 receptor on monocytes and neutrophils accepts the LPS from LPS-binding protein and forms a trimeric complex with TLR4 and MD-2, another membrane protein. Once formed, the complex activates a signal transduction pathway that phosphorylates IκB. As a result, IκB undergoes degradation and releases bound nuclear factor κB. The latter then migrates into the nucleus, where it induces transcription of a wide variety of immune- and inflammatory-response genes.[11] Transcription of these genes is responsible for the upregulation of tissue factor (TF) on monocytes/macrophages and endothelium and for the cytokine cascade that creates many of the elements of SIRS in patients exposed to LPS. These key elements of the inflammatory response are therefore linked to the coagulation cascade, with these two responses combining to form the major facets of the pathophysiologic derangements in septic humans. Surfactant appears to play an important role in maintaining innate immunity within the lung. This may be due to the protein's ability to block LPS signaling by inhibiting mitogen-activated protein and IκB kinases of alveolar macrophages.[14]

TF is responsible for initiating coagulation through the previously named *extrinsic pathway*, now called the *TF pathway*. TF is expressed constitutively on a limited number of cells and can be induced in a wide variety of cells after exposure to endotoxin or cytokines. Cells normally expressing TF include extravascular monocytes/macrophages and fibroblasts.[15] Sequestered from circulating factor VIIa, these cells are poised to activate coagulation immediately after disruption of a

blood vessel wall. TF expression can be upregulated in a variety of other cells that do not express the cell membrane protein constitutively. As a result, after exposure to TNFα, CRP, CD40 ligand, or other substances, TF expression can be identified on subsets of cells including circulating monocytes, vascular smooth muscle cells, a subset of endothelial cells, and possibly alveolar epithelial cells.[16] During acute inflammation, activation of the cytokine cascade is followed by rapid upregulation of TF on monocytes and a shift of components of the hemostatic system from an antithrombotic to a prothrombotic state. Circulating TF antigen and microparticles shed from inflammatory cells and platelets contribute to the process.

FLUID-PHASE ELEMENTS: CYTOKINES AND COMPLEMENT

Once monocytes/macrophages have been activated, there is a response by fluid-phase elements. These include cytokines and activated components of the complement system. TNFα is a central cytokine in this process. Once released, it functions in an autocrine, paracrine, and endocrine fashion in a positive feedback loop to stimulate additional TNFα production and production of other cytokines. Other proinflammatory cytokines are released, including interleukin (IL)–1, IL-2, IL-6, IL-8, IL-10, platelet activating factor (PAF), and interferon γ. The cytokine cascade produces a vast array of biological effects recognized as the systemic inflammatory reaction.

However, as sepsis persists, there may be a shift in the cytokine profile from an inflammatory to a predominantly anti-inflammatory one.[17] Loss of T cells, B cells, and follicular dendritic cells through apoptosis may contribute to the immunosuppression through two processes: loss of immunocytes and the direct immunosuppressive effect of apoptotic cells.[18,19] As the anti-inflammatory reaction progresses, the septic patient may become anergic. Although it may be helpful to think that the response of the immune system to a septic insult progresses in discrete and identifiable stages, this may not be true. Some have proposed that, distant from the original source or inflammatory focus, the body's reaction is predominantly anti-inflammatory from the onset.[20] The complex nature of this process may partly explain why clinical trials of various biologic response modifiers such as TNFα antagonists have not improved overall survival rate and have even been detrimental in some cases.

Plasma components of the complement system circulate in an inactive state and develop enzymatic activity only after proteolysis or a conformational change. The system works by depositing components of complement on foreign substances or organisms requiring opsonization and by promoting inflammation. Complement can be activated through three pathways: (1) classic pathway, (2) alternate pathway, and (3) mannan-binding lectin pathway. The classic pathway is activated by immunoglobulin (Ig) M or IgG antibodies bound to a particular pathogen or by CRP released during the acute phase reaction. The classic pathway serves as a link between the complement and hemostatic systems. Components generated during activity of the classic pathway increase the exposure of phosphatidylserine on endothelial cell surfaces.[21] This action provides the phospholipid that is essential for various phases of clot formation. Activation of the alternate pathway results when complement binds directly to pathogen-associated molecular patterns on the surfaces of bacteria or fungi. Mannan-binding lectin is an example of a secreted pathogen-associated molecular pattern receptor. It is synthesized in the liver and secreted into the plasma during the acute-phase reaction. It binds to carbohydrate structures common to gram-positive and gram-negative bacteria, yeasts, and some viruses and parasites. Once binding occurs, mannan-binding lectin-associated proteases are activated and help to destroy the organism. After complement activation, some of the molecular elements of the system are cleaved, thus producing fragments with biological activity. For example, N-terminal proteolysis of C3, C4, and C5 release small peptides (e.g., C5a) that bind to G protein–coupled receptors on a variety of cells to produce chemotaxis, increase vascular permeability, and so forth. It has been proposed that C5a in excess can paralyze neutrophil function.[22] In an experimental model, antibody-mediated neutralization of excess C5a protected animals against septic death.[22]

ENDOTHELIAL CELL DYSFUNCTION

With approximately 10^{11} endothelial cells and a surface area estimated to exceed 1000 m^2, the endothelium surpasses the skin as the largest organ in the body.[23,24] The great majority of the endothelium is located in the microvasculature; in that region, the endothelial surface area per unit of blood volume is 2000 to 3000 times greater than in the larger blood vessels.[25] The endothelium serves as the interface between inflammation and coagulation.[26] Situated at the junction of the flowing blood and extracellular space, the endothelium influences a variety of inflammatory and hemostatic processes (e.g., cell-trafficking, vasoregulation, thrombosis, and antithrombosis) and plays a key role in the inflammatory, prothrombotic, and impaired fibrinolytic components of sepsis.[27]

Endothelial dysfunction is a key element in the pathogenesis of severe sepsis. This may be secondary to the effects of endotoxin or proinflammatory cytokines on endothelial cells. For example, a single injection of endotoxin in rabbits produces desquamation of approximately 25% of the aortic endothelial surface area within 5 days.[28] Alternatively, organisms such as *Rickettsiae* can directly infect endothelial cells. Severe endothelial injury can produce a microvascular coagulopathy and acute organ dysfunction.[29] Importantly, however, endothelial cells are differentially regulated in space and time. That is, the endothelium of the lung may respond differently to a septic insult than similar cells in the spleen.[30] The phenotype of endothelial cells also changes over time. For example, an endothelial cell population with an antithrombotic phenotype may transiently switch to predominantly prothrombotic activity for some period after exposure to TNFα.

Thrombomodulin (TM), intercellular adhesion molecule 1, E-selectin, and von Willebrand factor (VWF) are normal membrane-bound and intracellular endothelial cell components. Therefore, elevated circulating levels of the soluble forms of these proteins are markers of endothelial dysfunction and injury.[31] In children with septic shock, soluble TM (sTM) levels are increased, and the levels correlate with survival status and the extent of organ dysfunction.[32] Immunohistochemical studies of skin biopsy samples from patients with meningococcal septicemia have demonstrated decreased stainable TM and endothelial cell protein C receptor (EPCR).[33] This appears to result from a combination of shedding of cell surface TM and EPCR plus downregulation of endothelial cell synthesis and/or expression of these essential

molecules. These changes suggest that many patients with sepsis may have insufficient TM and EPCR to convert protein C (PC) to activated PC (APC), although this is not universally true.[34] In a population of patients with sepsis, plasma levels of VWF, intercellular adhesion molecule 1, and sE-selectin were significantly increased within 8 hours of the development of the acute respiratory distress syndrome (ARDS).[35] Damaged endothelium and activated leukocytes and platelets also release microparticles with procoagulant properties (e.g., microparticle-associated TF).[36]

Apoptosis differs from necrosis because it is a highly regulated physiologic process that plays an important role in cell physiology. Apoptosis can be identified through morphologic and molecular techniques. Cytokines and inflammatory cells can damage the endothelium and induce apoptosis.[24] In patients with severe sepsis, the apoptotic process also changes in space and time. That is, the apoptotic process may not occur uniformly, in all organs, at the same time, or with all types of infections.[19,37] This may help to explain the commonality of ARDS in patients with severe sepsis. Endothelial cell apoptosis may produce abnormalities in cell trafficking, vasoregulation, and antithrombosis/thrombosis that may contribute to the pathogenesis of septic manifestations, such as multiple organ dysfunction, impaired microvascular blood flow, and inability of the body to restore homeostasis.

Pathophysiology

CARDIOVASCULAR SYSTEM

Severe sepsis is accompanied by significant alterations in cardiovascular physiology. Sepsis-induced hypotension is multifactorial in origin. Contributory factors include redistribution of blood flow, impaired metabolic autoregulation, release of vasoactive mediators, third-spacing of fluids, dehydration, increased insensible fluid losses, vomiting, diarrhea, etc. Early in the process, systemic vascular resistance may be high and cardiac output ($\dot{Q}_T$) may be decreased. However, the SVR typically decreases and $\dot{Q}_T$ increases, thus producing a hyperdynamic circulatory state.

MYOCARDIUM

Reversible myocardial dysfunction of variable severity may occur in as many as 40% of patients with severe sepsis.[38] Myocardial depression often occurs in survivors very early in the septic process, progresses over the first 3 days, and then resolves after 7 to 10 days.[39] Dysfunction may be systolic, diastolic, left ventricular, or biventricular. Potential explanations include myocardial injury mediated by cytokines such as TNF, release of noncytokine mediators such as prostanoids and nitric oxide (NO), catecholamine-induced myofibrillar damage, and myocardial ischemia with reperfusion injury.[40] An aggregate of clinical studies suggests that a circulating myocardial depressant factor, not global myocardial ischemia, is a major contributor to myocardial dysfunction in patients with severe sepsis. In a study of coronary hemodynamics in patients with severe sepsis and septic shock, Dhainaut et al reported that coronary blood flow and net myocardial lactate consumption are increased in this disorder.[41]

Cardiovascular dysfunction may also manifest as ventricular dilation, abnormalities of wall motion, increased levels of cardiac troponin, and electrocardiographic changes. The explanation for the paradoxical association of a hyperdynamic circulation and myocardial dysfunction involves an interaction of compensatory mechanisms that may maintain $\dot{Q}_T$ in the face of impaired myocardial contractility. Fluid resuscitation raises the mean systemic pressure while sepsis acts on the systemic vessels to reduce the resistance to venous return. These factors combine to maintain venous return (i.e., cardiac output) in the face of pump dysfunction (see chapters 20 and 21). It is important to note that, by the time initial resuscitation measures are conducted, most patients with severe sepsis will exhibit high-output hypotension; when this circulatory abnormality is encountered in the critically ill, sepsis should be considered to be present if it has not already been contemplated.

The introduction of pulmonary artery catheters with thermodilution $\dot{Q}_T$ capacity and portable radionuclide cineangiographic techniques has allowed a greater understanding of cardiovascular physiology and outcomes in patients with severe sepsis. Parker et al reported that patients who survived severe sepsis experienced an acute decrease in left ventricular EF that was accompanied by left ventricular dilatation, pathophysiologic abnormalities that resolved over a 7- to 10-day period.[42] This was associated with a negative correlation between EF and left ventricular end-diastolic volume index.[43] Conversely, nonsurvivors did not undergo left ventricular dilation, had preserved EF, exhibited a lower SVR, and had a positive relation between EF and left ventricular end-diastolic volume index. There are several potential explanations for this apparently paradoxical phenomenon. The lower SVR in nonsurvivors may allow them to maintain their $\dot{Q}_T$ without the need for ventricular dilation. Alternatively, the endothelial damage and microvascular dysfunction may be more severe in nonsurvivors; this could lead to a significant microcapillary leak, severe interstitial edema of the myocardium, and impaired cardiac compliance. The inability of the heart to dilate may be a surrogate for significant multiorgan dysfunction and inability of the host to respond to the multiple alterations associated with severe sepsis.

VASCULAR SYSTEM

Vasoconstriction is the physiologic response to low blood pressure (BP) in patients with hemorrhagic or cardiogenic shock. In contrast, shock in patients with severe sepsis is vasodilatory in nature. That is, their peripheral blood vessels not only dilate but all too often fail to show an adequate physiologic or pharmacologic contractile response to vasopressors. Severe sepsis is the most common cause of vasodilatory shock.[44] However, vasodilatory shock is also a component of disorders with impaired tissue oxygenation, such as carbon monoxide intoxication, and can serve as a final common pathway of any form of profound and long-lasting shock. At the vascular level, the pathophysiology of shock in patients with severe sepsis involves three major mechanisms: (1) activation of adenosine triphosphate–sensitive potassium (K_{ATP}) channels in vascular smooth muscle cells, (2) synthesis of increased amounts of NO through induction of the inducible form of NO synthase (iNOS), and (3) vasopressin deficiency.[44]

VASCULAR SMOOTH MUSCLE CELL MEMBRANE HYPERPOLARIZATION IN VASODILATORY SHOCK

When the membrane potential of vascular smooth muscle cells is within the physiologic range of −30 to −60 mV,

vasopressors such as norepinephrine and angiotensin II open voltage-gated calcium channels and allow calcium to enter cells; through a complex process involving calmodulin, myosin phosphorylation, and myosin ATPase, cytosolic hypercalcemia produces muscle contraction. Under conditions of tissue hypoxia or increased tissue metabolic activity, lactic acidosis activates the K_{ATP} channels. The resultant entry of potassium into the cell hyperpolarizes the vascular cell membrane, closes the calcium channels, decreases intracellular calcium concentrations, relaxes smooth muscle, and dilates the blood vessels. In patients with severe sepsis, elevated circulating levels of atrial natriuretic peptide, calcitonin gene-related peptide, NO, and adenosine can also open K_{ATP} channels and contribute to membrane hyperpolarization.[45–47]

ROLE OF NITRIC OXIDE IN VASODILATORY SHOCK

NO is a potent endogenous vasodilator. In patients with severe sepsis and shock, cytokines upregulate iNOS in a number of cells including vascular smooth muscle and endothelium.[48] NO then presumably exerts its vasodilatory activity through activation of myosin light-chain phosphatase and perhaps by activating vascular smooth muscle cell potassium channels such as the calcium-sensitive channel. The latter would then augment the K_{ATP}-induced hyperpolarization of the membrane of vascular smooth muscle cells.

ROLE OF VASOPRESSIN DEFICIENCY IN VASODILATORY SHOCK

In addition to its role in water conservation, vasopressin secreted under baroreceptor control constricts vascular smooth muscle. During the initial phases of shock in patients with severe sepsis, vasopressin helps to maintain arterial BP. However, over time, neurohypophyseal stores of the hormone become depleted, and plasma vasopressin concentrations decline.[44] Administration of vasopressin in doses large enough to produce plasma concentrations comparable to those seen in acute hypotension will raise arterial BP by 25 to 50 mm Hg.[49] This marked hypersensitivity to exogenous vasopressin in patients with vasodilatory shock appears to result from a number of factors, including: (1) availability of receptors for occupancy by the exogenous hormone, (2) autonomic dysfunction, (3) ability of vasopressin to potentiate the activity of high levels of circulating endogenous catecholamines, (4) direct and indirect blunting of the contributions of NO to vasodilation, and (5) inactivation of K_{ATP} channels with restoration of vascular smooth muscle cell membrane potential toward normal. The role of vasopressin in inhibiting the effects of NO and blocking vascular K_{ATP} channels has been used clinically in patients with severe sepsis and shock who are refractory to other maneuvers to raise mean arterial BP (MAP). The efficacy of vasopressin in septic shock is currently being evaluated within the context of a multicenter, randomized controlled trial in Canada.

RESPIRATORY SYSTEM

Approximately 40% of cases of acute lung injury (ALI) are ascribed to sepsis (see Chap. 38).[50] Presumably, this is a consequence of the organ's large microvascular surface area. In patients with severe sepsis of extrapulmonary origin, ALI initially occurs through an indirect process; however, as the disease progresses, secondary pneumonia, mechanical ventilation, and its associated complications may contribute to ALI and, through direct and indirect mechanisms, produce ARDS.

SYSTEMIC COMPONENTS OF ACUTE LUNG INJURY

The alveoli and pulmonary capillary bed are separated by two layers of cells: pneumocytes (types I and II) and endothelial cells. In patients with severe sepsis, ALI appears to begin with endothelial injury from circulating bacterial products plus cytokines released into the circulation during the initial stages of SIRS. Endotoxin has been shown to be a potent proinflammatory molecule that can induce a variety of endothelial cell inflammatory responses and produce endothelial cell dysfunction or apoptosis.[51] Under the influence of IL-1, TNFα, components of complement and other endogenous mediators, the endothelial phenotype is altered. Activated endothelial cells become prothrombotic, upregulate adhesion molecules, and secrete different inflammatory mediators including chemoattractants.[24] Neutrophilic leukocytes attracted to the pulmonary microvasculature become adherent and activated and migrate from the capillary lumen into the alveolar space, a process accompanied by the release of different oxidants, proteases, leukotrienes, and inflammatory mediators such as PAF. In response to alveolar wall damage, pulmonary macrophages also secrete cytokines that amplify the process. Damage to endothelium and the easily injured type I pneumocytes allows flooding of alveoli by proteinaceous edema fluid. Injury to type II pneumocytes decreases the production and turnover of surfactant, whereas the protein-rich alveolar fluid inactivates it.[52,53] All of these factors contribute to the dyspnea, tachypnea, pulmonary infiltrates, and decreased ratio of arterial partial pressure of O_2 (Pa_{O_2}) to fractional inspired O_2 (FI_{O_2}) of ALI.

The coagulopathy of sepsis is also seen at the individual organ level and can contribute to the development and progression of ALI. Compared with controls, the bronchoalveolar lavage fluid of patients with ARDS showed significant increases in the concentrations of TF and activated coagulation factor VII ($p < 0.001$).[54] Activation of the TF pathway of coagulation in the presence of large amounts of fibrinogen-rich intra-alveolar exudate can lead to extravascular fibrin deposition, hyaline membrane formation, inflammation, and pulmonary dysfunction.[55] With the passage of time, this exudative stage can be replaced by proliferative and fibrotic changes that can lead to pulmonary fibrosis. Deposition and persistence of alveolar fibrin are potentiated by depression of pulmonary fibrinolytic activity.[56] The fibrinolytic defect is largely the consequence of local amplification of plasminogen activator inhibitor 1 coupled with inhibition of urokinase plasminogen activator and downregulation of its receptor.[57] Failure of urokinase plasminogen activator to bind to urokinase plasminogen activator receptor on pneumocytes and alveolar macrophages can impair the remodeling that is an essential element of recovery from ALI and ARDS. At autopsy, patients with ARDS also showed a predictable gamut of vascular changes that mirror those within the pulmonary parenchyma.[55] For example, postmortem angiograms of patients with ARDS demonstrated the presence of serial vascular alterations that included thrombotic, fibroproliferative, and obliterative changes. The clinical significance of these lesions is signified by the development of pulmonary hypertension in patients with severe ARDS.

MECHANICAL VENTILATION AND ACUTE LUNG INJURY

Mechanical ventilation is a common supportive measure in patients with severe sepsis who develop respiratory failure. In addition to its many life-saving benefits, mechanical ventilation is potentially harmful to patients with severe sepsis and other types of critical illness (see Chaps. 37 and 43). The presence of an endotracheal tube bypasses normal airway defenses. When combined with impaired host defenses and malnutrition, patients with severe sepsis from an extrapulmonary source are at risk of a ventilator-associated pneumonia (VAP). In the absence of pre-existing disease, pneumonia may be the primary cause of ALI and ARDS. Further, high concentrations of inspired oxygen can damage alveolar membranes and worsen ALI. Moreover, barotrauma can mechanically stress alveolar and capillary walls, and shear forces generated during intratidal opening and closing of pulmonary units can damage lung tissue.[58] In addition to regional effects, barotrauma can induce release of cytokines into the pulmonary parenchyma and systemic circulation. These cytokines can contribute to the development of the multiple organ dysfunction syndrome (MODS) in mechanically ventilated patients with severe sepsis.[59] As an example of how dysfunctional organs may interact in the septic patient, it is thought that ALI (and mechanical ventilation) may contribute to dysfunction of other organs; through its effects on splanchnic blood flow, neurohumoral systems and proinflammatory cytokines, mechanical ventilation has the potential to adversely affect the gastrointestinal (GI) tract and predispose the patient to GI complications.[60] In the Acute Respiratory Distress Syndrome Network (ARDSNet) Lower Tidal Volume Study, patients ventilated with the lower tidal volumes (6 mL/kg ideal body weight) had lower levels of IL-6, more days without organ failure, and improved survival rate.[61] The complicated therapeutic considerations regarding mechanical ventilatory support in ALI are discussed later in this chapter.

GASTROINTESTINAL SYSTEM

With the decrease in the effective arterial blood volume, hypoperfusion of the gut becomes an important pathophysiologic component of severe sepsis. Early in the process, experimental evidence indicates that autoregulation of the microcirculatory blood flow is largely intact.[62] Before adequate fluid resuscitation, this regulatory process diverts blood from the muscularis mucosa to the more metabolically active mucosa. Redistribution of blood flow within the gut may preserve the mucosal barrier protection and prevent bacterial translocation. However, this redistribution of blood flow may not always be sufficient to meet mucosal oxygen demand. During this time, the intracellular PH of the gut decreases and lactate levels in the portal venous blood rise. Experiments have indicated that mesenteric lymph, rather than portal blood, may be the avenue that disseminates cytokines, endotoxin and other bacterial products, and microorganisms from the compromised gut to other parts of the body. In separate experiments, Magnotti, Sambol, and their associates showed that gut-derived mesenteric lymph, not portal blood, increases endothelial cell permeability and promotes lung injury after hemorrhagic shock and that ligation of the mesenteric lymphatic duct provides long-term organ protection.[63,64] However, Alverdy et al cautioned that experimental demonstrations of alterations in the permeability of the gut mucosa to substances such as labeled dextran do not indicate a cause-and-effect relation between the "leaky mucosa" and gut-derived sepsis or multiorgan failure.[65] Instead, the two processes may be unrelated, and gut-derived sepsis may be a manifestation of nosocomial pathogens that express "potent virulence traits while competing for scarce resources in the hostile environment of the intestinal tract of a critically ill patient." Whatever the mechanism of gut-derived sepsis, experimental evidence has shown that early enteral feeding protects against bacterial translocation.[66] Whether or not such effects of enteral feeding are beneficial to overall patient outcomes is the point of ongoing study.

HEPATOBILIARY TRACT

The liver plays multiple key roles in patients with severe sepsis.[67] As previously described with regard to the lungs, the liver is a source and a target of inflammatory mediators. Its central role in the pathophysiology of severe sepsis is a function of the organ's blood flow and its cellular composition. In the postabsorptive state, the liver receives approximately 25% of $\dot{Q}_T$. Decreased perfusion is the most important event initiating hepatic dysfunction in the first hours after a septic insult.[68]

The three most important cellular elements participating in the liver's response to severe sepsis are Kupffer cells, hepatocytes, and endothelial cells. Although described separately, the liver's reaction to severe sepsis represents a collective and interactive response of all three cellular elements. The central role of the endothelium in sepsis pathogenesis has been discussed in detail above.

KUPFFER CELLS

Kupffer cells are the fixed macrophages of the liver. They represent approximately 70% of the organ's total macrophage pool. They clear the portal blood of endotoxin, bacteria, cytokines, toxins, and activated coagulation factors. Once primed, Kupffer cells secrete a variety of cytokines, including TNFα, IL-1, IL-6, IL-8, IL-12, IL-18, granulocyte colony-stimulating factor (GCSF), and granulocyte-macrophage colony-stimulating factor (GM-CSF). In a paracrine fashion, Kupffer cells modulate the response of adjacent hepatocytes to inflammatory signals through synthesis and release of acute-phase proteins and other mediators.

HEPATOCYTES

Hepatocytes play an integral role in the body's response to severe sepsis.[67] They bear receptors for endotoxin, vasoactive substances, various inflammatory mediators, and a number of cytokines. As a result of metabolic alterations during sepsis, hepatocytes re-prioritize their metabolism toward gluconeogenesis, amino acid uptake, and protein synthesis. Alterations in protein synthesis, however, are nonuniform, with levels of albumin, PC and antithrombin (AT) decreasing and concentrations of a variety of acute-phase proteins increasing. The latter include α_1-antitrypsin (α_1AT), ceruloplasmin, α_2-macroglobulin (α_2MG), CRP, fibrinogen, C4-binding protein, and thrombin-activated fibrinolysis inhibitor (TAFI). Antiproteinases such as α_1AT neutralize elastase and other proteases released by leukocytes. Ceruloplasmin and α_2MG serve a scavenger function by inactivating superoxides, hydroxyl

radicals, and cytokines such as IL-6. Because many of the aforementioned proteins are involved in the hemostatic response to sepsis, they are discussed in the following section. As the septic process evolves, patients may develop a secondary hepatocellular dysfunction. This is a consequence of hepatocellular inflammation that results from the local release of inflammatory mediators and damage to the hepatic parenchyma by activated neutrophils within the hepatic sinusoids.

BLOOD AND BONE MARROW

Although dispersed in space, the blood and bone marrow comprise an organ system equal in importance to any other. During severe sepsis, the hematologic system attempts to restore homeostasis by eliminating the pathogen and isolating the infected focus. In patients with a localized infection, this process functions to the complete benefit of the host. However, in patients with severe sepsis, an exuberant response of the hematologic system can have detrimental effects. Elements of the hematologic system can be divided into cellular and fluid components.

Although the cellular elements originate in the marrow, the response of the bone marrow to sepsis is reflected in the peripheral blood. Fluid-phase elements of the hematologic system consist of various coagulation proteins. Changes in the hematologic system in patients with severe sepsis are the result of the influences of cytokines and hematopoietic growth factors, such as GM-CSF.

CELLULAR RESPONSE TO SEPSIS

Cellular elements of the peripheral blood involved in patients with severe sepsis include red blood cells, leukocytes, and platelets.[69] During the initial stages of severe sepsis, the hematocrit (HCT) reflects the opposing effects of third spacing of fluids and results of aggressive fluid resuscitation. Over time, the HCT decreases due to changes in the erythron, the red blood cell component of the hematologic system. Although an infection by a hemolytic organism such as *Clostridium perfringens* can acutely lower the HCT, the principal change in the mass of the erythron is due to a block in the reticuloendothelial transfer of iron to erythroid progenitors, erythroid hypoplasia, and a shortened survival of red blood cells. Changes in iron metabolism sequester this essential element from species of microorganisms that require iron as a growth factor. The white blood cell count may be high, normal, or low in patients with severe sepsis. The initial leukocytosis results from recruitment of neutrophils from the marginating pool and release of the more mature granulocytic elements from the bone marrow. As the process continues, the white cells show a "left shift" as less mature granulocytic elements enter the blood. This is associated with morphologic changes such as toxic granulation, Döhle bodies, and toxic vacuolation. Leukopenia may result from migration of large numbers of granulocytes into the infected focus or failure of the bone marrow to meet the demand; leukopenia resulting from infection itself is a sign of poor prognosis. Severe sepsis is usually accompanied by a variable degree of thrombocytopenia. Thrombocytopenia is a sign of dysfunction of the hematologic system and is due to platelet adhesion and aggregation throughout the microvasculature.

FLUID-PHASE RESPONSE TO SEPSIS

Severe sepsis is a prothrombotic state. This is the result of ongoing coagulation and impaired fibrinolysis. In response to acute inflammation, hepatic synthesis of the natural anticoagulants PC and AT decreases. At the same time, other elements of the PC system are compromised. Increased synthesis and release of α_1AT and α_2MG inhibit PC, whereas elevated levels of C4-binding protein bind protein S and prevent it from serving as a cofactor for activation of PC. In combination with the effects of microbial elements and cytokines, release of CRP by the liver upregulates the expression of TF on various cells. Increased production and release of fibrinogen and TAFI also contribute to the ongoing coagulopathy: the former by providing extra substrate for clotting, and the latter by inhibiting clot dissolution. The ongoing coagulopathy of sepsis is marked by a variable degree of thrombocytopenia; increased levels of D-dimer, a fibrin split product; and an elevation in the ratio of thrombin-antithrombin (TAT) to plasmin-antiplasmin (PAP). The TAT/PAP ratios are higher in patients with severe sepsis than in those who have sepsis without acute organ dysfunction.[21] This rise in TAT/PAP may precede the development of organ dysfunction, suggesting that enhanced coagulation and depressed fibrinolysis have a cause-and-effect relationship with the development of the MODS.

KIDNEY

Different factors present during an episode of severe sepsis have the potential to damage the kidneys. These include systemic hypotension or redistribution of blood flow, renal vasoconstriction, the effects of endotoxin and cytokines on the endothelium of the renal vasculature, and activation of inflammatory cells by LPS and inflammatory mediators.[70] In patients with severe sepsis, systemic vasodilation decreases the effective arterial blood volume. As the blood volume decreases, intrarenal vasoconstriction helps to maintain glomerular blood flow. Substances are released locally that promote intrarenal vasoconstriction in patients with severe sepsis and decreased effective arterial blood volume. They include endothelin, thromboxane A_2, and leukotrienes.[71] Eventually, however, compensatory mechanisms fail, the glomerular filtration rate decreases, prerenal azotemia develops, and acute tubular necrosis can develop. Endothelial injury from proinflammatory mediators, contents of neutrophilic granules, and components of complement can impair autoregulation of renal blood flow and may lead to microvascular thrombosis. Because the hypoperfused kidney is sensitive to nephrotoxic agents that are commonly administered in severe sepsis, these patients may be predisposed to the development of acute renal failure. For example, nonsteroidal anti-inflammatory drugs used to treat fever can inhibit the production of prostaglandins by the afferent arterioles and impair the ability of the kidney to regulate its blood flow. In the patient with severe sepsis and decreased blood volume, this may be enough to precipitate acute tubular necrosis.

NERVOUS SYSTEM

Patients with severe sepsis have abnormalities of their central, autonomic, and peripheral nervous systems.

ABNORMALITIES OF THE CENTRAL NERVOUS SYSTEM

Septic encephalopathy is common in patients with severe sepsis. In a prospective study of 69 patients with sepsis, Young et al reported that 71% exhibited mild to marked abnormalities of cerebral function.[72] The diagnosis of septic encephalopathy in a patient with severe sepsis requires evidence of extracranial infection plus impaired cerebral function. In patients without previous neurologic disease, septic encephalopathy is characterized by symmetrical neurologic findings without the asterixis, tremor, and multifocal myoclonus observed in subjects with metabolic encephalopathies of hepatic, renal, or endocrine origin.[73]

Delirium is perhaps the most costly and prevalent form of septic encephalopathy. This form of organ dysfunction has been shown to occur in more than 80% of all mechanically ventilated patients and is an independent predictor of poor outcomes.[74] Delirium can now be diagnosed by bedside techniques in 1 to 2 minutes with a high degree of accuracy and reliability by using the Confusion Assessment Method for the ICU (CAM-ICU).

The etiology of disordered function of the central nervous system in patients with severe sepsis is multifactorial. It includes abnormalities in the blood-brain barrier, alterations in cerebral blood flow, abnormal cellular physiology, and changes in the composition of neurotransmitters in the reticular activating system. In contrast to hemorrhagic shock, in which there is no change, the blood-brain barrier is disrupted in patients with septic shock.[75,76] This appears to be secondary to effects of circulating cytokines on cerebral endothelial cells. Accumulated perivascular edema fluid may impede the diffusion of oxygen and metabolic substrates, with a resultant decrease in cerebral oxygen consumption. The latter can occur despite an increase in cerebral blood flow and may also reflect the presence of mitochondrial dysfunction.[77] Although severe sepsis is vasodilatory in nature, defects in the blood-brain barrier in some patients can allow vasopressors with α_1-adrenergic activity to constrict cerebral vessels in patients with this disease.[78] Glial and neuronal defects are also present in patients with severe sepsis. Damage to astrocytes can further impair the blood-brain barrier, disrupt the autoregulation of cerebral blood flow, disturb the transfer of metabolic substrates to adjacent neurons, and increase the susceptibility of neural elements to toxic oxygen radicals. Elevated concentrations of the breakdown products of aromatic amino acids in the brain tissue of patients with septic encephalopathy may disrupt central noradrenergic pathways.[73]

ROLE OF THE AUTONOMIC NERVOUS SYSTEM

In an experimental model of sepsis, the parasympathetic nervous system plays an important role in the body's response to sepsis. Stimulation of afferent vagal nerve fibers produces the release of corticotropin-releasing hormone (CRH), adrenocorticotropic hormone (ACTH), and cortisol.[79] Subdiaphragmatic vagotomy blocks cortisol release in this situation. Stimulation of the vagus nerve prevents the onset of shock in a mouse model of endotoxemia.[80] The febrile response to IL-1 can be attenuated by experimental vagotomy.[81]

ROLE OF THE PERIPHERAL NERVOUS SYSTEM AND SKELETAL MUSCLES

Abnormalities of the peripheral nervous system and neuromuscular units are a major cause of morbidity in patients with severe sepsis (see Chap. 66). Two major types of defects can be identified. The primary manifestation in this arena in survivors of severe sepsis and other types of prolonged serious disorders is electromyographic abnormalities. In a study by Fletcher et al, 95% of patients with prolonged critical illness had electromyographic changes indicative of chronic partial denervation, changes that were found up to 5 years after discharge from an ICU in more than 90% of patients who were in the unit for 28 days or longer.[82] Another manifestation is myoneuropathy, a critical illness present in almost 66% of patients. Clinical manifestations can be sensory or motor. The exact etiology of this process is unknown; however, it appears to result from a combination of factors including cytokines, impaired blood flow in the vasa nervosum, extended neuromuscular blockade, immobility, compression, and disuse.[83]

Diagnosis of Sepsis

After immediate stabilization, efforts should be directed toward determining the nature of the infection and identifying the presence of organ dysfunction. Special attention should be directed toward any predisposing condition such as trauma, surgery, organ transplantation, or immunosuppression (e.g., HIV infection, chemotherapy, and malignancy). Steps that define the nature of the infection and assess the degree of organ dysfunction include a complete history and physical examination, laboratory testing including selected microbiology procedures, and medical imaging studies.

CLINICAL EVALUATION

Vital signs are routinely recorded and monitored, although the frequency and method of monitoring depend on the severity of the process. As a general rule, patients can be considered febrile when they have a temperature of at least 38.0°C (100.4°F) or hypothermic with a temperature no higher than 35°C (95°F). Although the presence of fever is most accurately evaluated by assessing core temperature with a bladder or intravascular thermistor, electronic probes in body orifices (e.g., ear) are acceptable in appropriate patients. Notably, temperature must be assessed in a fashion that does not facilitate the transfer of nosocomial pathogens. Importantly, fewer than 50% of febrile episodes are infectious in origin, and almost 50% of septic patients are normothermic or hypothermic.[84] Variables related to fever may help in the differential diagnosis. Temperatures higher than 41.1°C are most probably noninfectious (e.g., drug fever or thyroid storm). Fever with a relative bradycardia and a rash may be drug induced or indicate *Salmonella typhi* or *S. paratyphi* infection. Vital signs can also provide a wealth of information about the patient's prognosis. In a study of community-acquired pneumonia (CAP), a temperature below 35°C or 40°C or higher, a pulse 125 beats/min or faster, a respiratory rate of at least 30 breaths/min, and a systolic BP lower than 90 mm Hg were independently associated with increased mortality rate.[85]

Altered mental status of the patient is an important clue to the presence of organ dysfunction. Delirium is an acute disorder of attention and cognition. It develops in 60% of older hospitalized patients and in more than 80% of mechanically ventilated patients.[76,86] Delirium may be hyperactive (agitated) or hypoactive. Whereas health care workers commonly recognize the former, hypoactive delirium is commonly missed. The presence of delirium is often an important early indication of sepsis, and it can be very hazardous and prolonged in

the elderly. Delirium is associated with prolonged hospital stays, institutionalization, and death. Photophobia, nuchal rigidity, papilledema, or cranial nerve palsies should direct attention to a focus of infection, such as meningitis, within the central nervous system. Orbital pain, periorbital erythema, proptosis, or unilateral rhinorrhea may be seen in a patient with bacterial or fungal sinusitis. Although this may be the presenting illness in an immunocompromised patient, it can also be a secondary infection resulting from the obstruction of sinus ostia by nasotracheal or nasogastric tubes. Fetid breath may be detected in some patients with anaerobic oropharyngeal or pulmonary infections. Oral candidiasis may be a clue to fungal septicemia, although it is more commonly a local phenomenon. Immunosuppressed and neutropenic patients may be unable to produce purulent sputum or other exudates and may be unable to vigorously cough. Tachypnea may be the only sign of pneumonia. Careful auscultation of the lung fields may detect localized rales (crackles). Patients with lower lobe pneumonia may sometimes complain of upper abdominal pain. Associated hypoactive bowel sounds in these patients may be mistakenly ascribed to an intra-abdominal focus of infection. Tenderness over the right upper quadrant may indicate the presence of a hepatic or subphrenic abscess or acalculous cholecystitis. Abdominal tenderness and hypoactive bowel sounds may be the only evidence of a localized intra-abdominal infection or peritonitis. Pain or tenderness (direct and/or rebound) localized to the right or left lower quadrant may be evidence of appendicitis or a ruptured sigmoid diverticulum, respectively. Right lower quadrant pain in a neutropenic patient (often leukemic) may indicate the presence of typhlitis, an inflammation of the cecum that may require altered medical management or surgery.

The skin should be carefully examined. Livedo reticularis and poor capillary refill are a signs of impaired cutaneous perfusion and are associated with a poor prognosis in patients with severe sepsis. In neutropenic patients, the nail folds, axillae, perianal region, and groin provide ready entry for systemic pathogens. In this subset of patients, pain and erythema may be more reliable clues to infection than the leukocyte count. The dressings around any implanted device should be removed, and the area should be carefully inspected for purulent discharge, erythema, increased warmth, pain, and crepitus. Patients with vascular catheters also should be carefully checked for evidence of vascular compromise or embolic events originating from an infected device. Sudden hypotension after access of a vascular access device or line is a clue to the presence of an infected line. Operative wound infections are the second most common type of hospital-acquired infection. All surgical dressings should be removed to allow adequate inspection of operative sites. Patients with recent GI or gynecologic surgery, diabetes mellitus, or peripheral vascular disease are at risk for invasive polymicrobial infections such as necrotizing fasciitis or synergistic gangrene. Clues to the diagnosis include swelling around the wound, rapidly advancing border, crepitus, blisters, necrosis, or the radiographic appearance of gas within the soft tissues.

MEDICAL IMAGING STUDIES

Although universally obtained in critically ill patients, technical limitations of plain radiographs from portable machines render them of limited value in characterizing the nature of the infection in patients with severe sepsis. For example, in the critically ill population with pneumonia, portable chest radiographs have a diagnostic accuracy of 0.5, a sensitivity of 0.6, and a specificity of only 0.28.[87] Notably, chest radiographs may be essentially normal if the films are taken within the first 24 hours after the onset of symptoms or if the patient is neutropenic. Importantly, portable supine chest radiographs may be of value for other diagnostic purposes, such as estimating the patient's intravascular volume status or the nature of pulmonary edema by using the vascular pedicle width (especially when other invasive procedures are not planned).[88] Therefore, imaging studies should be selected based on the presumed nature of the infection, the clinician's need for other data related to the patient's overall clinical status, and the advantages and disadvantages of various approaches.

Plain films and ultrasound have limited utility in establishing the diagnosis of sinusitis. Therefore, a clinical diagnosis of septic sinusitis should be evaluated by computed tomographic (CT) scans of the paranasal sinuses. Although the presence of air or fluid levels is abnormal, the diagnosis is not established without recovery of infected material by sinus puncture, aspirate, and culture. A flat plate of the abdomen may demonstrate the presence of an ileus, a potential explanation for bacteremia in a patient without localizing findings. Abdominal radiographs may also show evidence of a perforated viscus or an intra-abdominal abscess. Ultrasonography of the gallbladder may demonstrate evidence of calculous or acalculous cholecystitis or of biliary tract obstruction in a patient with biliary sepsis. Ultrasound or CT studies of the abdomen may demonstrate localized fluid collections, abscesses, ureteral dilation or a perinephric abscess.

MICROBIOLOGY

All potential infected foci should be cultured in patients with severe sepsis. For example, the presence of pleural fluid adjacent to an infiltrate on a chest radiograph may provide valuable diagnostic information regarding the cause of a patient's severe sepsis. However, in 20% to 30% of patients, a definite site of infection cannot be identified.[89] The search for the responsible pathogen should include all measures necessary to establish the site and nature of infection, including direct examination and culture of material from the lower respiratory tract, fine-needle aspirates, and cultures of infected lines. The blood is also an appropriate material to culture. However, 70% of patients with sepsis will not have organisms recovered from the blood.[89] Material obtained for culture should be immediately gram stained. Cultures should also be supplemented with appropriate immunologic procedures such as detection of microbial antigens in body fluids and immunostaining. In patients with intra-abdominal infections, wound infections, and lung abscesses, the material should also be cultured anaerobically.

LABORATORY MARKERS OF SEPSIS

Several biochemical markers have been used to identify the patient with systemic activation of the cytokine cascade. None of the markers are currently widely used to diagnose sepsis, although some clinicians have argued that they should be incorporated into the entry criteria for patients in clinical trials of severe sepsis. Elevated levels of IL-6, IL-1, IL-8, TNFα, and monocyte chemotactic proteins 1 and 2 are present in septic patients and often correlate with the severity

of the disease. Levels of IL-6 are increased in most patients with sepsis and have been shown to correlate with prognosis, but IL-6 is not used in clinical practice for diagnosis or prognostication.[90] Although the level of IL-6 may be able to differentiate cases of infectious from noninfectious SIRS, no correlation has been established between the concentration of IL-6 and outcomes.

CRP is an acute-phase reactant synthesized in the liver. After exposure to IL-1, IL-6, or TNFα, CRP levels increase. Levels of CRP have been used for years as a diagnostic marker of systemic inflammation. Whereas levels are normally low, they rise rapidly in patients with sepsis, paralleling the course of infection.[91] The complement system is activated in patients with sepsis; this may be mediated in part through CRP. Interactions of the complement system with microorganisms generate increased amounts of C3a and terminal components of the cascade. Elevated levels of C3a have been found to be one of the single and most sensitive and specific laboratory markers that can differentiate between sepsis and noninfectious causes of SIRS.[90]

PCT is derived from the preprohormone, pre-PCT. Although PCT levels are elevated in patients with sepsis, little is known about its source and function. Interestingly, calcitonin levels are normal in this population. In a porcine model of polymicrobial sepsis, immunoneutralization of calcitonin precursors was found to attenuate the adverse physiologic response to the infection.[92] For diagnostic purposes in critically ill patients, PCT levels have a better predictive value for sepsis than do IL-6 or CRP. When PCT concentration was combined with levels of C3a in a "sepsis score," the combination had a sensitivity of 91% and a specificity of 80% for sepsis versus noninflammatory SIRS.[90] As a prognostic marker, PCT levels have been shown to correlate with mortality rate, although the clinical utility of this prognostic marker remains uncertain at this time.[93–95]

Management
