THIRD EDITION

PRINCIPLES OF CRITICAL CARE

Jesse B. Hall
Gregory A. Schmidt
Lawrence D.H. Wood

PRINCIPLES OF CRITICAL CARE

Editors

Jesse B. Hall, MD
Director of Critical Care Services
Professor of Medicine and of Anesthesia and Critical Care
Section of Pulmonary and Critical Care
University of Chicago
Chicago, Illinois

Gregory A. Schmidt, MD
Director, Critical Care Services
Professor of Medicine and of Anesthesia and Critical Care
Section of Pulmonary and Critical Care
University of Chicago
Chicago, Illinois

Lawrence D. H. Wood, MD, PhD
Faculty Dean of Medical Education
University of Chicago Pritzker School of Medicine
Professor of Medicine and of Anesthesia and Critical Care
Section of Pulmonary and Critical Care Medicine
University of Chicago
Chicago, Illinois

Associate Editors

Jameel Ali, MD, M Med Ed, FRCS[C], FACS
Professor of Surgery, University of Toronto
Toronto, Ontario, Canada
National ATLS faculty and Educator
American College of Surgeons Committee on Trauma
Toronto, Ontario, Canada
Chapters 87, 88, 92, 95

Keith R. Walley, MD
Associate Professor of Medicine
University of British Columbia
Pulmonary Research Laboratory
Vancouver, British Columbia, Canada

Under no circumstances shall McGraw-Hill and/or its licensors be liable for any indirect, incidental, special, punitive, consequential or similar damages that result from the use of or inability to use the work, even if any of them has been advised of the possibility of such damages. This limitation of liability shall apply to any claim or cause whatsoever whether such claim or cause arises in contract, tort or otherwise.

DOI: 10.1036/0071416404

We dedicate this edition to:

Larry Wood, who, through his guidance, clarity, and wisdom, revealed to us the beauty of critical care;

Change, which excites and refreshes us;

and Karin and Barbara, who remind us of balance.

NOTICE

Medicine is an ever-changing science. As new research and clinical experience broaden our knowledge, changes in treatment and drug therapy are required. The authors and the publisher of this work have checked with sources believed to be reliable in their efforts to provide information that is complete and generally in accord with the standards accepted at the time of publication. However, in view of the possibility of human error or changes in medical sciences, neither the editors nor the publisher nor any other party who has been involved in the preparation or publication of this work warrants that the information contained herein is in every respect accurate or complete, and they disclaim all responsibility for any errors or omissions or for the results obtained from use of the information contained in this work. Readers are encouraged to confirm the information contained herein with other sources. For example and in particular, readers are advised to check the product information sheet included in the package of each drug they plan to administer to be certain that the information contained in this work is accurate and that changes have not been made in the recommended dose or in the contraindications for administration. This recommendation is of particular importance in connection with new or infrequently used drugs.

CONTENTS

Contributors xi
Preface xxiii
Introduction xxv
V. Theodore Barnett

PART I

AN OVERVIEW OF THE APPROACH TO AND ORGANIZATION OF CRITICAL CARE

1 *AN APPROACH TO CRITICAL CARE 3*
Jesse B. Hall/Gregory A. Schmidt/Lawrence D.H. Wood
2 *ASSESSING COST EFFECTIVENESS IN THE INTENSIVE CARE UNIT 11*
Michael T. Coughlin/Derek C. Angus
3 *IMPROVING THE QUALITY OF CARE IN THE INTENSIVE CARE UNIT 21*
Allan Garland
4 *INFECTION CONTROL AND SURVEILLANCE IN THE INTENSIVE CARE UNIT 41*
David K. Warren/Marin H. Kollef
5 *LEGAL ISSUES IN CRITICAL CARE 53*
Marshall B. Kapp
6 *ASSESSMENT OF SEVERITY OF ILLNESS 63*
Cheryl L. Holmes/Genevieve Gregore/James A. Russell
7 *TRANSPORTATION OF THE CRITICALLY ILL PATIENT 79*
Ira J. Blumen/Frank Thomas/David H. Williams
8 *TELEMEDICINE 93*
Michael Breslow
9 *PREPAREDNESS FOR CATASTROPHE 101*
Jeffrey G. Walls/J. Christopher Farmer

PART II

GENERAL MANAGEMENT OF THE PATIENT

10 *PREVENTING MORBIDITY IN THE ICU 111*
Deborah Cook/Graeme Rocker
11 *NUTRITION IN THE CRITICALLY ILL 117*
Daren K. Heyland/Steve A. McClave
12 *INTRAVASCULAR DEVICES 131*
John F. McConville/John P. Kress
13 *CLINICAL USE OF THE PULMONARY ARTERY CATHETER 139*
James W. Leatherman/John J. Marini
14 *PAIN CONTROL, SEDATION AND USE OF MUSCLE RELAXANTS 165*
Brian Gehlbach/John P. Kress
15 *CARDIOPULMONARY RESUSCITATION 181*
Benjamin S. Abella/Terry L. Vanden Hoek/Jason Alvarado/Lance B. Becker
16 *THERAPEUTIC HYPOTHERMIA 193*
Benjamin S. Abella/Terry L. Vanden Hoek/Lance B. Becker
17 *WITHHOLDING OR WITHDRAWING OF LIFE-SUSTAINING THERAPY AND ADMINISTERING OF PALLIATIVE CARE 201*
John M. Luce
18 *CHRONIC CRITICAL ILLNESS 207*
Shannon S. Carson
19 *LONG-TERM OUTCOMES OF CRITICAL ILLNESS 217*
Margaret S. Herridge/Ramona O. Hopkins

PART III

26 ACUTE RIGHT HEARTH SYNDROMES 335
Ivor S. Douglas/Gregory A. Schmidt
27 PULMONARY EMBOLIC DISORDERS: THROMBUS, AIR, AND FAT 347
Nuala J. Meyer/Gregory A. Schmidt
28 PERICARDIAL DISEASE 373
Israel Belenkie/John Tyberg
29 VALVULAR HEARTH DISEASE 385
Matthew J. Sorrentino
30 AORTIC DISSECTION 401
Jospeh J. Austin

PART IV
PULMONARY DISORDERS

31 THE PATHOPHYSIOLOGY AND DIFFERENTIAL DIAGNOSIS OF ACUTE RESPIRATORY FAILURE 417
Lawrence D.H. Wood
32 VENTILATOR WAVEFORMS: CLINICAL INTERPRETATION 427
Gregory A. Schmidt
33 NONINVASIVE VENTILATION 445
Laurent Brochard
34 UPPER AIRWAY OBSTRUCTION 455
Brian Gehlbach
35 AIRWAY MANAGEMENT 465
Michael F. O'Connor/Andranik Ovassapian
36 MANAGEMENT OF THE VENTILATED PATIENT 481
Gregory A. Schmidt/Jesse B. Hall
37 VENTILATOR-INDUCED LUNG INQUIRY 499
John T. Granton/Arthur S. Slutsky
38 ACUTE LUNG INJURY AND THE RESPIRATORY DISTRESS SYNDROME 515
Jason Christie/Paul Lanken
39 ACUTE-ON-CHRONIC RESPIRATORY FAILURE 549
Ivor S. Douglas/Gregory A. Schmidt/Jesse B. Hall
40 STATUS ASTHMATICUS 567
Thomas Corbridge/Jesse B. Hall
41 MASSIVE HEMOPTYSIS 583
Richard K. Albert
42 RESTRICTIVE DISEASE OF THE RESPIRATORY SYSTEM AND THE ABDOMINAL COMPARTMENT SYNDROME 587
Thomas Corbridge/Lawrence D.H. Wood
43 VENTILATOR-ASSOCIATED PNEUMONIA 599
Jean Chastre/Jean-Yves Fagon
44 LIBERATION FROM MECHANICAL VENTILATION 625
Constantine A. Manthous/Gregory A. Schmidt/Jesse B. Hall

PART V
INFECTIOUS DISORDERS

45 PRINCIPLES OF ANTIMICROBIAL THERAPY AND THE CLINICAL PHARMACOLOGY OF ANTIMICROBIAL DRUGS 641
Fred Y. Aoki
46 SEPSIS WITH ACUTE ORGAN DYSFUNCTION 699
E. Wesley Ely/Richert E. Goyette
47 APPROACH TO INFECTION IN PATIENTS RECEIVING CYTOTOXIC CHEMOTHERAPY FOR MALIGNANCY 735
Eric J. Bow
48 AIDS IN THE INTENSIVE CARE UNIT 771
Peter Phillips/Julio S.G. Montaner/James A. Russell
49 ENDOCARDITIS AND OTHER INTRAVASCULAR INFECTIONS 801
James M. Sizemore, Jr./C. Glenn Cobbs/Mark B. Carr
50 INFECTIOUS COMPLICATIONS OF INTRAVASCULAR ACCESS DEVICES USED IN CRITICAL CARE 815
John M. Conly
51 PNEUMONIA 823
R. Bruce Light
52 BACTERIAL INFECTIONS OF THE CENTRAL NERVOUS SYSTEM 845
Allan R. Tunkel/W. Michael Scheld
53 ENCEPHALOMYELITIS 863
John C. Galbraith/Robert Verity/D. Lorne Tyrell
54 LIFE-THREATENING INFECTIONS OF THE HEAD, NECK AND UPPER RESPIRATORY TRACT 881
Anthony W. Chow
55 SOFT TISSUE INFECTIONS 897
John M. Conly
56 URINARY TRACT INFECTIONS 905
Gerard J. Sheehan/Busi Mooka
57 GASTROINTESTINAL INFECTIONS 913
Steven G. Weber
58 SEVERE MALARIA 923
David A. Warrell
59 TETANUS 933
Perry R. Gray
60 VIRAL HEMORRHAGIC FEVERS 939
Susan P. Fisher-Hoch
61 BIOWARFARE AGENTS 955
Manoj Karwa/Raghu S. Loganathan/Vladimir Kvetan

PART VI
NEUROLOGIC DISORDERS

62 DELIRIUM IN THE INTENSIVE CARE UNIT 975
E. Wesley Ely
63 CEREBROVASCULAR DISEASE 985
Venkatesh Aiyagari/William J. Powers/Michael N. Diringer
64 SEIZURES IN THE INTENSIVE CARE UNIT 997
Sarice L. Bassin/Nathan B. Fountain/Thomas P. Bleck
65 INTRACRANIAL PRESSURE: MONITORING AND MANAGEMENT 1007
Axel J. Rosengart
66 NEUROMUSCULAR DISEASES LEADING TO RESPIRATORY FAILURE 1025
William M. Marinelli/James W. Leatherman
67 COMA, PERSISTENT VEGETATIVE STATE, AND BRAIN DEATH 1037
Axel J. Rosengart and Jeffrey I. Frank

PART VII

HEMATOLOGIC AND ONCOLOGIC DISORDERS

68 ANEMIA AND BLOOD TRANSFUSION 1055
Judith Luce
69 BLEEDING DISORDERS 1065
Jospeph M. Baron/Beverly W. Baron
70 THROMBOTIC THROMOBOCYTOPENIC PURPURA, HEMOLYTIC SYNDROMES, AND THE APPROACH TO THROMBOTIC MICROANGIOPATHIES 1081
Lawrence Tim Goodnough
71 ACUTE LEUKEMIA 1089
Richard A. Larson/Michael J. Hall
72 ONCOLOGIC EMERGENCIES 1099
Elizabeth B. Lamont/Philip C. Hoffman
73 HEMATOPOIETIC STEM CELL TRANSPLANTATION AND GRAFT-VERSUS-HOST DISEASE 1111
Stephen W. Crawford/Rodney J. Folz/Keith M. Sullivan
74 TOXICITIES OF CHEMOTHERAPY 1123
Apurva A. Desai/Gini F. Fleming

PART VIII

RENAL AND METABOLIC DISORDERS

75 ACUTE RENAL FAILURE 1139
Bharathi Reddy/Patrick Murray
76 ELECTROLYTE DISORDERS IN CRITICAL CARE 1161
Joel Michels Topf/Steve Rankin/Patrick Murray
77 ACID-BASE BALANCE 1201
David C. Kaufman/Andrew J. Kitching/John A. Kellum
78 DIABETIC KETOACIDOSIS, HYPERGLYCEMIC HYPEROSMOLAR NONKETOTIC COMA, AND HYPOGLYCEMIA 1209
John B. Buse/Kenneth S. Polonsky
79 ADRENOCORTICAL INSUFFICIENCY 1219
Paul E. Marik/Gary P. Zaloga
80 THYROID DISEASE 1231
Roy E. Weiss/Samuel Refetoff

PART IX

GASTRINTESTINAL DISORDERS

81 GUT AND HEPATOBILIARY DYSFUNCTION 1247
Eli D. Ehrenpreis/Thomas D. Schiano
82 GASTROINTESTINAL HEMORRHAGE 1261
Ram M. Subramanian/Timothy M. McCashland
83 FULMINANT HEPATIC FAILURE 1279
Sanjay Kulkarni/David C. Cronin II
84 MANAGEMENT OF THE PATIENT WITH CIRRHOSIS 1289
Gregory A. Schmidt
85 ACUTE PANCREATITIS IN THE CRITICALLY ILL 1299
Bryce R. Taylor
86 MESENTERIC ISCHEMIA 1309
Denis W. Harkin/Thomas F. Lindsay

PART X

THE SURGICAL PATIENT

87 SPECIAL CONSIDERATIONS IN THE SURGICAL PATIENT 1321
Jameel Ali
88 PREOPERATIVE ASSESSMENT OF THE HIGH-RISK SURGICAL PATIENT 1331
Fergus Walsh/Jameel Ali
89 THE ACUTE ABDOMEN AND INTRA-ABDOMINAL SEPSIS 1345
J.M.A. Bohnen/R.A. Mustard/B.D. Schouten
90 THE TRANSPLANT PATIENT 1355
Damon C. Scales/John T. Granton
91 CARE OF THE MULTIORGAN DONOR 1375
Frank D'Ovidio/D. McRitchie/Shaf Keshavjie
92 PRIORITIES IN MULTISYSTEM TRAUMA 1387
Jameel Ali
93 HEAD INJURY AND INTRACRANIAL HYPERTENSION 1395
Richard J. Moulton/Lawrence H. Pitts
94 SPINE INJURIES 1409
Garth E. Johnson
95 TORSO TRAUMA 1421
Jameel Ali
96 PELVIC RING INJURIES AND EXTREMITY TRAUMA 1443
A.S.L. Liew
97 ELECTRICAL TRAUMA 1451
Lawrence J. Gottlieb/Raphael C. Lee
98 BURNS: RESUSCITATION PHASE (0 TO 36 HOURS) 1457
Robert H. Demling/Leslie Desanti
99 BURNS: POSTRESUSCITATION PHASE (DAYS 2 TO 6) 1467
Robert H. Demling/Leslie Desanti
100 BURNS: INFLAMMATION-INFECTION PHASE (DAY 7 TO WOUND CLOSURE) 1473
Robert H. Demling/Leslie Desanti
101 INTEVENTIONAL RADIOLOGY 1479
Jennifer E. Gould/Daniel Picus

PART XI

SPECIAL PROBLEMS IN CRITICAL CARE

102 TOXICOLOGY IN ADULTS 1499
Thomas Corbridge/Patrick Murray/Babak Mokhlesi
103 CRITICAL CARE PHARMACOLOGY 1547
Vidya Krishnan/Thomas Corbridge/Patrick Murray
104 RHEUMATOLOGY IN THE ICU 1573
Walter G. Barr/John A. Robinson
105 CRITICAL ILLNESS IN PREGNANCY 1593
Mary E. Strek/Michael F. O'Connor/Jesse B. Hall
106 ANAPHYLACTIC AND ANAPHYLACTOID REACTIONS 1615
Jonathan Moss/Paul-Michel Mertes

107 DERMATOLOGIC CONDITIONS 1627
Mario E. Lacoutre/Michael J. Welsh/Anne E. Laumann
108 SICKLE CELL DISEASE 1655
Gregory J. Kato/Mark T. Gladwin
109 THE OBESITY EPIDEMIC AND CRITICAL CARE 1671
Brian Gehlbach/John P. Kress
110 HYPOTHERMIA 1679
Nicola A. Hanania/Janice L. Zimmerman
111 HYPERTHERMIA 1687
Janice L. Zimmerman/Nicola A. Hanania
112 DIVING MEDICINE AND NEAR DROWNING 1693
Claude A. Piantadosi/Steven D. Brown
INDEX 1707
Color plates appear between pages 930 and 931.

CONTRIBUTORS

BENJAMIN S. ABELLA, MD, MPhil
Department of Medicine
Section of Emergency Medicine
University of Chicago
Chicago, Illinois
Chapters 15, 16

VENKATESH AIYAGARI, MD
Assistant Professor of Neurology and Neurological Surgery
Washington University School of Medicine
St. Louis, Missouri
Chapter 63

RICHARD K. ALBERT, MD
Professor
Department of Medicine
University of Colorado
Health Sciences Center
Chief of Medicine
Denver Health Medical Center
Denver, Colorado
Chapter 41

JAMEEL ALI, MD, M Med Ed, FRCS[C], FACS
Professor of Surgery, University of Toronto
Toronto, Ontario, Canada
National ATLS faculty and Educator
American College of Surgeons
Committee on Trauma
Toronto, Ontario, Canada
Chapters 87, 88, 92, 95

JASON ALVARADO, BA
Department of Medicine
Section of Emergency Medicine
University of Chicago
Chicago, Illinois
Chapter 15

DEREK C. ANGUS, MD, MPH
Professor and Vice Chair
Department of Critical Care Medicine
Director, The CRISMA Laboratory
University of Pittsburgh
School of Medicine
Pittsburgh, Pennsylvania
Chapter 2

FRED Y. AOKI, MD
Professor of Medicine
Medical Microbiology, Pharmacology and Therapeutics
University of Manitoba
Winnipeg, Manitoba, Canada
Chapter 45

JOSEPH J. AUSTIN, MD
Cardiothoracic Surgery
Overlake Hospital Medical Center
Bellevue, Washington
Chapter 30

GEORGE BALTOPOULOS, MD
Professor of Critical Care and Pulmonary Diseases
University of Athens School of Nursing
Director
Athens University School of Nursing Intensive Care Unit at KAT Hospital
Athens, Greece
Chapter 23

JOSEPH M. BARON, MD
Section of Hematology/Oncology
University of Chicago
Chicago, Illinois
Chapter 69

BEVERLY W. BARON, MD
Department of Pathology
Blood Banking/Transfusion Medicine
University of Chicago
Chicago, Illinois
Chapter 69

WALTER G. BARR, MD
Professor of Medicine
Director
Training Program
Division of Rheumatology
Northwestern University Feinberg School of Medicine
Chicago, Illinois
Chapter 104

Department of Medicine
University of British Columbia
And Vancouver Hospital
Health Sciences Center
Director, MD/PhD Program, University of British
Columbia
Vancouver, British Columbia
Chapter 54

JASON D. CHRISTIE, MD, MS
Assistant Professor of Medicine
Division of Pulmonary, Allergy, and
Critical Care Medicine
Assistant Professor of Epidemiology
Department of Biostatistics and Epidemiology
University of Pennsylvania
School of Medicine
Philadelphia, Pennsylvania
Chapter 38

GLENN C. COBBS, MD
Professor Emeritus of Medicine
University of Alabama at Birmingham
Birmingham, Alabama
Chapter 49

JOHN M. CONLY, MD
Head
Department of Medicine
University of Calgary
Calgary Health Region
Foothills Medical Centre
Calgary, Alberta, Canada
Chapters 50, 55

DEBORAH COOK, MD
Professor of Medicine and Clinical Epidemiology
and Biostatistics
Chair
Critical Care Medicine
McMaster University
Hamilton, Ontario, Canada
Chapter 10

THOMAS CORBRIDGE, MD
Associate Professor of Medicine
Director, Medical Intensive Care
Northwestern Scholl of Medicine
Chicago, Illinois
Chapters 40, 42, 102, 103

MICHAEL T. COUGHLIN, MA
Project Manager, The CRISMA Laboratory
Department of Critical Care Medicine
University of Pittsburgh School of Medicine
Pittsburgh, Pennsylvania
Chapter 2

DAVID C. CRONIN II, MD, PhD
Assistant Professor of Surgery
Section of Transplantation
University of Chicago
Chicago, Illinois
Chapter 83

STEPHEN W. CRAWFORD, MD
United States Navy Medical Corps
Pulmonary Medicine
Naval Medicine Center San Diego
San Diego, California
Chapter 73

FRANK D'OVIDIO, MD, PhD
Thoracic Surgery and Lung Transplantation
Toronto General Hospital
University of Toronto
Toronto, Ontario, Canada
Chapter 91

ROBERT H. DEMLING, MD
Burn Center
Brigham and Women's Hospital
Boston, Massachusetts
Professor of Surgery
Harvard Medical School
Boston, Massachusetts
Chapters 98, 99, 100

APURVA A. DESAI, MD
Assistant Professor of Medicine
Section of Hematology/Oncology
The University of Chicago Medical Center
Chicago, Illinois
Chapter 74

LESLIE DeSANTI, RN
Burn Research
Brigham & Women's Hospital
Boston, Massachusetts
Chapter 98, 99, 100

MICHAEL N. DIRINGER, MD
Associate Professor of Neurology, Neurosurgery
and Anesthesiology
Washington University School of Medicine
Director, Neurology/Neurosurgery
Intensive Care Unit
Barnes-Jewish Hospital
Department of Neurology
St. Louis, Missouri
Chapter 63

IVOR S. DOUGLAS, MD, MRCP (UK)
Assistant Professor
Pulmonary and Critical Care Medicine
Director
Medical Intensive Care
Denver Health
University of Colorado Health Sciences Center
Denver, Colorado
Chapter 39

TONY T. DREMSIZOV
Senior Research Specialist
CRISMA Laboratory
Department of Critical Care Medicine
University of Pittsburgh
Pittsburgh, Pennsylvania
Chapter 2

ELI D. EHRENPREIS, MD
Assistant Professor of Medicine
Rush Presbyterian St. Luke's Medical Center
Adult Care Specialists
Chicago, Illinois
Chapter 81

E. WESLEY ELY, MD, MPH
Associate Professor of Medicine
Division of Allergy, Pulmonary, and Critical Care
Vanderbilt University Medical Center
Associate Director of Research
Tennessee Valley Veterans Administration Geriatric
Research Education and Clinical Center
Nashville, Tennessee
Chapter 46, 62

JEAN-YVES FAGON, MD, PhD
Professor of Medicine
Service de Réanimation Médicale
Hôpital Européen Georges Pompidou
Paris, France
Chapter 43

J. CHRISTOPHER FARMER, MD
Professor of Medicine
Division of Pulmonary and Critical Care Medicine
Program in Translational Immunovirology and
Biodefense
Mayo Clinic
Rochester, Minnesota
Chapter 9

SUSAN FISHER-HOCH, MD
Professor
Division of Epidemiology
University of Texas School of Public Health at Brownsville
Brownsville, Texas
Chapter 60

GERASIMOS S. FILIPPATOS, MD
Critical Care Unit and Heart Failure Unit
Evangelismos General Hospital
Chairman
Working Group on Acute Cardiac Care
European Society of Cardiology
Athens, Greece
Chapter 23

GINI F. FLEMING, MD
Associate Professor, Department of Medicine
Section on Hematology, Oncology
The University of Chicago Medical Center
Chicago, Illinois
Chapter 74

PREFACE

The field of critical care has exploded since we last revised this textbook in 1998. In particular, the large number of high-quality clinical trials performed to elucidate mechanisms of critical illness and to guide clinical care has reverberated through ICUs around the world and generated tremendous excitement. A decade ago, intensivists managed patients based largely on an in-depth understanding of cardiopulmonary pathophysiology, coupled with a broad understanding of internal medicine, surgery, and a few related fields. The last decade has added to this a wealth of evidence revealing that there are better and worse ways to manage our patients. The modern intensivist must both master a complex science of pathophysiology and be intimately familiar with an increasingly specialized literature. No longer can critical care be considered the cobbling together of cardiology, nephrology, trauma surgery, gastroenterology, and other organ-based fields of medicine. In the 21st century, the specialty of critical care has truly come of age.

Why have a textbook at all in the modern era? Whether at home, in the office, or on the road, we can access electronically our patients' vital signs, radiographs, and test results; at the click of a mouse we can peruse the literature of the world; consulting experts beyond our own institutions is facilitated through email, listserves, and web-based discussion groups. Do we still have time to read books?

We believe the answer is a resounding yes. Indeed, the torrent of complex—and, at times, conflicting—data can be overwhelming for even the most diligent intensivist. We have challenged our expert contributors to deal with controversy, yet provide explicit guidance to our readers. Experts can evaluate new information in the context of their reason and experience to develop balanced recommendations for the general intensivist who may have neither the time nor inclination to do it all himself.

A definitive text of critical care must achieve two goals: the explication of the complex pathophysiology common to all critically ill patients, and the in-depth discussion of procedures, diseases, and issues integral to the care of the critically ill. The exceptional response to the first two editions of *Principles* showed us that we succeeded in meeting these goals. In this third edition, we have made numerous changes in line with the tremendous evolution in our field. We have deleted the illustrative cases and their discussion to make room for exciting new chapters dealing with catastrophe-preparedness, therapeutic hypothermia, interpreting ventilator waveforms, adrenal dysfunction, telemedicine, biowarfare, intravascular devices, angioedema, massive hemoptysis, and evidence-based prophylactic strategies, among others. The changing nature of our patients and increasing recognition of complications following critical illness by weeks, months and years spawned chapters on obesity in critical illness, chronic critical illness, long-term outcomes, delirium, and economics of critical care. We have completely revised many chapters to keep pace with changing concepts in nutrition, myocardial ischemia, airway management, ARDS, severe sepsis, cardiac rhythm disturbances, pericardial disease, status epilepticus, intracranial hypertension, blood transfusion, acute renal failure, acid-base disorders, electrolyte disturbances, gastrointestinal hemorrhage, fulminant hepatic failure, cirrhosis, mesenteric ischemia, gastrointestinal infections, coma, care of the organ donor, toxicology, dermatologic conditions, sickle cell disease, hypothermia, and hyperthermia. Finally, a former colleague, Dr. V. Theodore Barnett, an intensivist with extensive experience in the melting pot of Hawaii, has contributed an introduction that reminds all of us of the challenges and opportunities we face when dealing with our multicultural patients and their families.

We have collected up front many of the issues of organization which provide the foundation for excellent critical care as well as topics germane to almost any critically ill patient. The remainder of the text follows an organ system orientation for in-depth, up-to-date descriptions of the unique presentation, differential diagnosis, and management of specific critical illnesses. While we have made many changes, we have preserved the strengths of the first two editions: a solid grounding in pathophysiology, appropriate skepticism based in scholarly review of the literature, and user-friendly chapters beginning with "Key Points."

We attempted to preserve our vision and approach in the third edition of *Principles of Critical Care* by contributing approximately one fourth of the total chapters ourselves and recruiting associate editors and colleagues who share our vision concerning academic critical care. In general, we are convinced that clinical scholarship in critical care is conferred by balanced involvement in both management and investigation of critical illness, so we invited two associate editors who actively deliver intensive care and publish about it. Our selection of associate editors having a shared spirit was

Copyright © 2005, 1998, 1992 by The McGraw-Hill Companies, Inc. Click here for terms of use.

considerably aided by our having practiced, researched, published, or taught with both.

Dr. Jameel Ali is a Canadian trauma surgeon actively involved in providing and teaching ATLS and critical care in North America. His wide range of publications on critical care topics addresses mechanisms in basic science journals such as the *Journal of Applied Physiology* and clinical investigations in the best surgical and medical journals. From this base in surgical critical care and its considerable overlap with anesthesiology and medicine, Dr. Ali coordinated most of the chapters aimed at essential surgical aspects of critical care and those related to the gastrointestinal system, while authoring (or co-authoring) four chapters himself. Dr. Keith Walley is another Canadian intensivist who combines basic and clinical investigation with his practice and teaching of critical care. He helped organize the sections covering general management and cardiovascular diseases and contributed two chapters himself.

We have encouraged our contributors to state cautiously and with experimental support their diagnostic and therapeutic approaches to critical illness, and to acknowledge that each approach has adverse effects, in order to define the least intervention required to achieve its stated therapeutic goal. With the help of our associate editors, our review process was closer to that enforced by excellent peer-reviewed journals than that encountered by most contributors of invited book chapters. We hope the attendant frustrations and revisions of the authors provide a better learning experience for the readers.

Our approach to patient care, teaching, and investigation of critical care is energized fundamentally by our clinical practice. In turn, our practice is informed, animated, and balanced by the information and environment arising around learning and research. Clinical excellence is founded in careful history taking, physical examination, and laboratory testing. These data serve to raise questions concerning the mechanisms for the patient's disease, upon which a complete, prioritized differential diagnosis is formulated and treatment plan initiated. The reality, complexity, and limitations apparent in the ICU drive our search for better understanding of the pathophysiology of critical care and new, effective therapies.

We enjoy teaching principles of critical care! We came to our affection for teaching the diagnosis and treatment of critical illness through internal medicine, albeit by different tracks. Two of us (JH, GS) were educated at the University of Chicago's Pritzker School of Medicine and Internal Medicine Residency before serving as chief medical residents in 1981 and 1985, respectively. The other (LW) graduated in medicine from the University of Manitoba in Winnipeg, Canada, completed a PhD program at McGill University in Montreal in the course of his internal medicine residency, then joined the critical care faculty in Winnipeg in 1975. There, critical care had a long tradition of effective collaboration among anesthesiologists, internists, and surgeons in the ICU and in the research laboratories. When we three began to work together at the University of Chicago in 1982, our experience in programs emphasizing clinical excellence combined with our questioning, mechanistic approach to patients' problems to help establish a robust and active clinical critical care service with prominent teaching and research activities. Our teaching program was built upon the components of: 1) an understanding of underlying pathophysiology; 2) a state-of-the-art knowledge of current diagnosis and management of problems in the ICU; 3) a familiarity and experience with the tools and results of basic and clinical investigation in critical care; and 4) an appreciation of the issues and methods of ICU organization and management. We have attempted to make this text incorporate just these components in its explication of the principles of critical care, and hope that the text continues to be a well-received and valued extension of our teaching methodology beyond the confines of the University of Chicago.

In addition to our associate editors and individual authors, others too numerous to mention facilitated the completion of this book. We are especially indebted to our own students of critical care at the University of Chicago who motivate our teaching – our critical care fellows; residents in anesthesia, medicine, neurology, obstetrics and gynecology, pediatrics, and surgery; and the medical students at the Pritzker School of Medicine. Our colleagues in providing critical care within the section, Edward Naureckas, John Kress, Brian Gehlbach, John McConville, Imre Noth, and Kyle Hogarth, combine with others in our institution such as Michael O'Connor, Avery Tung, Axel Rosengart, Jeffrey Frank, Michael Woo, Patrick Murray, and Lawrence Gottlieb, to make our practice of interdisciplinary critical care at the University of Chicago interesting and exciting.

Even with all this help, we could not have completed the organization and editing of this book without the combined efforts of many at McGraw-Hill. Our editors have guided this group of academic physicians through the world of publishing to bring our skills and ideas to a wide audience, and we are thankful for their collaboration.

Finally, the revision of a book such as this one is a major adventure that could not succeed simply through the efforts of its senior authors, nor the considerable contributions of our many colleagues, nor the meticulous work of its publisher. This book would never have seen the light of day without the untiring support of Cora D. Taylor, our editorial assistant, a remarkable colleague who guided all of our efforts through the day-to-day difficulties of writing this text. To this task she brought organization, persistence, and a sense of humor that delighted and aided all who were fortunate enough to work with her. We especially acknowledge her contributions, without which we would not likely have overcome the innumerable impediments during the three years of revising this book.

TABLE I-1 Communication During Critical Care

Subject	Possible Issue	Mechanism of Improving Care
Language	Miscommunication	Interpreter, translator second choice
Decision-Making	Alternate models	Clear delineation of decision maker early
Religion	Need for rituals	Trained chaplains, connections with sectarian clergy
Autonomy	No desire for autonomy	Clarify decision making with patient and family on admission
Visitation	Entire family with children	Allow maximal family interactions as possible including children

desire for care on each side of the physician/patient relationship. Unfortunately, cultural interpreters are uncommon and difficult–if not impossible–to obtain for all cultures that an intensivist may come into contact with. Many persons who act as interpreters can, although not trained, act as a valuable cultural resource. This, however, requires the practitioner to understand their limitations and the potential problems, and to ask the interpreter the proper questions about approach to the family and patient, and manner of dealing with them. A true interpreter, as opposed to a translator, will perform some of these tasks. They may say, for example, that in a particular culture the phrase "we'll think about it" generally means "we have decided to proceed but must wait a respectable period of time." That is the difference between a strict translator of words and an interpreter of meaning. An interpreter is the least that is required for true understanding; but again, this is not possible in many hospitals and in many situations, e.g., in the middle of the night where decisions are crucial and the abilities and resources at hand must be used. All too often a family member is recruited to translate. To make matters worse this is often a minor who knows English by virtue of school. Only under extreme circumstances should a family member be used to translate. Conscious and unconscious filtering are common in this situation. Almost as bad, a person who is available but untrained in either communication skills or medical interpreting is drafted into service. Hospitals have lists of translators but these persons have generally received little or no formal training. If these persons must be used (and realistically it cannot be avoided), training should be mandatory. It should not be forgotten, however, as with any other tool in the ICU, that using a strict translator is not using the optimal resource and obtaining the optimal information, and that inaccurate information may well be transmitted.

ETHICS

Many of the precepts of western biomedical ethics which are taken as undeniable truths in much of American medicine are simply cultural constructs which are subject to the same intercultural variability as all other cultural constructs. Three of these of primary importance in the ICU are autonomy, truth-telling, and beneficence.

Autonomy, as it regards decision making, becomes an issue as patients are admitted to the ICU and end-of-life discussions are begun. They often become a moot point by the time decisions occur concerning the pursuit of very aggressive care or withdrawal of care, as the patient is no longer capacitated for medical decision making. However, it must be noted from the beginning of the patient's admission that multiple models of decision making are possible. In many cultures, the concept that a patient would have the autonomy to bankrupt their family and put enormous strains on their community without input from those larger entities would simply be unacceptable. Therefore, it is important to identify the mode of family communication and the decision-making processes of the family, as much as possible. Simply asking the family who will make the decisions and how is important. Truth-telling enters into the autonomy equation. Many cultures consider it potentially harmful to tell a patient they have a terminal illness, because telling a person they are dying may make that likelihood a certainty.

What is therefore needed at times is a hybrid. We are unwilling to give up our ethics as we feel we must practice them, and yet we are ethically obliged to respect the wishes of the patient. At times we have to respect the autonomy of a patient to make the decision to not be autonomous. Discussions with the patient regarding whom they feel should make the decisions, whether it should be them or another member of the family, are necessary in many cultural contexts. In addition, along with that discussion, a discussion concerning whether the patient wants to know their diagnosis and prognosis is important. It would seem, if autonomy is to be respected fully, that a patient should have the right to say "I do not want to know and please give my family the medical information and allow them to make the decisions." It is sometimes helpful to have a discussion with patients who are ambiguous about full knowledge in a third person way. "What would you think about a person who had this diagnosis or who had this happening to them or was going to have this happen to them?" "How do you feel this type of situation should be handled?" Those kinds of discussions with some degree of individual dissociation can be helpful in allowing a patient of any culture to discuss subjects that would otherwise not be acceptable, or emotionally or intellectually possible, topics of discussion.

FAMILY AND VISITATION

Intensive care units have traditionally had very restrictive visitation policies. These have, in general, become less stringent in recent years. They still clash with the feeling of many families regarding family presence at a sick bed. In many cultures it is regarded as a familial obligation for at least one member of the family to be present at the sick bed of a gravely ill person at all times. Although this is at times inconvenient for the medical staff, it is only rarely contraindicated and at these times having a family member wait outside the room is generally acceptable for all. Visitation by children and the presence of children in the rooms of the gravely ill also varies. Whether children are capable of handling visitation in the ICU is a decision best left to those family members who know them best. Their presence should be allowed unless there is a significant contraindication, particularly in end-of-life situations. In many cultures it is seen as quite normal to expose children to all aspects of life and death, and their exclusion leads to

INTRODUCTION

"An elderly Hindu in a British hospital was found lying on the floor, so, thinking that he had fallen out of bed, the nurses placed him back. Shortly afterwards he was found on the floor again. He could not speak English to explain that he thought he was dying and wanted to die on the floor where he would be near Mother Earth, so that his soul could leave more freely than in a bed. Like many Hindus, he had a clear model of how he should die, yet he died alone, before his family could be summoned to perform the final rituals."

Shirley Firth, *Dying, Death and Bereavement in a British Hindu Community*

Caring For Critically Ill Patients and Their Families: Culture Matters

The probability of any two random persons in America being of the same ethnicity is 0.49; 58% of medical critical care fellows are graduates of foreign medical schools. These two facts are enough to explain why a discussion of cross-cultural medicine should be placed at the front of a critical care text. Diversity and cultural sensitivity are concepts which are much in the forefront of recent conversations regarding medicine. However, much of what is done with these concepts and realties is simplistic, and many of the tools purporting to help cultural sensitivity do little more than reinforce prejudgment and stereotypes.

Practitioners struggling to deal with the bewildering array of ethnicities, religions and cultures with which they are confronted and must interact could be forgiven for being overwhelmed. Learning the nuances of even one culture takes years of study. When that culture is confronted with an entrenched biomedical culture the complications multiply. It is therefore not possible to state in detail the proper way to approach any particular type of patient or family. The best that can be done is to learn what some of the fundamental issues are, and how to sensibly and practically approach them in the daily care of patients in the intensive care unit. Although there is some evidence of higher satisfaction when the patient and provider are similar in demographics, matching patients and physicians by demographics is neither reasonable nor desirable.

A look at the basic language and terms involved can illustrate the complexity of the situation and begin a process of coming to terms with this challenge. Culture has been described in many ways, but for purposes of simplicity can be defined as a system of beliefs and a learned and ingrained worldview that goes beyond surface belief to patterns of core values and meaning.

Culture should not be confused with either ethnicity or race. Race is a term which has no biological validity. The concept of race as a valid biological categorization has been refuted by the American Anthropological Association, and in general the term has no scientific meaning. Ethnicity refers to the ethnic background into which a person was born. It is generally similar to culture but can be very different (as in cross-ethnic adoption); although often used as a marker for culture, "ethnicity" and "culture" are not synonymous and cannot simply be used as such.

Acculturation modifies the effects of culture. This has long been recognized by immigrants themselves. The Japanese in America classify themselves as Issei, Nisei, Sansei, and Yonsei for successive generations after immigration. This is a tacit recognition that worldview and interaction with the dominant culture changes with increasing exposure to, and assimilation of pieces of, that culture. The rate of acculturation varies tremendously among immigrants, in part due to the degree to which cultural continuity is maintained in a specific locale as opposed to integration into the larger community.

A textbook discussion of specific issues and table of possible solutions does not remove the complexity of cultural diversity. What must be appreciated is the enormous variation in human belief and desires regarding health, illness, and dying. A realization and admission of lack of knowledge and beliefs is the first step. The one specific piece of information regarding your patient from whatever culture, ethnicity, nationality and religion that can be given is this: You do not know what they believe until you ask them, and that asking opens a dialogue of extraordinary value to all concerned.

Specific Considerations

COMMUNICATION

The ideal person to act as an interpreter in these situations is a cultural interpreter. This person can not only translate the words and conversation but interpret the appropriate social customs and mores and help in dealing with areas of cultural incongruity by interpreting the worldview and resultant

Copyright © 2005, 1998, 1992 by The McGraw-Hill Companies, Inc. Click here for terms of use.

a sense of lacking a full family presence. This is particularly true in withdrawal of care situations.

PAIN CONTROL

The question of pain control has been addressed in several recent discussions regarding end-of-life care. It is generally taken as a tenet of end-of-life care that pain should be abolished if possible and maximally controlled if removal of pain is not possible. There are beliefs, particularly religious beliefs, regarding the redemptive value of pain. This exists in several religious traditions including the Catholic and Islamic traditions. It should not, however, be presumed that a member of these religions wishes to suffer, or that members of other religions do not. The presence of multiple meanings of pain simply needs to be realized. Our beliefs must be checked with the those of the patient, and their wishes followed.

RELIGION

Religion is often closely tied to culture and ethnicity. In many tribal societies, prior to western contact, religion was not defined as separate from the rest of life. Most commonly, however, we are dealing with patients with specific religious beliefs. Virtually all hospitals have chaplains or ministers of specific denominations. It is best to make an institutional relationship with religious leaders of any denomination with which significant contact is likely given the population of intensive care patients. In general, a chaplain trained in hospital chaplaincy can deal with most contingencies in helping the family cope. There are, however, specific rites and rituals which do require the presence of a practitioner with knowledge and credentials of the religion in question.

Treatises on specific religious beliefs regarding health and end-of-life issues can be found, but given the extraordinary proliferation of subgroups within any religion, generalities should be avoided and specific guidance sought from the family and their spiritual counselor.

END-OF-LIFE AND WITHDRAWAL OF CARE

Death is where the effects of culture impact most strongly in the ICU. Biomedicine often views death as a simple physiologic concept which all staff know can be confirmed by a rapid exam. It is, in reality, a complex and mutable concept. As illness is culturally defined, even death is subject to cultural definition. There are persons in the mainstream of American culture who believe death is the final event of a physical body with nothing further. There are those who know with equal assurance that there is a soul which lives on after the body and goes to one of a number of different fates. To the individuals involved these are less beliefs than truths and ways of defining existence. It is important to realize that this same tremendous diversity of ethical certainty and potential incompatibility of beliefs occurs in many situations. Regarding death, there has also been a long tradition in several cultures of regarding persons as being in the category of the dead before what we would consider physiologic death. Lest this seem ridiculous, it is worth remembering that within the last few decades biomedicine has changed the definition of death to now include persons whose brain function has irreversibly ceased. The full import of this change in a definition of death which has existed for the entire history of mankind can be felt at times when dealing with families who have not kept up with the pace of our changing medical beliefs, or whose faith does not allow them to acknowledge brain death. There are places in America and throughout the world where religion determines whether a person is deemed dead or not–a remarkable example of the influence of culture and religion on what we often believe are definitive medical concepts.

The events surrounding end-of-life are of particular interest to clinicians and researchers today. We should in no way believe, however, that we have created the concepts of the dying, the near-dead, and persons who are for most purposes dead although physiologically alive. Each of those concepts exists in multiple cultures throughout the world and has for millennia. It would be extreme hubris on our part to believe that we have somehow discovered dying and can now somehow manage it. We must learn from the billions of human beings who have already faced this situation with their families and communities. To do otherwise would be a disservice to our humanity.

TRUST

Patients and families from traditionally underprivileged ethnicities and poorer socioeconomic classes may have issues with trust in the dominant biomedical structure. The legacy of grievous breaches of ethics, and even currently documented inequality in care, leave a cloud of suspicion over recommendations to withdraw care in some patients. Families, with some historical justification, have suspicions of the medical establishment and the motives for recommendations which are made. It is also a concern among some minority patients and families that recommendations, particularly regarding limitation of expensive technology or withdrawal of care, are potentially being made for economic and not medical reasons. These are very difficult situations to resolve once mistrust has arisen. Clear communication from the beginning can help avoid such situations. Once a situation arises, involvement of medical personal of similar cultural background and the involvement of community resources in the dialogue can be helpful.

Recommendations

Several articles have examined some of the specific issues addressed here in more depth and have resources and additional suggestions for approaches to cross-cultural care.

What we must focus on when faced with a culture and belief system different than our own is attempting to understand how that person or persons knows the world. We must ask and listen to their answers regarding how they know disease, life and death. We must learn how to discern what is important to our patients and families, not try to focus on any specific belief of any group. It is impossible to know all of the answers. The best we can hope for is knowing what questions to ask.

Chapter 1

AN APPROACH TO CRITICAL CARE

JESSE B. HALL
GREGORY A. SCHMIDT
LAWRENCE D. H. WOOD

KEY POINTS

- *Thoughtful clinical decision making often contributes more to the patient's outcome than dramatic and innovative interventions or cutting-edge technology.*
- *Formulate clinical hypotheses, then test them.*
- *Define therapeutic goals and seek the least intensive intervention that achieves each.*
- *Novel treatments require objective clinical trials before they are implemented, and traditional therapies require clarification of goals and adverse effects in each patient before their use can be optimized.*
- *Determine daily whether the appropriate therapeutic goal is treatment for cure or treatment for palliation.*
- *Critical care is invigorated by a scholarly approach, involving teaching, learning, and performing research.*

Intensive care has its roots in the resuscitation of dying patients. Exemplary critical care provides rapid therapeutic responses to failure of vital organ systems, utilizing standardized and effective protocols such as advanced cardiac life support and advanced trauma life support. Other critically ill patients in less urgent need of resuscitation are vulnerable to multiple organ system failure, and benefit from prevention or titrated care of each organ system dysfunction according to principles for reestablishing normal physiology. This critical care tempo differs from the time-honored rounding and prescription practiced by most internists and primary care physicians. Furthermore, the critical care physicians providing resuscitation and titrated care often have little firsthand familiarity with their patients' chronic health history, but extraordinary tools for noninvasive and invasive description and correction of their current pathophysiology. Though well prepared for providing cure of the acute life-threatening problems, the intensivist is frequently disappointed to be the bearer of bad news when recovery is impossible, and increasingly must develop and use compassionate pastoral skills to help comfort dying patients and their significant others, using clinical judgment to help them decide to forego further life-sustaining treatment. Accordingly, experienced intensivists develop ways to curb their inclination toward action in order to minimize complications of critical care, while organizing the delivery of critical care to integrate and coordinate the efforts of many team members to help minimize the intrinsic tendency toward fragmented care. In academic critical care units, teaching and investigation of critical care are energized by the clinical practice; in turn, the practice is informed, animated, and balanced by the information and environment arising from and around teaching and research programs. Yet the vast majority of critical care is delivered in community-based ICUs not affiliated with universities, where critical care physicians rely on their penchant for lifelong learning to update their knowledge and skills through informed reading and attending continuing medical education critical care conferences. These activities in providing, teaching, and investigating critical care contribute to a unique perspective on and approach to medicine among critical care physicians.

Providing Exemplary Care

DEVELOP AND TRUST YOUR CLINICAL SKILLS

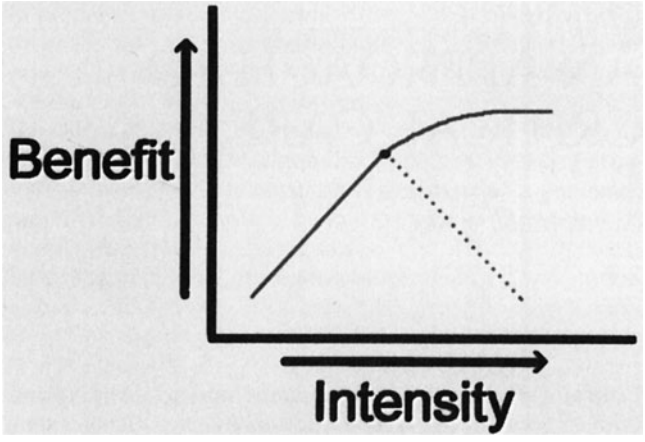
Clinical excellence is founded in careful history taking, physical examination, and laboratory testing. These data serve to raise questions concerning the mechanisms for the patient's disease, on which a complete prioritized differential diagnosis is formulated and treatment plan initiated. The reality, complexity, and limitations apparent daily in the ICU present several pitfalls on the path to exemplary practice. By its very nature, critical care is exciting and attracts physicians having an inclination toward action. Despite its obvious utility in urgent circumstances, this proclivity can replace effective clinical discipline with excessive unfocused ICU procedures. This common approach inverts the stable pyramid of bedside skills, placing most attention on the least informative source of data, while losing the rational foundation for diagnosis and treatment.

FORMULATE CLINICAL HYPOTHESES AND TEST THEM

An associated problem is that ICU procedures become an end in themselves rather than a means to answer thoughtful clinical questions. Too often these procedures are implemented to provide monitoring, ignoring the fact that the only alarm resides in the intensivist's intellect. Students of critical care benefit from the dictum: "Don't just do something, stand there." Take the time to process the gathered data to formulate a working hypothesis concerning the mechanisms responsible for each patient's main problems, so that the next diagnostic or treatment intervention can best test that possibility. Without this thoughtful clinical decision making, students of critical care are swept away by the burgeoning armamentarium of the ICU toward the unproductive subspecialty of critical care technology. So often in the ICU thoughtful compilation of the patient's health evaluation preceding the acute event is more helpful than acquiring new data defining the current pathophysiologic state. Accordingly, attention to this search for meaningful collateral history and the retrieval of prior radiologic studies and laboratory values often should precede the next invasive ICU procedure. The next intervention should be chosen to test a diagnostic hypothesis formulated by thoughtful processing of the available data.

Testing a therapeutic hypothesis requires knowing the goal of the intervention and titrating the therapy toward that end point. Too often students of initial care employ too little too late during resuscitation. For example, the patient with hypovolemic shock receives a bolus of 250 mL of crystalloid solution followed by 200 mL/h infused through two 18-gauge needles in peripheral veins, while the mean blood pressure

Copyright © 2005, 1998, 1992 by The McGraw-Hill Companies, Inc. Click here for terms of use.



(bp) rises from 50 to 60 mm Hg over 2 hours. A far better volume resuscitation protocol targets urgent restoration of a normal bp and perfusion, so it establishes central venous access for a bolus of 3 L of warmed crystalloid and colloid in 20 minutes, to continue at that rate until the bp exceeds 90 mm Hg without inducing pulmonary edema. As another example, a patient requires intubation and ventilation with 100% oxygen for acute hypoxemic respiratory failure. Positive end-expiratory pressure (PEEP) is increased from 0 to 5 to 10 cm H_2O overnight, while arterial O_2 saturation (Sa_{O_2}) increases from 70% to 80% to 90% and bp remains at 95 mm Hg. A better PEEP resuscitation protocol targets an Sa_{O_2} of >90% on an inspired O_2 fraction (FI_{O_2}) of <0.6, so it increases PEEP by 5-cm-H_2O increments from 0 to 20 cm H_2O at 5-minute intervals, dropping FI_{O_2} as tolerated until the end point is achieved unless bp falls. If bp does fall unacceptably, positive inotropic therapy or volume infusion corrects the hypotension, allowing further PEEP increments toward the end point. In each of the better protocols, a clinical hypothesis about the mechanism of the critical illness—(1) the patient is hypovolemic, so rapid volume infusion will correct the hypotension, or (2) the hypoxemia is due to airspace flooding, so PEEP will correct the shunt—can be tested by titration of therapy toward a thoughtful end point without causing common adverse effects (Fig. 1-1). The results are more timely correction of life-threatening conditions.

LIBERATE FROM INTERVENTIONS SO THERE ARE NOT MORE TREATMENTS THAN DIAGNOSES

One of the consequences of protocol-driven resuscitations is that the recovered patient now has more treatments than diagnoses. An effective approach to the adverse outcome of excess therapeutic interventions is the mindset that liberates the patient from these potentially harmful interventions as rapidly as their removal is tolerated. For example, the patient with hemorrhagic shock treated with volume resuscitation and blood products also received intravenous vasoconstricting agents to maintain perfusion pressure while hemostasis and volume resuscitation were achieved. Once a stable blood pressure and hemostasis are achieved, what is the time course for discontinuing the β-agonist therapy?

One answer is to wean the vasoconstrictor slowly (e.g., decrease the norepinephrine infusion rate from 30 μg per minute by 5 μg per minute each hour). Another approach is to liberate the patient from the vasoconstrictor by reducing the norepinephrine infusion rate by half every 15 minutes. The difference between these two approaches is more than the time taken to discontinue the agent, for if in the second approach the bp were to fall after reducing the norepinephrine to 15 μg per minute, the critical care physician learns that the patient remains hypovolemic and needs more volume infusion; the first approach would mask the hypovolemic hypoperfused state by the prolonged use of vasoconstrictor agents, leading to the adverse consequences of multiple organ hypoperfusion. Words convey meaning, and to *wean* connotes the removal of a nurturing, even friendly life-support system from a dependent, deprived infant, a process that should proceed slowly; by contrast, *liberation* is the removal of an unnecessary and potentially toxic intervention from an otherwise independent adult, a process that should proceed urgently.[1]

FIGURE 1-1 A schematic diagram relating therapeutic intensity (*abscissa*) to the benefit of therapy (*ordinate*). For many interventions in critical illness, there is a monotonic increase in benefit as treatment intensity increases (*solid line*), but concomitant adverse effects of the intervention cause harm at higher intensity (*interrupted line*) (for examples, see text). This leads to an approach to critical care that defines the overall goal of each intervention and seeks the least intense means of achieving it.

DEFINE THERAPEUTIC GOALS AND SEEK THE LEAST INTENSIVE INTERVENTION THAT ACHIEVES EACH

The principle from this example applies to many other critical care therapies, such as liberation from the ventilator, vasoactive drugs, and sedative and muscle-relaxing agents. Of course, the difficulty in all these examples is that the therapeutic intervention is initially life-saving, but how long the intervention needs to continue for the patient's benefit versus the patient's harm depends on a critical evaluation of the goal of therapy.

Figure 1-1 indicates the intensity-benefit relationship of many of these interventions (e.g., the continued use of high-dose norepinephrine in the hypotensive patient with hemorrhagic shock discussed earlier). During the initial resuscitation, the benefit of increasing the norepinephrine dose along the *x* axis (intensity) was demonstrated by the rising bp during hemostasis, volume resuscitation, and norepinephrine infusion. Yet bp is not the appropriate benefit sought in the hypoperfused patient, but rather adequate perfusion of all organs. Even without measuring cardiac output, an adequate perfusion state could be inferred from an adequate bp when the vasoconstrictor agent is diminished. However, with continued infusion of the vasoconstrictor, the adverse effect of a prolonged hypoperfusion state, even with an adequate bp, is indicated by the interrupted line, which illustrates a decreasing benefit as the intensity of the intervention and the shock it masks continues. Armed with this rationale, the intensivist should progressively reduce the intensity of norepinephrine infusion over a relatively short period to determine whether the volume resuscitation is adequate.

A second example is the use of fluid restriction and diuresis in the treatment of pulmonary edema. In Fig. 1-1 the intensity of the intervention is the reduction of the pulmonary capillary wedge pressure (PCWP), while the benefit would be the reduction of pulmonary edema. Considerable data suggest a monotonic relationship between the intensity of these therapeutic interventions and the benefit of reduced pulmonary edema.[2] Yet, if the PCWP is reduced too much, there is a consequent reduction in the cardiac output, so the benefit

to the patient is more than offset by the attendant hypoperfusion state. The thoughtful intensivist recognizes that the goal of reducing PCWP and pulmonary edema should not induce a hypoperfusion state, so the targeted intensity is the lowest PCWP associated with an adequate cardiac output and oxygen delivery to the peripheral tissues. Similarly, for PEEP therapy, considerable data suggest that the higher the PEEP intensity, the greater will be the reduction in intrapulmonary shunt as the benefit to the patient. Yet the thoughtful intensivist recognizes that PEEP has adverse effects, as indicated by the interrupted line in Fig. 1-1 showing decreasing benefit as the intensity increases due to pulmonary barotrauma and decreased cardiac output. Accordingly, the goals of PEEP therapy should be the least PEEP that provides the end points of PEEP therapy—90% saturation of an adequate circulating hemoglobin on a nontoxic $F_{I_{O_2}}$. Of course, the adverse effects of PEEP can be diminished by concomitant decreases in tidal volume, as currently practiced in "lung-protective ventilation" (see Chaps. 37 and 38).[2]

FIRST DO NO HARM

Beyond enhancing the clinical scholarship of critical care, this approach maximizes another hallowed principle of patient care—"First do no harm." Despite excited opinions to the contrary, effective critical care is rarely based on brilliant, incisive, dramatic, and innovative interventions, but most often derives from meticulously identifying and titrating each of the patient's multiple problems toward improvements at an urgent but continuous pace. This conservative approach breeds skepticism toward innovative strategies: Novel treatments require objective clinical trials before they are implemented, and traditional therapies require clarification of goals and adverse effects in each patient before their use can be optimized. Accordingly, intensivists should carefully consider the experimental support for each diagnostic and therapeutic approach to critical illness and acknowledge that each approach has adverse effects in order to define the least intensive intervention required to achieve its stated therapeutic goal.

ORGANIZE THE CRITICAL CARE TEAM

The ICU is no longer simply a room in which ventilators are used. Instead, in a well-functioning ICU, the physical plant and technology are planned to facilitate the delivery of care, while also responding to new opportunities in this rapidly evolving field. The physician director, the nurse manager, and the respiratory therapist must build a mutually supportive environment conducive to teaching, learning, and care. Intensivists must be aware of the economic and legal concerns as ICUs capture the interest of politicians, ethicists, and the courts. Furthermore, the managers of ICUs should build on experience. Quality assurance, triage and severity scoring, and infection surveillance are essential to the continued smooth running of ICUs and indeed to their improvement over time.[3]

Managing Death and Dying in the Intensive Care Unit

Perhaps no critical care issue is more emotionally charged and time-consuming than the decision to withhold and/or withdraw life-sustaining therapy (see Chap. 17). Practitioners and students of critical care are frequently called on to guide patients and their families through this new, complex decision-making process without much prior personal experience or literature on which to rely. Accordingly, we discuss an approach to managing death and dying in the ICU meant to minimize one current adverse outcome of modern critical care—our patients die alone in pain and distress because maximal care aimed at cure proceeds despite little chance of success.

DECIDE WHETHER THE PATIENT IS DYING

In a recent analysis of 6110 deaths in 126 ICUs between January and July of 1996, approximately half were associated with the decision to withhold or to withdraw ICU care, as distinguished from deaths after CPR or with full ICU care but no CPR.[4] One interesting feature of this study was the heterogeneity among different units, with some units reporting 90% of deaths associated with withholding and withdrawing ICU care, and others reporting less than 10% associated with this decision. Considerable discussion in the recent literature focuses on the definition of medical futility, and many intensive care physicians are perplexed regarding how to utilize the vagaries of survivorship data to be confident that continuing therapy would be futile.[5]

Yet many of these same physicians have a clear answer to another formulation of the question "Is this patient dying?"[6] An increasing number of critical care physicians are answering "yes" to this question based on their evaluation of the patient's chronic health history, the trajectory of the acute illness, and the number of organ systems currently failing. When the physician concludes that the patient is dying, this information needs to be communicated to the patient, or as so often happens in the ICU, to the significant other of the dying patient who is unable to communicate and has not left advance directives. This communication involves two complex processes: **1.** helping the patient or the significant others with the decision to withhold or withdraw life-sustaining therapy, and **2.** helping them process the grief this decision entails (Table 1-1).

CHANGE THE GOAL OF THERAPY FROM CURE TO COMFORT

In our view, this decision is best aided by a clear, brief explanation of the patient's condition and why the physician believes the patient is dying. When the patient or significant other has had the opportunity to challenge or clarify that explanation, the physician needs to make a clear recommendation that continued treatment for cure is most unlikely to be successful, so therapeutic goals should be shifted to treatment for comfort for this dying patient. In our experience, about 90% of such patients or their families understand and agree with the recommendation, most expressing considerable relief that they

TABLE 1-1 The Intensivist's Roles in Deciding to Forego Life-Sustaining Treatment

Guiding the Decision	Managing the Grief
Explanation	Patient's advocate
Recommendation	Empathic listening
Patient's response	Assemble support
Implementation	Acknowledge the loss

TABLE 1-2 Reconsdering the Goals of Therapy

Cure	Comfort
Ventilation	Treat pain
Perfusion	Relieve dyspnea
Dialysis	Allay anxiety
Nutrition	Minimize interventions
Treat infection	Family access
Surgery	Support
Differential diagnosis	Grieving

do not have to make a decision, but rather follow the recommendation of the physician. It is important to provide time and support for the other 10% while they process their reasons for disagreement with the physician's recommendation, but this remains a front-burner issue to be discussed again within 24 hours in most cases.

At this point, patients or their significant others who agree with the recommendation to shift goals from cure to comfort benefit from understanding that comfort care in the ICU constitutes a systematic removal of the causes of patient discomfort, together with the incorporation of comforting interventions of the patient's choice (Table 1-2). For example, treatment for cure often consists of positive-pressure ventilation associated with posturing, chest pummeling and tracheal suctioning, the infusion of vasoactive drugs to enhance circulation, dialysis for renal failure, aggressive intravenous or alimentary nutrition, antibiotics for multiple infections, surgery where indicated, and daily interruption of sedative infusions to allow ongoing confirmation of CNS status. Each of these components of treatment for cure includes uncomfortable interventions that need to be explicitly described so that patients or their significant others do not maintain the misconception that continued ICU care is a harmless, comfortable course of action. By contrast, treatment for comfort consists of intravenous medication effective at relieving pain, dyspnea, and anxiety. It also consists of withholding interventions that cause the patient pain or irritation, and of replacing both interventions and electronic monitoring of vital signs with free access of the family and friends to allow the intensive care cubicle to become a safe place for grieving and dying with psychospiritual support systems maximized. Once an orderly transition from treatment for cure to treatment for comfort has been effected in the ICU, timely transfer out of the unit to an environment that permits death and grieving with privacy and dignity is often appropriate. Whenever possible, continuity of care for the dying patient outside the ICU should be effected by the ICU physician-house staff team to minimize fragmentation of comfort measures and to keep the patient from feeling abandoned.

MANAGE GRIEF

The second process that is ongoing during this decision making allows the dying patient or the family and friends to begin to express their grief (see Table 1-1). The very best care of the patient is care for the patient, and the critical care physician's demeanor during the decision making process goes a long way toward demonstrating that he or she is acting as the patient's advocate. The urgent pursuit of an agenda that care should be withdrawn does not help the patient or family to trust in the physician's desire to help the patient. Instead, pastoral skills such as empathic listening, assembling the family and other support systems, and acknowledging and sharing in the pain while introducing the vocabulary of grief processing are constructive ways to help the patient and family reconsider the goals of therapy. This is not an easy task when the physician knows the patient and family well, but it is even more difficult in the modern intensive care environment, when the physician may have met the patient for the first time within hours to days preceding the reconsideration of therapeutic goals. Yet the critical care physician needs to establish his or her position as a credible advocate for the patient by being a source of helpful information, by providing direction, and by listening empathically. Because the critical care physician is often a stranger, all efforts should be made at the time of reconsidering the goals of therapy to assemble support helpful to the patient, including family friends, the primary physician, the bedside nurse, house staff and students caring for the patient, appropriate clergy, ethics specialists, and social services.

COMBINE EXCELLENCE AND COMPASSION

Since up to 90% of patients who die in modern ICUs do so with the decision to withhold and withdraw life-sustaining therapy, exemplary critical care should include a commitment to make this transition to treatment for comfort a humane and compassionate process, conducted with the same expertise and excellence sought during treatment for cure. In our view, the physician's conclusion that the patient is dying is the starting point. Thereafter, the physician's recommendation to shift treatment goals from cure to comfort is essential so that the patient and the family have no illusions that full ICU care will produce a cure. Third, understanding that comfort care is extensive and effective allows the ICU to become a safe place for grieving and dying. This is a distinctly different approach from that of many physicians who feel they have failed their dying patients by not providing cure; all too often this fear of failure leads to abandoning dying patients without providing effective comfort care. Since death is not an option but an inevitability for all of us, critical care physicians can bring their expertise and understanding to help patients decide when to forego life-sustaining therapy and to replace it with effective comfort care, making the ICU a safe and supporting space for the dying patient and his or her significant others. Note that the ministerial skills and attitudes required to implement this approach are more in the province and curriculum of social workers, psychologists, and clerical pastoral associates than critical care physicians. To the extent that experienced intensivists find this approach helpful, teaching it to students of critical care becomes an important contribution to a curriculum of critical care.

The Scholarship of Teaching and Discovery in Critical Care

The process of providing exemplary critical care is magnified and refined by learning interactions with students of critical care at all levels—from freshmen to senior medical students through residents in anesthesia, medicine, and surgery, to critical care fellows and practicing intensivists seeking continuing medical education. In such teaching sessions, these students always question the principles of critical care and how

best to impart them, thereby helping direct a search for better teaching methods. Of course, any active ICU is a classroom for learning the principles of critical care. Yet teachers of critical care need to avoid the pitfalls to learning when there is little time for the student to process the reasons for the formulations of differential diagnostic and treatment plans in each patient. There can develop a "shoot from the hip" pattern recognition of critical illness that often misses the mark and perpetuates a habit of erroneous interventions that delay a more rational, mechanistic, questioning approach to each patient's problem.

IMPLEMENT A CRITICAL CARE CURRICULUM IN THE INTENSIVE CARE UNIT

One helpful teaching technique is to implement a schedule providing students of critical care with the luxury of time to think. This priority provides a counterpoint to the work rounds and clinical problem-solving activities that unfettered, tend to dominate the daily activities of the unit. A good start is to ritualize a curriculum for critical care learning. In many academic centers, house staff and fellows rotate through the ICU on monthly intervals. Accordingly, a monthly series of well-planned seminars addressing the essential topics that house staff and fellows need to know can incorporate medical students and nursing staff, and lay the foundations of conceptual understanding necessary to approach the critically ill patient effectively. In our teaching program, we emphasize a conceptual framework based on the pathophysiology of organ system dysfunction shared by most types of critical illness (Table 1-3).

This approach complements the specific etiology and therapy of individual illnesses, because the opportunity for favorably treating many concurrent organ system failures in each patient occurs early in the critical illness, when the specific diagnosis and focused therapy are less important than resuscitation and stabilization according to principles of organ system pathophysiology. Critically ill patients present many diagnostic and therapeutic problems to their attending physicians and so to the students of critical care. Recent advances in intensive care management and monitoring technology facilitate early detection of pathophysiology of vital functions, allowing the potential for prevention and early treatment. However, this greater volume of diagnostic data and possible therapeutic interventions occasionally can create "information overload" for students of critical care, confounding rather than complementing clinical skills. The purpose of a syllabus addressing the pathophysiology of critical illness is to provide students with an informed practical approach to integrating established concepts of organ system dysfunction with conventional clinical skills. New duty hour regulations for U.S. house officers have made it difficult to include all members of the team in these teaching sessions, an issue we have not been able to fully solve. A syllabus of reading material that follows the seminar topics closely is helpful to students.[7]

TABLE 1-3 Critical Care Curriculum: The Pathophysiology of Critical Illness

1. O_2 delivery and the management of life-threatening hypoxia
2. Pulmonary exchange of CO_2, Vd/Vt and ventilatory (type II) failure
3. Pulmonary exchange of O_2, shunt, and acute hypoxemic (type I) respiratory failure
4. Respiratory mechanics and ventilator-lung model demonstration
5. Perioperative (type III) respiratory failure and liberation of the patient from mechanical ventilation
6. Right heart catheter, central hemodynamics, and lung liquid flux
7. Cardiovascular management of acute hypoxemic respiratory failure
8. Ventilatory management of acute hypoxemic respiratory failure, including ventilator-induced lung injury
9. Ventilator waveforms to guide clinical management
10. Status asthmaticus and acute-on-chronic respiratory failure
11. Control of the cardiac output and bedside differential diagnosis of shock
12. Volume and vasoactive drug therapy for septic, hypovolemic, and cardiogenic shock

ENCOURAGE INDEPENDENT INTERPRETING OF IMAGING TECHNIQUES, BIOPSIES, AND OTHER INTERVENTIONS

A second forum for teaching critical care is to review essential imaging procedures. Accordingly, we set aside about 45 minutes at 11:00 AM each day to systematically review the diagnostic radiology imaging procedures conducted in the last 24 hours on each of our patients, including computer-assisted tomograms, magnetic resonance images, and ultrasonography. This formal review allows faculty and fellows to teach medical students and house staff a systematic review of the chest radiograph and special features of ICU radiology, including identification and positioning of diverse diagnostic and therapeutic instruments (e.g., the endotracheal tube, intravascular catheters, feeding tubes, pacemakers, and others). We also set aside one day per week to review the echocardiographic studies performed during the previous week. Of course, these have been reviewed online when the procedures were done, but this forum allows students of critical care to become more comfortable with the types of diagnostic information we seek from these imaging techniques. Encouraging students of critical care to be active participants in bedside diagnostic and therapeutic procedures such as endoscopy, and to follow-up on all biopsy specimens by direct observation with the pathologist are other ways to encourage active learning concerning the interpretation of ICU procedures and their integration with the patient's clinical evaluation in a timely manner.

TEACH HOW TO TEACH

An essential component of the critical care fellowship is learning how to teach. It is common in academic medical environments to assume that completing medical school and residency confers the ability to teach,[8] but most critical care

fellows value the opportunity for supervised and guided enhancement of their teaching abilities by effective teaching faculty. The critical care syllabus outlined earlier gives the opportunity for fellows to observe faculty teaching during their first rotation through the unit and during subsequent months to organize and present selected topics from the syllabus with the help of their faculty preceptor. Our target is that our fellows have mastery of the complete syllabus by the time they complete their fellowship, an exercise that confers confidence and credibility on their teaching skills, and undoubtedly enhances their learning of the concepts they teach. Just as bench researchers go elsewhere and establish their laboratories, our clinical scholars have created the same learning programs elsewhere, exporting this approach and content rather than evolving it over years. A second forum is our daily morning report, where three to five new pulmonary and critical care patients are presented in a half-hour conference. One fellow provides a brief analysis and solution to each clinical problem, and suggestions or affirmations of the analysis by faculty and other fellows help develop the skill of processing and presenting complex patients.

LEARN AND USE A QUESTIONING APPROACH

Another important forum for encouraging active learning of critical care is the daily teaching round led by the intensive care faculty and critical care fellows. The format we have found most useful is to encourage the most junior member of the team responsible for the patient to provide a complete, systematic review of the patient, concluding with a differential diagnosis and treatment plan, while the attending faculty member provides an active listening presence. When the presentation is complete, the faculty member questions or confirms directly the essential points from the history, physical examination, and laboratory results, and provides any clarification helpful to the rest of the team on generic or specific teaching issues, integrating the input of more senior members of the team to encourage participation in the bedside decision making as a learning exercise.

Often the case discussions can be led to formulate questions not yet answered concerning the patient's problems. It is less important to provide answers to the questions formed than to point the students of critical care in the direction of how to find the answers, beginning with their reading of appropriate topics in a critical care text available in the ICU. This continues to the appropriate use of medical informatics to search the critical care literature electronically for answers expected in a short interval. Whenever the answer is not available, it is the teaching responsibility of the faculty and critical care fellows to help students of critical care formulate the clinical investigation that could answer the question. In this way, the rounds in the ICU become intellectually charged, and active participation of all members of the team is encouraged. A spin-off of this questioning approach to active learning in the ICU is much more informed cross-coverage between critical care teams. In units with active clinical investigation programs, this questioning approach stimulates interaction between the personnel delivering care and those conducting the research.

AFFIRM LEARNING

Students of critical care learn in a charged environment where some patients do not improve or actually deteriorate despite thoughtful, focused, and timely care. Teachers of critical care can diffuse the angst among students by appropriate, well-placed affirmation of the care being delivered. For example, exemplary case presentations, thoughtful and complete differential diagnoses, focused and insightful treatment plans, and well-formulated questions appropriately researched in the available literature are all targets for faculty approbation. When praised appropriately and without flattery, students of critical care respond with energy and enthusiasm, allowing them to learn to the limit of their potential.

TEACH CRITICAL CARE IN THE CURRICULA OF MEDICAL SCHOOLS AND RESIDENCY PROGRAMS

In many academic institutions, critical care faculty are well known among medical students and house staff as outstanding teachers. This can allow diverse outlets for teaching scholarship in the medical school curriculum and in residency training programs. In our medical school, freshmen students learn the physiology of the cardiovascular and respiratory systems during the winter quarter and have time for elective courses during the spring quarter. This created the opportunity for a freshman spring elective entitled "An Introduction to the Pathophysiology of Critical Illness," which attracts about a quarter of the freshman class each year. During two $2^1/_2$-hour sessions each week for the 10-week quarter, we review in detail with the students extensions of their cardiopulmonary physiology as it is deranged in critical illness, utilizing a core curriculum similar to the topics shown in Table 1-3. These students are stimulated by finding that their hard work in learning physiology has practical applications in treating critically ill patients, and are enthusiastic to apply this new knowledge of pathophysiology during preceptored visits on four occasions to patients with respiratory failure or hypoperfusion states. Utilizing clinically real teaching aids like a ventilator-lung model, an echocardiography teaching tape, and a heart sound simulator provides freshmen students with a vision of patient care at an early stage in their clinical exposure. During sophomore year, focused topics related to critical care are taught during our clinical pathophysiology course, including asthma and acute respiratory distress syndrome. In the junior year, students rotate twice through the ICU for 2-hour preceptored visits to patients illustrating manifestations of respiratory failure or hypoperfusion states. As described earlier, most senior medical students in our school spend a month as members of the critical care teams in our medical or surgical ICU.

In the medical ICU, medical residents and interns rotate for a least three 1-month periods during their 3-year residency program. To refresh and maintain the knowledge base acquired during these rotations, our critical care faculty leads two medicine morning reports per month, during which they review a syllabus of critical care meant to allow residents not on the ICU to utilize their critical care knowledge to process cases representing a specific aspect of critical care. Our faculty members are also regular participants in the house staff teaching conferences conducted by the departments of anesthesia and critical care, pediatrics, obstetrics and gynecology, and surgery, and this interaction fosters a collegial approach to critically ill patients among these different departments. Finally, the participation of academic critical care faculty in city, regional, national, and international critical care conferences

helps to fine-tune and update teaching approaches that can then enhance the scholarship of teaching critical care at one's home institution.

INVESTIGATE MECHANISMS AND MANAGEMENT OF CRITICAL ILLNESS

Clinical investigation of critical illness is essential for the continued growth of effective critical care. Indeed, one of the hallmarks of critical care in the last decade has been the large number of high-quality clinical studies leading to better care. Yet the practice of critical care is often so demanding that the intensivist's time is consumed with providing state-of-the-art care. Accordingly, clinical investigation in the ICU requires an organized program that is parallel to and integrated with the practice and teaching of exemplary critical care. Such a program allows an outlet for the creative formulation of hypotheses arising at the bedside of critically ill patients. It also enhances the morale of the critical care physician–nurse–respiratory therapist team by developing shared confidence that new concepts are being regularly learned during delivery of critical care.

An effective critical care research team consists of a research director, critical care nurse research coordinator, and several critical care fellows. Regular scheduled communications about ongoing research protocols, their significance, and their need for patient recruitment need to be maintained between the research team and the critical care team. The research team needs to meet on a regular basis to interpret and update data in each of its protocols, and to consider and discuss new hypotheses for testing. Ideally, the clinical investigation of critical illness should interface with a basic science research program to allow bench or animal extensions of hypotheses that are difficult to test in the intensive care environment. Together the basic and clinical investigative teams implement the essential steps in clinical research in critically ill patients: formulate a hypothesis, prepare a protocol, obtain institutional review board approval, obtain funding, perform the study, and communicate the results.[9]

Many challenges exist in conducting studies in the environment of the ICU. These include the unpredictable and unscheduled nature of events, the need to maintain complex schedules related to routine care in parallel with schedules for study protocols, and the very heterogeneous nature of patient populations. In the view of many, the greatest challenge is conducting studies of promising therapies for which the precise risks and benefits are unknown, yet doing so in patients in whom informed consent is not possible because of their critical illness. Some would say that such studies simply cannot be done without consent, but we find this an undesirable acceptance of the current state of our ignorance. We believe that true equipoise exists in the interface between many clinical problems and their potential treatments (i.e., a realization on the one hand that our understanding of an existing treatment for a disease process is inadequate, yet no secure knowledge that a new approach or therapy is completely safe and efficacious).[10] In this circumstance we believe that prospective, randomized trials offer the only hope of informing our practice of medicine, and that studies in the ICU, even if conducted with proxy or under some circumstances waived consent, are justified. The function of the institutional review board is to foster careful deliberation of the merits of each situation and proposed study to ensure that these balances are struck.

Chapter 2

ASSESSING COST EFFECTIVENESS IN THE INTENSIVE CARE UNIT

MICHAEL T. COUGHLIN
DEREK C. ANGUS

KEY POINTS

- *The care of critically ill patients in the modern ICU results in a large societal burden in terms of both manpower and monetary cost.*
- *The high cost of critical care can largely be attributed to high overhead costs (e.g., need for experienced staff and expensive equipment), high resource utilization (e.g., drugs, lab tests, and complex imaging procedures), and an ever-growing demand for ICU services.*
- *Complex economic analysis of health care decision making can be reduced to two fundamental questions that need to be answered: First, "Is a therapy worth using when compared with the alternatives?" The second question is broader and asks "Should a portion of available health care resources be allocated to a given therapy or program?"*
- *Routine incorporation of Cost Effectiveness studies is important to the conduct of high quality clinical trials research in the intensive care unit. Inclusion of cost effectiveness gives the clinician the opportunity to fully assess the effect of a new therapy in the ICU.*

The care of critically ill patients in the modern ICU results in a large societal burden in terms of both manpower and monetary cost. The high cost of critical care can largely be attributed to: high overhead costs (e.g., need for experienced staff and expensive equipment), high resource utilization (e.g., drugs, lab tests, and complex imaging procedures), and an ever-growing demand for ICU services. With the continuing rise in health care costs, there is an ever-increasing need to establish whether new therapies are not only efficacious, but also cost effective. The need for cost-effectiveness evaluations is spread throughout medicine, but the issue of cost effectiveness is especially important in critical care medicine. While ICU beds account for only about 10% of all inpatient hospital beds, ICU costs in the U.S. exceed $60 billion annually, and consume up to one third of all hospital costs.[1] Furthermore, attempts to reduce ICU costs by other mechanisms, such as reduction in length of stay, have proved to be difficult.[2] While access to new therapies is being tied increasingly to cost, physicians continue to be skeptical and suspicious of cost analyses. In large part, this skepticism is prompted by the variable quality of earlier cost analyses. However, skepticism is also due to the lack of familiarity many physicians have with the general principles of health economics. The U.S. Public Health Service (USPHS) attempted to set standards for the conduct of rigorous cost-effectiveness analyses in medicine.[3–5] In critical care medicine, the American Thoracic Society (ATS) established specific guidelines for the conduct of cost-effectiveness analyses based on the USPHS recommendations.[6] These standards have the potential to greatly improve the quality of future cost-effectiveness studies. However, if clinicians do not understand and embrace the principles of cost effectiveness, it is likely that such studies will continue to be viewed simply as ammunition for nonclinician administrators in the battle to restrict physician freedom of choice and to control clinical decision making.

In this chapter, we will cover many of the principal aspects of cost-effectiveness analyses and consider how such studies ought to be conducted on potential new therapies. We will use drotrecogin alfa (activated) as a working example of the type of therapy often utilized in the modern ICU that is expensive, but has potentially life-saving effects. The overall goal of this chapter is to encourage all of us to familiarize ourselves with cost analyses and to consider cost-effectiveness analysis as simply another tool in our evaluation toolkit, along with case reports, animal studies, and randomized clinical trials of potential new therapies. We have previously reviewed this topic,[7] and here will further describe the utility of economic analyses in critical care. For a more detailed in-depth discussion of economic analysis in health care, the reader is referred to the excellent text by Gold and associates.[8]

Economic Evaluations in Health Care

One can compress all of health economics down to two main questions. First, "Is a therapy worth using when compared with alternatives?" For example, what is the worth of a new antisepsis agent like drotrecogin alfa (activated) that has recently demonstrated a beneficial effect in a large randomized clinical trial? We can consider that worth represents some trade-off of cost and benefit (or effect). The second question is broader and asks "Should a portion of available health care resources be allocated to a given therapy or program?" This is principally a social policy issue and requires considering the worth of new therapies not only within a given disease, but also in comparison to other therapies in other diseases. For example, although drotrecogin alfa (activated) might be deemed worthwhile in the treatment of sepsis, a state Medicaid agency might be forced to compare its value to that of a hepatitis B vaccination program for newborns, or to influenza vaccinations for the elderly. These types of choices are becoming increasingly common in situations in which health care resources are limited and must be equitably distributed among multiple programs. In other words, we would wish to know if drotrecogin alfa (activated) is not only cost effective with respect to standard management for sepsis, but also whether we can afford it as a society.

There are a variety of different analytic approaches that address all or some part of these two questions. Though the approaches appear similar, and have similar names, there are key differences. In order to understand the strengths and weaknesses of each approach, we must first describe the various methodologies used to evaluate health care costs. There are essentially four types of cost analyses: cost minimization, cost benefit, cost effectiveness, and cost utility. The fourth, cost utility, is best viewed as a special case of cost effectiveness. In addition, there are situations in which a

cost-effectiveness analysis can produce a cost-minimization statement.

COST-MINIMIZATION ANALYSIS

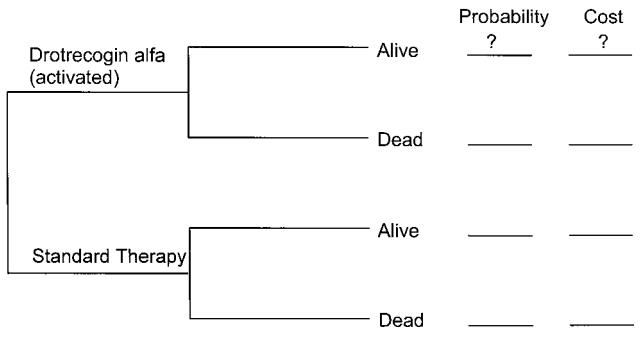
The cost studies that are most familiar to clinicians are cost minimization studies, and these consider only how much a drug costs to stock in the pharmacy. They are essentially studies of drug acquisition cost, and are most frequently conducted by hospital pharmacy departments. When comparing different products (e.g., two sulfonamides), each product is assumed to have equal efficacy and to equally impact all other aspects of treatment (although this may or may not be true). Drug effects such as shortened length of stay, reduced need for other therapies, and improved quality of life after illness are not considered in cost-minimization analyses. The preferred therapy is simply the one that costs the hospital less money per unit of treatment (e.g., per day of therapy, or per dose).

Additionally, a cost-minimization analysis can result when a formal cost-effectiveness analysis (CEA, see below) with sophisticated assessment of all potential changes in costs and effects between two programs demonstrates no difference in effect. However, in the situation in which there is no difference in effect, there may be significant differences in cost between the programs. This result does not produce a cost-effectiveness ratio (since one would be dividing the change in costs by zero), but does allow accurate assessment of the true differences in cost between two programs with comparable treatment effects. This explicit evaluation of costs and effects, as opposed to an assumption of no difference in effect, is in contrast to traditional cost-minimization studies done in the past.

COST-BENEFIT ANALYSIS

The term "cost benefit" is frequently confused with cost effectiveness.[9] In fact, a cost-benefit analysis is a very specific analysis, rarely conducted today, that expresses all costs and effects in monetary units. This means that a dollar value must be placed on all effects. For example, a life saved must be converted into a monetary value. This conversion of life into economic terms can be problematic and very nonintuitive. After conversion of all effects into monetary units, one then adds up all the costs (expressed in dollars) and subtracts them from all the benefits (effects, expressed in dollars). If the final total is negative, the costs outweigh the benefits, and vice versa. Although the final output is attractive in its simplicity, the manipulations required to convert all effects into dollar values are often very controversial. Because of this controversy concerning the "value" of effects, this type of analysis has largely fallen out of favor for health economic evaluations.

COST-EFFECTIVENESS ANALYSIS



Cost effectiveness is simply a ratio of the net change in costs (dollars) associated with two different programs or therapies divided by the net change in effects (health outcome). The denominator represents the gain in health (life-years gained, number of additional survivors, or cases of disease averted), while the numerator reflects the cost (in dollars) of affecting the gain in health. Since the units used are different for the numerator and denominator, the typical cost-effectiveness expression will take a form such as cost (dollars) per year of life saved. Cost-effectiveness analyses are the current dominant form of cost evaluation, and were endorsed by both the USPHS Panel on Cost-Effectiveness in Health and Medicine (PCEHM), and more recently by the ATS as the primary method by which to measure the costs and effects of health care programs and medical therapies.[4,6]

Deciding whether a therapy is cost effective is a subjective evaluation of the cost-effectiveness ratio. If $100,000 per year of life gained is deemed the threshold for effectiveness, then a new therapy with a cost-effectiveness ratio of $82,000 per year of life gained is viewed as cost effective. Though there is no absolute cut-off, there is general consensus that a level somewhere between $50,000 and $100,000 per year of life gained is acceptable in the U.S. today. However, the way in which both costs and effects are calculated can have profound effects on the resulting ratio, and therein lies much of the controversy over CEA.

The typical CEA requires the collection of a significant amount of information on costs and effects, much of which may be gathered from widely varying sources. Interpretation of this information is often difficult, and a decision analysis model is usually constructed that mimics the key clinical decisions and events. This model can most easily be represented by a tree in which each branch point is calibrated with a probability of occurrence and a cost. At its simplest, the tree will contain only branches for treatment allocation (e.g., drotrecogin alfa [activated] or standard therapy) and outcome (e.g., alive or dead). To calibrate such a tree, we would need to know only the probability of living or dying, depending on whether a given patient received the new therapy or not, and the average cost of care for survivors and nonsurvivors in the two treatment arms (Fig. 2-1).

Alternatively, we may be interested in understanding the key events that drive either morbidity or cost (e.g., mechanical ventilation or hemodialysis). This could be important for a variety of reasons; there may be evidence that the study population has a far lower rate of mechanical ventilation than is expected for septic patients in general. Therefore, the extent to which differences in cost are the result of the number of

FIGURE 2-1 Simple decision tree comparing outcome for patients treated with drotrecogin alfa (activated) versus standard care. In order to calibrate the tree, we must estimate: (1) the probability for a given patient to live or die, given whether they received the new therapy or not; and (2) the average costs associated with each of the four branches.

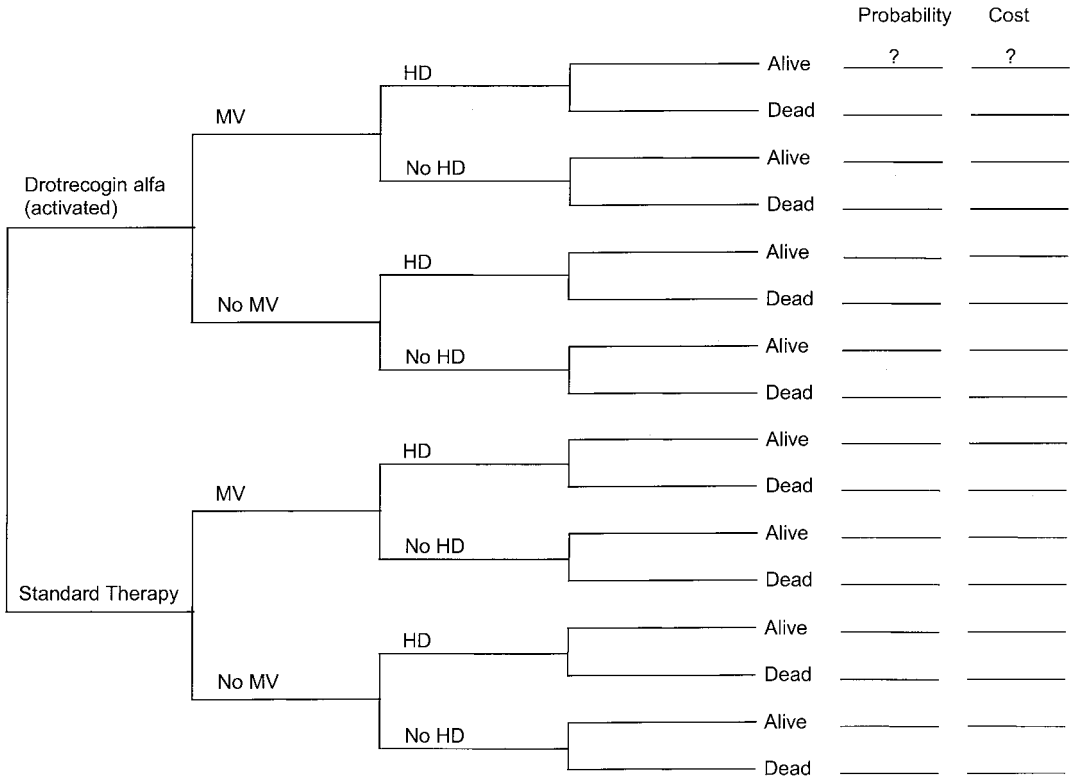


FIGURE 2-2 Decision tree comparing outcomes for patients treated with drotrecogin alfa (activated) versus standard care that incorporates the potential to undergo mechanical ventilation and receive hemodialysis. In order to calibrate the tree, we must estimate the probabilities and average costs for 16 separate trees. MV, mechanical ventilation; HD, hemodialysis.

patients undergoing mechanical ventilation may be important when estimating the cost effectiveness of the new therapy in the real world. Similarly, need for hemodialysis can be a significant cost driver. A new therapy that reduces the need for mechanical ventilation or hemodialysis may be expensive, but the cost of the therapy can be offset by the reduced need for supportive care, and hence deemed cost effective by CEA. In contrast, cost-benefit analysis would take into account only the expense of the new therapy, without considering the reduction in supportive care. However, considering changes in other care modalities leads to the addition of branch points for mechanical ventilation and hemodialysis, and thereby expands the model dramatically, creating 16 branches to consider. For each branch, we must know a patient's likelihood of entering such an arm and the average costs (Fig. 2-2).

COST-UTILITY ANALYSIS

A cost-utility analysis is a form of CEA in which the effects are converted into common units of utility. Typically, this approach involves adjusting the number of years of survival for the "quality" of that survival, in which a person living for one year with a quality-of-life score of 80% would be "awarded" 0.8 years of quality-adjusted survival. The advantage of this approach is that it allows comparison of different programs across different diseases. In this way we can compare the number of quality-adjusted life years (as opposed simply to the number of lives saved), and perhaps can more equitably compare drotrecogin alfa (activated) for critically ill adults to a hepatitis B vaccination program in newborns.

Methodologic Considerations in Cost-Effectiveness Analysis

Good cost-effectiveness analysis design requires consideration of multiple elements in order to both adequately explore the relationship between costs and effects, and to determine the robustness of the conclusions and the comparability of the results to those of other studies. Each of these elements is outlined in Table 2-1 with reference to both the PCEHM and ATS guidelines, and discussed individually in more detail below.

PERSPECTIVE

The costs considered in a CEA can vary depending on whose perspective is considered. As an example, consider the issue of early discharge from the hospital after childbirth. From the hospital's or managed care organization's perspective, cost may be reduced by early discharge. In contrast, from a societal perspective, the cost savings for the health care system may be offset by additional costs to the patient, such as extra time off work for the husband who must stay home to care for the new mother. Cost studies conducted to date have often been hampered by a lack of consistent perspective either within or among studies. Failure to maintain a consistent perspective hampers comparison of results across studies and threatens the validity of the study itself. Both the PCEHM and ATS

TABLE 2-1 Methodologic Considerations in Cost-Effectiveness Analysis

Aspect	METHODOLOGIC PROBLEMS			PCEHM	SECOND ATS WORKSHOP ON OUTCOMES RESEARCH	
	Individual CEA	Comparing CEAs	ICU-Specific	Recommendations (Rationale)	Position	Comment
Perspective	Not defined	Different		Societal (ethical, pragmatic)	Agree	• May be instances when provider perspective is useful
Outcomes (effects)	Data are inadequate or difficult to evaluate	Different outcomes	Long-term follow-up is rare	QALYs (pragmatic, conventional)	Agree	• Require better natural history of ICU conditions and modeling or longer follow-up; other outcomes may be useful depending on perspective
				Best-designed, least biased source (pragmatic)	Agree	• Consider modeling reduced efficacy in sensitivity analysis
Costs	Data are inadequate or difficult to evaluate	Different costs	Only hospital costs are usually measured; no international standard	Costs to include: health care services; patient time; caregiving; nonhealth impacts (theoretical)	Agree	• Standard approach to measuring these costs not yet developed; estimating units of resource use and multiplying by standard costs probably most practical approach currently; detail with which resource use is tracked should be tailored to nature of intervention and likely effects on costs
				Include or exclude other disease costs and test in sensitivity analysis (theoretical, pragmatic, user needs and accounting)	Include costs of other diseases (too hard to disentangle)	
Comparators (standard care)	Choice distorts results	—	Determining standard often difficult	Existing practice (conventional)	Agree	
				If existing practice is suspect, consider best-available, viable low-cost, or "do nothing" (conventional)	Agree	• Many existing ICU practices may be ineffective or cost-ineffective; therefore, consider comparison to "best practice" rather than standard practice
Discounting	Inadequate representation of the effect of time	Different rates	Not usually done	Discount costs and effects to present value (theoretical)	Agree	
				Use a 3% discount rate (theoretical, pragmatic)	Agree	
Uncertainty	Inadequate representation of uncertainty on results	—	Not usually done	Sensitivity analysis essential; multi-way sensitivity analysis preferred (user needs)	Agree	• Multi-way sensitivity analyses probably essential given high likelihood that several key assumptions will be necessary to generate reference case from critical care trials
Reporting	—	Not standard		Reference case (user needs)	Agree	• But, also present "data-rich" case
				Compare to available ratios (user needs)	Agree	
				Journal and technical report (user needs)	Agree	• Also file (e.g., on internet) intended analysis plan prior to unblinding when concurrent with randomized clinical trial

recommend adoption of the societal perspective when conducting cost-effectiveness studies.

OUTCOMES (EFFECTS)

This is an exceedingly difficult problem for CEA for a variety of reasons. First, information on outcomes usually comes from randomized clinical trials (RCTs), which often do not reflect the actual clinical practice of medicine. Conversely, the implications of a CEA are intended for real-world practice. A cost-effectiveness ratio is intended to capture the expected relationship between the costs incurred and the effects gained in actual practice. Conversely, an RCT is usually designed to maximize the likelihood of finding an effect. As such, an RCT can represent a rather idealized situation, which is quite distinctly different from the real world. For example, only specific patients may be selected, the dosage and timing of therapy will likely be optimized, and other aspects of care may be protocolized and carefully controlled. The effect size generated under such rigorous situations is termed a therapy's *efficacy* (or maximal effect). In the real world, the effect of a new therapy is likely diluted by less appropriate patient selection, changes in dosing and timing, and increased variability in other aspects of patient care. The effect of a new therapy under these real-world conditions is termed a therapy's *effectiveness*. The more RCTs are refined, the further removed they are from the reality of using a therapy in clinical practice.[10] Thus, the relationship between cost and effect in some RCTs becomes increasingly distorted.

A cost analysis conducted using efficacy from an RCT might better be termed a cost-efficacy study, rather than a cost-effectiveness study. However, there are no clear guidelines on how to reduce the bias introduced by using efficacy data instead of effectiveness data. One possibility is to consider adding an open-label, open-enrollment arm to clinical trials in which a CEA is being conducted.[11] However, this presents both many logistic and ethical problems. The more accepted alternative is to expose the cost model to varying estimates of reduced effect from those seen in the RCT during sensitivity analysis (see below).

Another problem encountered when determining effect or outcome is that the outcome measure evaluated in the RCT may not be directly relevant in the cost analysis. The PCEHM recommends, and the ATS agrees, that quality-adjusted life years (QALYs) be used as the units of effect, or utility. However, most RCTs in critical care use short-term (day 28 or hospital) mortality as the primary end point, and still others use indices such as "organ failure–free days" as outcome measures.[12] Although short-term survival likely correlates with long-term quality-adjusted survival, the relationship is not explicitly clear. Whether there is any relationship between organ failure–free days and long-term quality of life is even less clear. A recent study by Clermont and associates showed that patients who develop acute organ dysfunction are at risk for poor long-term quality of life (QOL), but that the risk is largely due to poor baseline health status, and not directly to organ failure in the ICU.[13]

This problem is only slowly evolving. While the PCEHM recommends long-term outcome, a National Institutes of Health (NIH)–sponsored workshop on sepsis studies recommended day 28 mortality.[12] More recently, the United Kingdom Medical Research Council workshop still recommended that day 28 mortality was an appropriate primary end point, but recommended follow-up to $\geq$90 days, and whenever possible to $\geq$6 months.[14] Recent successful trials in sepsis reported mortality at widely varying time points: 28 days (drotrecogin alfa [activated]),[15] 28 days and one year (steroids),[16] 60 days (early-goal directed therapy),[17] and a recent study of ARDS (Low Tidal Volume)[18] reported mortality to 180 days.

Proponents of short-term outcome state that longer follow-up is too expensive and not necessarily related to the therapy being studied. Advocates of longer follow-up state that short-term survival, of indeterminate quality of life, and possibly with death a short time thereafter, is of little utility to society.[8] They further argue that the ability to prioritize health care spending on the basis of value requires that we compare the long-term value of alternative programs for alternative disease processes. Many health care programs are administered, and/or have effects lasting, over a long period of time, making long term follow-up of patients enrolled in these programs essential.

There is currently relatively little long-term follow-up information on ICU patients. However, the available evidence does suggest that there is considerable mortality and morbidity beyond hospital discharge, supporting the notion that we should consider longer follow-up.[19–21] Quartin and colleagues showed that continuing mortality occurs in sepsis patients for many months after discharge from the hospital.[19] Studies exploring quality of life after ICU care have yielded conflicting results, but certainly several suggest considerable diminution of quality of life that appears to be sustained over time.[22]

Thus, until more evidence is available, studies of new ICU therapies upon which CEAs are to be performed should have some mechanism (e.g., a subset study or parallel cohort) to incorporate mortality follow-up for 6 to 12 months with an accompanying quality-of-life assessment.

COSTS

Which costs should be included? Debates over this subject can be very contentious and can resemble debates over whether to give colloids or crystalloids to hypotensive patients. The subject is further complicated by economic terms such as direct versus indirect costs and tangible versus intangible costs. We will attempt to avoid using too many accounting terms and to suggest alternative ways to understand this issue.

Let us reconsider the cost-effectiveness ratio. It is a ratio of *net costs* divided by *net effects*. Thereby, regardless of whether the costs of any given element seem important, if they are distributed equally in both comparison groups, the net difference will be zero and we therefore need not worry about them. In other words, we need consider only those costs we believe to be relevant *and* likely to differ between the treatment groups. As an example, the PCEHM believed that the intangible costs of pain and suffering were relevant costs that should be measured in CEAs, but we have never measured these costs in any critical care CEA. Therefore, if a new therapy is unlikely to cause either more or less pain, then we can continue to ignore such intangible costs, even though they are considered relevant. The caveat here is that we have now made the important assumption of no difference in pain, which may or may not be true.

We have of course glossed over the term "relevant." Which costs are relevant? All costs to society could be considered relevant from the societal perspective. Utilizing this perspective, one could argue that the costs of lost wages while a patient is sick are relevant. In response to this issue, the PCEHM recognized there are no correct answers. However, in order to promote standardization of CEA methodologies, they recommend inclusion of all health-related costs, and the ATS concurs that this is the current best approach. They also recommended including opportunity costs, and suggested that lost wages, not only as a postdischarge consequence of the illness but also during hospitalization, represents an example of an opportunity cost. Direct application of these guidelines to critical care is not easy. But one way to consider them is to think about a health care system without drotrecogin alfa (activated) and a health care system with the new therapy. We then need to include all possible cost elements that could differ between these two health care worlds.

ESTIMATING, MEASURING, OR GUESSING COSTS

Not all costs included in a CEA are necessarily measured empirically. The CEA is a model that is often calibrated using estimates. Some of these estimates come from measurements. For example, the estimate of differences in the mortality rate between a drug and placebo often is derived from the effect of size in an RCT. Other estimates can be based on expert opinion, or some combination of measurement and opinion. For example, the cost of the actual therapy is usually unknown since the therapy is often not yet approved, and no price has been set by the company that manufactures the therapy. One is therefore forced to estimate on the basis of an educated "best guess," perhaps with some knowledge of preliminary pricing from the company. While one might be alarmed at this notion of educated guesswork, it is important to appreciate that such estimates can be wildly erroneous, yet have minimal impact on the cost-effectiveness ratio. In order to test how sensitive a CEA ratio is to various estimates in the cost model, the completed CEA model is exposed to a rigorous sensitivity analysis (see below). In this way, we can decide to include many costs in a CEA, yet only measure specifically some portion of that total. As long as the estimated costs have little impact on the overall final CEA conclusions, the strategy regarding which costs to measure and which to estimate can be considered robust.

FOR HOW LONG DO WE MEASURE COSTS?

When the cost of therapy is computed, the duration of the costs attributed to the therapy must also be considered. For example, if our new therapy allows more people to leave the ICU, but causes a higher incidence of renal failure requiring long-term dialysis, shouldn't all the costs of dialysis be attributed to that therapy? The answer is yes.

Although most intensivists do not accept this concept of blaming therapy received in the ICU for incurred long-term costs, it is difficult to argue to the contrary. In producing a survivor, one must also take responsibility for the cost of maintaining survival, which means following the cost streams for a significant length of time. Furthermore, if chronic renal failure leads to a lower quality of life, the new therapy will be doubly penalized, both for the cost of the dialysis and for the reduced quality-adjusted survival.

HOW SHOULD COSTS BE MEASURED?

For those costs that we choose to measure, we must decide what represents true cost. When we consider hospital costs, true costs are generally assumed to be those generated by formal cost-accounting mechanisms. For example, the cost of a complete blood count includes the wage rate for and time spent by the employee who drew the blood, the cost of the tube, and some tiny amortized fraction of the cost of the equipment upon which the test is run. However, detailed information such as this is rarely available as part of a CEA. Another frequently used approach is to collect hospital charges and adjust them by the hospital- or department-specific cost-to-charge ratios. The relationship between hospital charges and costs has long been a source of skepticism for physicians. However, recent work by Shwartz and associates comparing department-specific cost-to-charge ratio-adjusted charges to estimates generated from a formal cost-accounting system, found good correlation when assessing patients in groups.[23] Agreement was much worse when comparing individual patients and when using hospital-specific ratios. However, CEAs rely on average grouped estimates of costs, and therefore department-specific cost-to-charge ratios appear adequate for estimating hospital costs.

Other proxy measures of cost, such as the Therapeutic Intervention Scoring System (TISS) or length of stay, can also be used.[24,25] As stated above, their value will depend on how sensitive the conclusions are to variations in the relationship between these measures and true costs.

DEFINING STANDARD CARE (COMPARATORS)

When comparing a new therapy, the choice of comparator, or standard therapy, is also critical. For example, the cost-effectiveness ratio of a 1-year cervical cancer screening program is quite different than that of 2-year or 3-year programs. Similarly, a tissue thromboplastin activator has a different cost-effectiveness ratio when compared to standard acute myocardial infarction therapy with no thrombolytic therapy as opposed to standard therapy with streptokinase. The PCEHM recommended that the control therapy used for comparative purposes be the least expensive available standard therapy. However, in the field of critical care this view is currently changing. In the treatment of sepsis, should standard care include early goal-directed therapy, steroids, and/or drotrecogin alfa (activated), even though these may be expensive? If so, do we consider all treatments to be standard therapy, or just one or two? The ATS Guidelines recommend that standard care isn't always "best practice," and that best practice should be the comparator of choice in critical care.

DISCOUNTING (TIME)

Discounting costs due to time is another important factor to consider when conducting a CEA. When we borrow money, we must pay it back with interest. This is because money is worth more now than it will be in the future. Therefore, $10 is more valuable now than $10 delivered at a rate of $1 per year for the next ten years. Thus, to pay back $10 that we just received over the next 10 years, we would be required to pay back more than $1 per year. Worldwide economic growth is occurring at approximately 3% per year, and therefore the PCEHM has recommended that all costs be discounted at a

3% rate per annum, and the ATS has agreed with this recommendation.

But what about effects; should they also be discounted? Are ten people living for one year more valuable than one person living for ten years? Although this issue may seem inhumane, consideration of this point is vital. Discounting costs without discounting effects will incur the Keeler-Cretin procrastination paradox wherein we would forever favor health care programs that take place some time in the future.[26] This situation would have us forever putting off until tomorrow that which could be done today, and therefore we also discount effects at 3%, the same rate as costs.

ROBUSTNESS AND UNCERTAINTY

When we perform an RCT, our primary conclusion is a statement of effect: did the new therapy change the outcome of interest? While it is highly likely that the outcome rates will be different (rarely would the mortality rates in both trial arms be identical), we rely on statistical significance to tell us whether the observed difference is due to a true effect of the therapy and not chance alone. We traditionally infer statistical significance when the p-value is <0.05. In this instance, we are 95% certain that the observed difference did not occur by chance alone. If we are interested only in effect, then we care only about which therapy arm is better, not how much better.

It is important to appreciate, however, that the p-value does not confirm the magnitude of effect. Consider the case of drotrecogin, for which a recent large RCT found a mortality rate in the treatment arm of 25%, as opposed to a placebo rate of 31%, with a $p = 0.006$.[15] This does not mean that six lives are saved per 100 persons treated. Rather, it tells us that our best estimate is that six lives are saved. If we presume a binomial distribution around the mortality rates, we can generate confidence intervals around the two estimates. These confidence intervals might now tell us that new therapy saves between 2 and 10 lives per 100 persons treated, but cannot tell us where the true value falls within that range. The p-value simply confirms the likelihood that there are lives saved by the new therapy, not how many lives.

In CEAs, however, we must quantify the magnitude of effect (and cost) so that we can generate a ratio. The general principle is to first take our best point estimates of cost and effect to generate a base case. Thereafter, we vary all our measures and estimates across their range of probabilities (e.g., 95% CI) in order to determine the extent to which the cost-effectiveness ratio varies. This is a *sensitivity analysis* and can be done either with one or multiple variables simultaneously. In one respect, the sensitivity analysis can be considered analogous to the p-value in that it allows us to explore the robustness of our conclusions. In other words, if, despite varying several or all variables across their stochastic distributions, there is minimal change in the final ratio, then one can have considerable confidence in the CE ratio estimate.

Another aspect of the sensitivity analysis is that it can be used to determine which model estimates must be the most accurate. For example, the CE ratio may be exquisitely sensitive to the estimate of ICU costs, but relatively insensitive to the expected costs of postdischarge health care resource use. In this situation, one might need to measure ICU costs very carefully, yet rely only on approximate estimates of postdischarge resource use. A comprehensive sensitivity analysis can in fact often be considered more powerful than a p-value, because it can be used to graphically show all of the uncertainties inherent in the underlying assumptions of the CEA model.

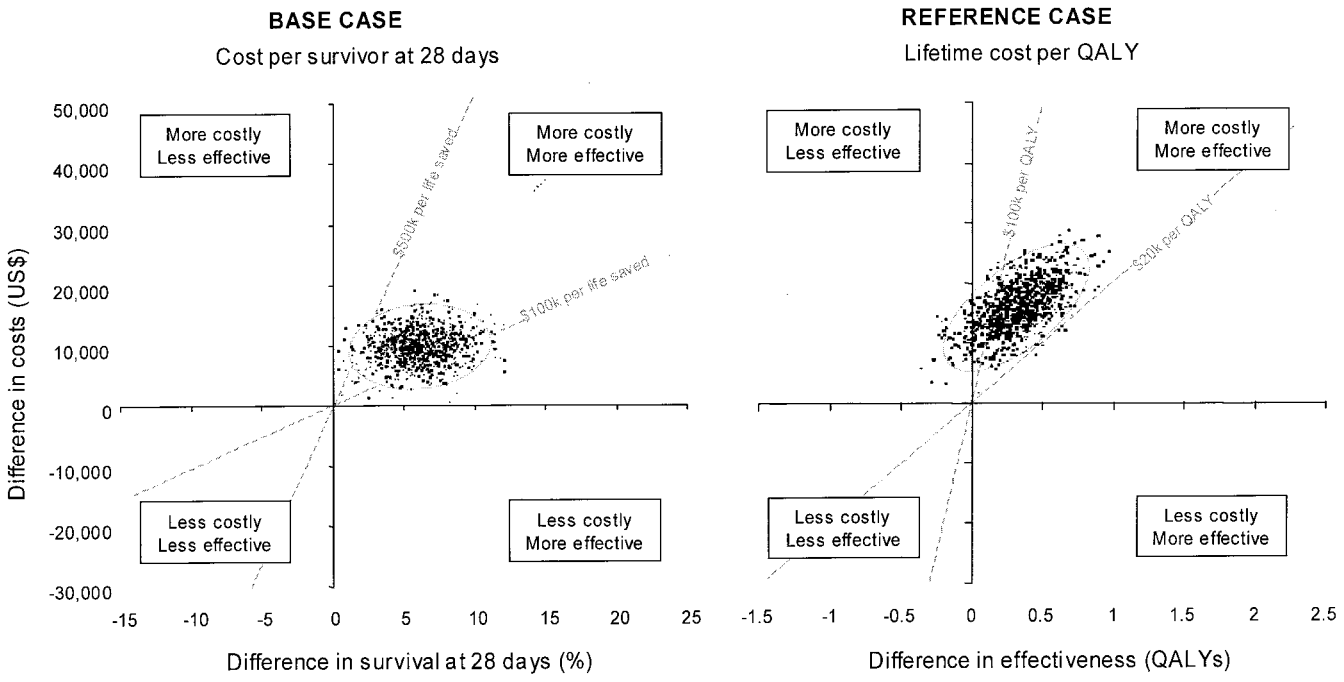
Figure 2-3 shows the base case cost effectiveness and reference case cost-effectiveness ratio estimates for drotrecogin alfa (activated) generated by running 1000 simulations.[27] This is a common graphic representation of the output from a rigorously conducted CEA. The *x* axis shows incremental effects and the *y* axis incremental costs. Quadrants to the right of the *y* axis represent where treatment with drotrecogin alfa (activated) was associated with a net gain in effect. Quadrants above the *x* axis represent a net increase in cost. The majority of the simulation estimates fall within the upper right hand quadrant, indicating a net gain in effect with an associated increase in cost (more costly, more effective). The dashed lines represent thresholds of cost, with regions below and to the right of the thresholds being more cost effective than regions above and to the left.

Reporting and the PCEHM Reference Case

The PCEHM also recommended that all future CEAs produce a *reference case.* This is accomplished by generation of the CE ratio by a standardized approach to estimating and measuring each of the important elements of the CEA (see Table 2-1). This includes the perspective chosen, determination of costs and effects, study time horizon, and measurement of uncertainty and sensitivity analyses. Use of this standardized approach allows for comparison of CEA results across studies. Comparison of reference cases between CEAs allows us to make inferences about the cost effectiveness of a new sepsis therapy like drotrecogin alfa (activated) vs. a therapy used to fight breast cancer. It allows us to compare apples to oranges and bananas and not just apples to apples. Figure 2-4 shows comparisons of costs for a variety of treatments in different diseases. These include both interventions against specific disease states (e.g., myocardial infarction, stroke),[28,29] and interventions designed to prevent injury or illness (e.g., airbags).[30] The ATS Guidelines also recommend the generation of a reference case, and further recommend the presentation of a data-rich case from the results of the randomized trial. This case would be generated using a minimal number of model assumptions and the maximum amount of available data from the clinical trial.

Policy Implications

Decision making based on the results of a CEA is founded on the idea of social utilitarianism. This valuation is in turn based on the assumptions that: (1) good is determined by consequences at the community level, these consequences being the sum of individual utilities (health and happiness); (2) all utilities are equal within the metric used to measure them; and (3) loss of benefit to some individuals is balanced by benefit to others. As a simple example, consider the decision to fund a childhood immunization program rather than a radical chemotherapy program to treat a rare cancer. This decision assumes that spending resources on immunizations will maximize the community's utility (health) more than money spent on treating a rare cancer. Social utilitarianism acts to



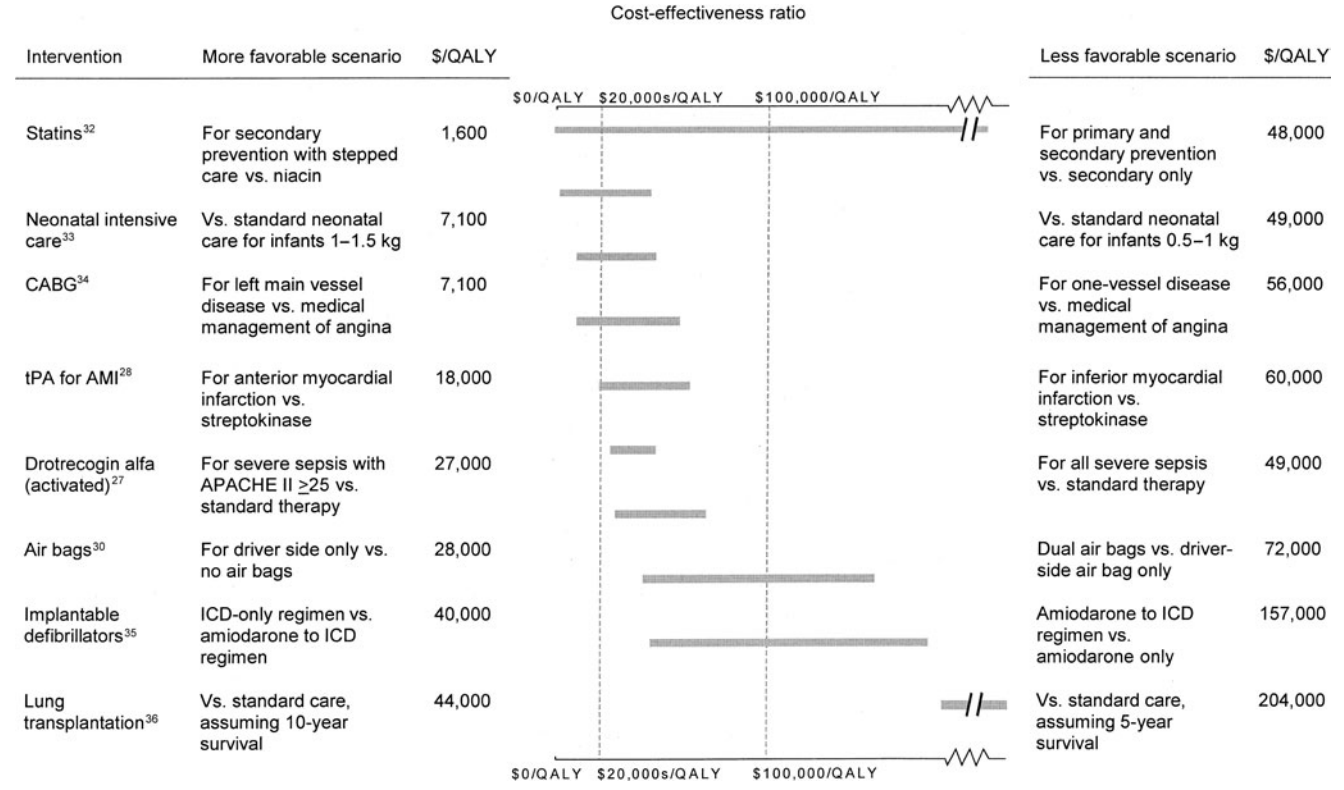


FIGURE 2-3 Cost effectiveness of drotrecogin alfa (activated) in severe sepsis. The figure shows the CE_{base} (*left panel*) and $CE_{reference}$ (*right panel*) distributions of cost-effectiveness ratios of the 1000 simulations with the corresponding 95% confidence ellipses generated by Fieller's method.[31] Incremental effects are shown on the *x* axes and incremental costs are shown on the *y* axes. Quadrants to the right of the *y* axes represent regions where treatment with drotrecogin alfa (activated) is associated with a net gain in effects. Quadrants above the *x* axes represent regions where treatment is associated with a net increase in costs. The dotted lines are illustrative thresholds. Regions below and to the right of the thresholds are more cost effective than regions above and to the left of the thresholds. The ellipses are the smallest areas containing the average incremental costs and effects, with 95% confidence. Both distributions are predominantly in the "more costly, more effective" upper right quadrant, with the majority of simulations falling below the $500,000 per life saved and $100,000 per quality-adjusted life year thresholds. Intervention	More favorable scenario	$/QALY	Less favorable scenario	$/QALY
Statins[32]	For secondary prevention with stepped care vs. niacin	1,600	For primary and secondary prevention vs. secondary only	48,000
Neonatal intensive care[33]	Vs. standard neonatal care for infants 1–1.5 kg	7,100	Vs. standard neonatal care for infants 0.5–1 kg	49,000
CABG[34]	For left main vessel disease vs. medical management of angina	7,100	For one-vessel disease vs. medical management of angina	56,000
tPA for AMI[28]	For anterior myocardial infarction vs. streptokinase	18,000	For inferior myocardial infarction vs. streptokinase	60,000
Drotrecogin alfa (activated)[27]	For severe sepsis with APACHE II ≥25 vs. standard therapy	27,000	For all severe sepsis vs. standard therapy	49,000
Air bags[30]	For driver side only vs. no air bags	28,000	Dual air bags vs. driver-side air bag only	72,000
Implantable defibrillators[35]	ICD-only regimen vs. amiodarone to ICD regimen	40,000	Amiodarone to ICD regimen vs. amiodarone only	157,000
Lung transplantation[36]	Vs. standard care, assuming 10-year survival	44,000	Vs. standard care, assuming 5-year survival	204,000

FIGURE 2-4 League table showing the range of cost-effectiveness ratios for a variety of medical or preventive interventions.[27,28,30,32–36] The vertical lines show the 20,000/quality-adjusted life year and 100,000/quality-adjusted life year levels. The range of values within an intervention indicates differences in conditions or assumptions included in the model.

maximize the health and happiness (utility) of the community, and consequently leads to maximum efficiency in use of health care resources for community benefit. CEA is designed to result in a ranked list of community benefits resulting from given cost outlays. While CEAs can inform us about where to spend money to improve utility, they cannot inform about how much money should be spent to improve health care overall.

The overall goal of CEAs is to provide decision makers with information that can be used to choose between medical care options when all options are not financially feasible. If monies are unlimited, the relevant question becomes "what treatment options minimize patient morbidity and mortality?" and CEAs are unnecessary. If funds are limited, the question becomes "what provides the best value?" and CEAs can help to answer this question. This was the overall conclusion of the ATS and the workshop further recommended that critical care researchers utilize the PCEHM Guidelines and conduct reference case cost-effectiveness analyses as part of the evaluation of ICU interventions. The rigorous application of this CEA methodology will allow more informative health care policy in the care of the critically ill.

Conclusion

The conduct of a rigorous CEA is clearly challenging. There are many methodologic complexities to consider within the study, and the analysis is likely to be highly dependent on the availability and quality of information from other studies (e.g., a phase III RCT). Much of the information required for thorough conduct of a CEA may in fact be missing, and therefore the analysis will require sophisticated modeling techniques to explore the impact of various assumptions and estimates. In order for the reader to be confident in the results of a CEA, the analysis must not only be robust, but must also be perceived as such. Accomplishing this requires clear reporting from the analyst and a commitment on the part of the reader to embrace cost-effectiveness analyses as a legitimate approach to determining the value of new therapies in the treatment of the critically ill.

Chapter 3

IMPROVING THE QUALITY OF CARE IN THE INTENSIVE CARE UNIT

ALLAN GARLAND

KEY POINTS

- *Improving ICU performance demands a systems-oriented approach embodied in total quality management (TQM).*
- *In most ICUs this requires a major paradigm shift away from the discredited notion that most omissions, errors, and other problems are the fault of individuals, and embraces the idea that meaningful and sustained improvement comes from transforming structures and processes into those that make it hard for people to make mistakes.*
- *Creating an effective program of TQM is much easier in an ICU having the resources to hire personnel and purchase information systems.*
- *The most difficult, labor-intensive, and expensive part of TQM is data collection, but there are ways to make this less burdensome.*
- *Every ICU should implement a system of TQM that is multidisciplinary and inclusive, has the vigorous support of hospital and ICU leadership, and has sufficient personnel and economic support to succeed.*

Intensive care units (ICUs) are an important component of modern health care. This importance derives from large costs that are both human and economic. Approximately one third of adult deaths in the U.S. occur in acute care hospitals,[1] and as many as half of these occur in ICUs.[2,3] An even greater fraction of people spend time in an ICU during the final 6 months of life.[3] Among patients admitted to ICUs, 8% to 17% die there, though for some diagnoses the ICU mortality rate is much higher.[4–6]

Beyond death rates, suffering is common among ICU patients. Half or more of ICU patients endure substantial pain.[7–9] Bergbom-Engberg and Haljamae found that 30% of patients surviving mechanical ventilation recall agony, panic, or both.[10] Among oncology patients in an ICU, 30% to 75% experienced dyspnea, hunger, anxiety, insomnia, or thirst, with increased suffering during even such innocuous procedures as turning.[9] Substantial dissatisfaction among relatives and friends of ICU patients[11–13] indicates that suffering in critical illness is not limited to the patients themselves.

To go along with these human costs, the economic costs of ICU care are staggering. Comprising just 8% of acute hospital beds,[14,15] ICU care consumes 20% of total inpatient expenditures,[15–17] equivalent to 0.9% of the gross domestic product of the United States, or $91 billion in 2001.[18] ICUs are a smaller portion of the health care systems in other industrialized countries, but still represent an important segment of medical care and its costs.[16,19–23]

A necessary starting point for improving ICUs is to recognize that problems of quality are common and serious. A recent Institute of Medicine Roundtable[24] stated that:

> Serious and widespread quality problems exist throughout American medicine. These . . . occur in small and large communities alike, in all parts of the country and with approximately equal frequency in managed care and fee-for-service systems of care. Millions of Americans are not reached by proven effective interventions that can save lives and prevent disability. Perhaps an equal number suffer needlessly because they are exposed to the harms of unnecessary health services. Large numbers are injured because preventable complications are not averted. . . . Quality of care is the problem, not managed care.

The U.S. health care system is by far the most expensive in the world, while ranking thirty-seventh in overall performance, and seventy-second in population health.[25] Canadian health care is the tenth most expensive, ranking thirtieth and thirty-fifth on these measures, respectively. This poor performance is not explained by society's violence, poor health habits, or high cholesterol levels.[26]

There are many factors contributing to this poor performance. Inappropriate use of medical interventions is common throughout the health care system,[26–29] with nonadherence to established standards of care being related to poor outcomes.[30,31] Medical errors are prevalent, often leading to disability and resulting in 27,000 to 98,000 deaths/year.[26,32,33] A study in Veterans Administration hospitals found that 6% to 34% of deaths there may be preventable.[34] A study limited to certain subsets of patients with iatrogenic complications in ICUs observed them to occur in 31% of patients, and to be severe in 13%.[35] Errors were observed to occur in 1% of all the interventions done each day to patients in an Israeli ICU.[36]

Another problem is variation in practice and outcomes not explained by patient or illness characteristics. Since wide and widespread variation could not exist if most practitioners practiced optimally, and such variation is evidence that suboptimal care is common. Variation has been found for many outcomes in a broad range of settings, with important differences by geographic region,[3,37,38] hospital,[39–41] physician,[40,42–48] and insurance status or payer system.[42,49–53] Such variation occurs in ICUs as well.[45,49,51,54–56] Lest one think otherwise, such variation is not just an American phenomenon.[48,57–62]

Given the primary function of ICUs, it is particularly troubling that they suffer from serious deficiencies regarding palliative and end-of-life care. In addition to the high prevalence of suffering discussed above, caregivers often don't ask about their patients' end-of-life preferences, with consequent discordance between the care desired and that received.[7,63] The conversations that do occur are often much delayed.[63–66] Communication between caregivers and ICU patients or their surrogates is frequently poor. Azoulay and associates found that 20% to 43% of surrogates did not understand what they had been told about diagnosis, prognosis, and therapeutic options, and that these problems correlated with family-doctor meetings that were too brief.[67] In other studies families expressed dissatisfaction with the amount and nature of communication, and many experienced actual conflict with the

caregivers.[12,68] Even more worrisome was that 24% of patients said they were not aware of the current approach to care, and 47% of those who preferred a palliative approach felt the care they were receiving was inconsistent with that wish.[63] In addition, the variation in practice present in other aspects of ICU care is also present in end-of-life and palliative care.[3,4,62,64,65,69,70]

The data above demonstrate that ICUs are an important, expensive, and problematic component of health care. Therefore, vigorous efforts are needed to critically examine and improve every aspect of how well and how efficiently they perform their functions. Because "quality" is an extremely vague term often used to encompass various, often equally vague, concepts, this chapter will instead refer to the more tangible concept of ICU performance, and use the term performance improvement (PI) in place of the various alternatives.

Since it would require us to believe that ICU care is different than every other area of human endeavor, it is implausible that all ICUs perform equally well, or even that any given ICU is performing optimally. To identify how well a given ICU performs requires quantitation of relevant indices of performance. However, ICUs are complex organizations, and it is difficult to clearly define or measure such indices. In fact, the meaning, scope, and measurement of performance in health care have evolved and broadened over the past two decades. Some of the most widely used approaches to improving performance in health care have proved inadequate. This chapter will discuss both the conceptual basis and practical aspects of a superior method of evaluating and improving ICU performance.

Defining Intensive Care Unit Performance

Defining ICU performance is a difficult exercise that embraces diverse elements such as medical knowledge, ethics, economics, systems engineering, sociology, and philosophy. Efforts to measure ICU performance should follow two essential principles: (1) evaluate a variety of measures that span the dimensions of ICU performance; and (2) use performance measures that are directly relevant, or have an unequivocal relationship to measures that possess such relevance.

There are a number of domains within which an ICU should be judged (Table 3-1). While ultimately an ICU exists to serve the medical needs of critically ill patients, it also provides important services for families and friends of patients, health care workers in the ICU, the hospital, and society. Rating ICUs only on narrowly defined measures of health outcomes fails to recognize the larger social value associated with expert care of these patients. In addition, no single metric is adequate to address all of the categories of outcomes listed in Table 3-1.

Assessing performance requires direct measurement of end points that are relevant—to patients, society, and the hospital. Table 3-1 lists relevant measures of ICU performance. Because they are usually easier to measure, surrogate parameters are often used in PI efforts. While assessing surrogate end points is often a component of PI, this should not substitute for measuring and addressing the truly important parameters. For example, errors in drug administration have a proven association with detrimental outcomes,[32] and therefore the rate of such errors is a relevant performance measure. Processes instituted within the pharmacy to try and reduce errors, such as altered drug labeling or direct communication with nurses, represent surrogates for the relevant index. While addressing such processes is in fact the necessary means to the end, changing a given process may or may not result in improvement in the rate of such errors, and does not obviate the need to measure it.

TABLE 3-1 Domains and Measures of Intensive Care Unit Performance

Medical outcomes
• Survival rates: ICU, hospital, and long-term
• Complication rates related to care
• Medical errors
• Adequacy of symptom control
Economic outcomes
• Resource consumption: ICU, hospital, and posthospital
• Cost effectiveness of care
Psychosocial and ethical outcomes
• Patient satisfaction
• Family satisfaction
• Concordance of desired and actual end-of-life decisions
• Appropriateness of medical interventions provided
• Long-term functioning and quality of life among survivors
Institutional outcomes
• Staff satisfaction and turnover rate
• Effectiveness of ICU bed utilization
• Satisfaction of others in the hospital with the care and services supplied by the ICU
• Efficiency of the processes, procedures, and functions involved in ICU care

The ICU readmission rate is not listed in Table 3-1 because it is at best a questionable indicator of ICU performance. Its potential value derives from observations that readmitted patients have a higher mortality rate and longer length of stay.[71] However, for it to be a meaningful surrogate requires that: (1) premature ICU discharge was the cause of a subsequent detrimental outcome due to a problem that was already present in the ICU, and (2) it would not have occurred if the patient had remained longer in the ICU. There are no data that have demonstrated this.[71,72] The optimal readmission rate is unknown, and a low one could indicate that on average, patients are inappropriately remaining in the ICU too long, when they could be adequately cared for in less expensive venues.

All of the performance parameters listed in Table 3-1 have limitations. ICU or hospital mortality rates are commonly used measures of ICU performance that are relatively simple to collect. While some data indicate that hospitals with higher death rates have more preventable deaths,[30] short-term survival tells us nothing about the things that are much more important to people, long-term survival and quality of life (QOL).[73–75] Also, certain attitudes about death and dying can mean that higher short-term mortality represents superior care by virtue of being more concordant with patients' end-of-life wishes.[76,77]

The laborious nature of collecting data on posthospital survival and QOL undoubtedly contributes to low usage of these important measures.[78] It is even more work to combine these into a quality-adjusted measure of long-term survival, such as

quality-adjusted life years.[79] A variety of questionnaire-based tools have been developed for quantifying patients' QOL.[80–83] The most commonly used is SF-36.[84] These generally gauge health-related QOL on multiple domains, with heavy emphasis on functioning.[80,85] Indeed, ICU survivors often have demonstrated poor QOL.[86–88] Assessment of cognitive functioning, depression, and posttraumatic stress disorder also shed light on the long-term consequences of ICU care[89,90] (see Chap. 19).

Complication and error rates are often used as measures of ICU performance. These are relevant because of potential causal relationships of such adverse events with increased mortality, morbidity, or costs.[32] However, such adverse events do not necessarily lead to clinically relevant consequences, and some studies have found little effect.[34,35] Therefore, care must be taken to ensure that an established relationship to relevant outcomes exists for any medical error or complication whose rate is used as a surrogate for ICU performance. Since only a fraction of medical practices have been rigorously proved to be efficacious,[91] many deviations from recommended practice may have no such relationship.

Symptom control and end-of-life decision making are important aspects of ICU care. As discussed above, there is much room for improvement in this area. Use of these outcomes as measures of ICU performance has been limited by lack of training and orientation among physicians,[92,93] a paucity of pre-existing tools to measure them,[94] and other factors.[69]

Because of the enormous costs of ICU care, resource consumption should be part of every institution's assessment of ICU performance. The best measure that balances simplicity and information content is ICU length of stay. Others that require much effort to acquire include total monetary charges or costs,[95] usage of various diagnostic and/or therapeutic procedures, and Therapeutic Intervention Scoring System (TISS) score.[96] TISS is a relatively comprehensive attempt to measure resource utilization for ICU patients that works well for cohorts.[97,98] However, because spending a lot of money is justifiable if the benefits are commensurately large, while even small expenditures that generate no benefits are wasted, resource use is most relevant in combination with the noneconomic outcomes in Table 3-1. While the formalism associated with this concept, cost effectiveness, is well beyond the scope of local attempts to improve ICU performance,[99] it would be a powerful tool to assist society in clarifying the value of ICUs, as well as to assess the performance of individual ICUs. A simpler approach to assessing cost effectiveness that could be adapted within a single ICU depends on case-mix adjustment of short-term mortality and length of stay (see below).[100]

Effective use of ICU beds is important for a number of reasons. The ICU is an expensive and limited resource.[101,102] Moving patients out of the ICU prematurely due to limited availability has serious negative consequences.[103] But ICU triage decisions are often inefficient, and can be made more effective without adverse medical consequences.[104] Arguing that rationing of critical care is common but often inequitable, Kalb and Miller published a thoughtful framework for consideration of ICU triage in which they propose that the use of critical care be limited to clinical settings in which it has been demonstrated, or at least is presumed, to be cost effective.[105] They and others[106,107] provide arguments for using medical suitability as the primary determinant of such triage decisions, proposing that a low priority for ICU beds be assigned to those too healthy to require such care and to those too hopelessly ill to benefit. While rates of adherence to written or published admission and discharge standards is a common means of measuring ICU bed utilization, such information is not likely to result in much useful information, as such standards have not been subjected to scientific validation of whether they affect relevant outcomes.[108] Possible measures of utility include: (1) the percentage of ICU patients who only receive care that could be provided elsewhere in the hospital, (2) the fraction of patients for whom ICU care represents an exercise in medical futility,[109–111] and (3) patients who remain in an ICU for longer than they need its special capabilities.

The importance of satisfaction among patients and their families as measures of ICU performance is highlighted by data documenting that poor communication and dissatisfaction are common.[12,13,67,68] Unfortunately, at the local level there is usually more talk than action on this topic. This is partly because unfamiliar survey instruments, questionnaires, or interviews that are time-consuming to administer and analyze, are utilized to gather this data. There are numerous potential dimensions to such surveys in ICU care, including satisfaction with: (1) level of care from physicians, nurses, and other ancillary health care personnel; (2) involvement in decisions regarding care; (3) amount and quality of communications with health care and administrative personnel; (4) outcomes of care; (5) administrative hospital functions such as admissions, discharge, and billing; (6) food; and (7) housekeeping. While there are doubts about the validity of currently used methods,[112,113] a variety of tools exist to measure these aspects of satisfaction, including some created specially for use in ICUs.[11,13,68,114–117]

The satisfaction of all those who work in an ICU should likewise be considered a component of ICU performance. Job dissatisfaction contributes to higher rates of staff turnover,[118] which: (1) wastes training time and money;[119,120] (2) diminishes the ability of the ICU to perform as an experienced, highly functioning team;[121] and (3) further degrades staff morale while increasing stress on managers and remaining staff. The nursing shortage is already substantial, especially in ICUs.[122–125] That of respiratory therapists is not far behind,[126] and a shortage of ICU physicians is looming.[127] Problems related to dissatisfaction and turnover are obviously worse if those who quit cannot be replaced. In fact, dissatisfaction and burnout is common among nurses,[128–131] respiratory therapists,[132] and ICU physicians.[133–136] While staff retention rates are easily obtained from personnel records, data about job satisfaction are collected from questionnaires or interviews. Many survey tools exist to assess job satisfaction, burnout, and related constructs.[128,133,136–144]

A large class of performance measures quantifies problems in the processes, procedures, and functions occurring within the ICU, or that link the ICU to the rest of the hospital. This group of measures is strongly related to many of the other outcomes in Table 3-1, but possesses independent importance because of its relationship to the quality of interpersonal interactions, and the staff's perceptions of their workplace. An example is inefficiency or conflict in the course of interactions between the ICU and the pharmacy. Even in the absence of identified errors in drug administration resulting from such incidents, they have the potential to lead to errors, waste, or rework, and in any case generate negative feelings among the staff.

Measuring and Interpreting Intensive Care Unit Performance

The effectiveness of PI efforts depends on the type and quality of performance data collected. If that information is irrelevant, inaccurate, incomplete, or otherwise misleading, the effort expended may be wasted. This is a real problem, in part because in many hospitals PI efforts are primarily an exercise in analyzing individual adverse events (AE), such as complications, errors, or deaths.[145] Unfortunately, this inclination has been augmented by recent publicity about medical errors[32] and the response of regulatory entities toward such sentinel events.[146]

Though every performance measure can be phrased in terms of an AE that occurs in relation to individuals, *it is fundamental that detection of individual AEs cannot be used to measure performance*. This does not mean that analysis of individual AEs has no role in PI, but knowing that any given number of deaths, or even potentially avoidable errors occurred cannot inform us about performance without determining the rate of AEs. The number of individual events must be pooled and expressed as the rate of events by dividing by the aggregate number of at-risk patients, patient-days, or other appropriate denominator. This rate then is compared to some standard. The benchmark for comparison could be some accepted norm, the rate in other ICUs, the rate derived from analyses of databases, or the prior rate in that same ICU. It is this form of cumulative information—rates of death, errors, complications, family dissatisfaction, or others—that truly represents ICU performance.

There are multiple reasons that simply accumulating information about AEs, without their rates, is inadequate and potentially misleading. First, not all AEs are due to poor care. Even with implementation of every known beneficial practice, it is not plausible that AEs will disappear; rather the goal is to reduce their rate to an acceptable level, or below what they were previously. Second, an individual AE does not necessarily cause harm or increase costs (e.g., administering the incorrect dose of a drug often does no harm). Third, even an AE apparently caused by human error that led to harm is not proof that overall performance is poor; for example, it is entirely plausible that a surgeon who once amputated the wrong leg could have a superior overall complication rate. Fourth, the usual methods for identifying AEs, incident reports or chart review, are inefficient, inaccurate, and subject to significant disagreement.[34,36,147–150] This last point highlights the necessity of creating reliable methods of systematically collecting accurate data on the performance parameter being surveyed. Both the denominator and numerator must be accurate. This topic is beyond our scope, but a few guidelines are: (1) prospectively collected data are superior to retrospective data; (2) information collected by computerized information systems is superior to that collected by humans, especially if they are specifically programmed to acquire the desired information; and (3) identification of AEs should be based on objective, predefined criteria rather than subjective human judgment.

Measuring ICU performance using variables such as those in Table 3-1 is effected by calculating the rate for binary variables such as survival or complications, and the mean, median, or interquartile range for continuous variables, such as a 0- to 100-point patient satisfaction scale. Whatever the data type, care must be taken to collect a sample size that is large enough to allow reliable statistical comparisons.[77,151,152] This point is illustrated by the example of a complication that occurs in approximately 3% of patients, with monthly tracking showing rates that fluctuate between 0% and 6%. If the rate jumps from 1% to 3% from January to February, this cannot be taken as indicative of anything other than statistical variation unless the confidence intervals are narrower than these fluctuations. In this example, there would have to be 1120 patients at risk per month to reduce the 95% confidence interval to $\pm 2\%$.[153] Fewer are needed if the AE rate under consideration is higher, and if wider confidence intervals will suffice to convince oneself that the observed changes are real. A related issue in interpretation of comparative statistical performance data is the phenomenon of regression to the mean.[154] This principle tells us that if a performance indicator is either high or low at one time, due to innate statistical fluctuation it will tend on the next measurement to be more intermediate. Thus it is important not to overinterpret short-term changes in performance measurements.

A very important issue is that all these parameters are strongly influenced by patient demographics, comorbidities, and type and severity of acute illness, cumulatively referred to as case-mix. This may be true even for institutional outcomes such as staff satisfaction.[155] While raw data are "correct," they are problematic for comparing ICU performance between different time periods (a primary element of PI) if there have been important changes in case-mix. For example, an increase in ICU mortality over time may not represent worse care if sicker patients were admitted in the second epoch. Even the seasonal differences that occur in some critical illnesses[156–158] can create this problem. Case-mix differences are even more important in comparing performance between different ICUs.[76,159,160] Thus it is important for PI efforts to collect at least some case-mix data.

Within a single ICU the simplest way to handle this potential problem is to collect and compare case-mix data for the separate time periods under consideration. When appropriate to the performance issue being surveyed, comparisons might be made in the same season of successive years. If the case-mix variables are similar in the different intervals, then it is reasonable to believe that the performance comparisons are valid. The argument against this simple approach is that finding similarity among any given number of case-mix variables cannot exclude the possibility that there are other differences between the cohorts that remain undetected. While the point is valid, this simple approach is reasonable and the only practical one in many institutions having limited resources for PI efforts.

The case-mix variables chosen for assessment should follow the purpose of the PI project. For general purposes it is straightforward to record patient age, gender, race, the presence or absence of important comorbid states, and the organ system most responsible for ICU admission. With more data collection resources one should consider collecting socioeconomic variables such as insurance category (e.g., private or Medicare vs. Medicaid vs. none),[161–163] and measures of severity of illness such as the Acute Physiology and Chronic Health Evaluation (APACHE) score, TISS score, or Multiple Organ Dysfunction Score (MODS).[96,152,164] Special case-mix variables should be chosen for special purposes. For example,

measuring outcomes of mechanically ventilated patients might lead one to record each patient's initial Pa_{O_2}/FI_{O_2} ratio as a measure of the severity of respiratory failure.

When the case-mix is not similar across time periods, it is best to make adjustments for the observed differences. A common method is to use one of the available ICU risk prediction systems.[100,165,166] Some of these, such as APACHE, the Mortality Probability Model (MPM), the Simplified Acute Physiology Score (SAPS), and IMPACT are for general adult ICU patients,[164,167] the Pediatric Risk of Mortality (PRISM) score is for general pediatric ICUs,[168] and others have been developed for specialized subsets of critically ill patients such as trauma or cardiac surgery patients.[169,170] These systems use equations derived from multivariable linear modeling of demographic and clinical data that predict one or more outcome variables for each patient by comparison with the large inception cohort of ICU patients used to create the equations (see Chap. 6). Nonlinear models achieve similar predictive power.[171] This approach is, in effect, an application of benchmarking against the outcomes in the inception cohort.[146,172] Most of these systems explicitly generate scores reflecting the severity of illness that are used within the equations. These scores should not be confused with the predictions, but are themselves good and convenient tools for evaluating case-mix as described above.

Unfortunately, these systems are very limited, and most of them only predict short-term mortality. This can be used to measure performance using the standardized mortality ratio (SMR). The SMR is calculated as the observed mortality rate of an ICU cohort divided by the average mortality rate predicted by the equations. The SMR is thus a death rate that is case-mix–adjusted by comparison with the original inception group.[77,165,166] Though unable to predict individual outcomes with sufficient accuracy to evaluate care for a given patient,[173,174] these perform reasonably well for groups of patients.[6,165,167,175–177] Other than short-term mortality, the list of performance measures for which validated prediction equations allow case-mix adjustments is short. The proprietary APACHE III system predicts ICU length of stay, days on mechanical ventilation, and the likelihood of receiving "active" intervention, though there has been published validation only for length of stay.[54] Similarly, in pediatrics the PRISM investigators have published a prediction of ICU length of stay.[55] Validated, ready-made tools to case-mix adjust the other important ICU performance measures do not yet exist.

Even for the few performance parameters included in these systems, there are problems related to calibration,[159,160,173] accuracy within some diagnostic subsets,[173,178] generalizability to other countries,[179,180] aging of the inception data set,[166,181] and even their utility in measuring performance.[176,182] In addition, none of these systems adjusts for nonphysiologic parameters that may be important determinants of outcomes, such as socioeconomic factors. While the older versions of these systems are in the public domain, some of the most current and usable ones, such as APACHE III and Project IMPACT, are proprietary and expensive.[183,184] It should be noted, however, that updating to the latest version often produces only modest increases in predictive power over earlier versions in the public domain.[177,185,186]

All of the prognostic systems mentioned are prospective. Predictions are generated from data available at the outset of the ICU admission, representing the clinical situation before ICU care was provided. However, use of commercially available, retrospective prognostic systems based on administrative or claims data is growing, in some cases mandated by governmental regulatory agencies. Many of these methodologies factor information about events that occurred during the course of care into the predictions. This represents a fundamentally flawed approach to evaluating performance and should not be used for this purpose. Not only is the accuracy of administrative databases problematic,[187–189] but such an approach is not capable of distinguishing whether poor outcomes are due to bad care or to pre-existing severity of illness.[76,187,190] Thus an ICU where many patients die due to avoidable complications could fail to be identified as a poor performer by a system that incorporated those complications into its prediction of the risk of death.

A more flexible approach that allows customized case-mix adjustment of any numerical performance parameter is to create your own multivariate regression analysis.[152,191] With the performance measure as the dependent variable, the case-mix variables as covariates, and an indicator variable to represent the different time periods, this avoids many of the disadvantages of the ready-made systems. The magnitude and statistical significance of the coefficient for the time period indicator variable then informs whether there has been a change in performance after adjusting for case-mix. A relatively simple implementation might include covariates of age, gender, race, important comorbid states, the organ system most responsible for ICU admission, and a measure of severity of illness. This approach requires some expertise in computer applications and statistical methods, but can be implemented within individual ICUs.[192]

Special comments must be made discouraging the use of diagnosis-related groups (DRGs) in PI efforts. In most hospitals, the DRG choices are not made by clinicians, and contain significant inaccuracies.[193] In addition, the DRG on hospital discharge is generally chosen to maximize reimbursement, and need not bear any relationship to the reason for ICU admission. Indeed, it may reflect a potentially avoidable complication of care.[194] Likewise, the admission DRG may not represent the reason for transfer to ICU.

In summary, every ICU should collect cumulative data on a variety of relevant measures of ICU performance. Efforts must be made to ensure the accuracy and completeness of the data collected. The data should be used to calculate summary measures, such as rates or means, for the patient cohort being assessed. Sufficient data must be accumulated to make these rates meaningful. At least some case-mix parameters should be collected as well. If there are substantial differences in case-mix between cohorts being compared, then some adjustment should be made for these differences. However, in the real world, the resources needed to collect and adjust for case-mix may exceed those available, requiring dependence on unadjusted data. In addition, the methodologies used for case-mix adjustment are not perfect. Such limitations should not lead to nihilism and inaction. Though unadjusted data could be misleading, it cannot possibly be more misleading than having no performance data at all. Similarly, adjustments made with the best available, though imperfect, methodologies are better than raw data.[195] Since the most common kind of performance comparison done in a single ICU is between two or more time intervals that are contiguous or nearly so, most of the potential difficulties in data interpretation mentioned

above (except for the issue of seasonal variation) are probably of little significance.

Improving Intensive Care Unit Performance: Conceptual Framework

Improving ICU performance in a given area involves sequential steps of: (1) measuring indices of ICU performance relevant to that area, (2) making one or more interventions aimed at improving those measures, and then (3) remeasuring the indices to document the effect of the intervention.[196] Measurement is discussed above. This section will develop a framework for understanding the scope and nature of change.

There are two main domains of change for improving ICU performance. These are the technical components of ICU care, and the organizational features of the ICU. Both medical training and literature almost exclusively emphasize the technical. Thus the attention of clinicians is dominated by choices such as ventilator settings, vasopressors, imaging modalities, and the angle of the bed during tube feeding. While these are important, changes to ICU structures and processes are given little attention, but are at least as significant.[194] Indeed, it requires extensive organizational change to ensure effective, uniform application of the technical choices.

A useful framework for addressing technical interventions to improve care in individual ICUs is adapted from Berwick.[197] He tells us that we must: (1) know what works, (2) use what works, and (3) do what works adeptly. Knowing what works amounts to reading and understanding the literature. This includes recognizing the limits of current knowledge. With estimates that only 10% to 20% of medical practices are supported by rigorous studies,[91] many diagnostic and therapeutic interventions are used in the absence of clearly demonstrated efficacy. Many studies focus narrowly on physiologic efficacy instead of relevant outcomes.[198] Also, understanding and correctly interpreting the literature is impeded because many physicians lack the statistical and logical skills needed for such critical evaluation.[198,199]

As problematic as is our state of knowledge, the single most important deficiency in health care today is ensuring that we use what works, and do it well.[3,24,200] Even seminal studies in the most widely read journals often do not change practice.[201] To understand this deficiency, it is necessary to recognize that these things do not happen by themselves. Ensuring that all patients uniformly receive every applicable evidence-based "best practice" requires a paradigm shift. The historical, physician-centered paradigm holds individual physicians entirely responsible and free to guide care as they see fit, regardless of whether their choices concur with best practices, and independent of outside oversight except the risk of malpractice suits. Kassirer states that "...when it comes to setting standards of accountability and ethical behavior, our professional organizations and medical institutions have often faltered. In the guise of accountability, their efforts have often yielded lax standards that were intentionally and flagrantly self-serving."[202] Such a system, in which patients are entirely dependent on the knowledge and memory of their physicians, is not rational, and is not in the best interests of the patients or the clinicians. As Wennberg states: "the 'system' of care in the United States is not a system at all, but a largely unplanned and irrational sprawl of resources."[107] There are too many important things to know and remember to reasonably expect that any individual physician will always do all the right things. Even simple, universally accepted practices such as giving aspirin and β-adrenergic blockers to patients with acute myocardial infarction are often forgotten, leading to many unnecessary deaths.[203] This is not an indictment of physicians—it is unreasonable to harbor such expectations in the modern medical environment. Instead, it is necessary to create structures and implement processes that ensure that every ICU patient, every time, receives all applicable evidence-based practices. Doing so will ensure, for example, that no mechanically ventilated patient receiving tube feedings will fail to have the head of the bed elevated to reduce the risk of nosocomial pneumonia because their physician forgot to write that order among the dozens that were written.[204]

But ensuring the uniform application of beneficial medical practices is not the only reason we need to re-engineer ICU organization. ICUs are complex systems, and it has been known for many decades in the industry that "the structure of a system significantly determines the performance of the system."[205] By emphasizing that most opportunity for improving performance derives from altering the system itself, Deming, Juran, and others created the most effective method known of improving the performance of complex systems.[206,207] This methodology of PI, called total quality management (TQM), applies equally well to service industries such as health care,[205,208–210] and tells us that making changes in ICU organization offers opportunities to improve performance that are equal to or greater than the gains from purely technical improvements.[211–213] Though the systems approach of TQM is largely alien to health care, it is the recommended method of PI.[146]

The concept of TQM began with the seminal recognition that only 15% of errors and problems are a result of inadequate performance by individuals. Rather, 85% of the opportunities for performance improvement relate to flaws in institutional systems and processes that hinder the ability of individuals to perform their jobs well.[206] As stated by Berwick,[209] these original thinkers understood that problems had:

> ...been built directly into the complex production processes they studied, and that defects in quality could only rarely be attributed to a lack of will, skill, or benign intention among the people involved with the processes. Even when people were at the root of the defects, they learned, the problem was generally not one of motivation or effort, but rather of poor job design, failure of leadership, or unclear purpose. Quality can be improved much more when people are assumed to be trying hard already, and are not accused of sloth.

TQM is about improving the *systems* that are used to deliver ICU care. It is a continuous and relentless process of examining and improving *structures* and *processes*[194] for the purpose of improving relevant outcomes. It is driven by systematically collected and appropriately interpreted data on outcomes.[208,210,214] In TQM *every* structure, process, activity, function, and relationship, clinical and nonclinical, that influences the ICU in any way is open to scrutiny and change. Table 3-2 contains an illustrative list of areas for scrutiny.

Examples will aid in making these concepts more concrete. Evans and colleagues developed a computerized antibiotic

TABLE 3-2 Potential Areas for Improvement in the Intensive Care Unit

- The need for a function
- How a function is performed
- Which personnel perform a function
- The functional relationship between personnel
- How personnel communicate with each other
- The existence, frequency, and nature of ICU rounds
- The role of equipment (including computers)
- The interactions between personnel and equipment (including computers)
- The administrative, medical, and functional structures of the ICU
- The administrative, medical, and functional structures of personnel who provide care in, or support to, the ICU
- The rules governing responsibilities, practice privileges, etc
- The training, skills, competence, knowledge, and experience of personnel
- The scheduling of personnel, including shift coverage, night coverage, and weekend coverage
- Workload per worker
- The availability of supportive technology in the hospital (e.g., advanced imaging)
- The choice of products and services used in the ICU
- The number of ICU beds
- The physical layout of the ICU
- Availability of intermediate care and ward beds
- Availability of outcomes data to the ICU and hospital community
- Availability of outcomes data to public

consultant, available from every hospital workstation, to assist physicians in the selection of appropriate empiric antibiotics.[215] They found that this increased the adequacy of the initial antibiotic choice from 77% to 94%, and that the delay in ordering adequate antibiotics was reduced. Leape and coworkers altered the structure of morning work rounds in an ICU to include the participation of a senior pharmacist.[216] This simple structural change reduced avoidable drug errors by 65%. Bernstein found that what at first glance seemed like the ultimate in individual human error, surgery on the wrong side of the body, actually represented inadequacy of the procedures that should have been in place to prevent this problem.[217]

TQM views performance as a moving target that can be improving all the time, even in the absence of identified problems. Benchmarking, most simply against performance in the same ICU at earlier time period, allows for realization of this goal. TQM does not respect existing professional standards; rather it continually demands development of new ones that are more effective and efficient.[210] The purpose is to reduce waste, rework, and complexity, while improving relevant outcomes, reducing costs, generating loyalty, and creating a climate of teamwork.[208,209]

Shifting the focus from identifying and remediating defective workers, to identifying and re-engineering defective structures and processes is necessary to correct "the defects that we have built into our complex medical systems . . . the waste we encounter in outmoded habits, the rework we pay for when things fail to work correctly the first time, complexity we build into our processes for no good reasons at all, the random and unpredictable variation from our predicted aims."[197] One result of TQM is that it becomes easier for people to do their jobs right, and harder for mistakes to occur.

An important tenet of systems engineering is that organizational performance inevitably deteriorates unless the structures and processes of the organization evolve along with the needs they must serve. The most natural way to cope with a changing environment is to supplement the structures and processes already in existence; as demand grows, the system gets multiplied to scale. However, such growth by accretion inevitably leads to a cumbersome, inefficient system. What is needed instead is evolution of new systems and processes that match the new environment. Obviously, the nature of ICU patients and ICU care, as well as the size of ICUs, has changed dramatically over the years, and projections show that this growth will continue.[127] But the organization of many ICUs is not the result of thoughtful planning driven by improving outcomes, but rather reflects their historical origins and subsequent growth by accretion. As a result, their organization is inadequate to support the current demands.

The systems-oriented strategy of TQM is very different from the quality assurance/quality improvement (QA/QI) method that is still used in many ICUs. QA/QI responds to adverse events, errors, or other problems that are found. Obviously, problems are found only after they occur, and so QA/QI is reactive, instead of proactive. Leadership then convenes a group, usually composed of supervisory-level personnel, to do "root cause analysis." Most commonly, this takes the form of trying to identify the errors made by individuals who allowed the problem to occur. The morbidity and mortality conference held regularly in most institutions is an example of such a flawed approach to improving quality.

In fact, both components of QA/QI, identification of problems and errors, and root cause analysis, are fundamentally deficient. QA/QI relies on occurrence screening to identify problems.[145,218] This can take the form of medical record reviews, incident reporting, or use of prospective indicators. An example of an indicator is a document that bedside nurses complete when a mechanically ventilated patient is inadvertently extubated. Retrospective occurrence screening using the medical record is limited by the many inadequacies of that document as a window into actual events.[187] Incident reporting is also an inadequate method of identifying adverse events in hospitals. Only a small fraction of adverse drug events are identified by incident reports,[147,148] and a study of direct observation in an ICU estimated that only about half of errors were reported.[36] So-called audit filters, groups of prospectively defined and collected occurrence screens, are of low sensitivity.[219,220] Even prospective occurrence screening can obscure the magnitude of a problem, due to the changes individuals make in their behavior when they know that they are being watched, known as the Hawthorne effect.[221] In addition, medical care is so complex and variable that screening for even a large list of specific occurrences is unlikely to have much impact on overall performance.

Root cause analysis is a process in which medical professionals who are knowledgeable in the area under consideration perform a detailed review of an adverse event to identify its causes. As stated by Berwick:[222]

> Even when hospitals find ways to notice the injuries to their patients, their theories of cause often remain scientifically Neanderthal. They cling to unsound but deeply entrenched beliefs. They believe that bad people cause bad errors. . . . They believe that retrospection will allow them to find a single root cause,

> even though in fact the very idea of a "root cause" is misleading, since most system failures result from complex interactions between latent failures . . . and specific actions; conclusions about root causes are often illusions created by hindsight bias.

One reason for the ineffectiveness of root cause analysis is that there is very poor agreement among experts about the causes, and even the occurrence, of adverse events.[34,149,150] The poorest agreement is for identifying management errors or negligence as the cause of adverse events.

QA/QI is about meeting minimum standards, detecting poor performance by individuals, and taking punitive actions. It is "at best inefficient, and at worst a formula for failure."[209] Despite prolonged and extensive use, there are almost no published data showing that health care is improved or behavior changed by PI methods that target individuals rather than structures and processes.[223] Chassin concludes that there is a "paucity of evidence that, as a whole, previous quality-assurance programs actually did anything to improve outcomes for patients."[224]

Implementing a Total Quality Management Program in the Intensive Care Unit

The ICU is an opportune place to establish a TQM program. ICUs are usually physically localized, well-defined entities that often already possess high degrees of organization. Compared with many other parts of the health care system, there are fewer people working there, making it easier to effect the necessary indoctrination into TQM concepts and to include a substantial fraction of personnel directly in the TQM process. Also, compared to other areas of health care, there are fewer confounding variables, with a relatively high degree of control over them. Methods to adjust for case-mix variation are more highly developed for ICUs than almost any other area of medical care.

TQM is a complex process. Implementing it in a hospital or ICU requires substantial commitments of leadership, resources, and time. It is estimated that 3 to 5 years are needed to adopt and fully institutionalize a new TQM program.[210] Outside assistance can be helpful. This can come from a similar institution that has been successful in creating a TQM program, or by contracting with a consulting firm. Specific training is needed for those who will lead the effort. While a complete delineation of its methods is beyond our scope, this section will outline important issues in the implementation of TQM.

Meaningful participation of every type of ICU personnel in TQM is needed because both performance and improvement are recognized to be shared responsibilities. Since the best people to identify and solve problems are those directly involved in them, the basic functional unit of TQM is the multidisciplinary quality team. Unlike most other PI efforts used in health care, TQM is not controlled by clinicians, though obviously they are included in it. Thus for PI purposes, TQM replaces managerial authority with a participatory approach that emphasizes collective rather than individual responsibility.[210]

Initiating a TQM program within an ICU is difficult, though not impossible, without the existence of a hospital-wide TQM program. In the following five-step outline for implementing TQM in an ICU, it is assumed to be part of such a larger effort.

The first step is that top leadership must take the lead. Those at the top of the administrative and medical hierarchy must make an overt and highly visible commitment that TQM is a clear priority. They demonstrate this by providing the leadership, encouragement, and economic and political support necessary for the institution to evolve into a "TQM culture." It has been observed that TQM is more readily assimilated in hospitals with corporate cultures that emphasize teamwork and development of human potential, are willing to take risks, and seize on opportunities as they arise.[225]

Second, investments must be made in education and training. Key administrative and medical managers undergo specialized education and training in the methods of TQM that they then bring back to the institution. Those who will act as facilitators for quality teams also require training. Subsequently the entire ICU staff needs to be familiarized with TQM concepts and the blueprint for improvement. Their involvement at all levels is necessary for TQM to succeed, and it is vital to elicit their support. An element of the human equation is that there must not be fear on the part of personnel that TQM is a smoke screen for downsizing, or that the discovery of problems, even of human error, will lead to retaliation.[214,224] The TQM environment must be one of trust. Everyone, from the top to the bottom, must become convinced of the central truth of TQM, that the problems are due to faulty systems, not faulty people. More informed personnel will be more motivated and better participants. Part of the framework for success is that the institutional leadership finds ways to encourage, recognize, and reward individuals who participate effectively.

Third, investments must be made in data gathering and analysis capabilities. As discussed in detail above, TQM requires extensive measurement and statistical analysis of performance parameters. Therefore these functions must be given the necessary institutional support, and often require the acquisition of additional personnel and/or information systems. This is the most costly part of a TQM program, and must be accepted as the price of becoming serious about PI. Some measures of ICU performance should be constantly gathered as surveillance for commonly recognized problems. Examples include rates of major nosocomial infections and overall ICU length of stay. Others are collected for limited times related to a specific PI project. Caution is indicated regarding use of existing clinical personnel to collect data. Because they are in the best positions to accurately collect certain types of data, bedside nurses, respiratory therapists, and physicians can be involved in this part of TQM. However, it is necessary to resist the cost-saving impulse of placing the major burden for data collection on clinical personnel who are already overloaded with work, and who lack special training in this area. Resentment and failure of the program can result if the hospital's top leadership does not provide adequate economic support for TQM.

Fourth, a TQM leadership team for ICU performance is formed. Made up of a multidisciplinary group of administrative, clinical, and nonclinical personnel, this group coordinates TQM activities. It (1) solicits, develops, and prioritizes proposals for areas to be surveyed; (2) selects and supports

the individual quality teams created to work on areas of interest; (3) contributes to the choice of primary and surrogate performance measures used to assess ICU performance; and (4) facilitates implementation of proposals for change. Areas given priority often are those that represent high volume, possess high risk, or are perceived to be a problem.

Last, and most importantly, TQM quality teams (QTs) are created and trained. An appropriately constituted QT addresses the area of concern assigned to it by the leadership team. QTs must be of manageable size, usually no more than 8 to 10 individuals representing different departments and different levels. Each QT must be constructed to include all the expertise and experience needed for thorough understanding of the inner workings of the area or topic under consideration. This dictates that the teams be heavily weighted with lower level personnel who actually do the work. No group of ICU workers should be omitted when relevant to the performance issue at hand. For example, housekeepers are an important component of infection control efforts. They, as well as unit clerks and other nonprofessional personnel play important roles that must be addressed within QTs. QTs comprised primarily of managers and physicians are usually doomed to fail because they lack truly intimate knowledge of the systems that make the ICU work.

An ICU may have one or more QTs. A QT may be permanent, or it may be constituted to address a given area, then disband. In smaller ICUs there is often nearly complete overlap between the membership of the leadership team and the quality team.

One person who has undergone TQM training functions as the QT's facilitator. The facilitator guides the group in its central functions: (1) brainstorming to break down the topic of concern into its component structures and processes,[208,226–228] and (2) identifying practicable ways to modify or replace those components to improve the relevant outcomes. This procedure typically requires measurement of the relevant outcome parameter of interest, and of surrogate measures related to the structures and/or processes. With institutional support, data are collected, case-mix adjusted if necessary, statistically analyzed, and displayed to illuminate important relationships.[228] Following implementation of changes, the performance parameters are remeasured to document improvement.

The focus of a QT can range from big to small. One may be convened to deal with an unusually high rate of death among mechanically ventilated patients. The death rate is the primary, relevant end point, but this team's scope and range will include a large number of structures, processes, and procedures used in the care of such patients. Data collection will be a formidable task for this team. Another team may be asked to find ways to decrease conflict about roles between nurses and respiratory therapists on the night shift.

QTs are potent tools for improvement. In the process of their assigned task they often identify other cumbersome or otherwise deficient processes, even if no obvious error has been related to them. Such proactive problem solving should be encouraged by endowing the QTs with considerable latitude of scope. When embarking on an assigned task, QTs should be encouraged to think expansively. No arbitrary limitations should be placed on what may be altered to improve performance.

In starting their work, QTs should perform a literature review to identify what is already known about the topic under consideration. Practices of proven effectiveness should be incorporated into the structures and processes of every ICU. For many major topics there have been systematic reviews of the literature that can serve as a starting point. However, it is often necessary for one or more members of the QT to review the original studies and summarize the findings for the entire team.

The role in TQM of analyzing individual adverse events deserves mention. As discussed above, such analysis cannot serve as the primary method of PI. However, within an active QT, discussion and analysis of individual events can effectively focus the attention of the group, and assist in identifying the structures and processes that require alteration.[229] For this reason, it is still important that ICUs work to identify individual errors and other problems. Morbidity and mortality conference reviewing of each death and major adverse event is recommended, but its limited place within the larger context of TQM must be explicitly understood. There has been much discussion recently of improving error reporting in health care by creating a nonpunitive environment based on the systems and principles of TQM.[230] Such approaches have proved successful in the airline industry and elsewhere.[231]

There are significant challenges to implementing a TQM system in the ICU. These include substantial time commitments, financial investments, and commitment of top leadership in the ICU and hospital. Often the largest impediment to successful implementation of TQM is resistance from physicians. Physicians frequently respond to objective results about performance by insisting that the data are inaccurate, and usually resist proposals perceived as abridging their professional autonomy.[200] One contributor to this resistance is that their training and work experience generally do not instill physicians with the concepts of systems engineering. While there are a number of ways to try and change physicians' habits and performance,[232] the evidence amply demonstrates that this is difficult.[233–235] Nonetheless, gaining physician acceptance and participation in any TQM effort is necessary. Various strategies to achieve this goal have been discussed elsewhere.[208,228] One particular experience of note was the effort of the Cleveland Health Quality Choice consortium to gain provider and purchaser confidence for its hospital quality efforts.[236] Adapting its approach to the problem of gaining physician confidence in TQM would emphasize: (1) a large-scale effort to incorporate large numbers of physicians in the process from the start, especially those considered opinion leaders; and (2) sensitivity to physicians' concerns about presentation of data in ways that could be perceived as dangerous or threatening to their practices. The role of vigorous physician leadership in this regard cannot be overstated.[237]

Despite the difficulties, successful examples of implementing TQM in the ICU are there for emulation. Investigators at Intermountain LDS hospital in Utah described TQM implementation in their medical/surgical ICU, with extensive utilization of information systems support.[211] They reported improved cost effectiveness, comprised of an 18% reduction in costs, with no change in case-mix adjusted mortality or length of stay. A regional TQM initiative in New England reduced hospital mortality after coronary artery bypass surgery by 24%.[213]

Specific Strategies to Improve Performance

Improving ICU performance requires making organizational changes. A modest but growing body of research has studied strategies to improve performance via organizational changes in health care systems. These strategies range from simple to complex, and address widely differing aspects of change. They fall loosely into two categories: (1) strategies to increase use of evidence-based best practices, and (2) changes in structures and processes that are *not* directly related to the technical aspects of medical care. The former include education, clinical practice guidelines, reminders, audit with feedback, ordering policies, and combinations of these individual interventions. The latter are a diverse group of interventions. This section reviews much of that literature as it is applicable to ICUs. Strategies found to be effective in research studies are convenient, ready-made tools that individual ICUs can adopt, and are likely to be effective within their own TQM efforts. Of course, interventions that were effective in one setting may not be so in a different setting; as in all changes made under TQM, it is best if their local efficacy is demonstrated by local data.

STRATEGIES TO INCREASE USE OF EVIDENCE-BASED BEST PRACTICES

Didactic educational interventions are the traditional method of teaching health care practitioners how to optimally care for patients. Continuing medical education (CME) is a requirement for health professionals in most venues. Recently, Davis and coworkers published a systematic analysis of studies assessing the efficacy of traditional didactic CME methods, such as conferences, rounds, meetings, and symposia.[238] They found that the quality of these data is poor, that any benefit present was small and apparently limited to CME interventions having interactive elements. Another review of the topic also concluded that passive educational methods did not improve physician performance or patient outcomes.[233] One must be careful in reading this literature, because in fact the analyses that seem to show more impressive gains from CME have mixed together didactic education with other modalities such as reminders and audit with feedback.[239]

Practice guidelines represent attempts to increase use of evidence-based best practices by making available to clinicians a set of recommendations for care. The concept is born of the belief that these practices are omitted because clinicians are not aware of them. They can be simple, or complex and comprehensive. They have been promulgated by professional organizations, governments, consulting firms, HMOs, hospitals, and other groups. Many physicians harbor negative attitudes about practice guidelines.[240] In evaluating this body of literature, it is important to distinguish studies that assess clinically relevant outcomes from those that evaluate the surrogate of compliance with recommended patterns of care. This is especially important because many or most published guidelines fall short of the desirable features of practice guidelines.[241–244] While some studies of guidelines have demonstrated improvement in outcomes, most have found that the guidelines are of limited effectiveness without concomitant use of other strategies.[233,243] Numerous factors have been shown to influence acceptance, use, and effects of practice guidelines. These include their complexity, manner of dissemination, local input into their construction, characteristics of the targeted practitioners, and the ease with which they are accessible at the bedside.[233,242–243,249] Nonetheless, it is quite reasonable that practice guidelines be used as tools of ICU TQM, with attention to these acceptance factors, and in conjunction with other strategies.

Because the number of best practices that modern clinicians are expected to remember and implement is prohibitively large, automatic reminders could be a powerful tool to improve ICU performance. The bulk of evidence identifies reminders as one of the most effective methods of improving adherence to best practices.[233,242] The major limitation of this concept is effecting reliable and timely delivery of reminder messages to clinicians. Reminders can be delivered to clinicians in a number of ways. The most promising is via computers, as discussed below.

Audit with feedback can be defined as any summary of clinical performance of health care over a specified period of time that is communicated back to practitioners. These may or may not include recommendations for clinical action. Recent systematic reviews have concluded that this body of literature is of poor quality, and that while audit with feedback appears useful, the effects are small.[250,251] Isolated studies have, however, observed substantial benefits from audit with feedback. Eagle and associates reported that it led to economically relevant reductions in length of stay for patients admitted with chest pain, congestive heart failure, or syncope in three medical ICUs.[252] A review of 26 studies found that audit with feedback was less effective than reminders.[233]

Another potential method of ensuring best practices is to create groups of orders that have those practices built into them. The ICU is an opportune locale for such an approach by virtue of: (1) the relatively limited subset of diagnoses that gain a patient entry there, and (2) the applicability to many patients of a small set of proven safety practices. Sets of ICU admission orders can easily be created, either on paper or computer, to include by default orders such as prophylaxis against stress gastritis bleeding for patients who are mechanically ventilated.[253]

A recurrent theme seen in studies to improve use of best practices is that combining multiple strategies is more effective than the use of individual ones.[211,213,233,242,254]

CHANGES TO INTENSIVE CARE UNIT STRUCTURES AND PROCESSES NOT DIRECTLY RELATED TO TECHNICAL ASPECTS OF CARE

Table 3-3 summarizes a substantial portion of this literature. The interested reader who uses the listed references for further information will note that evidence-based information is sparse for some of these topics, with conflicting data for others.

The most prominent and best studied of these topics addresses whether the ICU is "closed" or "open." These terms refer to whether or not all the patients in the ICU at a given time are under the care of a single attending physician. Several groups of investigators have shown that outcomes are superior in closed ICU systems.[298–302] However, there are multitudinous organizational differences between different ICUs,[303] and the seemingly simple issue of closed vs. open is interrelated to considerations such as: (1) involvement of subspecialists in critical care medicine, (2) the relative roles

TABLE 3-3 Literature Assessing the Effect of Structures and Processes on Outcomes

Structure or Process	Reference Numbers
Open vs. closed ICU structure	255, 256
Telemedicine	257
24-Hour intensivist presence	258
Length of shifts for ICU physicians	259
Nighttime cross-coverage by house officers	260
Role of the ICU's medical director	261
Availability of an intermediate care unit	101, 102
Pharmacist participation in ICU rounds	262
Utilization of advanced nurse practitioners	263–266
Nurse:patient ratio	267–273
Formation of a ventilator team	274
Supplying cost information to ordering physicians	275–277
Disallowing standing orders	254, 277, 278
Infection control processes	279–281
Dissemination of performance data	262, 282, 284
Family visiting hours	285–288
Palliative and end-of-life care	7, 289–293
Nurse-physician communication and other aspects of ICU culture	254, 273, 294–297

TABLE 3-4 Benefits of Information Technology in Intensive Care Unit Performance Improvement

- Acquire, integrate, store, analyze, and display information
- More efficient and less error-prone entry of orders
- More efficient, available, and legible entry of progress notes and other patient information
- Make clinical data more readily available
- Make knowledge more readily accessible
- Facilitate availability and use of clinical practice guidelines
- Facilitate communication
- Provide clinical reminders
- Assist with calculations
- Assist with clinical monitoring
- Continuous, real-time monitoring for complications, adverse events, etc
- Provide decision support
- Automated assistance with technical aspects of care
- Verify correct administration of medications, blood products, etc (e.g., via bar coding with bedside scanning)
- Facilitate data collection and case-mix adjustment for total quality management purposes

of the intensivist and the primary attending physician, (3) the presence of residents and critical care fellows, (4) the existence and nature of daily rounds for ICUs having house staff, (5) the role of the ICU medical director, and (6) differences between daytime and nighttime physician coverage. Interpretation of this literature is problematic because: (1) intermixing of these interrelated topics leads to many gradations between open and closed ICU structures; (2) there is substantial variation in study design, outcome parameters assessed, and case-mix adjustments among published studies; (3) many of the individual investigations suffer from weak study design; and (4) the possibility of publication bias. A recent systematic review of these topics avoided restrictive definitions of open vs. closed, and instead analyzed 26 studies according to whether intensivists were involved in a fashion rated as high intensity (defined as a closed ICU staffed by intensivists, or a mandatory consultation by an intensivist) or low intensity (no intensivist involved in ICU care, or elective intensivist consultation).[255] High-intensity involvement of intensivists results in lower mortality rates and shorter lengths of stay. After case-mix adjustment, no individual study observed worse outcomes with more intensivist involvement in care. Another study concluded that high-intensity involvement by intensivists in care of all ICU patients in the U.S. would save almost 54,000 lives per year.[256] Trying to fill the evidence-based policymaking void present in U.S. health care, a consortium of large businesses, The Leapfrog Group, is attempting to improve hospital outcomes for its employees by making high-intensity involvement of intensivists in ICUs a requirement for any hospital to contract with their health plans.[304]

Information Systems in Intensive Care Unit Performance Improvement

Computers and other information technologies are powerful tools for improving ICU performance. Unlike people, computers can keep track of almost limitless amounts of information, never forget, and are essentially flawless in doing their assigned tasks. Table 3-4 lists some ways that computers can advance PI efforts in the ICU. Although there are as yet few studies evaluating whether such technologies improve ICU outcomes,[305] their further development and widespread diffusion will likely be necessary for improving health care.[200]

Computers have facilitated access to clinical data for several decades. In most hospitals clinicians can obtain laboratory and other test results on terminals throughout the hospital. More recently, many hospitals have bought picture archiving communications systems (PACS), making it possible to view radiologic images without leaving the ICU. Although there is conflicting evidence that PACS lead to more timely viewing of images by clinicians,[306,307] they do make viewing more convenient and save time.[308]

Keeping track of patient-related information is an ever-increasing challenge. Data about ICU patients originate from observations and manual measurements made by health care workers, bedside monitors, the laboratories, radiology, devices such as infusion pumps and ventilators, progress notes, clinical flowsheets, the hospital information system, and other sources. In most ICUs, collecting this mass of diverse information requires physicians to read paper records, use several different computer systems, and leave the ICU to obtain information residing elsewhere. This situation makes it difficult and inefficient for clinicians to acquire and integrate all the necessary data, and is obviously prone to oversight and error. Only highly competent computer systems can solve all of these problems.[309] Via various interfaces, such systems[311,312] can automatically acquire data from electronic connection to bedside devices and other computer systems in the hospital, and manual input via bedside workstations. They can display the data as customizable tables and graphs that people can understand and use at any enabled workstation, including those at remote locations via the internet. Because of these advantages, electronic, paperless medical records should become increasingly common.[312–314] The future likely includes use of

hand-held devices for wireless remote access to clinical data, and more rapid communication to clinicians of problems such as critical laboratory values.[315]

Computer technologies have vastly improved access to sources of medical knowledge. Textbooks, databases such as MEDLINE, full text journals, and other authoritative sources are widely available around the clock from internet-ready terminals in ICUs. It no longer requires a time-consuming trip to the hospital library to learn state-of-the-art answers to clinical questions about the patient who just arrived in the ICU. An increasing amount of medical knowledge is even more conveniently accessible within software for hand-held devices.[316]

Errors in order writing are the most common sort of medical error.[32,317] Handwritten orders suffer from illegibility, mistakes in transcription, erroneous dosing, and other ills. Computerized order entry dramatically reduces such errors[319,320] and can reduce costs.[320] Computerized order entry is already relatively common and increasing in prevalence, driven by safety concerns of influential organizations such as the Leapfrog Group.[304]

As discussed above, reminders and clinical practice guidelines are strategies to increase use of evidence-based best practices. However, both are limited by problems making the information available to clinicians in a reliable, convenient, and timely way. Information systems can solve these problems. Each time a physician, nurse, or respiratory therapist logs on to the computer for any purpose is an opportunity to deliver a reminder message or offer up a relevant guideline. Having these occur during order entry makes it especially easy for the clinician to execute orders to act on the reminder or initiate the guideline's protocol. Simpler implementations of this concept would be triggered by the order being written.[322] For example, a computer-generated reminder could be displayed to order elevation of the head of the bed every time a clinician orders tube feedings.[204] Intelligent systems with access to other patient data residing in the electronic medical record are required to allow this concept to achieve its fullest potential. An integrated ICU information system linked to both the ventilator and the electronic medication administration record could identify that a patient is mechanically ventilated and not receiving prophylaxis for stress gastritis,[322] and automatically generate a reminder. If the patient was receiving sedatives, the computer could suggest use of the ICU's sedation protocol[323,324] and automatically generate the necessary orders for the clinician to implement. Currently, only sparse evidence exists about the effect of such systems. Computerized reminders have demonstrated benefit in most[321,325] but not all[326] studies. Studies of complex interventions that included computer-aided practice guidelines have observed improvements in care or reduced costs.[211,245,327]

Extending these uses of information systems is computer-aided decision support (CADS). In CADS, systems having electronic access to patient data provide clinicians with expert medical advice. Take the example of a physician doing computer entry of an order for gentamicin. Combining the latest creatinine value from the laboratory, the patient's weight from the daily nursing notes, and age from the admitting department's computer, the computer system estimates pharmacokinetic parameters and recommends a dosing regimen. When peak and trough levels become available, it would include those in the calculations, and the next time the clinician accessed that patient's electronic medical record, it would suggest revised dosing. These smart systems can help avoid incorrect dosing, and proactively identify drug interactions. Indeed, most studies of CADS have evaluated the effects on choice and dosing of pharmaceuticals. These have found an impressive variety of improvements in clinically relevant outcomes, including better empiric antibiotic choices, better dosing, reduced drug costs, reduction in adverse drug events, and others.[215,320,328–332]

The potential of computers to assist in management of ICU patients extends beyond providing technical advice. A computer linked to real-time monitoring can be programmed to automatically adjust devices such as ventilators and infusion pumps to maintain optimal parameters in a way that would be impossible for humans to accomplish.[333,334] In a recent study of computer control over ventilators in pressure support mode using ordinary closed-loop linear programming, a computer continuously monitoring respiratory rate, tidal volume, and end-tidal P_{CO_2} simultaneously maintained all three within desired limits 93% of the time, while humans did so 66% of the time.[333] Use of fuzzy logic controllers may have even wider ICU applications.[335] The ability of computers to tirelessly monitor and analyze the entire ICU data stream in real time makes them ideal, and superior to people, for tasks such as early detection of physiologic instability, adverse events,[148] and surveillance for care practices outside of established practice guidelines.[336]

In addition to assisting in care of individual patients, computer applications greatly facilitate implementation of TQM. Even within a single ICU, acquisition, analysis, and presentation of the information necessary for TQM is expensive and labor intensive.[194] Setting up the infrastructure for a comprehensive, electronic ICU patient database is an important step that will considerably ease the personnel demands for TQM. Likewise, collection of case-mix variables, and even adjustment for case-mix, can be automated. Manual calculation of scores for APACHE, SAPS, PRISM, or other prognostic systems is cumbersome and time consuming. Computer software linked to hospital information systems can compile, organize, calculate, and store these parameters automatically. Such databases are themselves potent tools for TQM. They can be queried to identify subtle relationships between variables that suggest opportunities for improving performance that are not obvious, even to those intimately involved in day-to-day operations. For example, an evaluation of database information identified laboratory ordering patterns in an ICU that led to policy changes and subsequent cost savings.[246] The best system for TQM purposes would be one that also serves as the electronic medical record and clinical information system for the ICU. Such systems do exist.[311]

Unfortunately, there are currently a number of barriers to widespread use of information technologies to improve ICU performance.[309,315,337] These include a paucity of user-friendly commercially available systems, high costs for those that do exist, a lack of interfacing standards leading again to high costs, and opposition from clinicians. Nonetheless, such highly capable systems do exist, and a few forward-looking institutions have invested in them, to their benefit.[311,338]

Chapter 4

INFECTION CONTROL AND SURVEILLANCE IN THE INTENSIVE CARE UNIT

DAVID K. WARREN
MARIN H. KOLLEF

KEY POINTS

- *Focused surveillance for nosocomial infections is the cornerstone of infection control activities in the ICU.*
- *Commonly used invasive devices such as central venous and urinary catheters and endotracheal tubes are significant risk factors for nosocomial infection. Evidence-based ICU policies and procedures and staff education can reduce the risk of device-related infections.*
- *Antibiotic resistance is an increasing problem, and its containment and prevention require a multifactorial approach, including adequate hand hygiene, surveillance for resistant pathogens, enforced infection control precautions, and prudent use of antibiotics.*
- *Standard infection control precautions should be applied to all ICU patients. Precautions for contagious or epidemiologically significant pathogens are based on modes of transmission.*

Nosocomial, or hospital-acquired, infections result in significant morbidity and mortality. Nosocomial infections have been reported to affect approximately 2 million hospitalized patients in the United States annually, at an estimated cost of $57.6 billion in 2000.[1,2] ICU beds, while only accounting for 5% to 10% of all hospital beds, are responsible for 10% to 25% of health care costs generated.[3] Patients admitted to the ICU have been shown to be at particular risk for nosocomial infections, with a prevalence rate as high as 30%.[4] Given the increasing strain on health care resources in the United States and other countries and the personal impact that these infections have on patients, the prevention of nosocomial infections in the ICU should be an important goal of any critical care clinician.

A likely explanation to account for the observation that ICU patients are more vulnerable to acquiring a nosocomial infection compared with other hospitalized patients is that critically ill patients frequently require invasive medical devices, such as urinary catheters, central venous and arterial catheters, and endotracheal tubes. Data on a sample of ICUs from the Centers for Disease Control and Prevention (CDC) show that adult ICU patients have central venous catheters in place and receive mechanical ventilation an average of 53% and 42% of their total time spent in the ICU, respectively.[5] These devices result in infection by compromising the normal skin and mucosal barriers and serving as a nidus for the development of biofilms, which provide a protected environment for bacteria and fungi. In a survey of cases of ICU-acquired primary bacteremia, 47% were catheter-related.[6] While the increased severity of illness of ICU patients makes intuitive sense as a potential risk factor for nosocomial infection, few studies have shown a consistent relationship.[7] This may be explained, however, by the fact that scoring systems were developed primarily to predict mortality and may not adequately capture markers for nosocomial infection, such as the need for prolonged parenteral nutrition.

Infection control in the ICU arose from hospital-wide infection control programs developed in response to the staphylococcal pandemic of the late 1950s and early 1960s. In 1976, the CDC initiated the Study on the Efficacy of Nosocomial Infection Control (SENIC) to better understand the impact of infection control programs on nosocomial infection rates in a random sample of 338 U.S. hospitals.[8] Programs that had the greatest impact in reducing nosocomial infection rates had the following components: organized surveillance and active intervention in patient care by infection control staff to reduce the risk of infection, a physician trained in infection control methods, a fixed ratio of infection control specialists to patient beds, and a system for reporting surgical infection rate to surgeons. In hospitals that implemented infection control programs meeting these criteria, the incidence of nosocomial infections decreased hospital-wide by 32%, whereas in hospitals with ineffectual programs, infections increased by 18% over a 5-year period. These findings led to regulations requiring that hospitals demonstrate that their infection control programs meet the preceding criteria in order to maintain accreditation.

Surveillance

Surveillance for nosocomial infection is the cornerstone of effective infection control activity in the ICU. Surveillance activity serves several key functions, including the early detection of potential nosocomial outbreaks, the identification of high endemic rates of infection as targets for intervention, and evaluation of the effectiveness of efforts to prevent infection. The process of surveillance itself involves the continuous and systematic collection, tabulation, analysis, and dissemination of information on the occurrence of nosocomial infections within the ICU. It was noted early in the development of infection control programs that feedback of nosocomial infection rates to clinicians, along with active intervention, is a necessary element to a successful program and that collection of surveillance information without this feedback is ineffectual at reducing infection rates.[8] Nosocomial infection surveillance in the ICU involves the cooperation of both infection control and ICU personnel for both exchange of data and developing effective infection control measures.

Infection control surveillance, particularly when it involves chart review, can be labor-intensive. Because of the reality that limited resources are available for infection control surveillance and intervention, a practice known as *focused* or *targeted surveillance* is commonly employed. This involves both hospital infection control and ICU personnel making determinations of the particular nosocomial infections to be monitored routinely. The factors involved in making the decision include the degree of morbidity or mortality that results from the infection, the frequency that the infection is known or perceived to occur in the ICU, the proportion of ICU patients at risk of

Copyright © 2005, 1998, 1992 by The McGraw-Hill Companies, Inc. Click here for terms of use.

becoming infected, the extent to which effective interventions can be implemented by the ICU team, and finally, the perception by both infection control and ICU personnel that a particular infection represents a significant problem for that unit.

Infection control surveillance data in the ICU typically are reported as the occurrence of a particular infection over a defined time period at risk (e.g., cases of ventilator-associated pneumonia per total number of patient days spent on mechanical ventilation per month), also known as an *incidence density.* For infections that result from a point exposure (e.g., the number of tracheostomy site infections per total number of tracheotomies performed in one quarter), a *cumulative incidence* can be determined. Cumulative incidence is reported less commonly in the ICU owing to the observation that infections in the ICU result primarily from invasive devices that are in place for days to weeks.

In order for the information collected for infection surveillance to be interpretable, a case definition for infection has to be developed. Criteria for the diagnosis of nosocomial infections have been developed by the CDC[9] and are widely accepted. It is important to note that greater accuracy is required on the part of the infection control practitioner in determining if an episode represents a true nosocomial infection compared with the critical care physician, who may initiate antibiotic therapy in the case of a presumptive diagnosis.

Several methods exist for performing surveillance in the ICU, including the traditional methods of medical chart review and review of microbiology, radiology, and autopsy reports. More recently, the use of computerized expert systems and medical informatics in nosocomial infection surveillance has reduced the need for manual chart review, improved case ascertainment, and allowed for more resources to be used for intervention and prevention.[10]

Structural/Organizational Factors That Affect ICU Infection Control

ICU DESIGN AND LAYOUT

While published architectural guidelines require that isolation rooms be included in the layout of critical care units, few data are available to address the impact of ICU design on prevention of nosocomial infection. Mulin and colleagues[11] demonstrated a lower rate of bronchopulmonary colonization with *Acinetobacter baumannii* among mechanically ventilated patients in a surgical ICU after the unit was converted from one with a mixture of enclosed isolation rooms and open rooms to all enclosed rooms with hand washing facilities. Another study demonstrated a reduction in the incidence of ventilator-associated pneumonia and urinary tract infections in a pediatric ICU after it was converted from an open ward to separate isolation rooms, without a significant change in patient to staff ratios.[12] Despite the lack of data, it would seem prudent to ensure that adequate access to hand hygiene exists for ICU personnel.

NURSING STAFFING RATIOS

Much attention has been given recently to the issue of nurse staffing levels and the impact that this has on patient outcomes and complications, including infection. With increased workloads for registered nurses and the reliance on less trained health care personnel for the delivery of care, there is concern that lapses in infection control will occur, resulting in nosocomial infections. In a pediatric cardiac ICU over a 1-year period, a decrease in nurse-to-patient staffing ratios correlated significantly with an increase in nosocomial infections.[13] In a multicenter, retrospective cohort study among 2606 patients admitted to an ICU after abdominal aortic surgery, patients cared for in ICUs that reported nurse-to-patient ratio of 1:3 or greater on either day or night shifts were at greater risk of respiratory complications, including postoperative pneumonia.[14] This relationship was independent of patient age, comorbidity, level of surgical urgency, ICU size, and hospital procedure volume.

These studies, along with several others, have limitations, including retrospective design, no determination of nursing experience or level of training, and no comment on the role that other types of health care worker staffing levels, such as respiratory therapists, have on nosocomial infections rates. Despite these limitations, a direct association between increased nursing workload and the occurrence of nosocomial infections among ICU patients appears to exist. The optimal level of both nursing staffing and experience needed to minimize the risk of infection in ICUs remains to be determined but is unlikely to be uniform for every type of unit.

INFECTION CONTROL POLICIES AND PROCEDURES

Given the complexity of delivering care to critically ill patients, policies and procedure are a necessary part of the organization of any ICU. These policies ensure that personnel perform certain procedures, such as central venous catheter insertion and care, in a consistent manner. Written ICU policies should incorporate evidence-based infection control practices. For policies to be effective, they should be clear, concise, and shared with the staff. Policies that are complex or unrealistic either will be ignored or will result in even wider variation in how care is delivered owing to individual interpretation. Most private and state hospital accreditation programs base their review of ICUs not only on whether ICUs have required policies but also on whether they actually follow them. Therefore, it is important that ICU physician and nursing staff review these policies on a routine basis in consultation with infection control practitioners or the hospital infection control committee and revise these policies when needed.

Invasive Devices and ICU-Acquired Infections

CENTRAL VENOUS CATHETERS/PULMONARY ARTERIAL CATHETERS

Catheter-associated bloodstream infection is one of the most common nosocomial infections seen in ICU patients. Approximately 80,000 of these infections have been estimated to occur annually in ICUs in the United States (excluding insertion-site infection and septic thrombophlebitis).[15] These infections are associated with increased ICU length of stay, health care costs, and use of broad-spectrum antibiotics.

Risk factors for catheter-associated bloodstream infections include the anatomic catheter insertion site, type of catheter

used, and the patient population. The pathogenesis includes microbial colonization of the subcutaneous catheter tract by skin flora with subsequent colonization of the catheter and biofilm formation, as well as colonization of the catheter hub from microbes introduced during use of the catheter. While intravascular catheters can result in bloodstream infections by other means, such as the infusion of contaminated fluids, the mechanisms just mentioned are the primarily methods by which nontunneled central venous catheters in place for less than 2 to 4 weeks cause bloodstream infections.

Numerous infection control practices have been effective in preventing intravascular catheter-related infections (Table 4-1). Meticulous hand hygiene before and after handling intravascular catheters, along with maintaining an intact, nonsoiled dressing at the catheter insertion site, are essential to preventing device-related infections. Maximal sterile barrier precautions (i.e., sterile gowns, gloves, surgical mask and hat, and a large surgical drape) during insertion reduce the incidence of infection.[16] In one randomized trial, subclavian vein insertion was associated with a lower incidence of infectious complications and complete vessel thrombosis when compared with femoral insertion.[17] Structured educational programs incorporating the use of maximal sterile precautions have reduced the incidence of catheter-associated bloodstream infections by 27% to 66%.[18,19] Antibiotic-coated catheters are also effective.[20] The unexplored issue of emerging resistance associated with the use of these catheters makes their role in an overall infection control strategy unclear.

TABLE 4-1 Specific Recommendations for Preventing Intravascular Catheter–Related Infections

- Proper hand hygiene before and after manipulation of intravascular catheter or catheter insertion site
- Aseptic technique during catheter insertion and care
- Use of hat, mask, sterile gowns and gloves, and large sterile drape during central venous catheter (CVC) insertion
- Use of 2% chlorhexidine or other skin antiseptic (tincture of iodine, iodophor, or 70% alcohol) for insertion-site antisepsis
- Use of sterile gauze or transparent semipermeable dressing to cover insertion site
- Prompt removal of catheters that are no longer essential
- Routine replacement of intravascular catheters to prevent infection:
  - Peripheral catheters—(adult) every 72 to 96 hours; (pediatric) remove if complication occurs
  - Central venous catheters—routine replacement not recommended
  - Pulmonary artery catheters—routine replacement not recommended
  - Arterial catheters—routine replacement not recommended
  - Umbilical catheters—routine replacement not recommended
- Do not replace catheters suspected of being infected over a guidewire
- Replace IV administration sets and tubing no more frequently than every 72 hours unless infection is suspected or blood products or lipid emulsions are used
- Antimicrobial/antiseptic-coated CVC should be used only after staff can demonstrate proper CVC care and insertion techniques
- Subclavian insertion site should be used when possible to reduce infection risk
- Avoid using arterial or venous cutdown procedures to insert catheters
- Replace catheter-site dressing when loose, damp, or soiled
- Use sterile sleeve for pulmonary artery catheters
- Pressure transducer systems:
  - Use disposable systems when possible with a sterile, closed flush system
  - Replace transducer, tubing, flush solution, and flush device every 96 hours

SOURCE: Adapted from O'Grady et al.[62]

ARTERIAL CATHETERS AND PRESSURE TRANSDUCERS

Compared with central venous catheters, the incidence of catheter-associated bloodstream infection attributable to arterial catheters has not been as well studied but is estimated to be roughly 1.5% per device or 2.9 cases per 1000 catheter-days.[21] Pressure transducer systems have been a common source of epidemic outbreaks of nosocomial infection. From 1977 to 1987, these devices were the most common source of epidemic bloodstream infection investigated by the CDC.[22] These outbreaks were prolonged (mean 11 months) and involved large numbers of patients (mean 24 patients). In each case, reusable transducers were either improperly disinfected or fitted with improperly sterilized domes. Recommendations for the proper care and use of both arterial catheters and pressure transducer systems are shown in Table 4-1.

URINARY CATHETERS

Urinary catheter use is the primary cause of urinary tract infections among critically ill patients. A survey of 112 medical ICUs in the National Nosocomial Infection Surveillance System found urinary tract infections to be responsible for 31% of all ICU-acquired infections, making urinary tract infections the most common nosocomial infection.[23] Most of these infections are asymptomatic, but between 0.4% to 3.6% of patients with a nosocomial urinary tract infection develop a secondary bloodstream infection.[24,25] Potentially modifiable risk factors for infections with urinary catheters include the use of open urinary drainage systems or breaks in closed drainage systems, prolonged or unnecessary urinary tract catheterization, and retrograde flow from collection bags into the bladder. Infection control measures for urinary catheters should include proper hand hygiene when caring for these devices and prompt removal of catheters when they are no longer needed (Table 4-2).

RESPIRATORY THERAPY EQUIPMENT AND NASOGASTRIC TUBES

Respiratory failure requiring mechanical ventilation is one of the most common indications for ICU admission. Nasogastric tubes are used often for both gastric decompression and to permit feeding of ICU patients. Both mechanical ventilation and nasogastric intubation bypass the normal mucosal defenses of the upper and lower respiratory tract, which leaves patients at risk for nosocomial sinusitis and pneumonia.

Among ICU patients, the vast majority of nosocomial pneumonias are ventilator-associated pneumonias. Ventilator-associated pneumonia is most likely the result of aspiration of contaminated oropharyngeal and gastric secretions and contaminated condensate in the ventilator circuit. Risk factors include the supine position, sedation or impaired

TABLE 4-2 Recommendations for Preventing Urinary Catheter–Related Infections

- Urinary catheters should not be used solely for the convenience of health care personnel and should be removed when no longer necessary.
- Personnel should be trained on proper aseptic insertion and maintenance of urinary catheters.
- Proper hand hygiene should be performed before and after manipulating catheters.
- Insertion of catheters should be performed using aseptic technique and sterile equipment.
- A sterile, continuously closed system should be maintained.
- If necessary, perform closed continuous irrigation of catheter with sterile irrigant.
- Urine samples from catheter and collecting bag should be collected aseptically.
- Urine collection bags always should be below the level of the bladder.
- Maintain unobstructed urinary flow.

SOURCE: Adapted from Wong.[63]

consciousness, and reduced gastric acidity.[25a] Contaminated respiratory equipment has been implicated as the source of outbreaks of nosocomial pneumonia. Devices that generate aerosols, such as nebulizer reservoirs used for humidification[26] and multidose medication nebulizers,[27] have been associated with outbreaks caused by hydrophilic bacteria. Bronchoscopes also have been a source of nosocomial pneumonia in the ICU, usually as a result of an incomplete or compromised disinfection between procedures.[28]

Guidelines for the prevention of ventilator-associated pneumonia focus on proper hand hygiene when handling respiratory equipment, nursing ventilated patients in a semirecumbent position (30 to 45 degrees), and maintaining a closed ventilator circuit (Table 4-3). The use of noninvasive ventilation in selected ICU patients results in a lower risk of nosocomial pneumonia when compared with endotracheal mechanical ventilation. In a randomized, clinical trial, patients ventilated noninvasively had a significantly lower rate of both pneumonia (3% versus 25%) and sinusitis (0% versus 6%).[29] Subglottic suctioning of oropharyngeal secretions using a specially designed endotracheal tube has been shown to reduce the incidence of ventilator-associated pneumonia and holds promise as another method to reduce the risk of nosocomial pneumonia among ventilated patients.[30]

The presence of a foreign body in the nasopharynx, such as a nasogastric feeding tube, predisposes to upper airway infections, particularly sinusitis. Nosocomial sinusitis is often difficult to diagnose. First, the classic signs and symptoms of sinusitis (i.e., sinus tenderness, pain, and fever) often are masked in the intubated and sedated patient. Also, sinus aspiration to determine if a sinus fluid collection is infected is performed only rarely. In a prospective study, paranasal sinus computed tomographic (CT) scans were obtained on all ICU patients with purulent nasal discharge and fever not attributable to another source, followed by sinus aspiration and culture of any fluid observed on CT scan.[31] Using this method, sinusitis was identified in 7.7% of patients. Risk factors for nosocomial sinusitis include nasotracheal intubation, feeding via nasogastric tube, and impaired mental status. These infections frequently are polymicrobial, with *Pseudomonas aeruginosa* and *Staphylococcus aureus* being the most common organisms identified.[31,32] Prevention involves avoiding nasotracheal intubation, placing feeding tubes through the mouth rather than through the nose, and minimizing sedative use.

TABLE 4-3 Selected Guidelines for the Prevention of Nosocomial Pneumonia

- Educate health care workers regarding nosocomial pneumonia and infection control and prevention methods.
- Use hand hygiene before and after contact with patient, respiratory devices, or objects contaminated with respiratory secretions.
- Do not routinely change ventilator breathing circuit components more frequently than every 48 hours.
- Periodically drain condensate from mechanical ventilator tubing; avoid draining of condensate toward the patient.
- Use sterile water to fill bubbling humidifiers and nebulizers.
- Do not use large-volume room-air humidifiers unless they undergo daily high-level disinfection; use sterile water in device.
- Devices used on multiple patients (e.g., portable respirators, oxygen sensors, Ambu bags) should undergo sterilization or high-level disinfection between patients.
- Thoroughly clean respiratory equipment prior to disinfection or sterilization.
- Use aseptic technique when changing a tracheostomy tube.
- Use only sterile fluid to remove secretions from respiratory suction catheter.
- Keep head of bed elevated at an angle of 30 to 45 degrees for patients on a ventilator or receiving enteral tube feedings, if possible.
- Discontinue mechanical ventilation and enteral tube feedings as soon as clinically feasible.

SOURCE: Adapted from Tablan et al.[64]

INTRACRANIAL PRESSURE MONITORING DEVICES

Several infectious complications can result from the use of intracranial pressure monitoring devices, including scalp exit-site and tunnel infections, osteomyelitis of the calvarium, meningitis, and ventriculitis. The rate of infectious complications has been reported at 7.4% to 14.1% per procedure.[33,34] Intracerebral or intraventricular hemorrhage, cerebrospinal fluid leaks, open head injuries, monitors in place for greater than 5 days, breaks in the pressure transducer system, and use of intraventricular versus intraparenchymal monitors have been associated with increased risk of infection. Coagulase-negative *Staphylococcus* spp. are the most common cause of intracranial pressure monitor–related infections, but gram-negative bacilli, such as *Acinetobacter baumannii*, *Klebsiella pneumoniae*, and *Proteus mirabilis*, have been reported in up to 50% of cases.[35] The role of prophylactic antibiotic therapy is unclear. Several cohort studies showed no impact on the incidence of infection among patients who received antibiotics during or after insertion of the devices,[34,36] but no randomized, controlled trials of sufficient sample size exist to address the question.

Interventions to Prevent Nosocomial Infections

Interventions designed to reduce nosocomial infections typically focus on device-related infection, are evidence-based,

and often employ physician and nursing education or introduce a change in the process of care. An intervention consisting of a self-study module on risk factors for catheter-associated infections, a pre- and posttest assessment of knowledge, posters and handouts on the infection control practices related to central venous catheters, and didactic teaching were given to the nursing staff of a surgical ICU.[19] The authors reported a 66% reduction in the incidence of ICU-acquired bloodstream infections in the 18-month period after the intervention compared with the 18 months preintervention ($p < 0.001$), without a significant change in the patient population. This study demonstrates that focused intervention in ICUs can reduce nosocomial infections, possibly through changes in ICU practice and staff behavior.

Another practice designed to prevent nosocomial infection is selective digestive decontamination. The hypothesis behind this practice is that colonization of the oropharynx and gastrointestinal tract by flora acquired while a patient is in the ICU serves as a source of nosocomial infection, particularly in patients requiring prolonged ICU stays and mechanical ventilation. By administering oral, nonabsorbable antibiotics, selective digestive decontamination seeks to prevent the overgrowth of gram-negative aerobic bacteria and yeast while maintaining anaerobic flora. The method has been useful in controlling outbreaks of resistant gram-negative bacteria.[37] Studies of its routine use have had conflicting results, with more methodologically rigorous studies tending to show no benefit in terms of preventing nosocomial pneumonia or mortality.[38,39] These observations, plus the concern of selective digestive decontamination leading to increased antibiotic resistance, leave the role of this practice unclear.

Antibiotic Resistance in the ICU

Intensive care units have long been associated with an increased prevalence of antibiotic-resistant organisms compared with other areas of the hospital. The frequent use of broad-spectrum antibiotics, a patient population with prolonged lengths of stay and the need for invasive devices, and the close interactions between health care workers and critically ill patients all contribute to the propagation of antibiotic-resistant microorganisms within the ICU. The recent emergence of highly resistant virulent organisms, such as vancomycin-resistant *S. aureus*, highlights the importance of understanding and controlling antibiotic resistance within the ICU.

THE EPIDEMIOLOGY OF ANTIBIOTIC RESISTANCE

The resistant organisms seen most commonly in the ICU include methicillin-resistant *S. aureus* (MRSA), vancomycin-resistant *Enterococcus faecium* or *E. faecalis* (VRE), and multi-drug–resistant gram-negative bacilli, such as *P. aeruginosa*, *Stenotrophomonas maltophilia*, and extended-spectrum β-lactamase–producing Enterobacteriaceae. While each of these organisms has individual differences that affect how it is transmitted in the ICU, patients who are colonized or infected with these organisms tend to share common characteristics (Table 4-4).

Patients either can enter the ICU with endogenous resistant bacteria already present or can become colonized during their ICU stay owing to cross-contamination from other colonized patients. Bruin-Buisson and colleagues[40] demonstrated through serial rectal swabs that 90% of all patients subsequently found to be colonized with multi-drug–resistant Enterobacteriaceae were negative on admission to a medical ICU and had a mean time to colonization of 14 days.[40] The primary mechanism by which patient-to-patient transmission of resistant microorganisms occurs within the ICU is on the hands of health care workers. Resistant bacteria can be carried on health care workers' hands and clothing.[41] Another source of transmission of antibiotic-resistant microorganisms is the ICU environment itself. This is particularly true for hydrophilic gram-negative bacilli, such as *Pseudomonas* spp., *Stenotrophomonas* spp., and *Acinetobacter* spp., as well as VRE. These organisms are particularly resistant to the effects of drying; therefore, they can survive on inanimate objects in the environment for extended periods of time. Outbreaks of nosocomial infections associated with these bacteria can persist if the environmental source is not addressed.[42]

TABLE 4-4 Factors Associated with Colonization or Infection with Multi-Drug–Resistant Microorganisms

- Extended length of hospitalization
- Interhospital or nursing home transfer
- Immunocompromised host
- Invasive devices (i.e., central venous catheters, mechanical ventilation)
- Advanced age
- Severity of illness
- Exposure to broad spectrum antibiotics

Preventing Antibiotic Resistance in the ICU

SURVEILLANCE

Understanding the extent to which ICU patients are colonized or infected with antibiotic-resistant microorganisms is important for identifying outbreaks or high endemic rates of particular pathogens and targeting methods for control. Strategies include both passive and active surveillance. Passive surveillance is employed most frequently in ICUs within the United States and consists of identifying patients colonized with resistant microorganisms by review of clinical specimens. While this strategy requires the least amount of labor and supplies, it fails to identify a significant proportion of colonized patients.[43] In active surveillance, cultures are obtained for the specific purpose of identifying colonized patients. These cultures can be performed on every patient or on selected high-risk subsets (see Table 4-4). Selective screening of high-risk patients, combined with other infection control interventions, reduced the prevalence of ICU-acquired MRSA infections in a medical ICU and was cost-effective.[44] Whether this approach is cost-effective for ICUs to use for other pathogens is an area of further study.

ANTIBIOTIC USE AND CONTROL

Inadequate initial antibiotic therapy of infections has been associated with increased mortality among ICU patients. This

observation argues for the use of broad-spectrum antibiotics. However, the increasing use of broad-spectrum antibiotics has been associated with the acquisition of antibiotic-resistant pathogens. Exposure to broad-spectrum antibiotics can alter the normal flora of patients and can facilitate colonization with resistant organisms or expansion of populations of already-existing organisms. The dilemma created by these competing pressures has shaped efforts to control the use of antibiotics within the ICU, particularly drugs with a broad-spectrum of activity.

Antibiotic use in the ICU can be divided into empirical use against a suspected community-acquired or nosocomial infection, targeted use against a specific pathogen, and prophylactic use. There is considerable overlap between these concepts. For example, critically ill patients often are started empirically on broad-spectrum antibiotics and then switched to an antibiotic with a more targeted spectrum once the pathogen causing infection is known. Selective digestive decontamination as a method to prevent nosocomial infections is an example of the prophylactic use of antibiotics in the ICU, which was discussed earlier in this chapter. Strategies that have been applied to control antibiotic use include closed or restricted pharmacy formularies, rapid narrowing of antibiotic spectrum of activity once a pathogen is known, discontinuation of empirical antibiotic therapy based on set clinical parameters, cycling or rotation of empirical antibiotics with gram-negative activity, and decision-support systems for physician prescribing.

Often, antibiotic therapy that is started empirically in a critically ill patient is continued even after evidence suggests that infection is not present. In a study by Singh and colleagues,[45] patients suspected of having ventilator-associated pneumonia were scored using a validated clinical pulmonary infection score. Patients suspected clinically to be at risk for pneumonia but not meeting a predetermined threshold score were randomized to two groups. The experimental group received a single antibiotic for 3 days, with re-evaluation at that time. If this group still did not meet the threshold criteria, antibiotics were discontinued. The type and duration of antibiotic used in the control group were at the treating physicians' discretion. Antibiotic use was continued after 3 days in only 28% of the experimental group versus in 90% of the controls ($p < 0.001$). Mortality and ICU length of stay did not differ between the two groups, but compared with controls, patients in the experimental group had significantly shorter durations of antibiotic use and a lower incidence of antimicrobial-resistant isolates and nosocomial infections during their ICU stay. This study suggests that basing decisions to discontinue antibiotic therapy on formal clinical criteria is an effective and safe method of reducing antibiotic use and resistance.

Cycling empirical antibiotics usually requires the use of only a single antibiotic for the empirical treatment of suspected nosocomial infection, followed by a switch to another agent after a predetermined time period. Raymond and colleagues[46] compared a period of non-protocol–driven antibiotic prescribing with a set quarterly empirical antibiotic rotation and demonstrated a reduction in the occurrence of infections owing to resistant gram-negative and gram-positive bacteria along with a significant reduction in mortality owing to infection during the rotation period. While antibiotic cycling appears promising, questions remain regarding the impact that this strategy has on bacteria with multi-drug–resistant plasmids and its applicability outside of a research setting.

Increased interest in computer-assisted physician order entry has allowed for the development of physician ordering support systems. A prospective study of a computerized antibiotic management program in one ICU found that patients treated using the computerized support system had a lower incidence of mismatches between antibiotics prescribed and the susceptibility of isolated bacteria.[47] The computerized support system also was associated with shorter durations of antibiotic use. Further studies need to be performed to see if the reduction in overall antibiotic use by this method can reduce the prevalence of antibiotic-resistant bacteria.

Hand Hygiene

Proper hand hygiene has been known to be fundamental in preventing nosocomial infections since the studies of puerperal fever by Semmelweis in the mid-nineteenth century. After contact with patients, health care workers' hands can become transiently colonized with pathogenic and antibiotic-resistant bacteria, which are then transferred to other patients. Hand soaps containing an antiseptic agent, such as chlorhexidine, or alcohol-based hand rubs have been shown to effectively reduce bacterial counts on hands when used properly.

Despite the known benefit of proper hand hygiene in preventing nosocomial infections and the transmission of antibiotic-resistant bacteria, observed compliance with hand hygiene among ICU personnel is poor, typically between 22% and 40% for each episode of patient contact.[48,49] The greatest barriers to compliance with hand hygiene are time and accessibility. An outbreak of *Enterobacter cloacae* infections in a neonatal ICU coincided with a period of patient overcrowding and short staffing of nurses.[50] During this time, adherence to hand hygiene was 25% and subsequently increased to 70% when staffing and patient census returned to normal levels. Accessibility to sinks in the ICU is often limited, particularly in older units. When personnel do wash their hands with antiseptic soap, it is often for a shorter period of time than the duration used to test the product's effectiveness.

Waterless alcohol-based hand rubs improve health care workers' compliance with hand hygiene in the ICU.[51] Compared with using traditional antiseptic soap and water, alcohol-based products require less time to use and are more convenient. Antiseptic soap and water should still be used, however, when hands are visibly soiled.

Other recommendations for ICU personnel concerning proper hand hygiene include avoiding the wearing of artificial fingernails owing to high periungual bacterial counts and outbreaks of nosocomial infections associated with these products, washing hands before and after using gloves, and providing staff with hand lotions to minimize the risk of irritant contact dermatitis.

Preventing Transmission of Pathogens between ICU Personnel and Patients

Health care workers in the ICU are potentially at risk of being exposed to infectious agents during the course of caring for patients. Likewise, the same health care workers potentially

can spread infectious agents, particularly antibiotic-resistant bacteria, to patients. A primary goal of infection control is to prevent both. Transmitting infectious agents in the ICU currently is prevented by what has been termed by the CDC as *standard precautions* and *transmission-based precautions* (i.e., airborne, droplet, and contact precautions).[52]

STANDARD PRECAUTIONS

The concept of standard precautions arose primarily from attempts to prevent patient-to-health-care-worker transmission of blood-borne pathogens, particularly HIV. The concept of standard precautions is based on the assumption that all body substances (i.e., blood and other body fluids, secretions, and excretions) and certain body sites (e.g., nonintact skin and mucous membranes) are potential sources of infectious agents. Therefore, health care workers should use the same basic precautions, regardless of whether a patient is known to have a particular infection. Standard precautions are designed to minimize the risk of transmission of both recognized and unrecognized sources of infection in hospitals and include (1) wearing clean gloves when there is the potential for contact with blood, body fluids, secretions, excretions, contaminated items, mucous membranes, or nonintact skin, (2) washing hands immediately after gloves are removed or when body fluids are inadvertently contacted, (3) wearing a gown, mask, and eye protection or a face shield when there is the potential for splashing or spraying with bodily substances, (4) avoiding practices that increase the risk of exposures and injuries, such as recapping or removing used needles from syringes.

TRANSMISSION-BASED PRECAUTIONS

A change in the CDC guidelines in the mid-1990s was the elimination of multiple levels of isolation categories found in previous recommendations and a simplification of isolation precautions based on what is currently known of the modes of transmission of either highly contagious or epidemiologically significant pathogens (Table 4-5). Institution of transmission-based isolation for an ICU patient should occur when infection or carriage of one of these pathogens is either confirmed or suspected. Transmission-based categories of isolation include airborne, droplet, and contact isolation.[52] The transmission-based isolation precautions require that patients be placed in either a private room or be cohorted with patients who have the same infection, if necessary. Transport of the patient out of the room should be limited to procedures that are medically necessary and cannot be performed in the room. When patients must be transported out of the room, the area receiving the patient should be notified of their isolation status, and special precautions (such as a surgical mask being placed on the patient for airborne and droplet precautions) should be taken to minimize infection risk during transport.

Airborne precautions are for agents transmitted by airborne droplet nuclei (generally less than 5 μm in size) or other similarly sized particles. These small particles can remain suspended in the air currents in a room for hours and may be dispersed widely. Examples of pathogens spread in this manner include *Mycobacterium tuberculosis* and rubeola virus. Patients with an infection caused by a pathogen transmitted via airborne particles should be housed in a private room that has negative-pressure ventilation or other special air handling relative to the outside hallway. In addition, susceptible persons who enter the room should wear an N95 respirator or other respiratory equipment capable of filtering small airborne particles; a standard surgical mask is not protective. Negative-pressure systems and other special air handling systems should be tested regularly to ensure that they function properly.

Droplet precautions are for infectious agents that are spread by larger respiratory droplets that can be generated during coughing, sneezing, talking, or performing procedures. These larger droplets do not remain suspended in the air and travel only short distances, usually 1 m or less. Examples of pathogens transmitted primarily via large respiratory droplets include influenza virus and *Neisseria meningitidis.* Patients who are known or suspected to be infected with an agent spread by large respiratory droplets should be placed in a private room, and all individuals should wear a surgical mask (at least) when entering within 1 m of the patient (for practical purposes, most hospitals require a mask when entering the patient's room).

Contact precautions should be employed for agents capable of spread through direct contact with the patient or contact with contaminated environmental surfaces or equipment. This is the most frequently employed transmission-based precaution in the ICU setting, typically used to prevent the spread of antibiotic-resistant bacteria. Contact precautions generally are defined as the use of gloves by all personnel entering the patient's room and the use of a gown when contact with the patient or environmental surfaces is anticipated. The use of dedicated equipment (e.g., stethoscopes, thermometers) is recommended to prevent this equipment from transmitting the infectious agent to others. Equipment should be cleaned and disinfected properly before it is used on other patients. The risk of nosocomial transmission of MRSA in a neonatal ICU was reduced 16-fold by the use of contact precautions.[53] Once the patient on contact precautions is discharged from a room, environmental surfaces must be cleaned thoroughly to eliminate organisms that might persist.

OCCUPATIONAL HEALTH AND THE ICU

Occupational or employee health plays an important role in preventing the spread of highly infectious agents among health care workers. The hospital's occupational health department is responsible for screening employees for contagious diseases and offering employees vaccination for preventable infections related to health care, particularly hepatitis B virus and varicella-zoster virus. In the case of an exposure to an infectious agent from a patient, occupational health's role is to evaluate and, if necessary, treat exposed employees. For particular infectious agents, such as exposure of a nonimmune health care worker to varicella-zoster virus, occupational health has the authority to remove a worker from direct patient care. In smaller hospitals, often a single individual will be responsible for both infection control and occupational health, but most large hospitals have two separate departments. The role of infection control is to determine which health care workers were exposed to a contagious agent and refer exposed workers to occupational health for follow-up.

TABLE 4-5 Isolation Precautions Required for Selected Infections and Conditions

Infection/Condition	Type[a]	Precautions, Duration[b]
Anthrax, cutaneous or pulmonary	S	
Clostridium difficile–associated diarrhea	C	DI
Conjunctivitis, acute viral (acute hemorrhagic)	C	DI
Corona virus (SARS)	D,C	DI
Diphtheria		
Cutaneous	C	CN
Pharyngeal	D	CN
Epiglottitis due to *Hemophilus influenzae*	D	U (24 hrs)
Hepatitis A virus, diapered or incontinent patients	C	F[c]
Herpes simplex virus		
Encephalitis	S	
Mucocutaneous, disseminated or primary, severe	C	DI
Influenza	D	DI
Measles (rubeola), all presentations	A	DI
Meningitis		
Hemophilus influenzae, known or suspected	D	U (24 hrs)
Neisseria meningitidis, known or suspected	D	U (24 hrs)
Other diagnosed bacterial	S	
Meningococcal pneumonia	D	U (24 hrs)
Meningococcemia (meningococcal sepsis)	D	U (24 hrs)
Multi-drug–resistant organisms, infection or colonization		
Gastrointestinal	C	CN
Respiratory	C	CN
Pneumococcal	S	
Skin, wound, or burn	C	CN
Mycoplasma pneumonia	D	DI
Parovirus B19	D	F[d]
Pertussis (whooping cough)	D	U (5 days)
Plague		
Bubonic	S	
Pneumonic	D	U (72 hrs)
Infant and young children	D	U (72 hrs)
Rabies	S	
Respiratory syncytial virus infection, infants, young children, or immunocompromised adults	C	DI
Streptococcal disease (group A streptococcus), skin, wound, or burn		
Major (no dressing or uncontained drainage)	C	U (24 hrs)
Minor or limited (contained drainage)	S	
Tuberculosis		
Extrapulmonary, draining lesion (including scrofula)	S	
Extrapulmonary, meningitis	S	
Pulmonary or laryngeal disease, confirmed or suspected	A	F[e]
Skin-test–positive with no evidence of current pulmonary disease	S	
Varicella-zoster virus[f]		
Varicella (chickenpox)	A,C	F[g]
Zoster		
Localized in immunocompromised patient, disseminated	A,C	F[g]
Localized in normal patient	S	
Wound infections		
Major (no dressing or uncontained drainage)	C	DI
Minor or limited (contained drainage)	S	

SOURCE: Adapted from Garner.[55]

[a] Type of precautions: A = airborne; C = contact; D = droplet; S = standard.

[b] Duration of precautions: CN = until off antibiotics and culture-negative; DI = duration of illness; U = until time specified after initiation of effective therapy; F = see footnote.

[c] Maintain precautions in infants and children younger than 3 years of age for duration of hospitalization; in children 3 to 14 years of age, for 2 weeks after onset of symptoms; for children over 14 years of age, for 1 week after onset of symptoms.

[d] Maintain precautions for duration of hospitalization when chronic disease occurs in an immunodeficient patient. For patients with transient aplastic crisis, maintain precautions for 7 days.

[e] Discontinue precautions *only* when patient is on effective therapy, is improving clinically, and has three consecutive negative sputum smears collected on different days or tuberculosis is ruled out.

[f] Persons susceptible to varicella are at risk of varicella when exposed to patients with herpes zoster lesions or varicella and should not enter the room.

[g] Maintain precautions until all lesions are crusted; see text.

Infection Control Issues Related to Specific Pathogens

SEVERE ACUTE RESPIRATORY SYNDROME (SARS)

The recent experience with the spread of infection related to a corona virus producing a severe form of the acute respiratory distress syndrome (ARDS) with significant morbidity and mortality has highlighted the challenges presented by emerging infectious diseases requiring controlling exposures in the health care environment by rapidly implementing effective infection control measures.[53a–53c] The outbreak of this viral illness in 2003 resulted in infection in more than 8000 people and more than 900 deaths. SARS is predominantly a respiratory illness, spread by large droplets which are inspired, and possibly by the fecal-oral route as well. Important lessons from the experience with outbreaks in Taiwan and Toronto include early identification of the epidemic, institution of strict isolation and control measures, careful screening of health care workers and others exposed to active cases, quarantine of individuals early in the course of the epidemic, and limitation of exposures to high risk interventions in the intensive care unit such as intubations or other airway manipulations. Effective responses to outbreaks such as this, which are predicted to increase in our complex and interconnected world, can only be achieved by a high degree of integration of critical care clinicians, infection control staff, and public health officials. Anticipating such problems and working to solutions in advance is a better approach than attempting to implement solutions ad hoc.

BLOOD-BORNE PATHOGENS: HIV, HEPATITIS C VIRUS, AND HEPATITIS B VIRUS

Because of the need for frequent invasive procedures, the often-urgent nature of these procedures, and the patient population that is served, critical care personnel are at risk of exposure and infection with blood-borne pathogens. The most common mechanism by which ICU personnel are exposed is by a percutaneous injury, usually an inadvertent needle stick. The risk of infection after a percutaneous exposure varies significantly depending on the virus. The risk of infection with HIV after a percutaneous exposure to infected blood or bloody fluids has been estimated to be 0.3%. The risks associated with occupational mucous membrane and cutaneous exposures to HIV-infected blood appear to be substantially smaller. For hepatitis C virus, the risk of infection after percutaneous exposure is between 0% and 7%, and for hepatitis B virus, the risk of developing serologic evidence of infection in a nonimmune person is 23% to 62%, depending on whether the source patient is positive for the hepatitis B e antigen.[54]

Infection control efforts against these viruses focus primarily on preventing exposure to blood and, in the case of hepatitis B virus, offering vaccination on employment. Practices that minimize the risk of percutaneous injury (e.g., discarding disposable sharp devices in puncture-resistant containers immediately after use) are key aspects of prevention. Precautions also should be applied to other body fluids containing visible blood and to cerebrospinal, synovial, pleural, peritoneal, pericardial, and amniotic fluids and vaginal secretions and semen.[55] Protective equipment (i.e., gloves, gowns, masks, and eyewear) should be used when there is a potential for exposure to these fluids. Following an exposure, the affected skin should be cleaned immediately with soap and water, and mucous membranes should be rinsed with copious amounts of water. Zidovudine chemoprophylaxis following needlestick exposure to HIV-1 decreases transmission risk by 80%.[56] Current guidelines recommend 4 weeks of combination antiretroviral therapy with either a two- or three-drug regimen for postexposure prophylaxis, taking into consideration degree of exposure, level of viremia in the source patient, and the potential for resistant virus. For hepatitis C virus, no prophylaxis is currently available; exposed workers generally are monitored for 6 months for evidence of infection. For hepatitis B virus exposure, the immune status of the employee should be determined, and hepatitis B immunoglobulin and vaccination should be offered to nonimmune employees.

VARICELLA-ZOSTER VIRUS

Patients with evidence of disseminated varicella-zoster virus (VZV) infection (e.g., chickenpox, varicella pneumonia, disseminated zoster) or immunocompromised patients with localized zoster are capable of transmitting VZV via respiratory droplets and shedding virus from noncrusted skin lesions. These patients should be placed on airborne precautions with negative-pressure ventilation and contact precautions until all skin lesions are crusted. Immunocompetent hosts with localized zoster can be cared for using standard precautions. Health care workers without a history of chickenpox or documented evidence of immunity should not enter the room of a patient with an active VZV infection. If a potentially nonimmune health care worker or patient is exposed, VZV serology should be obtained on that individual. Seronegative personnel should be removed from direct patient contact between 10 to 21 days after the exposure occurred. Likewise, if a seronegative patient is exposed to a patient with VZV infection, he or she should be placed in the appropriate precautions between 10 and 21 days after the exposure. The use of VZV vaccine and varicella-zoster immunoglobulin should be considered in both nonimmune exposed ICU patients and personnel when not contraindicated.

TUBERCULOSIS

Tuberculosis is frequently unsuspected in hospitalized patients, including those admitted to ICUs. This failure of diagnosis has emerged as an important contributor to mortality[57] and also may increase the risk of transmission to hospital personnel. ICU personnel who perform procedures that generate respiratory aerosols (e.g., endotracheal intubation, fiberoptic bronchoscopy, and ventilator management) may be at particular risk for acquisition of tuberculosis. It should be noted that a negative acid-fast smear does not eliminate the possibility of transmission to medical personnel. ICU physicians must maintain a high level of suspicion for tuberculosis and initiate airborne precautions whenever the diagnosis is considered. Health care workers must wear National Institute of Occupational Safety and Health (NIOSH)–approved 95% (N95) particulate respirator masks or high-efficiency particulate air (HEPA)–filtered respirator masks when caring for patients with known or suspected tuberculosis.[58] In addition, all ICU personnel should undergo tuberculin skin testing on hire and at regular intervals.

RESPIRATORY SYNCYTIAL VIRUS

Respiratory syncytial virus (RSV) is a leading cause of bronchiolitis and pneumonia in infants and small children and is a frequent cause of nosocomial outbreaks of lower respiratory tract infections in pediatric wards. While RSV has been long recognized as a cause of seasonal infection in children, transmission has been reported in adult patients, with significant morbidity and mortality in immunocompromised hosts.[59] The primary mode of transmission of RSV is inoculation of the eyes and nasal mucosa by the hands after handling objects or touching surfaces contaminated by respiratory secretions. Infants have been shown to shed high titers of RSV in respiratory secretions for up to several weeks, and the virus is stable in the environment for up to 24 hours. Health care workers in pediatric wards have been infected themselves and have transmitted the virus to other patients via contaminated hands or equipment. Infection control measures for RSV include placing infected young children, infants, and immunocompromised adults on contact precautions. Personnel with respiratory illnesses during RSV outbreaks should not care for children and immunocompromised adults at risk for severe RSV infection.[60]

MENINGOCOCCUS

Patients with meningitis and bacteremia caused by *N. meningitidis* frequently require admission to the ICU for circulatory collapse and airway management. Often the diagnosis is suspected but not confirmed until the organism is isolated in culture. Patients with known or suspected meningococcal infection should be handled using droplet precautions because this organism typically is carried in the nasopharynx and spread by large respiratory droplets. Personnel should wear a surgical mask when caring for infected patients and either goggles or a face shield when performing procedures capable of generating droplets. Precautions can be discontinued after the patient has been on effective antibiotic therapy for at least 24 hours.

The admission of a patient with suspected or known meningococcal disease can generate a significant amount of anxiety among personnel. Cases of meningococcal nosocomial infection in health care workers have been associated with close contact with respiratory secretions without the use of precautions.[61] However, transmission resulting in disease in health care workers is rare, and the risk of transmission from casual contact with a patient is likely negligible. The incubation period for meningococcal disease after exposure can range between 2 to 10 days but is commonly 3 to 4 days; therefore, whether antibiotic prophylaxis is warranted does not need to be determined emergently. Infection control and occupational health staff should evaluate all potential employee exposures, educate staff on the risk of infection, and determine if antibiotic prophylaxis is needed on a case-by-case basis.

Chapter 5

LEGAL ISSUES IN CRITICAL CARE

MARSHALL B. KAPP

KEY POINTS

- *In order to be considered legally effective, consent to medical treatment must meet three tests: (1) it must be voluntary; (2) it must be adequately informed or knowing; and (3) it is given by an individual with adequate mental capacity and legal authority.*
- *Whereas a variety of state laws in the United States pertain to decisional capacity and surrogate decision making, in most cases the physician relies on family members as the surrogate decision makers for an incapacitated patient, even in the absence of a specific statute, advance directive, or court order empowering the family.*
- *An increasing percentage of patients, especially as the population ages, lack available, willing relatives or friends to act as surrogate decision makers. In such cases physicians should seek guidance from living wills or other forms of advance directives, when these exist.*
- *Neither a patient nor his or her family has a legal right to, nor does the physician have the obligation to provide, medical treatment that would be futile—that is, nonbeneficial—for that patient.*
- *As directors of critical care units, critical care physicians should participate in creating institutional protocols that delineate operational principles of the critical care team and the individual physician's supervisory responsibilities.*

The making, implementation, and documentation of treatment decisions in the practice of critical care medicine raise a host of potential legal implications. This chapter briefly outlines some of the more salient issues and suggests avenues for their management and further exploration. Figure 5-1 depicts these issues as they arise within and impact upon the physician–patient relationship in ICUs.

It must be noted that what is described here are the evolving legal ramifications particular to critical care practice in the United States. For comparison, in critical care as practiced outside the United States, legal issues may impact much less on day-to-day decision making. It may be argued that the U.S. approach encourages greater sensitivity to and protection of the rights of patients. In contrast, the legal systems of many other countries, explicitly or by default, have elevated the role of the critical care physician as unquestioned advocate for the critically ill patient. A tangible outcome of this difference is that intensivists in the United States usually are more cautious in giving medical advice—especially advice with difficult ethical connotations—to their patients or surrogates compared to Australasian, European, or even Canadian intensivists, all of whom assume a more commanding presence at the physician–patient interface regarding critical care decision making. It is not uncommon to encounter U.S. critical care decision making suspended, awaiting the input of family or an institutional ethics committee that has yet to be apprised of the patient's condition or need for a decision; in contrast, quite similar situations are decided autocratically by the attending intensivist in other countries. Because critical care is evolving rapidly throughout the world, the contributions of the legal system—positive and negative—to health care and to society as a whole are not yet clear. It is clear, however, that legal issues become less dominating and intrusive, and ethical concerns become more central, when intensivists and their critical care teams initiate and continue sensitive, complete, consistent, and honest communication with their critically ill patients and significant others.

Informed Consent[1]

The well-established legal doctrine of informed consent is based on the ethical principles of autonomy (personal self-determination) and beneficence (doing good for the patient).[2] Early lawsuits growing out of medical interventions conducted in the absence of informed consent were predicated on a battery theory (i.e., touching the person without their consent). But most such cases today are framed as negligence actions, in which the alleged unintentional wrong is the physician's violation of the fiduciary or trust duty to inform the patient adequately as part of the permission process.

In order to be considered legally effective, consent to medical treatment must meet three tests (in the absence of an exception such as an unforeseeable emergency). First, consent must be voluntary—that is, not coerced—in nature. The patient (or surrogate decision maker) must retain the ultimate power to accept or reject the available interventions.

Second, consent must be adequately informed or knowing. A slight majority of U.S. jurisdictions still enforce a physician-oriented standard of information disclosure, inquiring whether the amount of information shared by the physician with the patient or surrogate was consistent with the usual practice of other prudent, competent physicians in similar circumstances. Almost half the states, however, have adopted a more patient-oriented standard, requiring physicians to disclose all the information that a reasonable patient would want to know under the circumstances. This latter approach is also termed the *materiality standard*, since it compels the disclosure of information that would be material—that is, information that might affect the decision making—for a reasonable patient.

Under either a physician- or patient-oriented approach, several particular kinds of information need to be disclosed in understandable lay language. These include: the nature of the patient's medical problem; prognosis with and without treatment; nature of the suggested intervention; likely benefits of treatment; reasonable alternatives; and foreseeable risks of the various alternatives. Additionally, many people today are interested in knowing the probable financial ramifications of their medical decisions.

Third, informed consent is sufficient only when it is given by an individual with adequate mental capacity and

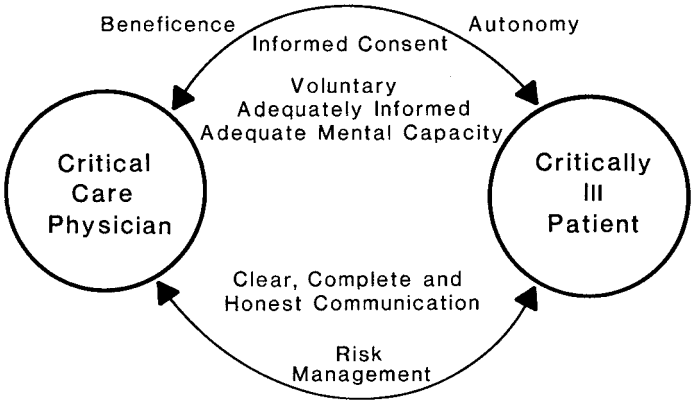

FIGURE 5-1 Outline of legal issues in critical care. The communication and interaction between critical care physician and critically ill patient involves areas (e.g., informed consent and risk management) with legal issues and precedents.

legal authority. This element of consent may be especially problematic in critical care and is discussed in the next section.

A note of caution regarding the legal value of written consent forms must be added here. Contrary to the usual mistake that health care providers make of treating the two things as synonymous, a written consent form is not the equivalent of legally effective informed consent. Informed consent is the process of mutual communication and ultimate patient or surrogate choice[3] as described earlier. The written form is only tangible documentation or evidence that the communication process occurred. This evidence may be very important to the physician in defending against a lawsuit claiming medical intervention in the absence of informed consent, by creating a legal presumption that consent was properly obtained. However, where inadequate communication actually took place, the presumption created by the consent form may be successfully rebutted or overcome by the plaintiff. While broad, blanket consent forms used in many hospitals are sufficient to authorize routine noninvasive medical treatments, more specifically tailored and informative forms are preferable for interventions that are nonroutine or invasive, and certainly for treatments that might be characterized as experimental or innovative.[4] One recent study[4a] of informed consent in critically ill patients suggested that early identification of patients at risk for needing invasive procedures facilitates an earlier discussion of risk-benefit relationships, fewer procedures performed as "emergent," and a possible reduction in surrogate consent.

Application of these general principles is somewhat complicated in critical care by the fact that in the ICU, interventions can be nearly continuous for the most unstable patients. Informed consent is necessary any time the doctor proposes doing anything to a patient (i.e., any "intervention"). For quasi-continuous interventions, informed consent must certainly be obtained at the initiation of the intervention, and the patient or surrogate must be afforded the opportunity to withdraw that consent at any later point.

Most interventions in critical care may be categorized as risky or invasive, that is, an intervention involving a higher degree of risk or intrusion for the patient than he or she would ordinarily face in normal, everyday life. However, this categorization is relevant only to the question of the extent of advisable documentation; the requirement of an informed consent process itself applies regardless of an intervention's level of risk or invasiveness.

Decisional Capacity and Surrogate Decision Making

Minor children (defined in almost every state for medical purposes as those younger than 18 years old) are presumed legally to be incapable of making their own medical decisions, and in the absence of an exception based on the minor's "emancipated" or "mature" status, the natural parent or court-appointed guardian is legally empowered as the medical decision maker. Adults, however, are presumed legally to be decisionally capable.[5] In critical care, many (although certainly not all) patients will be so ill and debilitated that they are not presently capable of making and expressing treatment choices resulting from a rational thought process of digesting and weighing information about the benefits and risks of different alternatives.[6]

Although in theory the same degree of mental capacity is necessary whether the patient is accepting or declining the recommended medical intervention, in practice, a formal inquiry into patient capacity usually occurs only in the case of patient refusal. Ideally, a judgment about patient decisional capacity, which may fluctuate widely over time because of a variety of natural and iatrogenic factors, is being made at least implicitly by the attending physician each time the patient is seen. Such an inquiry ought to be inherently built into every physician–patient encounter. Where decisional capacity is seriously questioned, a more focused examination needs to be conducted. In especially ambiguous cases, documentation in the patient's medical record by consultants who have evaluated the patient's decisional capacity is good risk management for the physician proposing an intervention, who is the one ultimately responsible for ensuring informed consent; the legal system affords psychiatrists a great deal (arguably an excessive amount) of deference as consultant capacity assessors.

For patients who in fact lack the ability to engage in a rational decision making process, the presumption of capacity is rebutted or overcome. This does not, however, mean that the physician may dispense with informed consent prior to initiating particular interventions. Consent remains necessary for treatment of incapacitated patients, but the consent must be obtained from a surrogate or proxy acting on the patient's behalf. Several approaches to surrogate medical decision making have developed.

Over half the states in the past three decades have enacted "family consent statutes," which specify relatives (ordinarily

in a priority order) who may legally make medical decisions for an incapacitated family member.[7] Advance proxy directives (see next section), especially the durable power of attorney, may be used by currently capable persons to designate their own surrogates in the event of subsequent incapacity. A formal guardianship or conservatorship (precise terminology varies among jurisdictions) proceeding may be initiated, in which a probate court finds the patient (the ward) to be decisionally incapacitated (the legal term usually employed is *incompetent*) and appoints someone else (the guardian or conservator of the person) as the surrogate decision maker.

In most cases, however, the physician relies on family members as the surrogate decision makers for an incapacitated patient, even in the absence of a specific statute, advance directive, or court order empowering the family. This informal process of making do using next of kin, even without explicit legal authority, works well in the vast majority of situations in which the family members agree on a course of conduct both among themselves and with the physician, and where they appear to act consistently with the patient's values and preferences (the "substituted judgment" standard) or with the patient's best interests.

Decisions to Limit Treatment[8,9]

Some patients retain a sufficient degree of capacity to make and express their own medical decisions even after admission to a critical care unit (CCU). Legal precedent is very clear that, except in cases in which the welfare of a third party such as a minor dependent is jeopardized, a properly informed, capable patient has the right to make personal medical decisions, including a decision to refuse even life-prolonging treatment.

If the patient is decisionally incapacitated, a more difficult scenario may confront the physician. A surrogate decision maker may be identified (see previous section) under a state family consent statute, the patient's prior execution of a durable power of attorney (see Appendix 1 for a model) naming a surrogate or health care agent, a court appointment of a guardian/conservator, or informally relying on available, willing family members.

The surrogate is legally expected in most states to make decisions consistent with what the patient would choose if he or she were presently able to make and express choices personally (substituted judgment standard, or "donning the mental mantle" of the incapacitated person). If there is no reliable indication (some states, e.g., Missouri[10] and New York,[11] require proof by "clear and convincing evidence") of the patient's preference under the circumstances, the surrogate must act in the patient's best interests, considering—from the patient's perspective—the proportionality of likely benefits and burdens associated with available medical alternatives.

An increasing percentage of patients, especially as the population ages, lack available, willing relatives or friends to act as surrogate decision makers.[12] In such cases, there are several potential sources of guidance for the physician.

The patient may have executed a living will document while still decisionally capable. This type of advance directive, which is authorized by statute (frequently called a natural death act) in almost every jurisdiction, permits a capable adult to make a record of personal preferences regarding future medical treatment in the event of subsequent incapacity and critical illness (see Appendix 2 for a model). Although usually this directive is used to indicate a preference for the limitation of future medical intervention, the directive could be employed to request maximum medical intervention if there is any likelihood of benefit to the patient. However, neither a patient nor his or her family have a legal right to, nor does a physician have the obligation to provide, medical treatment that would be futile—that is, nonbeneficial—for that patient.[13,14]

A physician who complies in good faith with the patient's expressed voluntary, informed wishes to limit life-prolonging treatment is on firm legal ground.[15] For the physician who for ethical reasons chooses not to follow a living will's directive to limit treatment, there is an ethical and legal obligation to notify the patient or surrogate (if one is present), and to make a reasonable attempt to transfer the patient to another physician who is willing to comply with the living will, or at least not to prevent such a transfer.

In many states, a public guardianship system has been created to make surrogate decision makers available, either through a government agency or through a private agency under government contract, for incapacitated patients who lack available, willing relatives or friends.[16] There are also demonstration projects in some locales that use privately funded agencies to act as surrogate medical decision makers for incapacitated patients.[17] The physician should consult hospital legal counsel to determine acceptable sources of surrogate decision making for the incapacitated patient without relatives or friends.

The most controversial and complicated issue in the treatment limitation arena is the status of artificial feeding and hydration.[18] The courts have been unanimous in holding that feeding tubes are merely another form of medical intervention, which could be withheld or withdrawn under the same circumstances that would apply to the withholding or withdrawal of any other type of medical intervention.[19] The American Medical Association[20] and other groups[21] endorse this analysis. However, some argue that feeding and hydration, even where accomplished through tubes surgically or forcibly inserted in the patient's body, are fundamentally different and more elemental than medical treatment, and therefore ought to be continued as long as they can keep the patient alive.[22] A number of state legislatures have embodied this argument in living will or durable power of attorney statutes that purport to severely restrict the ability of surrogate decision makers to authorize the removal of feeding tubes. Both the wisdom and the constitutionality of these purported restrictions are extremely questionable.[23,24]

The case of Nancy Cruzan remains the only case decided by the U.S. Supreme Court, on June 25, 1990, that sheds light on the issue of discontinuing life-prolonging treatment. Cruzan was an automobile accident victim who was kept alive in a permanent vegetative state within a state-operated (Missouri) long-term care facility, through the use of feeding and hydration tubes. Her parents asked that this intervention be discontinued, a request they claimed was consistent with the patient's previously expressed (although not documented) wishes. The physicians refused this request, and the Missouri Supreme Court upheld the lower court decision and refused the parents' request to discontinue treatment.

The U.S. Supreme Court held that a mentally capable person has a fundamental constitutional right, under the liberty provision of the Fourteenth Amendment's due process clause, to make personal medical decisions, even regarding life-prolonging treatments, including artificial feeding and hydration. For incompetent patients, though, the court ruled that a state's interest in preserving life was strong enough to permit a state, if the state so chooses, to require "clear and convincing" evidence of the treatment preference the patient would hold if currently able to make and express an autonomous choice, before the state must comply with a surrogate's instructions to withdraw life-prolonging medical care. Presumably, a written declaration made while the patient was competent would suffice as evidence of treatment preference in the event of subsequent incapacity. Under the Cruzan decision, states are also free to set lower standards of proof than "clear and convincing" evidence for incapacitated patients, such as proof by a preponderance of the evidence (i.e., greater than 51% likelihood). In the Cruzan case itself, Missouri by statute imposed the "clear and convincing" evidentiary standard, and since Cruzan had never clearly documented her treatment wishes while still competent, the proof was inconclusive, and the state was permitted to err on the side of continued treatment.

One form of treatment limitation around which there is a high degree of current consensus is the do-not-resuscitate (DNR) or no code order, which instructs caregivers to refrain from initiating cardiopulmonary resuscitation (CPR) for a patient who suffers an anticipated cardiac arrest. There have been very few legal cases in this arena, but the well-accepted rule is that a decisionally capable patient has the right to refuse CPR, and that surrogates may elect to forego CPR for a patient if the likely burdens of this intervention to the patient would be disproportionate to any benefits (e.g., mere continued existence until the next arrest) that might be derived.[25] As is true for all medical decisions, a DNR order should be made only after a thorough consultation with the patient or surrogates and should be clearly documented in the medical record.

Where the patient or surrogate has declined aggressive, technologically oriented interventions, the physician still retains the legal obligation to continue basic palliative (comfort and pain control) and hygiene measures. Failure to do so could constitute negligence or form the basis for professional disciplinary action.[26]

The other side of the coin on treatment decision making is presented when the patient, or more usually the family, insists on initiation or continuation of medical treatment ("doing everything possible") that the clinician judges to be futile in terms of benefit to the patient.[27] On the very rare occasions that courts have been involved prospectively with the futility issue, their holdings have been confusing, inconsistent, and often poorly reasoned.[28] No court has ever imposed liability for failure to begin or perpetuate futile interventions for a critically ill patient, even in the face of family insistence on doing everything possible. In practice, clinicians usually seem to take the path of least resistance in such circumstances and "treat the family," often out of misapprehension of potential liability exposure. In the vast majority of cases, better physician–family communication, in which the realistic implications of "doing everything possible" are spelled out clearly, can obviate serious disagreement over how to proceed.[29]

Institutional Protocols and Institutional Ethics Committees

Most hospitals have adopted written policies and procedures concerning patient admission to, retention in, and discharge from CCUs. The ability of physicians to consult institutional guidelines generally leads to better, more consistent decisions that are easier to defend against later claims of impropriety.[30] Clear protocols facilitate communication and cooperation among members of the health care team, decreasing both inadvertent mistakes and interpersonal tension. Institutional protocols are also essential as inevitable discussions of health care rationing take on increasing urgency.[31]

The development and dissemination of institutional protocols regarding critical care, especially DNR orders, is required by the federal Patient Self-Determination Act (PSDA)[32] and by some states.[33] It is also required for approval by the Joint Commission on Accreditation of Healthcare Organizations (JCAHO).[34]

Critical care physicians must be completely familiar with their own institutions' formal policies and procedures, and must assure familiarity with them on the part of nurses and other staff members. Ideally, members of the medical staff should contribute to the drafting, continuing re-evaluation, and revision of institutional protocols.[35] Questions regarding the meaning or implementation of these protocols should be addressed in a timely fashion (i.e., before a crisis erupts) to hospital legal counsel.

Similarly, the physician must be knowledgeable about the operation of his or her hospital's institutional ethics committee (IEC). The past three decades have seen a proliferation within health care institutions of entities designed to provide education, formulate policies and procedures, and offer advice regarding particular cases and issues with serious bioethical implications.[36] JCAHO standards require that hospitals have in place a mechanism for carrying out these functions.[37] Although the emphasis of IECs is, and ought to be, on better ethical decision making, salutary legal by-products may also result from their activities. Effective use of an IEC may preclude resorting to the judicial system, initiated either by the family or by a health care team member who feels his or her opinion has been inadequately taken into account, for definitive resolution of a case. Furthermore, in the relatively unlikely event of the informal decision making process breaking down and court involvement being invoked, utilization of an IEC may act as powerful evidence of the provider's good faith and appropriate concern for patient autonomy and welfare.[38]

Determinations of Death

One inescapable aspect of critical care medicine with important legal implications is the determination and declaration of when a patient has died. Traditional standards of death based on cessation of cardiorespiratory functioning are no longer sufficient by themselves in light of modern medical technology that frequently can maintain the human organism almost indefinitely. Questions relating to the discontinuation of medical intervention and the harvesting of organs for

transplantation have demanded new approaches to the legal definition of death.

In response to these questions, almost all states have adopted, either by statute or court decision, a version of "brain death." This definition provides, either as an alternative to or a replacement for the traditional heart-lungs approach, that a person is legally dead when there is irreversible cessation of all (including brain stem) brain function.[39] Brain death should be confirmed clinically according to the Harvard criteria,[40] as they have been periodically updated.[41,42] Once a patient has been declared dead, there are no longer any treatment decisions to be made (although autopsy and organ donation issues may remain). There is neither a legal duty nor a right to continue medical intervention on a patient who has become a corpse.[43]

Legal Responsibility and Vicarious Liability

Critical care medicine is an interdisciplinary team enterprise, and the manner in which members of the team relate to each other and to the patient and family carries legal consequences. Under the old doctrine of "captain of the ship," a physician in charge of a critical care unit automatically was held legally responsible for any negligently caused patient injury occurring in the unit, regardless of the physician's personal ignorance of or lack of involvement with the particular error or omission. The captain-of-the-ship doctrine has been abandoned by the courts over the past several years in recognition of the increasing complexity of health care delivery.

However, a physician still may be held responsible, under a vicarious liability rationale, for patient injuries proximately (directly) caused by negligent errors or omissions committed by nurses or other providers over whom the physician has supervisory power. The key inquiry in potential vicarious liability situations is not whether the physician actually was exercising supervisory power at the time of the supervisee's negligence, but whether he or she had the authority and opportunity to supervise properly if he or she had chosen to exercise that power.[44]

Thus, the vicarious liability doctrine has significant legal ramifications for the interdisciplinary team's conduct in rendering critical care. The physician and other team members must understand their legal relationships to each other, and their implications with regard to assignment of tasks, oversight, reporting, communication, and problem resolution. The physician must take their obligations as legal leader of the team seriously, without acting autocratically and thereby negating the benefits of broad interdisciplinary contributions to patient care.

Institutional protocols should delineate operational principles of the team and the individual physician's supervisory responsibilities. Where there are multiple consultants on a particular case (as is the norm), medical staff bylaws must spell out the continuing coordination and monitoring obligations of an identified attending or primary care physician; failure to do so unambiguously will increase the liability exposure of all involved clinicians and the hospital in the event of a bad clinical outcome. Consultants who are not hospital employees must be credentialed to practice within the hospital according to criteria contained in the bylaws. Hospital policies and procedures must designate their ICUs as either "closed" (in which case the patient is transferred to an intensivist who functions as the primary care physician) or "open" (in which case the original primary care physician retains ultimate authority and responsibility, but is permitted or required to consult with a critical care physician on the hospital's staff).

Similarly, methods of triaging patients into and out of the ICU should be delineated within the hospital's written policies and procedures. Included should be a specification of ultimate responsibility for a patient's admission or discharge.

As a general principle, when there is a question concerning allocation of responsibility for decisions or actions, development of an institutional policy may be advisable. Courts ordinarily grant hospitals broad leeway in the development and enforcement of the sort of institutional protocols discussed in this chapter, as long as policies and procedures appear to ensure patient care within currently acceptable medical standards. As noted earlier, accreditation standards of the JCAHO also set permissible parameters for internal institutional protocols.

For physicians who function as clinical instructors in teaching programs, residents and medical students may expose the attending physician to vicarious liability for negligent acts or omissions done in the course of the educational activity. The exercise of due care in the monitoring, supervision, task assignment, and evaluation of residents and students who are supposed to be under the physician's supervision cannot be overlooked.[45]

Documentation

The courts have held that creating and maintaining accurate records of patient care is an integral part of the duty that a health care provider owes to a patient. Good documentation is imperative to providing competent patient care, and since avoiding unexpected bad outcomes is the best legal prophylaxis, is therefore wise legal practice. Furthermore, in the event of accusations of substandard care, the physician's best (and often only) defense will lie in the quality of documentation created to explain and justify decisions made and actions taken. In addition, institutional accreditation and third-party reimbursement turn heavily on information drawn from medical records.

The quality of medical records is especially important in critical care, where patient conditions are subject to rapid change, many different professionals may be involved in treating the patient, cost considerations are ever present,[46] and decisions (such as limiting the application of life-prolonging technology) may be controversial. The watchwords of documentation are the same from the legal and medical perspectives: completeness, legibility (dictation is preferable, but dictated entries should be read and corrected before being signed), accuracy or truthfulness, timeliness, corrections should be made in a clear and unambiguous fashion, and objectivity.

A corollary to the subject of medical record keeping is confidentiality. In light of common law privacy principles and federal regulations effective in 2003 to implement the Health Insurance Portability and Accountability Act (HIPAA),[47] the

physician must guard against unauthorized disclosures of personal information about the patient. The party who has authority to give or refuse consent for medical treatment (i.e., the patient or her or his surrogate) ordinarily controls the release of identifiable medical information to third parties, absent a court order or countervailing government regulation. All questions about the release of medical information to third parties in specific cases should be directed to the institution's medical records department or legal counsel.

The counterpart to the right of the patient or surrogate to control the release of information to others is the patient's own right of access to the information contained in the medical record. This right of access is guaranteed, at least for in-hospital care, by the federal Privacy Act for federal facilities, and by the HIPAA regulations, state statutes, and JCAHO standards in most private and public institutions. Patients or their surrogates request access to records for a variety of reasons, ranging from curiosity to serious questioning of quality of care. A physician who is informed of a patient's or surrogate's request for access to records should offer to go through the record with the patient or surrogate, explain matters, and answer questions. In short, treating this circumstance as an opportunity to bolster or correct existing but perhaps unnoticed deficiencies in communication between the physician and patient or surrogate, rather than as a personal affront calling for defensive posturing, often can pay risk management dividends by preventing at an early stage potential misunderstandings that would otherwise eventually manifest themselves as legal action.

Risk Management Program

The hospital's overall program to identify, mitigate, and avoid potential problems that could result in legal, and therefore financial, loss to the institution (i.e., the risk management program), should incorporate specific activities designed to address legal risks prevalent in the delivery of critical care.[48] Particular areas of attention in a critical care–sensitive risk management program should include the organization and administration of CCUs, the roles and responsibilities of the different professionals having contact with patients in those units, medical records, equipment maintenance, equipment modification, equipment records, analysis of equipment malfunctions, incident reporting, and trend analysis of unexpected incidents.

The physician should be knowledgeable about the institution's risk management program and cooperate with it to ensure appropriate sensitivity to critical care practices and potential problems and their avoidance or mitigation. The physician should view the risk manager as a partner in pursuit of the common goal of providing, and if necessary proving after the fact, quality patient care.

Perhaps the single most influential aspect of effective risk management is the fostering of a positive relationship between the critical care team, led by the physician, and the patient and his or her family. There is a demonstrated correlation between patient (or family) psychologic satisfaction with the quality of the physician–patient (or –family) relationship, and the propensity to file a lawsuit if a bad outcome occurs.[49] Communicating openly and compassionately, especially acknowledging the vast uncertainty that pervades much of critical care medicine, is as important a tool in the malpractice prophylaxis arsenal as being proficient, up to date, and conscientious in knowing and applying technologic information and skills.[50]

APPENDIX 1

Florida Designation of Health Care Surrogate

Name: _____
(Last) *(First)* *(Middle Initial)*

In the event that I have been determined to be incapacitated to provide informed consent for medical treatment and surgical and diagnostic procedures, I wish to designate as my surrogate for health care decisions:

Name: _____

Address: _____

_____ Zip Code: _____

Phone: _____

If my surrogate is unwilling or unable to perform his duties, I wish to designate as my alternate surrogate:

Name: _____

Address: _____

_____ Zip Code: _____

Phone: _____

I fully understand that this designation will permit my designee to make health care decisions and to provide, withhold, or withdraw consent on my behalf; to apply for public benefits to defray the cost of health care; and to authorize my admission to or transfer from a health care facility.

Additional instructions (optional):

I further affirm that this designation is not being made as a condition of treatment or admission to a health care facility. I will notify and send a copy of this document to the following persons other than my surrogate, so they may know who my surrogate is:

Name: _____

Address: _____

Name: _____

Address: _____

Signed: _____

Date: _____

Witness 1:

Signed: _____

Address: _____

Witness 2:

Signed: _____

Address: _____

NOTE: Legal requirements of individual states may vary and should be consulted.

APPENDIX 2

Florida Living Will

Declaration made this _____ day of _____, 19 _____.

I, _____, willfully and voluntarily make known my desire that my dying not be artificially prolonged under the circumstances set forth below, and I do hereby declare:

If at any time I have a terminal condition and if my attending or treating physician and another consulting physician have determined that there is no medical probability of my recovery from such condition, I direct that life-prolonging procedures be withheld or withdrawn when the application of such procedures would serve only to prolong artificially the process of dying, and that I be permitted to die naturally with only the administration of medication or the performance of any medical procedure deemed necessary to provide me with comfort care or to alleviate pain.

It is my intention that this declaration be honored by my family and physician as the final expression of my legal right to refuse medical or surgical treatment and to accept the consequences for such refusal.

In the event that I have been determined to be unable to provide express and informed consent regarding the withholding, withdrawal, or continuation of life-prolonging procedures, I wish to designate, as my surrogate to carry out the provisions of this declaration:

Name: _____

Address: _____

_____ Zip Code: _____

Phone: _____

I wish to designate the following person as my alternate surrogate, to carry out the provisions of this declaration should my surrogate be unwilling or unable to act on my behalf:

Name: _____

Address: _____

_____ Zip Code: _____

Phone: _____

Additional instructions (optional):

I understand the full import of this declaration, and I am emotionally and mentally competent to make this declaration.

Signed: _____

Witness 1:

Signed: _____

Address: _____

Witness 2:

Signed: _____

Address: _____

NOTE: Legal requirements of individual states may vary and should be consulted.

APPENDIX 3

2.2 WITHHOLDING OR WITHDRAWING LIFE-PROLONGING TREATMENT.

The social commitment of the physician is to sustain life and relieve suffering. Where the performance of one duty conflicts with the other, the preferences of the patient should prevail. If the patient is incompetent to act in his own behalf and did not previously indicate his preferences, the family or other surrogate decisionmaker, in concert with the physician, must act in the best interest of the patient.

For humane reasons, with informed consent, a physician may do what is medically necessary to alleviate severe pain, or cease or omit treatment to permit a terminally ill patient to die when death is imminent. However, the physician should not intentionally cause death. In deciding whether the administration of potentially life-prolonging medical treatment is in the best interest of the patient who is incompetent to act in his own behalf, the surrogate decisionmaker and physician should consider several factors, including: the possibility for extending life under humane and comfortable conditions; the patient's values about life and the way it should be lived; and the patient's attitudes toward sickness, suffering, medical procedures, and death.

Even if death is not imminent but a patient is beyond doubt permanently unconscious, and there are adequate safeguards to confirm the accuracy of the diagnosis, it is not unethical to discontinue all means of life-prolonging medical treatment.

Life-prolonging medical treatment includes medication and artificially or technologically supplied respiration, nutrition or hydration. In treating a terminally ill or permanently unconscious patient, the dignity of the patient should be maintained at all times. (I,II,IV,V)

2.21 WITHHOLDING OR WITHDRAWING LIFE-PROLONGING MEDICAL TREATMENT—PATIENTS' PREFERENCES.

A competent, adult patient may, in advance, formulate and provide a valid consent to the withholding or withdrawal of life-support systems in the event that injury or illness renders that individual incompetent to make such a decision. The preference of the individual should prevail when determining whether extraordinary life-prolonging measures should be undertaken in the event of terminal illness. Unless it is clearly established that the patient is terminally ill or permanently unconscious, a physician should not be deterred from appropriately aggressive treatment of a patient. (I,III,IV,V)

Chapter 6

ASSESSMENT OF SEVERITY OF ILLNESS

CHERYL L. HOLMES
GENEVIEVE GREGOIRE
JAMES A. RUSSELL

KEY POINTS

- *In the last three decades, intensive care units (ICUs) and critical care researchers have amassed a body of pathophysiologic knowledge that has advanced the care of critically ill patients. Severity of illness scoring systems are tools that have been designed both to predict and to evaluate, from multiple perspectives, the outcomes of critically ill patients.*
- *Most of these scoring systems have evolved from multivariate regression analysis applied to large clinical databases to identify the most relevant factors for prediction of mortality. Scoring systems are then validated by prospective application to other patient populations.*
- *The ideal components of a scoring system are data collected during the course of routine patient management that are easily measured, objective, and reproducible.*
- *The most widely applied scoring systems in adults at the present time are the Acute Physiology and Chronic Health Evaluation (APACHE), the Mortality Probability Models (MPM), Simplified Acute Physiology Score (SAPS), and Sequential Organ Failure Assessment (SOFA).*
- *The potential uses of severity-of-illness scoring systems as applied to patient groups include clinical investigation (to standardize or compare study groups), ICU administration (to guide resource allocation and budget), and assessment of ICU performance (to compare performance over time or between health care settings).*
- *The use of scores in the delivery of care to individual patients is controversial; in some studies the accuracy of prediction of outcomes of scoring systems is not greater than that of the individual clinician's judgment.*

Severity-of-illness scoring systems were developed to evaluate the delivery of care and provide prediction of outcome of groups of critically ill patients who are admitted to intensive care units (ICUs). The purpose of this chapter is to review the scientific basis for these scoring systems and to make recommendations for their use. While there is a growing recognition that when properly administered, these tools are useful in assessing and comparing patient populations with diverse critical illnesses, their use for predicting individual patient outcome is controversial and unresolved.

Purposes of Scoring Systems

There are five major purposes of severity-of-illness scoring systems (Table 6-1). First, scoring systems have been used in randomized controlled trials (RCTs) and other clinical investigations.[1–5] The second purpose of severity-of-illness scoring systems is to quantify severity of illness for hospital and health care system administrative decisions such as resource allocation. The third purpose of these scoring systems is to assess ICU performance and compare the quality of care of different ICUs and within the same ICU over time. For example, severity-of-illness scoring systems could be used to assess the impact on patient outcomes of planned changes in the ICU, such as changes in bed number, staffing ratios, and medical coverage.[6] The fourth purpose of these scoring systems is to assess the prognosis of individual patients in order to assist families and caregivers in making decisions about ICU care. Finally, scoring systems are now being used to evaluate suitability of patients for novel therapy (e.g., the use of the APACHE II assessment for prescription of recombinant human activated protein C [drotrecogin alfa]).

The general hypothesis underlying the use of severity-of-illness scoring systems is that clinical variables that can be assessed on ICU admission predict survival and other outcomes of critically ill patients. This hypothesis is based on observations that increasing age, presence of underlying chronic disease, and increasingly severe abnormalities of the physiology of critically ill patients are associated with increased mortality. Scoring systems that have evolved combine relevant clinical variables to yield prediction of risk of mortality. Early in this evolution, severity-of-illness scores calculated at ICU admission or in the 24 hours following ICU admission predicted hospital mortality. More recently, scores have been calculated over the course of the ICU stay to provide updated prediction of hospital mortality. This dynamic approach uses change in organ dysfunction over time to add further accuracy and precision to outcome prediction.[7–11]

It is important to note that scoring systems have been developed using databases from patients already admitted to ICUs and not from the pool of patients outside the ICU, where the triage decision to admit a patient to the ICU is made. While severity-of-illness scoring systems in theory could be used to increase the accuracy of triage decisions regarding appropriateness of ICU admission, reformulation of the scoring methods would likely be necessary to better reflect the patient population outside the ICU, in whom triage occurs. Obviously, ICU resources should be focused on patients who are most able to benefit from ICU care. However, to date there are no reports regarding the use of scoring systems to assist in decisions regarding appropriateness of ICU admission.

Development of Scoring Systems

The major scoring systems that are the focus of this chapter were designed specifically to predict outcome of critical illness. Initially, clinical and physiologic variable selection was based on subjective judgment of clinicians, review of the literature, and development of consensus. Subsequently, logistic regression modeling techniques were used to select predictive variables from a derivation data set. Ideal variables are simple, well-defined, reproducible, and widely available measurements or data that are collected routinely in the course of patient care. A large number of clinical and physiologic

TABLE 6-1 Potential Uses of Severity-of-Illness Scoring Systems

Uses of scoring systems in randomized controlled trials (RCTs) and clinical research
To compare different RCTs and clinical studies
To determine sample size
To do stratified randomization (to determine subgroup identification and stratification for severity of illness)
To assess success of randomization
To assess treatment effects in subgroups (posttreatment subgroup identification)
To compare study patients to patients in clinicians' practices
Uses of scoring systems for administrative purposes
To describe resource utilization of ICU
To describe acuity of illness
To relate resource utilization to acuity of care
To guide reimbursement and budget of ICU
Uses of scoring systems to assess ICU performance
Quality assurance
To assess performance of an ICU in general or for a specific disease category
To assess performance of an ICU over time
To compare individual intensivists' performances
To assess the performance of a therapeutic intervention
Comparison of ICU performance in different categories of hospitals, countries, etc.
To assess performance for different ICU administrative characteristics (open/closed unit, communication, ICU director task, etc.)
Effectiveness
Uses of scoring systems to assess individual patient prognosis and to guide care
Triage of patients
Decisions regarding intensity of care
Decisions to withhold and withdraw care

variables were collected on many patients, and their survival status at ICU and hospital discharge was recorded. Multiple logistical regression identifies the specific variables that best predicted survival and assigns relative weights to each variable. This set of variables is then tested prospectively for accuracy of prediction in another sample of patients to validate the selection process and appropriate weighting of variables.[12]

The sampling frequency and the period of measurements of physiologic variables are additional methodologic considerations that are important in the development of scoring systems. Most scoring systems use the most abnormal measurement of a physiologic variable in the 24 hours prior to ICU admission. More recently, scoring systems have used the most abnormal value of a physiologic variable for each successive 24-hour period while a patient is in the ICU, and have then correlated physiologic variables during this period with subsequent ICU outcome. Therefore prediction prognosis could be adjusted daily based on the patient's course and response to treatment. Furthermore, the change in organ dysfunction could be used to improve outcome prediction.[7–11] Studies have shown that the change in organ dysfunction from day 0 to day 1, from day 0 to day 3,[9] and indeed from day to day,[13] can be used to accurately predict outcome of the critically ill.

Another important consideration in the development of severity-of-illness scoring systems is the patient sample used to derive the scoring system. For example, it is relevant to know whether scoring systems were derived in medical, surgical, or medical-surgical ICUs, whether community or tertiary care teaching hospital ICUs were used, whether ICUs were selected from one country or from many countries, and how many different ICUs were used to establish the scoring system. Furthermore, scoring systems derived from the sample of patients involved in a clinical trial may be biased and may not represent a general population of critically ill patients.

METHODOLOGIC CONSIDERATIONS

Critical appraisal of severity-of-illness scoring systems involves the measurement of accuracy (calibration and discrimination), reliability, content validity, and methodological rigor.[14]

Discrimination describes the ability of a model to distinguish between a patient who will live and one who will die. If discrimination is perfect, there is no overlap in probability estimates between patients who live and those who die.[15] Discrimination is described by the area under the receiver operating characteristic (ROC) curve[15,16] (Fig. 6-1). The ROC curve shows the relation between the true-positive rate (sensitivity) and the false-positive rate (100%-specificity). Because sensitivity and specificity are computed from independent columns in the decision matrix, and are therefore independent of sample mortality, the area under the ROC curve represents the proportion of patients who not only died, but who also had a higher probability of death than the patients who lived.[14]

The area under the ROC curve ranges from the lower limit of 0.5 for chance performance to 1.0 for perfect prediction. A model is considered to discriminate well when this area is greater than 0.8. An area of 0.9 means that a randomly selected actual nonsurvivor will have a more severe score than a randomly selected survivor 90% of the time.[12] It does not mean that a prediction of nonsurvival occurs with probability 0.9, nor does it mean that a prediction of death is associated with observed nonsurvival 90% of the time. The area under the ROC curve illustrates the discriminating ability over the entire range of prediction scores.[15]

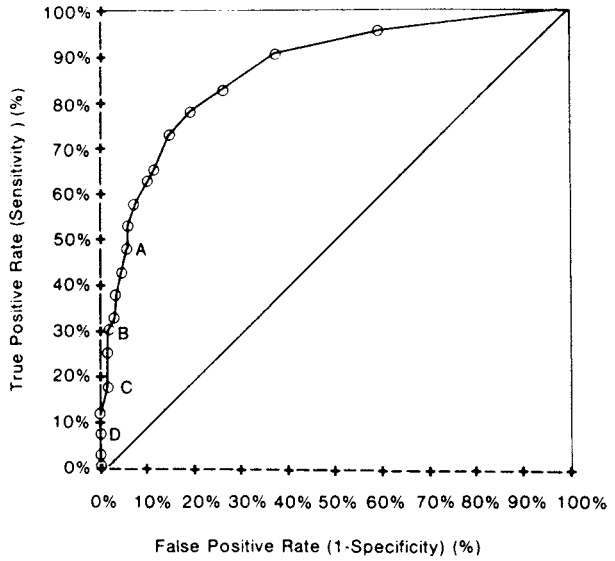

FIGURE 6-1 The receiver operating characteristic (ROC) curve. The diagonal line indicates an index that operates no better than chance and has an area under the ROC curve of 0.5. Points *A*, *B*, *C*, and *D* correspond to decision criteria of 50%, 70%, 80%, and 90% predicted risk of death, respectively. A decision criterion of 0.5 (point A) means that every patient with a risk greater than 0.50 is predicted to die. The overall correct classification rate was 86%, with a sensitivity of 47% and a specificity of 92%. A decision criterion of 0.80 (point C) had an overall correct classification rate of 83%, with a sensitivity of 19% and a specificity of 93%. For a 90% predicted mortality, a scoring system has low sensitivity but high specificity. It is most specific for minimizing the prediction of a positive outcome (survival) when it actually does not occur, and poorly sensitive to predict the outcome (survival) when it actually occurs. (*Reproduced with permission from Knaus et al.*[18])

.

Calibration compares the observed mortality with that predicted by the model within the severity strata. Patients are placed into subgroups according to predicted risk. Typically, 10 strata are formed, called *deciles* of risk.[15] Calibration is evaluated using goodness-of-fit tests; the most commonly used is the Hosmer-Lemeshow χ^2 statistic [17]. Typically, a $2 \times 10 \chi^2$ table is created, with 10 strata of probabilities. The lower the overall χ^2, the better the fit. The calibration test must be interpreted with care, as it is very sensitive to sample size.

Reliability refers to inter- (between) and intra- (within) observer agreement in the use of any severity of illness score, and represents the agreement in the data collection.[14] The greater the subjectivity involved in the scoring system (i.e., choosing a primary diagnosis or assessing the level of consciousness in a sedated, intubated patient), the poorer the reliability of the system. Intraobserver reliability can be measured using a variety of techniques, and is expressed on a range between 0 (measurement involves nothing but error) and 1 (no variable error). A reliability coefficient of greater than 0.7 (suggesting that no more than 30% of the score is due to error) has been used as a statistical standard.[14] The kappa statistic is a measure of interobserver reliability.

Content validity reflects the comprehensiveness of the model.[14] Mortality is dependent not only on measured physiologic derangements and underlying health status, but may also be influenced by factors that are difficult to quantify, such as duration of organ system failure before treatment was instituted, and whether the admission was planned or unplanned, among others. However, as the number of variables increase in a scoring system, the reliability and ease of capturing the data decrease. The inclusion of many variables (overfitting) may actually reduce the performance of the model because some of these variables will be correlated with the outcome by chance alone. It has been proposed that stepwise regression should not be used unless there are at least 10 outcome events for each potential predictor.

Methodologic rigor refers to the avoidance of bias in development of a model. It is important that any severity-of-illness scoring system is based on a large database of all consecutive eligible patients in order to avoid bias.[14] Several ICUs should be involved in data collection to avoid local bias in interpretation of coding or scoring rules. Clinical and laboratory variables should be those that are routinely collected, because collection of unusual data (such as serum ammonia) may bias treatment (treatment effect). Rigor must be applied in the consistency of data collection, and rules for dealing with missing data need to be uniformly applied. Validation using a second independent patient population is important in assessing the reliability of the model. Finally, the usefulness of a rigorously developed and validated scoring system can be degraded by poor application.

Severity-of-Illness Scoring Systems in Clinical Use

SCORES ESTABLISHED AT ADMISSION

The scoring systems most commonly used in critically ill adults are APACHE II,[18] APACHE III,[19] MPM II,[20] SAPS II,[21] and SOFA.[7,22] The variables included in each of these scoring systems are summarized in Table 6-2. The Pediatric Risk of Mortality (PRISM) score[23] is the most widely used scoring system in pediatric critical care.

Some clinical variables are common to APACHE II, APACHE III, MPM II, SAPS II, and SOFA, probably because these variables measure specific clinical and physiologic functions that are major determinants of mortality. Specifically, each of these scoring systems uses age, type of admission, heart rate, blood pressure, assessment of renal function (blood urea nitrogen, creatinine, and/or urine output), assessment of neurologic function (Glasgow Coma Scale or presence of coma), assessment of respiratory function (mechanical ventilation, Pa_{o_2}/FI_{o_2}, or alveolar-arterial oxygen gradient), and assessment of chronic health status. In contrast, other variables are not uniformly shared: serum potassium in APACHE II, glucose and albumin in APACHE III, and serum bicarbonate in SAPS II. These unique variables exist because of differences in the derivation of each scoring system, such as patient sample size, types of patients included, and statistical methods used to derive each score. An important difference between severity of illness scoring systems is how the predictor variables were chosen.[24] For instance, in the APACHE II model, the developers selected those variables they thought relevant to patient outcome and then arbitrarily weighted each variable. In the development of MPM II, SAPS II, and APACHE III, statistical techniques were applied to identify those variables that were independently associated with death. These

variables were then further refined by use of linear discriminant function and stepwise logistic regression analysis, and the final set of variables were then weighted by statistical methods and analyzed and presented as a cumulative score to predict mortality.

The Acute Physiology and Chronic Health Evaluation II (APACHE II) system[18] is the most commonly used clinical severity-of-illness scoring system in North America. APACHE II is a disease-specific scoring system. It uses age, type of admission, chronic health evaluation, and 12 physiologic variables (acute physiology score or APS) to predict hospital mortality (see Table 6-2). The 12 physiologic variables are defined as the most abnormal values during the 24 hours after ICU admission.

The predicted hospital death rate is computed from the weighted sum of APACHE II score, a variable determined by whether the patient had emergency surgery, and the specific diagnostic category weight. APACHE II score was validated in 5815 ICU admissions from 13 hospitals. The correct classification rate for a 50% predicted risk of death was 85%. APACHE III[19] extended APACHE II by improving calibration and discrimination through the use of a much larger derivation and validation patient sample. However, at this time, APACHE III is a proprietary commercial product.

The main disadvantages of the APACHE II system are its failure to compensate for lead-time bias,[25] the requirement to select only one clinical diagnosis, and inaccuracies in clinical subsets, which produce poor interobserver reliability. In spite of these shortcomings, APACHE II remains the most well known and most widely used severity of illness scoring system.[24]

APACHE III is a disease-specific score that was developed from 17,440 admissions in 40 U.S. hospitals. Eighteen variables (see Table 6-2) were included, and their respective weights were derived by logistic regression modeling. To improve the accuracy of assessment of neurologic function, the Glasgow Coma Scale (GCS) score was changed, because reliability testing suggested the need to eliminate similar GCS scores that could occur in patients who had different neurologic presentations. The APACHE III score is a sum of physiology, age, and data from seven potential comorbid conditions. The final APACHE III score can vary between 0 and 300. Risk estimate equations for hospital mortality are calculated from the weighted sum of disease category (78 diagnostic categories are included), a coefficient related to prior treatment location, and the APACHE III score. In the original derivation sample, estimates of mortality for the first day in the ICU had an area under the ROC curve of 0.90, and the correct classification at 50% mortality risk level was 88%. Although APACHE III scores can be calculated from published information, weights to convert the score to probability of death are proprietary, therefore the APACHE III system has not been widely accepted or used.

The Mortality Probability Model (MPM II)[20] was developed from 19,124 ICU admissions in 12 countries. MPM II is not disease specific. MPM_0 is the only severity-of-illness scoring system that was derived at ICU admission and can therefore be used at ICU admission. MPM II does not yield a score, but rather a direct probability of survival. Burn, coronary care, and cardiac surgery patients are excluded. MPM_0 includes three physiologic variables, three chronic diagnoses, five acute diagnoses, and three other variables: cardiopulmonary resuscitation prior to admission, mechanical ventilation, and medical or unscheduled surgery admission (see Table 6-2). Each variable is scored as absent or present and is allocated a coefficient. The sum of these coefficients constitutes the logit that is used to calculate the probability of hospital mortality.

The MPM_{24}[20] was designed to be calculated for patients who remained in the ICU for 24 hours or longer. MPM_{24} includes 13 variables, 5 of which are used in the MPM_0. In the validation data set, the area under the ROC curve was 0.82 and 0.84 for the MPM_0 and MPM_{24}, respectively.

The most recent version of the Simplified Acute Physiology Score II (SAPS II)[21] was developed from a sample of 13,152 admissions from 12 countries, based on a European/North American multicenter database. SAPS II is not disease specific. SAPS II uses 17 variables (see Table 6-2) that were selected by logistic regression: 12 physiology variables, age, type of admission (scheduled surgical, unscheduled surgical, or medical), and three underlying disease variables (acquired immunodeficiency syndrome, metastatic cancer, and hematologic malignancy). The area under the ROC curve was 0.86 in the validation sample. The probability of hospital mortality is calculated from the score.

The Sequential Organ Failure Assessment (SOFA) was originally developed as a descriptor of a continuum of organ dysfunction in critically ill patients over the course of their ICU stay.[22] The SOFA score is composed of scores from six organ systems, graded from 0 to 4 according to the degree of dysfunction/failure. The score was primarily designed to describe morbidity; however, a retrospective analysis of the relationship between the SOFA score and mortality was developed using the European/North American Study of Severity System database.[7,21] Subsequently, SOFA was evaluated as a predictor of outcome in a prospective Belgium study.[13] SOFA score on admission was not a good predictor of mortality (area under the ROC curve 0.79); however, mean SOFA score and highest SOFA score had better discrimination (area under the ROC curve 0.88 and 0.90, respectively). Independent of the initial value, an increase in the SOFA score during the first 48 hours of ICU admission predicts a mortality rate of at least 50%.

DYNAMIC SEVERITY OF ILLNESS SCORING SYSTEMS

All severity-of-illness scoring systems at ICU admission have a relatively high rate of misclassification of survivors and nonsurvivors. Misclassifications may be caused by the following: (1) exclusion of strong outcome risk factors that cannot be measured or have not been measured at ICU admission, (2) exclusion of complications that occur during ICU stay[26], and/or (3) exclusion of treatment effects that modify outcome. Scoring systems applied over the course of the ICU stay can diminish the impact of these factors. However, discrimination of scoring systems applied during the ICU course is lower than discrimination of scoring systems evaluating outcome at the time of initial admission to the ICU.

MPM_{48} and MPM_{72}[27] were developed to estimate the probability of hospital mortality at 48 and 72 hours in the ICU. MPM_{48} and MPM_{72} have the same 13 variables and

coefficients that are used in MPM_{24}, but the models differ in the constant terms, which reflect the increasing probability of mortality with increasing length of ICU stay, even if physiologic parameters are constant. In the validation group, the areas under the ROC curves of MPM_{48} and MPM_{72} were 0.80 and 0.75, respectively.

APACHE III also can be used to calculate a daily risk of hospital mortality.[28] A series of multiple logistic regression equations was developed for ICU days 2 to 7. The APACHE III daily risk estimate of mortality includes the acute physiology score (APS) on day 1, APS on current day, change in APS since the previous day, the indication for ICU admission, the location and length of treatment before ICU admission, whether the patient was an ICU readmission, age, and chronic health status.

The SOFA score has been used to describe increasing accuracy of outcome prediction when used over the first 7 days of the ICU course.[13] More recently, the changes in SOFA score in cardiovascular, renal, and respiratory dysfunction from day 0 to day 1 of sepsis were significantly correlated with 28-day mortality in two large cohorts of patients who had severe sepsis.

COMPARISON OF THE DIFFERENT SCORING SYSTEMS

Comparing the accuracy of the different scoring systems is difficult because of differences in populations used to derive these scores and different statistical methods. Thus there have been few head-to-head comparisons of different scoring systems. A multinational study[29] compared different generations of the three main severity-of-illness scoring systems in 4685 ICU patients. APACHE III, SAPS II, and MPM II all showed good discrimination and calibration in this international database and performed better than did APACHE II, SAPS, and MPM. APACHE II and APACHE III have been compared in 1144 patients from the United Kingdom.[30] APACHE II showed better calibration, but discrimination was better with APACHE III. Both scoring systems underestimated hospital mortality, and APACHE III underestimated mortality by a greater degree.

COMPARISON OF CLINICAL ASSESSMENT WITH SCORING SYSTEMS

Clinical judgment to predict outcome has been criticized because it is not very reproducible, it has a tendency to overestimate mortality risk, and bias is introduced by the ability to recall particularly memorable, rare, and recent events.[15] Three studies compared APACHE II with physicians' mortality predictions in the first 24 hours of ICU admission,[31–33] and one study evaluated physicians' predictions only.[34] Discrimination by physicians had ROC curve areas ranging between 0.85 and 0.89, which were similar to[32,34] and even significantly better than those of APACHE II.[31,33] In contrast to ability to discriminate, calibration rate of physicians' predictions of mortality versus APACHE II differed. For high-risk patients, APACHE II and physicians had similarly correct predictions for mortality, ranging from 71% to 85%. However, for estimated mortality risks below 30%, rates of correct classification of physicians' predictions were 39% to 69%, compared with 51% and 67% for APACHE II.[31]

CUSTOMIZATION OF SCORING SYSTEMS FOR SPECIFIC DISEASES

Severity-of-illness scoring systems have been developed, derived, and validated for specific diseases to improve the accuracy of general scoring systems. APACHE III uses 74 disease classifications and derives a unique mortality risk prediction for each of these disease classifications. New scoring systems have been introduced to better predict mortality for patients with multiple organ failure and sepsis. The original models of SAPS II and MPM II did not perform well in patients who had severe sepsis, because mortality in severe sepsis was higher than mortality in patients with other diagnoses. Both models subsequently were customized[5] for sepsis by using the original data to derive coefficients unique for sepsis to calculate predicted mortality. Furthermore, severity-of-illness scoring systems specifically designed for sepsis have been developed.

Prediction of mortality in sepsis will likely benefit from a dynamic approach that is based on evolution of multiple organ dysfunction. Commonly used organ failure–based systems that have been studied include the Sequential Organ Failure Assessment (SOFA) score,[22] the Multiple Organ Dysfunction Score (MODS),[35] and the Logistic Organ Dysfunction System (LODS).[36]

All three systems attribute points for organ dysfunction in six different organ systems. MODS,[35] which applies to surgical patients, differs from SOFA and LODS in the cardiovascular assessment. MODS scores the cardiovascular system based on the "pressure-adjusted heart rate," defined as the product of the heart rate multiplied by the ratio of the right atrial pressure to the mean arterial pressure. LODS and MODS have excellent discrimination, with ROC curve areas of 0.85 and 0.93, respectively.[35,36]

APACHE II, MODS, and SOFA were recently used to compare outcome prediction in and prospective study of 949 ICU patients.[37] There were no significant differences between MODS and SOFA in terms of mortality prediction. The area under the ROC curves for APACHE II, SOFA, and MODS were 0.880, 0.872, and 0.856, respectively. In patients with shock, the MODS and SOFA scores were slightly better mortality predictors than APACHE II score (area under ROC curve 0.852 and 0.869 vs. 0.825).

Some have suggested that organ failure–based scoring systems could provide an outcome measure to be used as a surrogate for the end point of mortality.[38] Thus, for large (and expensive) randomized clinical trials such as those recently conducted in the treatment of sepsis or acute lung injury, could a reduction in some score of organ failure be taken as a measure of reduced morbidity and hence high drug efficacy?

Many randomized controlled trials in critical care have successfully evaluated organ dysfunction as secondary outcome variables by using scoring systems. Important recent examples include the ARDS Network study of 6 mL/kg vs. 12 mL/kg of ideal body weight tidal volume in patients who had acute lung injury.[39] The use of a protocol of 6 mL/kg ideal body weight, positive end-expiratory pressure (PEEP), and guidelines for respiratory rate and minute ventilation decreased mortality from 40% (with 12 mL/kg tidal volume) to 30%. In addition, the 6 mL/kg tidal volume strategy significantly increased the number of days patients were alive

and free of respiratory, hepatic, cardiovascular, coagulation, and renal dysfunction[39] as assessed using the Brussels scoring system.[9] The randomized controlled trial of recombinant human activated protein C (rhAPC; drotrecogin alfa) showed that rhAPC decreased mortality of severe sepsis from 31% to 25% compared to placebo.[40] The SOFA score was used in this study to evaluate organ dysfunction and rhAPC improved markers of organ dysfunction.

SCORING SYSTEMS SPECIFIC FOR TRAUMA PATIENTS

Scoring systems have been developed to improve triage of trauma patients and to predict their mortality (see Chap. 92). Trauma scoring systems were developed using general trauma patient samples, not specifically critically ill trauma patients. The initial scores were either anatomic (Injury Severity Score or ISS[1,41]) or physiologic (Trauma Score or TS[42] and Revised Trauma Score or RTS[43]). Recently, trauma scoring systems have been expanded to include age, anatomy, and physiology, including the Trauma and the Injury Severity Score or TRISS methodology,[2] and A Severity Characterization of Trauma or ASCOT.[44] Large trauma registries facilitated implementation and validation of trauma scoring systems in large samples of patients. Table 6-3 summarizes the main trauma scoring systems.

The accuracy of TRISS and APACHE II have been compared in critically ill trauma patients.[45] APACHE II classifies trauma patients under only four diagnostic categories: postoperative multiple trauma, postoperative head trauma, nonoperative multiple trauma, and nonoperative head trauma. In APACHE II, patients with combined head and other injuries were assigned to multiple trauma, which was given a lower weight than the isolated head trauma category in predicting mortality.[46] The number of derivation patient samples of APACHE II were much smaller than the samples used for the trauma scores. TRISS tends to perform better than APACHE II. APACHE II significantly overestimates the risk of mortality in the lower ranges of predicted risk and underestimates the risk of mortality in the higher ranges. APACHE III attempted to improve prediction of mortality for head-injured patients by revising the definition for head trauma, allowing assignment of patients with isolated head trauma as well as head trauma and other injuries to the head trauma category. This resulted in a higher predicted mortality that more closely reflected the actual mortality.

TABLE 6-3 Characteristics of the Major Trauma Scoring Systems

Name	Purpose and Main Characteristics	Variables Included	Comments
ISS	Description of the severity of injury Anatomic description Blunt trauma	Anatomic variables: 3 highest scoring body regions from the AIS are squared and summed Value 3–75	Developed for MVA (blunt) trauma victims
TS	Triage Survival probability Physiologic score Blunt and penetrating trauma	Respiratory rate Respiratory effort Systolic blood pressure Capillary refill GCS Range 1–16[a]	Immediately available for triage Determination of respiratory effort and capillary refill are subjective
RTS	Triage Survival probability Physiologic score Blunt and penetrating trauma	Respiratory rate Systolic blood pressure GCS Each coded 0–4 Range 0–12[b]	Value of each variable empirical, but weight of variables for probability of survival by regression analysis. Better goodness of fit than TS
TRISS	Survival probability Considers anatomy, physiology, age, blunt and penetrating trauma	RTS ISS (with revised AIS-85) Age < or >55 years Blunt/penetrating trauma	Coefficients by regression analysis Different values for blunt or penetrating trauma
ASCOT	Survival probability Considers anatomy, physiology, age, blunt and penetrating trauma	RTS Anatomy profile component—ICD/AIS-85 Age (5 subclasses) Blunt/penetrating trauma Set aside: very severe or very minor injury	More variables for calculation of survival probability Better performance than TRISS for blunt and penetrating trauma

[a] A score of 1 is the worst prognosis.
[b] A score of 0 is the worst prognosis.
ABBREVIATIONS: AIS, Abbreviated Injury Scale; AIS-85, the fifth review of the Abbreviated Injury Scale; ASCOT, A Severity Characterization of Trauma[44]; GCS, Glasgow Coma Scale; ICD, International Classification of Diseases; ISS, Injury Severity Score[1,41]; MVA, motor vehicle accident; RTS, Revised Trauma Score[43]; TRISS, Trauma and the Injury Severity Score; TS, Trauma Score.[42]

Clinical, Administrative, and Management Uses of Scoring Systems

SCORING SYSTEMS IN RANDOMIZED CONTROLLED TRIALS AND OTHER CLINICAL RESEARCH

Clinical research in critical care often includes heterogeneous samples of critically ill patients. Severity-of-illness scores are commonly used to describe the acuity of illness so that readers can compare different studies and so that studies can be compared with a clinician's practice. Scoring systems are used in randomized controlled trials (RCTs) to describe severity of illness, to assess comparability at baseline of control and treatment groups, to assess the expected mortality, to determine sample size, and to perform stratified randomization. The success of randomization is often assessed by using scoring systems to confirm that the baseline characteristics of control and treatment groups were not significantly different.

In a randomized controlled trial, if the randomization is not balanced, then outcomes may be altered by the imbalance in baseline characteristics. In that instance, severity of illness scoring systems may be used to do an adjusted analysis (i.e., by adjusting groups for differing severity of illness and then calculating adjusted mortality). For example, very recently a large multicenter RCT of two different PEEP regimens in patients who have acute lung injury was reported. There was no difference in mortality between groups, but unfortunately age was significantly higher in the high PEEP group. Therefore, an adjusted analysis using age and severity of illness was done to adjust for differences in baseline characteristics and found no difference in adjusted mortality. Scoring systems are also used to determine the effect of the therapeutic intervention across different disease severity and mortality risk strata. In a study with no positive drug effect, finding efficacy in a subgroup of patients (e.g., in the sickest patients[47]) can be hypothesis-generating for new studies involving these sicker patients only. Finally, the clinicians reading the results of an RCT can compare the severity of disease of patients in the study with the severity of disease of patients in their practices to decide whether to use the new treatment.

SCORING SYSTEMS FOR ADMINISTRATIVE PURPOSES

The major purposes of scoring systems in administration are to describe utilization of ICU beds and resources, to describe acuity of illness, and to relate resource utilization (e.g., funding, drug utilization, and/or personnel) to acuity of care in an ICU. Resource utilization can be described, for example, by the Therapeutic Intervention Scoring System (TISS) score,[48,49] developed at the Massachusetts General Hospital in 1974. The purpose of TISS was to provide quantitative data to determine the severity of illness in individual patients, in order to determine appropriate utilization of intensive care facilities. TISS quantifies the amount of critical care provided to patients by measuring 76 nursing activities, monitoring techniques, resuscitation procedures, and technology. Each intervention is given 1 to 4 points. Therefore, TISS assesses severity of illness indirectly by the level of services provided to the patient. TISS was designed as a descriptor of the intensity of care, and was not designed specifically to predict outcome.

TISS scores have been used to categorize the level of care that patients require.[49,50] Beck and coworkers used TISS scores at ICU discharge as an objective assessment of the risk of premature discharge, and investigated the relationships of discharge time, TISS scores, and discharge destination on post-ICU mortality.[51] There was a significant association between increasing TISS scores and post-ICU mortality at ICU discharge (χ^2 for trend $= 0.90$, $p = 0.028$). Patients with high TISS scores (>30) who were treated in hospital wards had significantly increased severity-adjusted mortality risks compared with a comparable group of patients who were discharged to high-dependency units.

In addition, acuity of care can be correlated with indices of resource utilization.[52] Furthermore, reimbursement can be guided by assessment of severity of illness. For example, planning for ICU bed allocation, staffing, and budget can be aided by measures of admission numbers, diagnoses (e.g., diagnosis-related groups [DRGs] and case-mix groups [CMGs]), and severity of illness.

SCORING SYSTEMS TO ASSESS INTENSIVE CARE UNIT PERFORMANCE

Scoring systems can be used by ICUs to evaluate quality of care (quality assurance; see Chap. 3), to assess performance of an ICU over time, to assess performance of different intensivists, and to assess performances of different ICUs (see Table 6-1). The scoring systems provide a tool to normalize for differences in severity of illness of different samples of patients. Although quality assurance has largely been supplanted by newer approaches such as continuous quality improvement, severity-of-illness scoring systems nonetheless can be used to assess predicted and actual mortality. ICUs can review the outcomes of patients in general, or for specific disease categories, and compare the actual outcomes with predicted mortality. The performance of an ICU also can be followed over time. Evaluation of new technologies or new treatment modalities in an ICU also can be the object of continuous quality improvement evaluations.

There are potential problems associated with the use of scoring systems to compare actual with expected mortality in an ICU. For example, biases in the regression techniques used to calculate the risks of mortality can lead to situations in which hospitals providing care to more severely ill patients will tend to have actual mortality rates above predicted, and thus will appear to be giving suboptimal care. This occurs because most scoring systems underestimate mortality of high-risk patients. Also, medical and nursing interventions can improve physiologic data, leading to a lower estimated risk of mortality for the same patient.[53] The outcomes of individual intensivists can be adjusted for severity of illness to better assess performance. This is controversial for several reasons. First, patient sample size of the intensivist may be insufficient to draw legitimate conclusions regarding performance.[54] Second, ICU care is team care, including house officers and other caregivers, so outcomes are less influenced by the behavior of individual physicians.

Scoring systems can be used to compare ICUs in different hospital settings (tertiary care, community, academic, etc) and to compare ICUs of different countries. A comparison of New Zealand and U.S. hospitals demonstrated different patient selection and fewer admissions to ICUs in New Zealand, and yet

hospital mortality rates were comparable.[55] A similar comparison between hospitals in Canada and in the United States revealed similar results.[56] However, important differences in mortality have been observed between pediatric ICUs in the United Kingdom and Australia. For comparable severity of illness, the mortality rates of critically ill children were higher in the United Kingdom than in Australia.[57]

Severity-of-illness scoring systems also can be used to assess ICU performance in different models of organization. For example, Carson and coworkers[58] evaluated the effects of changing from an "open" to a "closed" model of ICU care by dedicated intensivists by using a "before/after" study design. Patient severity of illness as assessed by APACHE II was greater, yet care costs were similar, and the ratio of actual to predicted mortality was lower after converting a medical ICU from open to closed care. Similar studies involving patients with sepsis demonstrated that changing ICU staffing to include physicians formally trained in critical care medicine reduced mortality.[59,60] Other examples of the use of scoring systems to assess ICU performance include studies of availability of ICU technology and studies of organizational practices and outcomes.[61]

Rapoport and coworkers[62] described a method to assess cost effectiveness of ICUs. A clinical performance index was defined as the difference between actual and MPM II predicted mortality. The economic performance (resource use) used a surrogate for costs: the "weighted hospital days," a length-of-stay index that weights ICU days more heavily than non-ICU days. Predicted resource use was calculated by a regression including severity of illness and percentage of surgical patients. The actual and predicted survival and actual and predicted resource use of hospitals were compared with the mean. A scatterplot illustrated which units were more than one standard deviation off for clinical and economic performance.

The cost effectiveness of ICUs should include nonmortality measures of effectiveness such as quality of life, return to independent living, and patient/family satisfaction.[63] These nonmortality measures of outcome need to be adjusted for ICU severity of illness by using severity-of-illness scoring systems.

SCORING SYSTEMS TO ASSESS INDIVIDUAL PATIENT PROGNOSIS AND TO GUIDE CARE

The assessment of individual patient prognosis is complex. Moreover, the use of severity-of-illness scoring systems for assessment and prediction of individual patient prognosis is controversial. We believe that management decisions cannot be based solely on prognosis as evaluated by the scoring systems. Assessment of individual patient prognosis influences decisions regarding triage of patients (i.e., ICU admission), decisions regarding intensity of care, and decisions to withhold and withdraw care.

Theoretically, a very accurate estimate of patient prognosis could be used to triage patients who have such a good prognosis that ICU admission would be unnecessary and inappropriate, and to identify patients who are so hopelessly ill that ICU admission would be futile and inappropriate. Scoring systems may complement physician judgment regarding appropriateness of ICU admission. However, it is important to emphasize that most scoring systems were derived from patients already admitted to an ICU using data from the first 24 hours of ICU admission. The Mortality Probability Model (MPM II) might be more accurate and appropriate because MPM_0 used variables available immediately at ICU admission rather than the worst values of variables over the first 24 hours in the ICU. However, none of the commonly used scoring systems were validated for the purpose of triage of ICU patients.

Scoring systems have been used to assist in triage of patients to intermediate care (monitoring) or to intensive care (life support). Recently, APACHE III was modified to estimate the probability of need for life support of patients admitted for ICU monitoring.[64] Among 8040 ICU admissions for monitoring, 79% were predicted to have a low probability (<10%) for active treatment during their ICU stay. These patients were admitted to an intermediate care unit and 96% received no subsequent active treatment. The predictive equation had a ROC curve area of 0.74. There are scoring systems designed specifically for triage of trauma patients. The Triage Index[65] for trauma patients assesses injury severity and predicts an outcome using physiologic variables available before admission. The Trauma Score[42] and the Revised Trauma Score[43] are derived from the Triage Index. In the part of the Revised Trauma Score used for triage, the T-RTS, specific decision rules are proposed to indicate appropriate transfer to a trauma center.[43] These rules are based on the score and the GCS score. There are at least two caveats regarding use of scoring systems to guide ICU triage decisions. First, a patient who could be admitted to the ICU who has a very low probability of mortality estimated by the MPM_0, might in fact have a higher actual probability of mortality if ICU admission were denied,[20] because outcome could be adversely affected by ward admission and the associated lower intensity of monitoring and treatment. Second, physicians tend to underestimate mortality in low-risk patients. Thus scoring systems can be more accurate than clinician judgment for risk estimate of low-risk patients.[31]

A novel use of severity of illness scoring systems is in patient selection for specific therapies. The advent of a new therapy for severe sepsis, recombinant human activated protein C (rhAPC; drotrecogin alfa), is an example. In a multicenter RCT (the PROWESS trial), rhAPC significantly decreased mortality compared to placebo in treatment of severe sepsis.[40] Treatment with rhAPC activated was associated with a reduction in the relative risk of death of 19.4% (95% confidence interval [CI], 6.6 to 30.5) and an absolute reduction in the risk of death of 6.1% (31% vs. 25%, $p = 0.005$). The number needed to treat (NNT) with rhAPC was 16 to save 1 life. A post-hoc analysis of the study data performed by the FDA reported a differential benefit according to APACHE II score (Fig. 6-2); among patients with an APACHE II score of 25 or more, the relative risk of death among patients treated with rhAPC, as compared with those given placebo, was 0.71 (95% CI, 0.59 to 0.85), whereas among those with a score of 24 or less, the relative risk of death was 0.99 (95% CI, 0.75 to 1.30). Consequently, the FDA concluded, "efficacy of drotrecogin alfa has not been established in patients with lower risk of death (e.g., APACHE II scores <25),"[66] and the drug has not been approved for use in patients with lower severity of illness. Therefore, in the U.S. and in some other countries, regulatory and payer groups permit use of rhAPC only in patients who have severe sepsis and a high risk of death as defined by an APACHE II score greater

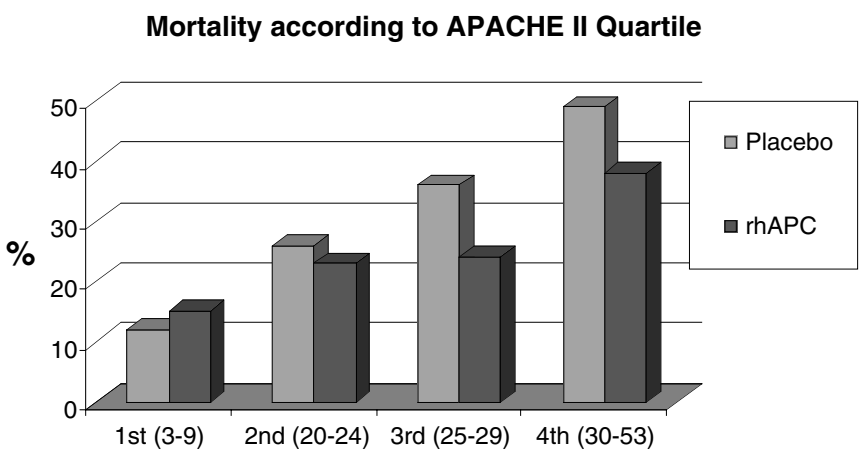

FIGURE 6-2 Data from PROWESS. Differential mortality benefit of rhAPC according to APACHE II quartile. In a subgroup analysis conducted by the U.S. Food and Drug Administration, the use of human recombinant activated protein C (rhAPC; drotrecogin alfa) was associated with a mortality benefit only in patients in the highest two quartiles of APACHE II. (*Data used by permission from Warren et al.*[123]).

than 25. In contrast, in Europe rhAPC was approved for use in patients who have severe sepsis and two or more organ dysfunctions *or* an APACHE II score greater than 25. These differing regulatory approvals and clinical practices likely reflect differences in how APACHE II scores can be used to make individual patient therapeutic decisions.

In support of this approach (i.e., use of APACHE II to identify high-risk patients), a cost-effectiveness analysis by Manns and coworkers[67] found that rhAPC is relatively cost effective when targeted to patients with severe sepsis, greater severity of illness (an APACHE II score of 25 or more), and a reasonable life expectancy if they survive the episode of sepsis. In a second cost-effectiveness analysis by Angus and coworkers, rhAPC cost $27,400 per quality-adjusted life-year when limited to patients with an APACHE II score ≥25, and was cost-ineffective when limited to patients with a score <25.[68] Clearly, the results of this subgroup analysis are dependent on the validity of the post hoc reanalysis performed by the FDA. Manns and coworkers concluded, "given the discrepancy between the published study results and the reanalysis, it would be reasonable to restrict the use of activated protein C to patients with an APACHE II score of 25 or more until convincing evidence of effectiveness and cost effectiveness in patients with less severe illness becomes available."[67]

There are several criticisms of using baseline APACHE II scores in individual patients to guide therapy.[69] First, the PROWESS trial was not powered to determine an efficacy difference among APACHE II subgroups. Even more importantly, the APACHE II disease severity scoring system was not designed and has not been validated for use to discriminate any parameter in the individual patient. Furthermore, the interobserver and intraobserver variability in the determination of APACHE II scores among experienced intensive care physicians may be as high as 10% to 15%.[70] To our knowledge, this is the only example of a proven therapy in critical care that is allocated based on an individual patient's APACHE II score.

Ethical Issues Relevant to Use of Scoring Systems to Guide Management

Use of severity-of-illness scoring systems to assist in decision making regarding withholding and withdrawal of care is controversial for several reasons. First, scoring systems are designed to describe severity of illness and probability of death in groups of patients, not individual patients. Second, even in groups of patients, no system is perfectly calibrated and such systems cannot perfectly discriminate survivors from nonsurvivors. Third, scoring systems can guide care decisions only in the context of appropriate understanding of the ethical principles relevant to withholding and withdrawal of care.[71] Nonetheless, scoring systems could assist in deciding that ICU care is futile. Schneiderman and coworkers[72] proposed that "when physicians conclude (either through personal experience, experiences shared with colleagues, or considerations of published empirical data) that in the last 100 cases a treatment has been useless, they should regard that treatment as futile." Using this definition of futility, let us consider use of scoring systems and physician judgment to help predict futility. Calibration of APACHE III found that for an estimated mortality rate above 90%, the rate of correct classification was 85%, with a specificity of 99.8%. By comparison, for the same estimated mortality rate above 90% strata, physicians' predictions yield a correct classification of 70% to 76% and a specificity of 97% to 99%.[31,32] Thus APACHE III may be more accurate than physicians in predicting that a group of patients have a 90% chance of mortality. However, at a quantitative threshold of futility of less than 1% chance of survival, scoring systems are not precise enough. The highest precision of any scoring system to date was a 95% probability of death, meaning that 5% of patients with that score would survive[28] (Fig. 6-3). Therefore, severity-of-illness scoring systems may not accurately identify patients in whom ICU care is futile if futility is defined as less than 1% chance of survival. The SUPPORT study[73] (Study to Understand Prognoses and Preferences for Outcomes and Risks of Treatments) is important because it was designed to determine whether providing physicians with accurate predictions of death would change physician behavior, patient satisfaction, and decisions regarding care. SUPPORT was designed to estimate survival of seriously ill hospitalized patients who were not necessarily in an ICU. The SUPPORT[73] prognosis model includes nine diagnostic groups and the following 15 prognostic factors: disease group, 11 physiologic variables, age, history of malignancy, and the number of days the patient was hospitalized before study entry. In phase I of the study, the investigators noted shortcomings in communication, variability in frequency of aggressive treatment,

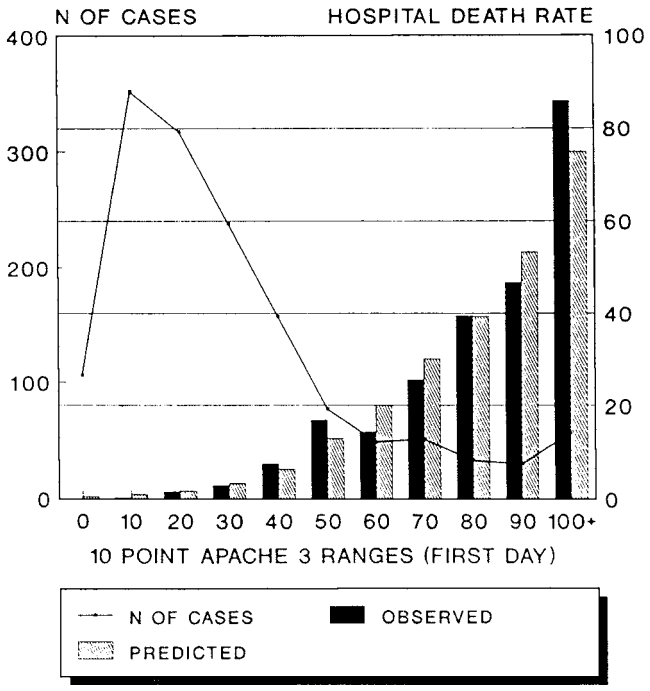

FIGURE 6-3 Relationship between first-day APACHE III score and risk of hospital mortality for trauma admissions to APACHE III study. With distribution of the sample into specific disease categories, the number of high risk of mortality patients used in the validation set is fairly low. In the highest score subset of patients, the mortality for these groups remains much lower than 99%. Also, severity-of-illness scoring systems are prone to underestimating the risk of mortality in high-risk patients. (*Reproduced with permission from Watts and Knaus.*[122])

and variability in care at the time of death (CPR, comfort care, pain management, etc). In phase II of the study[74] physicians in the intervention group received probability estimates of 6-month survival, outcome of cardiopulmonary resuscitation, and incidence of functional disability at 2 months. Specifically trained nurses made multiple contacts with the patients, families, physicians, and hospital staff to elicit preferences, improve understanding of outcomes, encourage attention to pain control, and facilitate advance care planning and patient-physician communication. Importantly, the phase II intervention did not improve care or patient outcomes. Patients experienced no improvement in patient-physician communication. Also, there was no change in the incidence or timing of written DNR (do not resuscitate) orders, physicians' knowledge of their patients' preferences not to be resuscitated, number of days spent in the ICU before death, or use of hospital resources. Thus the SUPPORT study showed that providing physicians with objective outcome predictions did not change physicians' attitudes and behavior.

Several observations suggest that there is a gap between scoring system predicted outcome and decisions to withhold and withdraw ICU care. Patients in whom care was withdrawn in a medical ICU had APACHE II predicted mortality on the day of ICU admission of only 61% ± 22%.[75] Furthermore, patients with prolonged multiorgan system failure who continue to require life support generally do not have very abnormal physiologic parameters[54] and thus have relatively low APS scores. Finally, an increasing proportion of critically ill patients in ICUs die without CPR (cardiopulmonary resuscitation),[76] and many die after withholding or withdrawal of care.

A major portion of ICU resources is spent on patients who have minimal chances of survival. However, until a public consensus is reached about dealing with these very difficult issues,[77] broad ethical principles of beneficence, nonmalfeasance, and autonomy are likely to be more important components of end-of-life decisions than quantitative data provided by scoring systems. Broader social and economic policy issues should be separate concerns.

Sources of Error and Bias in Scoring Systems

Severity-of-illness scoring systems are not perfect, partially because of error and bias. Error and bias limit the reproducibility of scoring systems outside the original sample of patients, and thus limit the applicability of scoring systems to different clinical situations. Specifically, bias of scoring systems can be related to the selection of included variables, to the collection of data, to the lead time before the onset of the acute disease and admission of the patient to the ICU, to the imprecision in choosing a principal admission diagnosis, to the inaccuracy of certain scoring systems for specific disease categories, and finally to the use of scoring systems for purposes they were not meant to accomplish.

BIAS RELATED TO THE SELECTION OF VARIABLES AND TO THE COLLECTION OF DATA

Variables can be included in a severity-of-illness score by a multivariate analysis that shows that each variable is a statistically independent predictor of mortality. Alternatively, variables can be selected by consensus of experts. Consensus panel selection of variables is subjective, and variables can be interrelated.[15] The problem with interrelated variables is that two such variables are not independent of each other as predictors of mortality. Noncontinuous variables increase error in the computation of risk of mortality. Noncontinuous variables are classified as present or absent, so a single misclassification results in a large error in outcome prediction.[15]

Detection bias is another cause of bias of the included variables. *Detection bias* means that variables are only detected if measured. However, because scoring systems use variables measured in clinical practice, not all variables will be measured on all patients on all days. Therefore, in several scoring systems, unmeasured (undetected) variables are assigned a normal value. The assumption that unmeasured physiologic variables are normal can underestimate the risk of mortality. APACHE II, APACHE III, and SAPS II contain some variables that are not used routinely in daily care, such as albumin and bilirubin levels.

Use of the worst value of a variable in 24 hours also causes errors. Most scoring systems use the worst value of a variable in a 24-hour period. However, selection of the worst value can be subjective. There are other errors associated with collection of data, including temperature conversion from Fahrenheit to Celsius, creatinine conversion to the international system, use of the Glasgow Coma Scale on deeply sedated patients,[54]

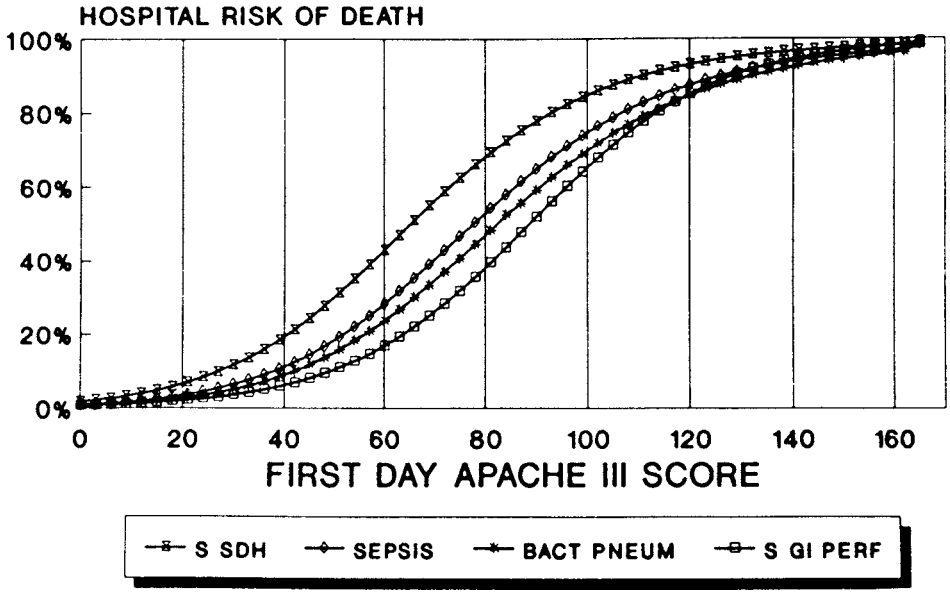

FIGURE 6-4 The influence of the choice of a single disease category for the prediction of hospital risk of death in APACHE III. Relationship between APACHE III score and predicted risk of hospital death for patients with postoperative subdural hematomas (S SDH), sepsis (other than urinary tract), bacterial pneumonia (BACT PNEUM), and postoperative gastrointestinal perforation (S GI PERF). The same APACHE III score can lead to different estimated hospital risk of death, depending on the choice of main diagnosis. (*Reproduced with permission from Knaus et al.*[19])

transcription errors, and errors in analysis of data. Direct computer data entry may decrease transcription error.

BIAS RELATED TO POOR CALIBRATION

Statistical regression in scoring systems has a propensity for poor calibration. Regression techniques tend to underpredict the likelihood of death of more severely ill patients, and tend to overpredict the likelihood of death of patients with less severe illness (Fig. 6-3). These errors can create a pernicious bias. For example, hospitals providing care to more severely ill patients will tend to have actual mortality rates above predicted, and thus will appear to be giving poor care. On the other hand, hospitals with less severely ill patients will tend to have actual mortality rates lower than predicted, and will appear to be giving better than average care.[78]

LEAD-TIME BIAS

Lead-time bias refers to the different lengths of time that patients are ill prior to ICU care and scoring. Lead-time differences also influence mortality. Acute physiology scores do not assess previous treatments. Thus, for the same score, a patient hypoxemic in the emergency room can improve rapidly and have a better outcome than a patient referred from another hospital for persistent hypoxemia. Because of lead-time bias, APACHE II underestimates the mortality of patients referred from other ICUs,[25] other hospitals, or even within other parts of the same hospital.[15] APACHE III contains a variable to assess patient location and treatment prior to ICU admission in an attempt to minimize lead-time bias.

Therapies provided prior to and immediately after ICU admission change physiologic variables and thus influence physiologic scores. Rapid and successful resuscitation in the emergency department prior to ICU admission or early in the ICU will hide abnormally low values of variables that would have been recorded as the worst over 24 hours. Theoretically, poor care would increase physiologic scores and increase predicted mortality rate, whereas good care would decrease scores and reduce predicted mortality rate.[78] The effects of treatment can be minimized and mortality prediction might be enhanced by using hospital presentation data.

IMPRECISE PRINCIPAL DIAGNOSIS

Inaccurate diagnosis is another source of error in many scoring systems. Some scoring systems (e.g., APACHE III) adjust for the differing prognoses of patients who have different diseases but similar physiologic abnormalities. Accurate diagnosis can be difficult in the critically ill for several reasons. First, patients in the ICU often suffer from several conditions. APACHE II and APACHE III require identification of one diagnosis or organ failure that prompted ICU admission. Consider a patient with bacterial pneumonia and sepsis who is admitted to the ICU. In APACHE III, patients who have bacterial pneumonia and patients who have sepsis who have similar physiologic scores have different predicted mortality (see Fig. 6-4). Thus the assignment of appropriate diagnosis is very important in making an accurate mortality prediction.[15] The principal diagnosis could differ between prospective identification versus retrospective chart review.[54]

SEVERITY-OF-ILLNESS SCORING SYSTEMS FOR SPECIFIC DISEASE CATEGORIES

For patients with specific disease processes, it is debated whether specific severity scoring systems are better than general ones. Because inaccuracy of diagnosis can cause error, we recommend that scoring systems be tested for different diagnostic categories. Both disease-specific systems (APACHE II and APACHE III) and non–disease-specific systems (SAPS II and MPM II) need to be compared in external validating patient samples.[15]

APACHE II, APACHE III, and SAPS II have performed well in several disease-specific categories, including liver failure,[79,80] malignancy,[81–83] cardiac bypass surgery,[84–86] sepsis,[87] peritonitis,[88–90] pancreatitis,[91–97] acute myocardial infarction,[98–101] HIV patients,[102,103] obstetric patients,[104] and stroke.[105] APACHE III performed well in head-injured patients.[106,107] In general, the performance of APACHE II,

APACHE III, and SAPS II for these disease processes was similar to that reported for heterogeneous ICU patients.

APACHE II and III have consistently performed poorly in trauma,[46,108,109] in postoperative patients,[110,111] and in women with eclampsia.[112]

INACCURACY OF SCORING SYSTEMS FOR CERTAIN TYPES OF INTENSIVE CARE UNITS OR DIFFERENT GEOGRAPHIC REGIONS

The patient sample used to derive and validate a scoring system can influence the mortality predictions. There are potentially important differences in outcomes of comparable patients in community versus teaching hospitals, in different regions of a country, and in different countries because of the influence of health care funding and policy. For example, a comparison of New Zealand and U.S. hospitals demonstrated different patient selection and fewer ICU admissions in New Zealand, and yet found similar hospital mortality.[55]

Some investigators have used scoring systems to compare critical care in different countries but came to sharply different conclusions. For example, Sirio and coworkers[113] used APACHE II to compare Japan and the United States. Despite an ROC curve area of only 0.78 in the Japanese patient sample, they concluded that APACHE II performs well in Japan. In contrast, the Intensive Care Society APACHE II study[114] examined 8724 critically ill patients and reported that crude death rates in hospital varied more than twofold between intensive care units in Britain and Ireland. Application of the APACHE II equation produced an ROC value of 0.83 and failed to explain outcome in four intensive care units. They concluded that the American APACHE II equation did not fit their data uniformly, and cited systematic differences in medical definitions and diagnostic labeling, diagnostic mix, measurement of physiologic variables, effectiveness of treatment, and differences in age-specific health status between the two countries.

The performance of APACHE III has been assessed in several countries including Brazil,[115] the United Kingdom,[116] Korea,[117] and Australia.[118] In most countries, the observed hospital mortality was significantly higher than the APACHE III predicted mortality rate. In the Australian study, when the model was corrected for hospital characteristics, the observed hospital mortality rate was not different. The area under the ROC curve was 0.92. The APACHE III mortality model, when adjusted for hospital characteristics had good discrimination and calibration in the Australian adult ICU population.

Recommendations for Clinical Use

There has been rapid growth in the number and types of severity-of-illness scoring systems in critical care, and they are increasingly used for clinical research, administrative tasks, quality assurance, and individual patient prognosis. Therefore, physicians and administrators must understand the principles underlying development and testing of these systems, as well as the sources of errors in their development, to interpret the literature and to decide how and which system to use. We recommend four uses of severity-of-illness scoring systems. First, scoring systems are useful in clinical trials and in clinical research. The scoring system used must be validated and published in peer-reviewed literature. When researchers and clinicians have a common language for description of severity of illness, clinicians can compare the patients in studies with the patients in their own practices to decide how the results of the studies influence their own practices.

Second, scoring systems may be used for administrative purposes, to describe resource utilization relative to acuity of illness, and to assist with resource-allocation decisions.

The third potential use of scoring systems is to assess ICU performance. However, several biases limit this application because very little is known about accuracy of generalizations of scoring systems to different categories of hospitals, hospitals from different countries with different health care systems, or even different ICUs in the same hospital. Therefore, we believe that use of scoring systems to compare ICU performance is limited and requires further evaluation.

The fourth potential use of scoring systems is to assess individual patient prognosis and to guide care. We believe that scoring systems have limited use for individual patient prognosis and care decisions. At best, they can guide physicians, families, and patients in difficult decisions. Patients' preferences and patients' quality of life prior to ICU admission cannot be integrated into mathematical models. Severity-of-illness scoring systems predict probability of mortality, but they are not helpful in assessing probability of death in the 6 months following discharge from the ICU. Finally, scoring systems do not predict quality of life or return to independent living of patients.

Chapter 7

TRANSPORTATION OF THE CRITICALLY ILL PATIENT

IRA J. BLUMEN
FRANK THOMAS
DAVID WILLIAMS

KEY POINTS

- *The objective of critical care transport is to provide an equivalent or higher degree of monitoring and medical care than the patient was receiving prior to transport.*
- *Each contemplated transport requires an evaluation of the risks and benefits of the transport.*
- *The risks to the patient during interhospital and intrahospital transport can be minimized through careful planning, use of appropriately qualified personnel, selection of appropriate transport equipment, and proper patient evaluation and stabilization.*
- *For interfacility transport, the referring physician is responsible for the transport-related decisions. It is common and appropriate for the receiving physician or critical care transport specialist to make recommendations regarding the mode of transport or need for specialty personnel or equipment.*

In recent years, advances in bedside capabilities, diagnostics, and therapeutic interventions have dramatically improved care for critically ill and injured patients. In addition, comprehensive critical care units are no longer limited to academic and urban tertiary care centers, and have expanded to other clinical settings in suburban and rural areas. Despite these advances, the movement of critical patients may still be required for optimal patient care.

Transport of critically ill patients may be divided into two categories: transport within the hospital (intrahospital) and transport between hospitals (interhospital). Despite the evolution in the bedside management of critical patients, it is anticipated that the number of critical patients who will need to be moved from one location to another will not diminish. Patients in outlying hospitals will need to be transferred to critical care centers, and patients in critical care units may require transfer to intermediate or special care units. Also, with continued advances in medical technology, it is expected that more critically ill patients will require transport for sophisticated diagnostic studies and therapeutic interventions, such as magnetic resonance imaging (MRI), computed tomography (CT), nuclear medicine imaging, angiography, and gastrointestinal contrast studies.

From a historical perspective, the United States government began to pay a great deal of attention to highway-related accidents and fatalities with the passage of the 1966 National Highway Safety Act. By the early 1970s, civilian medical helicopters were being used in the prehospital transport of trauma victims and in the interhospital transport of critically ill and injured patients.

In contrast, despite these advances in prehospital and interhospital transport, very little attention had been paid to the transport of patients within a facility. Intrahospital transports of critically ill patients are more likely to occur and require the same comprehensive and systematic approach as the interfacility transports.

The focus of this chapter is on the transport of the critically ill or injured patient. These transports can originate from a number of locations that include the various intensive care units, the emergency department (ED), the operating room (OR), and so forth. Patients may go into the operating room with nothing more than a peripheral IV, but leave the OR intubated, with chest tubes, an arterial line, and various drainage tubes. More important than where the patient comes from is the patient's condition and the need for comprehensive monitoring and highly skilled medical personnel in attendance during the patient transport.

It has been well documented that critically ill or injured patients can be transported safely, without evidence of major complications and without adverse impact on clinical outcome.[1–6] These studies support the transport of critical patients if the benefits outweigh the possible harm of the transport. The goal of critical care transport must be to minimize these risks and provide necessary ongoing care.

Risk Analysis and Prevention

The movement of any critically ill or injured patient is not without hazard. Though these patients may be considered "stable," their physiologic reserve is often limited. Even minor adverse physiologic changes in these patients during transport may cascade into life-threatening complications.

It is essential for everyone involved in the care of critical patients to have a basic understanding regarding the transport environment, personnel, equipment, and vehicles. Current technology makes it possible to nearly replicate the critical care environment during transport. Even with the best planning, personnel, and equipment, there may be times during transport when monitoring may be difficult and the capability to manage emergencies may be limited. As a result, ongoing therapy may be interrupted and a patient's clinical condition may be compromised.

While there are distinct differences between interhospital and intrahospital transport, there are numerous common concerns and considerations. To reduce transport-related risks, an appropriate level of monitoring and clinical support is necessary before departing the point of origin. It is not uncommon for these complex patients to have a variety of lines, tubes, and mechanical support devices that must be addressed before any patient movement is possible. Transport represents a period of potential cardiopulmonary instability for these critical patients. Central to a safe transport is the avoidance of any inadvertent interruption in the monitoring or maintenance of the patient's vital functions. Therapeutic modalities that are in place prior to transport must be continued to support the patient's airway, breathing, circulation, and disability, and to prevent physiologic complications.

AIRWAY

Intubated patients are at risk for accidental extubation during transport. This is especially true during multiple transfers between beds, carts, and vehicles. Endotracheal tubes are to be secured and placement documented before the transport begins. It is also recommended that the placement be verified following the movement of the patient from bed to cart, cart to CT table, vehicle to vehicle, and so forth. Physical restraints or sedation may be applied as needed to prevent accidental extubation.

Securing and maintaining a patent airway is considered the highest priority of medical transport personnel. Making the head of the bed or stretcher easily accessible will facilitate airway control. Patients with an unstable or potentially unstable airway should be accompanied during transport by personnel who have the skill and necessary equipment to reintubate.[7,8]

BREATHING

It is essential that adequate oxygenation and ventilation be maintained throughout the transport. Improper ventilation (overventilation or underventilation) may result in hypoxemia, hypocarbia, hypercarbia, or undesirable acid-base changes.

Some transport teams routinely use a portable transport ventilator, while others favor the bag-valve-mask (BVM) and manual ventilation. Weg and Haas[9] concluded that manual ventilation during intrahospital transport is safe if the person doing the manual ventilation can approximate the pretransport inspired oxygen fraction and minute ventilation. In a prospective study by Braman and colleagues involving 36 critically ill, ventilator-dependent patients transported outside the ICU, a rise in P_{CO_2} of at least 10 mm Hg during transport occurred in 14 of 20 patients manually bagged.[10] Of the 16 patients transported using a portable mechanical ventilator, six patients showed significantly fewer changes in their arterial blood gases. Braman and colleagues concluded that the use of portable mechanical ventilators during transport might reduce the incidence of acid-base changes, cardiac arrhythmias, and hypotension. Nakamura and coworkers[11] studied spontaneously breathing patients who needed ventilatory support during transport out of the ICU. They concluded that although both manual and mechanical ventilation could be used safely, the use of a transport ventilator with a patient-triggering function provided more consistent ventilation and less deterioration in the Pa_{O_2}/FI_{O_2} ratio.

Regardless of whether a portable transport ventilator or BVM ventilation is used, adequate oxygenation and ventilation must be assured. It is essential to establish an appropriate FI_{O_2}, tidal volume, rate of ventilation, and level of positive end-expiratory pressure (PEEP). While there are many transport ventilators that can perform comparably to traditional ICU ventilators, not all transport ventilators are created equal.[12] Pressure limitations may make some transport ventilators incapable of providing high minute ventilation, airway pressures, or PEEP when these are required. In these types of patients, manual bagging for long periods of time may prove to be impractical.

There are many monitoring devices that may be helpful to the transport team, including a spirometric device (for bag ventilation), end-tidal CO_2 monitors, transcutaneous P_{O_2} monitoring, and pulse oximetry. Transport personnel should also assess for and document the symmetric rise and fall of the chest wall.

In recent years, the therapeutic options available to treat respiratory failure have advanced to include noninvasive mask ventilation (NIMV), inhaled nitric oxide (iNO), and heliox. Without portable delivery systems to continue treatment, patients may be severely compromised or transports may be impossible. Patients who require positive pressure ventilation via NIMV to treat their acute respiratory failure may quickly deteriorate if taken off the ventilator. Discontinuation of iNO, which may be used in the treatment of acute hypoxemic respiratory failure, may result in a rebound phenomenon, with worsened gas exchange and cardiovascular instability.[13] The discontinuation of inhaled heliox may raise the work of breathing in obstructed patients, causing respiratory decompensation.[14]

CIRCULATION

Cardiovascular and hemodynamic complications may be a direct result of patient transport. The severity of these changes during transport generally corresponds with the patient's status before movement out of the protective critical care environment. Complications commonly include hypotension, hypertension, and cardiac dysrhythmia. To reduce the risk of these preventable complications, vasoactive agents are continued, and electrolyte abnormalities should be corrected.

During the movement of patients, there is the possibility of dislodging intravascular lines or inadvertently disconnecting lines carrying drug infusions. Battery-powered infusion pumps can also fail. It is essential that there is careful attention and supervision to prevent these problems.

DISABILITY

Neurologic compromise may be a direct result of the potentially life-threatening complications already identified, including hypoxia, hypotension, hypertension, hypoxemia, and hypercarbia. Cerebral ischemia and secondary brain injury yield a significant rise in mortality that may be preventable.

Andrews[15] found that the most common complications during intrahospital transports that led to secondary brain injury included systemic hypotension and hypertension, increased intracranial pressure (ICP), decreased cerebral perfusion pressure, and arterial desaturation. It was determined that adequate resuscitation and stabilization before transport may have prevented some of these secondary injuries. Bekar[16] observed that an increase in ICP might have been prevented by appropriate pretransport ventilation, sedation, and analgesia. If possible, patients with increased ICP should be transported with the head elevated. If a transducer and ventricular drain are in place, their heights are best kept at the pretransport level to prevent inaccurate readings or major cerebrospinal fluid shifts.

Transport Coordination—An Overview

Minimum standards for intrahospital and interhospital transport of critically ill patients were developed by a committee from the Society of Critical Care Medicine, the American Col-

TABLE 7-1 Guidelines for Safe Patient Transport

- Plan in advance for patient transfer and transport
- Prevent delays through comprehensive coordination and detailed communication
- Make appropriate selection and utilization of available resources (personnel, vehicles, and equipment)
- Ensure patient stabilization prior to transport
- Verify that all tubes and lines are functional and well secured
- Provide a safe transport environment for patient and staff
- Continuously monitor the patient during transport for any change in condition
- Treat as indicated for any changes in status
- Safely deliver the patient to a critical care unit for further monitoring, evaluation, and management

lege of Critical Care Medicine, and the American Association of Critical Care Nurses.[7] These guidelines list the minimum requirements for personnel, equipment, and medication to facilitate the movement of critical patients. Other associations and publications have also written standards and guidelines to ensure the appropriate and safe transfer of critically ill patients.[17–20]

While there are unique considerations for interhospital transport (e.g., vehicle selection), many issues regarding preplanning, equipment, and personnel are similar for both categories of transport (Table 7-1). Written hospital policies provide consistency and reduce the likelihood of intrahospital or interhospital transport errors.

TRANSPORT PERSONNEL

The transport of critically ill or injured patients is not a benign endeavor. Critical care transports, both intrahospital and interhospital, should be performed by specially trained transport personnel.[7] Whether it is a dedicated transport team, unit-based personnel, or on-call staff, it is essential for them to have the necessary training and experience for the unique transport environment. The medical personnel must also have the clinical abilities and equipment to adequately evaluate the critical patient and initiate appropriate treatment promptly.

TRANSPORT EQUIPMENT

For both interhospital and intrahospital transport, it is necessary that all equipment be appropriate for both the specific critical care patient and the transport environment. The basic equipment requirements are essentially the same whether you are transporting a patient several floors, several miles, or several hundred miles. Monitoring during the transport of critically ill patients should be similar to that received in the ICU. However, portable monitors have limited capabilities when compared with bedside monitors.[21] In addition, monitoring during transport may be compromised by vibration, motion artifacts, electromagnetic interference, and limited visibility.

Critically ill or injured patients require real-time monitoring. Pulse oximetry and electrocardiographic (ECG) monitoring can provide continuous oxygenation and cardiac assessment. The blood pressure can be measured using an automatic noninvasive blood pressure device if continuous measurements via arterial line are not indicated.

Suitable transport monitors and equipment are portable, durable, lightweight, and battery powered. The capability to be plugged directly into a power source helps prevent unnecessary battery consumption. Audible and visible alarms for monitors, infusion pumps, and ventilators are necessary in quickly assessing important patient changes or equipment failures. It is also important to be certain that transport equipment will be compatible with the lines, fittings, and power outlets at the destination unit or in the transport vehicle.

All transport equipment should fit into elevators and transport vehicles, while leaving enough room for transport personnel to function. The ability to secure the equipment within the transport vehicle or to the patient's bed improves visibility while protecting it from accidental damage. Some ICU, ED, and OR beds have footboards that can double as equipment trays. Some institutions have designed trays or carts that can attach directly to the patient bed.

Limiting the number of bed-to-bed transfers will further reduce the likelihood of an inadvertent equipment disconnect. Several military and commercially available self-contained stretcher-based miniature ICUs or modified beds have been designed for adults, children, and neonates. They are equipped with ventilators, cardiac monitors, blood pressure monitors, and infusion pumps, and some are compatible with radiologic equipment. These devices may result in a more efficient use of resources necessary to safely transport a critically ill patient and reduce movement from cart to cart.

Besides the equipment used for monitoring and physiologic support, airway (intubation) and IV equipment and medications must also be available and transportable. Transport medications include the standard resuscitation drugs, analgesics, sedative/hypnotic agents, and neuromuscular blocking agents as indicated. Commercially available carrying cases that contain these essentials help to efficiently organize these supplies.[22] Numerous organizations and publications provide lists of suggested equipment and medication for in-house transport or interfacility transport.

A failure in oxygen supply can have disastrous consequences when caring for the critically ill. Therefore it is important for the oxygen source to be sufficient to exceed, by a substantially safe margin, any patient transport time.

Transport equipment often differs from routine bedside equipment. Dedicated transport personnel, working in a familiar environment, may better test, maintain, and troubleshoot complex equipment than those who only occasionally are called to accompany a patient during transport. All personnel must assure properly functioning equipment before departure.

Interhospital Transport

Most commonly, interhospital transfers occur when a referring facility lacks sufficient resources, equipment, personnel, or expertise to meet the needs of the critically ill or injured patient. The patient may require further diagnosis, specialized care, or timely treatment that is not available at the referring hospital. There are data supporting the value of regional referral centers, as well as the organized systems and specialized teams to bring patients safely to them.[23,24] Nevertheless, there remain common misconceptions among many physicians that some patients are too ill to transfer. This generally

stems from a lack of knowledge regarding sophisticated patient transport systems.[25]

In the past decade, changes in how decisions regarding patient transfers are made have occurred due to changes in government regulations, methods of reimbursement to hospitals, and third-party managed care providers.[26,27] It is not uncommon for patients (or their designees), their personal physicians, or managed care providers to request transfers to a specific hospital that may have similar critical care capabilities to those at the referring facility. These lateral transfers may be motivated by many factors, including continuity of care, patient (or family) preference, or insurance plan requirements, and their appropriateness is often controversial.

There are three essential participants in a successful interfacility transport that can be viewed as a "transfer triangle." This 3-cornered approach has the referring and receiving physicians/facilities at the bottom corners of the triangle, creating the foundation for the patient transfer. Direct physician-to-physician contact and exchange of patient information is optimal, but in many situations physicians may rely on a designee to coordinate a transfer between facilities. At the apex of the triangle are the transport personnel, in contact with both the referring and receiving facility, and serving as a vital link between them. Working together, these collaborators should assure that each patient transfer results in the appropriate utilization of available resources, which include vehicles, personnel, and equipment.

RESPONSIBILITIES OF THE REFERRING PHYSICIAN AND FACILITY

If a treating physician recognizes that hospital capabilities are inadequate to safely care for a critical patient, or if specialized treatment or expertise is indicated but not available, the patient will need to be transferred to a facility capable of providing these services. Knowing the services a referring hospital provides is best addressed prospectively in hospital policy so that all hospital physicians, administrators, and staff have the same information readily available.

In addition to the above medical responsibilities during interfacility patient transfers within the United States, referring facilities and physicians face several legal obligations. The interhospital transport of critical patients may be initiated from referring emergency departments, inpatient units, and other various locations. When the transfer is from an emergency department within the United States, the Emergency Medical Treatment and Active Labor Act (EMTALA)[28] requires that all unstable patients be transported by qualified personnel and transportation equipment. Transport decisions are no longer merely a patient care issue, but also a federal requirement for EMTALA compliance.

EMTALA was established in 1986 and created patient stabilization and transfer requirements for hospitals and physicians. The law applies to any individual who "comes to the emergency department," but interpretation by the Centers for Medicare & Medicaid Services (CMS) has clearly expanded this to include other areas of the hospital campus. The original EMTALA regulations did not specifically address the interfacility transfer of unstable admitted patients. As a result, varying conclusions had been reached in different federal courts and regional CMS offices. However, in September 2003, CMS published new regulations to resolve this issue. CMS concluded that "the transfer and stability issues for a patient, once he or she is admitted, are governed by the Medicare hospital conditions of participation, State law, and professional considerations, not EMTALA requirements."[29] While CMS has clarified its position regarding the admitted patient, the basic EMTALA transfer provisions seem to be in the best interest of the patient and therefore warrant careful consideration.

If an individual presents to the ED with an "emergency medical condition," a hospital cannot transfer the patient unless specific requirements are met. The referring hospital is to examine the patient and "provide the medical treatment within its capacity which minimizes the risks to the individual's health." If the hospital cannot stabilize a patient, then the patient may be transferred (an "appropriate transfer" under EMTALA) only after complying with the remaining provisions of the law. EMTALA does not allow for an "automatic transfer" from one hospital to another based on established referral patterns or affiliations (e.g., managed care, trauma systems, and perinatal networks, among others).

The referring physician determines which receiving facility and physician is most appropriate for the patient. The most appropriate hospital may not always be the closest. A more distant facility may be preferable, but not practical due to a lack of time or means of transport. In addition, a specific institution may be deemed more appropriate if they have a specialized transport team that can provide an appropriate level of care during the transport.

Ideally, in consultation with the receiving physician, the referring physician verifies that the receiving facility has the available space, can provide the appropriate medical treatment, and agrees to accept the transfer. Finally, it is also the referring physician's responsibility under EMTALA to be certain that "the transfer is effected through qualified personnel and transportation equipment, as required including the use of necessary and medically appropriate life support measures during the transfer."

It is necessary for the referring physician to explain to the patient (or family) the reasons for transfer, the receiving facility and physician, and the method of transport. Considerable time may be lost if a transfer is set into motion only to have family members refuse the selected receiving hospital or mode of transport. Written, signed consent for transfer is to be obtained by the referring hospital. Many transport teams use their own supplemental consent forms as well.

A summary of the risks and benefits of a transfer are to be included in the patient records. It is no longer adequate to simply state that the benefits of transfer outweigh the risks. EMTALA requires that specific risks and benefits be considered and explained to the patient or the "legally responsible person acting on the individual's behalf." Some hospitals have prepared forms with checklists to facilitate completion of the necessary transfer documents. All medical records (or copies) related to the emergency condition, preliminary diagnosis, treatment provided, results of any tests, and the informed written consent for transfer are to be sent by the referring hospital to the receiving facility.

For patients transferred from the inpatient setting, the medical records should include copies of the physicians' and nurses' notes, consultations, medication sheets, order sheets, flow sheets, ECGs, radiology reports, lab results, and pertinent x-rays. Whenever possible, a discharge summary or transfer note is included. This document summarizes the

major events in the patient's hospital course, and should be readily available for the transport team to review. With appropriate planning, the medical records and x-rays are copied and available at the patient's bedside before the transport team departs.

RESPONSIBILITIES OF THE RECEIVING PHYSICIAN AND FACILITY

Any hospital that strives to be a regional resource and receiving hospital for critical care referrals should have a system in place to facilitate communications and transfers. Communications can be enhanced through a designated communications or transfer center, dedicated telephone lines, or the hospital operator. The most efficient tertiary care centers have a consulting/receiving physician available 24 hours a day who has the authority to accept transfers and experience in off-site patient management.

Being familiar with hospital resources, bed availability, and transport options will expedite transfer decisions. Once the patient is accepted for transfer, the referring and receiving physicians should agree on the mode of transport, the transport team composition, and the equipment that may be necessary during the transport.

Federal law also has implications for receiving institutions. EMTALA identifies "obligations of hospitals with specialized services," and specifies that "participating hospitals with specialized facilities shall not refuse to accept an appropriate transfer if they have the capacity to treat the individual." Receiving hospitals should document in hospital policy which of their services are "specialized," addressing the capabilities and capacities of these services. Under EMTALA, a receiving hospital cannot refuse to accept the transfer of a patient who is unstable or has an emergency medical condition if they have the capacity and ability to care for a patient.

COORDINATION OF THE INTERHOSPITAL TRANSFER

It is the referring physician who is ultimately held accountable to coordinate the transfer of a critical patient. Formal transfer policies and transport agreements between the referring and receiving hospitals and physicians can greatly facilitate patient transfers while minimizing EMTALA violations and preventable delays. Regional tertiary and specialty care centers (ICUs, trauma centers, burn units, and transport services) are best listed in these resource documents.

Patient transfer agreements identify the available specialty areas at potential receiving hospitals and the admission criteria for each of these services. Including the point(s) of contact, key telephone numbers, and procedures to secure patient acceptance are also helpful. Transfer agreements with multiple facilities for the various specialty services may be needed, as an individual hospital may at times be unable to accommodate a patient.

Patient *transport* procedures and agreements may also be incorporated into patient *transfer* agreements, or may be separate contracts with independent third-party transport services. Third-party transport providers may be independent or hospital transport services. Many transport agreements delineate the availability and composition of transport teams, medical crew capabilities, and resource availability (medical equipment and transport vehicles). When appropriate, this document may also address issues of billing and payment, and clarify questions pertaining to medical control during transport. Transport agreements streamline patient transfer by minimizing delays in processing a transport request. A resource directory that includes phone numbers, specific capabilities of each air or ground transport service, and receiving medical facilities should be readily available in the ICUs and ED.

A timely and accurate initial contact with a receiving physician will minimize delays, facilitate decision making, and promote transfer arrangements. Ideally, to assure a smooth and safe transfer, the referring and receiving physician discuss the patient directly. Without this interaction, significant gaps in the transfer of essential patient information may occur, resulting in missed or delayed diagnoses and treatment. It is often helpful for the referring and receiving physicians to use a systematic checklist to review and fill out while discussing the patient.

To begin the process, the referring physician provides his or her name and easy access callback number, which may be a specific telephone number, pager number, or mobile phone. The name and phone numbers of the referring hospital and unit should be logged by the receiving institution to facilitate follow-up phone calls. The patient's name, age, nature of illness or injury, vital signs, physical findings, results of pertinent diagnostic studies, treatment, current condition, and reason for transfer are described in detail to the receiving physician. This same information will need to be relayed to the transport team by physicians and eventually to the nursing staff at the receiving facility.

Once the patient is accepted for transfer, it is appropriate for the accepting physician to make recommendations regarding ongoing patient management. Both the referring and receiving physicians should document these recommendations.

In addition, the receiving physician or a specialist who is frequently involved in the transport of critically ill or injured patients may make recommendations regarding the mode of transportation, composition of the transport team, and preparation of the patient prior to transport. This happens most often when the receiving facility has its own critical care transport team. However, a receiving hospital cannot insist that their own transport team undertake a transport in order for them to accept the patient in transfer.

Critical transport decisions are often made under adverse conditions with limited information and limited time. The emphasis is on protecting the patient from further injury or medical deterioration, and optimizing the patient's chances for survival. Individuals with the most experience in transport should be a part of the transport decision making process. However, despite external recommendations of others, it remains the responsibility of the physician caring for the patient at the referring institution to make the transport-related decisions.

TRANSPORT DECISION MAKING

Anticipating patient care requirements prior to and during transport determines the method of transport. EMTALA states that the transfer is "effected through qualified personnel and transportation equipment." However, the law does not define "qualified." This leaves the interpretation and responsibility primarily up to the referring physician. In

practical terms, the skills of the transport personnel include the ability to care for the patient's current condition and any reasonable foreseeable complications that could arise during transport. It is not possible to predict all the potential complications that may occur during any given transfer. However, it is imperative for referring facilities and physicians to have a reasonable understanding of the capabilities of transport services within their service area, even if that service is provided by the receiving hospital or a third party.

There are several key decisions to consider when making arrangements for a patient transport, including the personnel, the type of vehicle, and the proper equipment or medications to have on hand. The referring physician must accurately assess the patient's real and potential illnesses or injuries and anticipate complications that might occur during transport. He must also estimate the pace of illness in order to judge whether "team or time" represents the greater opportunity to improve outcome.

Level-of-care options for interfacility transport include basic life support (staffed by EMTs), advanced life support (staffed by two paramedics), and critical care/specialty care (staffed by a minimum of a nurse and a second crew member). The special requirements of high-risk neonates, complex obstetric patients, and those needing complex ventilator or hemodynamic management may dictate the transport personnel and equipment. However, for time-dependent disorders, urgent transfer may be more crucial than specialty transfer. For example, because a patient with a dissecting aortic aneurysm may require immediate surgical intervention, delaying the transport for a critical care transport team may be inadvisable. A dilemma arises when the patient's medical condition is both time-dependent *and* team configuration–dependent. Specialists experienced in transport medicine can greatly assist in making these complex judgments.

VEHICLE SELECTION

In determining the most appropriate method of transport, several considerations are addressed, including the availability of local resources (referring hospital, receiving hospital, and ambulance services, among others); speed of the transport vehicle; weather considerations (inclement weather, snow, or fog); ground traffic, construction, or accessibility of roads and landing areas (helipads or airports); and the total distance to travel to deliver the patient (one-way vs. round trip or two legs of a three-legged transport). A vehicle dispatched directly from the referring hospital to the receiving hospital constitutes a one-way transport. More commonly, the transfer will be two-way, with the vehicle and crew being sent from the receiving hospital to the referring hospital to pick up the patient. Three-legged transports describe those in which a third party (hospital-sponsored program or independent ambulance company) provides the vehicle and team from a location other than the receiving or referring hospital. Options for transport include ground and air ambulances (helicopter and airplane).

GROUND AMBULANCES

Ground ambulances are the most common vehicles used for interfacility transport and continue to be the primary means of prehospital patient transport. A major advantage is availability, since most geographic areas have ground ambulances. They also provide door-to-door service, without the need for a runway, helipad, or landing zone. Once placed on the stretcher and secured in the ambulance, the patient can be transported directly to the receiving facility without movement from one vehicle to another, limiting the most dangerous aspect of transport. The patient compartment of a ground ambulance tends to be larger than those found in helicopters and airplanes, accommodating up to four medical crew members and one to two patients. In addition, fewer restrictions apply to the size, weight, and amount of equipment that can be taken by ground transport when compared to flying. It is also easier to stop a ground ambulance to facilitate patient assessment and intervention. If necessary, ground ambulances can also be easily diverted to alternate destinations as dictated by patient condition or the need for an unanticipated intervention. Finally, ground ambulances operate in most weather conditions that restrict safe air operations.

There are also disadvantages to using ground ambulances, the most important being the increased amount of time required to transfer a patient from one facility to a distant facility in comparison to air transport. Ground vehicles are subject to delays imposed by poorly maintained roads, traffic congestion, construction, and inclement weather. In addition, ground ambulances may not be able to gain access to patients who are located in remote areas with limited road availability. In rural areas with limited numbers of ground ambulances, the dispatch of one unit on a distant transport may cause other areas to be temporarily without service. Finally, tight vehicle suspensions, narrow wheelbases, and high centers of gravity predispose ground vehicles to rough and turbulent rides, which may be detrimental or excessively painful to patients with spinal cord injury, intracerebral hemorrhage, or orthopedic injuries.

ROTOR-WING AIR AMBULANCE (HELICOPTER)

The use of the air ambulance has grown significantly over the past 30 years. Speed of travel is an important consideration for helicopter transport and the primary reason it is chosen over ground ambulances. Depending on the type of aircraft, weather conditions, flight altitude, and total load, helicopters may travel at speeds of 120 to 180 miles per hour. This speed and the fact that helicopters can make direct point-to-point transfers may reduce transport time to one third to one fourth that required by ground transport. The helicopter needs only a small (100-by-100-foot), flat area that is clear of obstructions to take off and land. In addition, the helicopter has the ability to fly into locations inaccessible to other modes of travel. This capability becomes extremely valuable when traffic is delayed or roads are impassable after snowstorms, floods, tornadoes, and other disasters, or when a patient is located in rural or wilderness areas. With a service area that generally ranges between 50 to 200 radial miles from its base, helicopters cover a much greater service area than would a ground ambulance, but less than a fixed-wing aircraft. Helicopters are often the fastest mode of transport for distances of 25 to 150 miles.

Helicopters also have inherent disadvantages. If an appropriate landing area is not readily available, the time needed to identify and secure a landing zone, in addition to the time needed to transport the patient to and from the distant landing site, may erode the helicopter's speed advantage. The patient cabin is typically smaller than in ground ambulances, and even in larger helicopters, patient access may be limited.

Weight restrictions may also prevent transport of some obese patients.

Fog, sleet, heavy snowfall and rain, low clouds, high winds, and lightning may significantly limit the utility of helicopter transport. Most helicopter programs operate under visual flight rules (VFRs), but travel under instrument flight rules (IFRs) is becoming more common. The majority of IFR flights are conducted airport-to-airport, but newer Global Positioning System (GPS) technology makes possible IFR missions directly to precertified hospital helipads.

Helicopters are unpressurized and a basic knowledge of flight physiology is important to understanding the effects of a changing altitude are essential. While airplane travel is clearly impacted by flight physiology and the stresses of flight, helicopter transport is also susceptible. It is often thought that only altitudes above 8000 feet impact the patient or crew, but this is not always the case. Boyle's law states that, as altitude increases and atmospheric pressure decreases, gas volumes expand (and vice versa on descent). As a result, crew members or patients flying with sinus problems, ear problems, or upper respiratory infections may feel the effects of barometric pressure changes with an altitude change of as little as 1000 to 2000 feet.

Henry's Law is another important gas law affecting air medical transport. According to this law, the amount of gas dissolved in liquid is determined by the partial pressure and the solubility of the gas. The *bends*, a decompression sickness, is a clinical condition affected by this law. When a scuba diver ascends too quickly, nitrogen gas bubble formation in the blood can occur. Special precautions should be taken for decompression victims who must be transported by helicopter. In some cases, even a minimal gain in altitude can cause significant gas bubble formation. It is advised that patients suffering from decompression illness be transported in nonpressurized aircraft at an altitude of not more that 1000 feet about the diver's ascent.

Patients, medical personnel, and pilots may all be impacted by the stresses of flight. Vibration, noise, and turbulence are generally more severe in helicopters than in other forms of transportation, and they may interfere with patient assessment or the function of medical equipment. Flight crew members wear headsets or helmets to facilitate in-flight communication and to minimize the long-term effects of working in a loud environment. Awake patients are commonly given headsets or earplugs.

FIXED-WING AIR AMBULANCE (AIRPLANE)

Fixed-wing transports usually lose their speed advantage at distances of less than 100 miles because of ground delays during airport transfers. Furthermore, these additional patient transfers to and from ground ambulances expose the patient to possible dislodgment of vital equipment. Despite these disadvantages, fixed-wing aircraft offer several advantages. Airplanes often have sufficient space to accommodate more than one patient, patient family members, and additional crew members or equipment. In addition, weight restrictions, weather, noise, and turbulence are less of a factor when compared to rotary-wing transport. Smaller unpressurized airplaines offer no benefit over the helicopter in combating the effects of the gas laws, and therefore are generally limited to altitudes under 10,000 feet. Pressurized fixed-wing aircraft, however, can fly higher while counteracting the negative effects of altitude. At flight altitudes of 30,000 to 40,000 feet, pressurized aircraft can often create an internal cabin altitude of 7000 to 8000 feet. Flying at lower altitudes, aircraft with a high differential cabin pressure have the ability to create a cabin pressure that exceeds ground altitude pressures, a feature that may aid in transport of victims with decompression illness.

TABLE 7-2 Effects of Altitude on Oxygenation When Breathing Ambient Air

Altitude, Feet	Barometric Pressure, mm Hg	PA_{O_2}, mm Hg	Pa_{O_2}, mm Hg	Pa_{CO_2}, mm Hg	Oxygen Saturation
Sea level	760	159.2	103.0	40.0	98%
8000	565	118.4	68.9	36.0	93%
10,000	523	109.6	61.2	35.0	87%
15,000	429	89.9	45.0	32.0	84%
18,000	380	79.6	37.8	30.4	72%
20,000	349	73.1	34.3	29.4	66%
22,000	321	67.2	32.8	28.4	60%

Due to the impact of Boyle's Law, on ascent a simple pneumothorax may expand to become hemodynamically significant or intestinal gas may expand to rupture a hollow viscus. Medical equipment that has an enclosed air space can also be affected, including endotracheal tube cuffs, intravenous lines (whose flow may be driven by air-filled pressure bags), and air-containing splints.

Hypoxia represents the greatest risk associated with high-altitude transport. Dalton's law states that the total pressure of a gaseous mixture is equal to the sum of the partial pressure of the gases. Therefore, any change in barometric pressure directly affects the partial pressure of oxygen (Table 7-2).

During fixed-wing transport, the most threatening concern with hypoxia is its insidious onset. The medical crew may not notice the early onset of signs or symptoms in the patient or themselves.[30] No one is exempt from the effects of hypoxia, even though the onset and severity of symptoms may vary with individuals. While altitude-related patient hypoxia is a concern, the routine use of pulse oximetry and supplemental oxygen minimizes this hazard. In the setting of hypoxemia, increasing $F_{I_{O_2}}$ levels or adding PEEP easily compensates for the hypoxic effects of altitude. However, in the rare patient who is on maximal oxygen support, flight at lower altitudes may allow the artificial cabin pressure to approach sea level, in this manner increasing the partial pressure of oxygen.

Hypoxia is more of a concern for the pilots and crew members who generally are not monitored. The Federal Aviation Administration (Federal Aviation Regulations [FAR], Part 135, which applies to on-demand air taxis) requires pilots to use supplemental oxygen if they are flying at cabin altitudes above 10,000 feet for more than 30 minutes and any time above 12,000 feet.[31] At cabin pressure altitudes above 15,000 feet each occupant of the aircraft must use supplemental oxygen.[32] During high-altitude transport, periodic assessment of the pulse oximetric saturation of medical crew members is prudent.

The medical crew must be prepared to deal with the effects of a malfunction of the pressurization equipment or aircraft structural damage. During a rapid decompression, the sudden drop in temperature causes the aircraft to fill with fog. A

Patient: _____ Transport Date: _____ Flight # _____

Referring Hospital: _____ City/State: _____ Loaded Miles: _____

General Criteria for Air Medical Transport

- ☐ Distance to the closest appropriate facility was too great for safe and timely transport by ground ambulance.
- ☐ Patient's clinical condition required that the time spent in transport be as short as possible.
- ☐ Patient's condition was time critical, requiring specific/timely treatment, not available at the referring hospital.
- ☐ Potential for transport delay associated with ground transport was likely to worsen the patient's clinical condition.
- ☐ Patient required critical care life support during transport, not available from the local ground ambulance service.
  - ☐ Monitoring _____ ☐ Personnel _____
  - ☐ Medication _____ ☐ Special equipment _____
- ☐ Patient was located in an area inaccessible to regular ground traffic, impeding ambulance egress or access due to
  - ☐ Road obstacles and/or conditions ☐ Wilderness rescue or geographic considerations
- ☐ Local ground units were not available for long distance transport.
- ☐ Use of a local ground transport service would have left the local area without adequate EMS coverage.

Indications for Transfer to an Appropriate Receiving Facility

- ☐ Patient required further diagnosis, specialized care and/or timely treatment, not available at the referring hospital.
- ☐ Patient required care by physician(s) at a receiving hospital where the patient had previously undergone specialized treatment and where medical records were located which were likely to significantly influence patient care.
- ☐ Patient's attending physician requested transport to a specific hospital based on medical needs/continuity of care.

Medical/Surgical Criteria for Critical Care Transfer

- ☐ Patient has unstable vital signs represented by:
  - ☐ Respiratory Rate: <10 or >30
  - ☐ Heart Rate: <50 or >150
  - ☐ Systolic BP: <90 or >200 mm Hg
- ☐ Respiratory arrest within the past 12 hours
- ☐ Unstable or potentially unstable airway
- ☐ Patient required mechanical ventilator support or any constant positive airway pressure (CPAP)
- ☐ Patient has an indwelling pulmonary artery catheter, intra-aortic balloon pump, arterial line, or intracranial pressure monitor
- ☐ Patient required diagnostic procedures, specific therapy, or intensive care not available at the referring hospital, for any of the following critical conditions
  - ☐ Acute respiratory failure
  - ☐ Acute deterioration in mental status
  - ☐ Acute cerebrovascular accident in evolution
  - ☐ Acute neurologic or neurosurgical emergency
  - ☐ Severe hypothermia requiring active therapy
  - ☐ Acute hemodialysis
  - ☐ GI bleeding
  - ☐ Severe poisonings or overdoses
  - ☐ Significant acidosis
  - ☐ Status epilepticus
  - ☐ Complications of cancer and chemotherapy
  - ☐ Decompression sickness
  - ☐ Life threatening infectious process
  - ☐ Dissecting or leaking aneurysm
  - ☐ Organ transplantation or procurement
- ☐ _____

Cardiac Criteria for Critical Care Transfer

- ☐ Cardiac arrest within the past 12–48 hours
- ☐ Patient had an acute myocardial infarction requiring therapy or diagnostic procedures not available at the referring institution
  - ☐ Thrombolytic therapy
  - ☐ Cardiac catheterization
  - ☐ Intra-aortic balloon pump
- ☐ Patient required continuous intravenous vasoactive medications or mechanical ventricular assist to maintain a stable cardiac output
- ☐ Uncontrolled life threatening dysrhythmia
- ☐ Patient required continuous intravenous anti-dysrhythmia medications or a cardiac pacemaker to maintain a stable cardiac rhythm
- ☐ Any unstable cardiac conditions requiring urgent cardiac catheterization or cardiac surgery

Obstetrical Criteria for Critical Care Transfer

- ☐ Patient required urgent transport to a perinatal center for a high risk obstetrical condition
  - ☐ Placenta previa
  - ☐ Abruptio placenta
  - ☐ Eclampsia
  - ☐ Pre-eclampsia
  - ☐ Premature labor
  - ☐ Abnormal fetal lie
  - ☐ Uncontrolled maternal diabetes
  - ☐ Severe maternal medical illness

FIGURE 7-1 Medical necessity for air medical transport for adult patients. ***(Used with permission from the University of Chicago Hospitals Aeromedical Network [UCAN]).***

rapid drop in the cabin P_{O_2} quickly leads to hypoxia in crew members. Supplemental oxygen for the pilot, medical crew, and patient is essential. Any chest or nasogastric tube should then be unclamped to allow decompression of any gas subject to expansion.

EFFICACY OF AIR MEDICAL TRANSPORT

Despite over 30 years of air medical transport, definitive data indicating which types of patients should be flown are generally lacking. Questions regarding the triage of patients to air or ground transport, the efficacy of aeromedical care, and the effects of air medical transport on morbidity and mortality in both medical and surgical conditions remain controversial. To assist programs and physicians in determining the appropriateness of air medical transport, the Medical Advisory Committee of the Association of Air Medical Services has established criteria for the proper utilization of air medical transport.[33] These time, distance, and logistical indicators have been adopted by many air medical programs and EMS systems to aid in the appropriate triage of patients. An example of these general criteria for the adult nontrauma patient is summarized in the form reproduced as Figure 7-1.

Trauma patients have been the most studied with regard to helicopter EMS transport. Studies have shown that patients transported by aeromedical services may exhibit improved survival.[34–36] When patients are transported from rural areas, the higher level of care aboard the medical helicopter and the timely arrival to a trauma center were felt to be the main contributing factors to decreased mortality. The helicopter appears to provide no advantage for patients transported from an urban area.[37,38]

Transport of cardiac patients has raised concern because altitude raises heart rate and myocardial oxygen demand. Studies of patients with acute myocardial infarction and unstable angina revealed that complications such as hypotension, dysrhythmias, and exacerbation of chest pain occurred during transport and that most were managed effectively en route.[39,40] In one study, complications were more frequent in the group transported by air when compared to those transported by ground.[41] In general, it was found that major in-flight events were uncommon.[40–42]

Aeromedical transport of the gravida is felt to be generally safe for both mother and fetus. If the fetus is at risk, the mother should be given supplemental oxygen during flight.[43] Another concern is the transport of women in active labor, since in-flight delivery is best avoided. It may be wise to defer transport of the patient whose cervix is dilated greater than 4 cm on preflight assessment.[44]

SAFETY OF TRANSPORT

Accidents occur with all modes of patient transport. Generally speaking, ground ambulances have a higher probability of being involved in an accident, but offer a better chance of survival than aircraft mishaps. A safety report published by the Air Medical Physician Association researched accident data for ground and helicopter EMS (HEMS).[45]

Since 1972, HEMS has flown an estimated 3 million hours while transporting approximately 2.75 million patients. In 31 years (through September 2002) there were 162 HEMS accidents in the United States, 67 of them fatal, with 183 deaths including 21 patients. From 1987 to 1997, HEMS averaged 4.9 accidents per year, but this has risen since 1998 to 10.75 accidents per year. Over the course of the 22 years reviewed, the death rate for HEMS patients was 0.76 per 100,000.

EMS experts estimate that 15,000 ground ambulance crashes occur each year, with as many as 10,000 injuries annually, 10 serious injuries daily, and 1 fatal ambulance crash each week. "Emergency vehicle passengers," which includes patients, medical personnel, and patient's family members account for 22% of the fatalities, with most deaths being occupants of the other vehicles.

MEDICAL PERSONNEL FOR INTERHOSPITAL TRANSPORT

Air and ground transport present many unique challenges to its medical personnel. Numerous associations and many state EMS agencies have developed training requirements for critical care transport. In addition to the appropriate clinical components, knowledge of altitude physiology and the stresses of transport, vehicle safety, stress management, and appropriate survival training are included.

Factors other than direct patient needs may determine the composition of the transport team. Since critical care transport teams are expensive, financial considerations may affect crew composition and availability. Utilizing in-house or on-call staff to transport patients may reduce the cost of transport, but this may result in crew members being unfamiliar with the transport environment and could deprive the home institution of adequate physician or nurse coverage. Receiving or referring physicians may also request the presence of a transport physician to ameliorate a perceived decrease in the level of care provided during a transport.

Medical personnel for interfacility transport represent the broad spectrum of health care providers. EMS ground ambulances are commonly staffed with paramedics who function at advanced life support (ALS) level, or emergency medical technicians (EMTs) who provide basic life support (BLS). Referring physicians must carefully evaluate the needs of critical care patients and the capabilities of ground EMS providers to determine if optimal patient care can be accomplished by these caregivers.

The majority of fixed-wing (61%) and rotor-wing (71%) programs in the United States staff their critical care transport teams with a nurse/paramedic crew. Nurse/nurse is the next most common medical crew configuration for both helicopter and airplane transport (8%). Other team combinations of registered nurses, EMTs, doctors, and EMT-paramedics (RN/EMT, RN/MD, and EMT-P/EMT-P) each account for 5% or less of the totals.[46]

Flight nurses generally have extensive experience in intensive care units or EDs. Paramedics often make their greatest contribution in the transport of critical patients from accident scenes since most of their training revolves around being first responders. Respiratory therapists bring expertise in airway and ventilator management and oxygen delivery systems.

The benefit of physicians on medical transport teams, as is common in Europe, remains unclear. Studies are conflicting on the subject of whether physician attendance improves patient outcome.[47–50] Optimal transport systems have the flexibility to send a physician on a case-by-case basis. Flight

physicians are often residents in emergency medicine or surgery, and on occasion they may be attending physicians or medical directors of flight programs.

In some regions, transport services provide specialty care teams for specific patient populations, most commonly for pediatric critical care patients, high-risk neonates, or high-risk obstetric patients. Some nonspecialty teams may replace a team member or provide additional personnel for certain missions, such as intra-aortic balloon pump transports. A limited number of studies compare specialty teams to nonspecialty teams. Edge and colleagues found that adverse events occurred in only 1 of 49 (2%) pediatric transports by a specialized team compared to 18 of 92 (20%) of transports by nonspecialized personnel.[51] In another study comparing 1030 transports by a pediatric specialty care team to 55 transports by a nonspecialty care team, children were 22 times more likely to have an unplanned event and 2.4 times more likely to die when transported by a nonspecialty care team.[52] The most common unplanned events identified were airway problems (specialty, 0.4%, nonspecialty, 18%) and hypotension (specialty, 0.1%, nonspecialty, 10.9%).

THE TRANSPORT

Once the transport team arrives at the referring location, it is essential that a thorough but expeditious patient assessment be completed. Considerations include taking the time to perform stabilizing interventions prior to departing the referring unit. Gebremichael and colleagues[6] concluded that patients with profound respiratory failure benefited when stabilized prior to transport. However, with trauma patients[53,54] and cardiac patients,[55] it has been shown that rapid transport with minimal stabilization prior to transport may be beneficial, since the delay in getting to definitive care or therapeutic intervention is minimized.

Decisions regarding airway management are critical when it comes to interfacility transport. While patients can be intubated in the various transport vehicles—sometimes with extreme difficulty—it may be preferable to intubate in the more controlled environment of the referring unit. The threshold to intubate for transport may be appropriately lower compared to a patient who would otherwise not be leaving the in-hospital setting.

In preparing a patient for transport, other anticipated therapeutic changes are also best handled initially in the referring unit in order to determine the patient's response. Changing to a portable ventilator or to manual ventilation within the controlled ICU, ED, or OR setting will enable the transport team to identify any ventilation or oxygenation complications that arise and correct them before leaving the unit. A change in any medication to support the patient's blood pressure or cardiac rhythm is also best handled initially in the referring unit. It is often preferable to simplify transport by limiting the number of continuous IV infusions to necessary vasoactive agents and volume expanders. Paralytics and sedatives may be given by IV bolus during transport rather than by continuous infusion.

MEDICAL DIRECTION AND MEDICAL CONTROL

All medical transports require some form of medical direction and medical control. ALS ground ambulances are generally under the direction and control of an EMS system. Individual transports would generally be under the direction of an EMS resource hospital or standing medical orders (SMOs). Hospital-sponsored or independently operated air medical services or mobile intensive care programs generally have their own medical direction and medical control physicians.

While EMTALA leaves the transferring physician responsible for patients in transfer until they physically arrive at the receiving facility,[56,57] the law does not make any reference to the transport service, its medical director, or medical control. Out-of-hospital medical transport is regulated state by state, with all states requiring some type of physician medical direction and medical control.[58]

There are three options for medical control. On-line medical control represents direct real-time voice communication between the medical control physician and the transport team. With off-line medical control there is no direct contact between the transport team and the medical control physician. Written medical protocols or standing orders provided by the medical director, medical control physician, referring physician, or receiving physician will direct patient management. Visual medical control occurs when a physician is physically present during the transport.

Medical control during interfacility transport may be assumed by the transferring physician, receiving physician, EMS base station, or the medical director/designee of the transport service. The National Association of EMS Physicians (NAEMSP) has concluded that medical direction of the interfacility transport is a shared responsibility,[58] stating that the referring physician, transport service medical director, and accepting physician should agree on the responsibility of medical direction prior to the transport. The Air Medical Physician Association (AMPA), however, believes that medical control during transport should remain the responsibility of the air medical director or his or her designee.[59] AMPA states that any variation from this standard should be specified in a patient transfer agreement or at the time of request for air medical transport.

It is important to note that despite having interfacility transfer and transport agreements in place, the requirements of EMTALA are still in effect. Some physicians believe that the presence of a physician on the transport team relieves the referring physician of his or her liability and obligations. Others feel that when a transport team from the receiving hospital arrives at the referring facility and assumes patient care, the patient is considered to be admitted to the receiving hospital and that the responsibility shifts completely to the receiving institution. While these shifts of authority and liability may be implied or incorporated into transfer agreements or hospital policies, nothing in EMTALA can be interpreted to endorse these beliefs. The transferring physician and hospital may only decrease their liability and accountability by prospectively addressing these issues in transport agreements and hospital policies, but the responsibility for an "appropriate transfer" remains with the referring hospital and physician. Ideally the transferring physician is available and continues to assist in patient care until the patient has physically left the facility. The medical control physician, however, is responsible for the care provided by transport personnel during patient stabilization and preparation for transport. If a difference of opinion occurs regarding options for care, the referring physician and the medical control physician must reach an accord. This is when knowledge and

experience regarding the transport environment is most important to ensure the quality of medical care and the safety of transport.

Intrahospital Transport

For the critically ill patient, it may be preferable for diagnostic studies and therapeutic or surgical procedures to be done at the bedside in the ICU or ED. This avoids the inherent hazards of transport outside of the unit and provides the patient with the additional benefits of the ICU environment, including advanced monitoring capabilities, and presence of additional critical care personnel who may provide additional assistance as needed. However, critical patients may require procedures that cannot be performed in the ICU or ED itself. Patients may need to be transported to the radiology department, operating room, or other locations within the hospital to receive specialized diagnostic or therapeutic procedures. In addition, many patients now leave the ICU for intermediate care units while still marginally stable and often with multiple indwelling catheters and other devices.

Intrahospital transport of critical patients has been associated with significant clinical complications. Braman and colleagues[10] found that 75% (15 of 20) of ventilator-dependent ICU patients had an increase in P_{CO_2}, with corresponding hypotension or cardiac dysrhythmias. These patients were transported using manual ventilation. Indeck and associates[60] reported a total of 113 serious physiologic changes of at least 5-minute duration during intrahospital transport. Of the 103 patients in the study, 68% experienced complications, including a change in systolic or diastolic blood pressure of at least 20 mm Hg (40% of the patients), a change in pulse by 20 beats per minute or more (21%), and a decrease of 5% or more in the arterial oxygen saturation (17%). Rutherford and Fisher[61] reviewed the transport of 31 critical ICU patients and reported 14 life-threatening complications. This study identified hypotension in four patients, severe respiratory distress in another four patients including an extubation, disconnection of central lines in three patients, and treatment for ventricular dysrhythmias in two patients. Szem and coworkers[1] identified an overall occurrence rate of complications of 5.9% in a study of 203 surgical ICU patient transports. A total of 12 complications included: marked hypoxemia (4), cardiac arrest (3), hypotension (2), cerebral infarction (1), pneumothorax requiring chest tube placement (1), and rupture of an infected arteriovenous fistula (1). Waddell[62] identified three transport-related deaths in a study of 86 intrahospital transports, with an overall complication rate of 8.1%. Complications seen were hypotension (3), cardiopulmonary arrest (1), airway obstruction (1), hypertension (1), and rebleeding from a pelvic fracture (1).

RESPONSIBILITIES OF THE ATTENDING PHYSICIAN

Any decision to transport a critical patient within a facility necessitates careful consideration. Physicians who transfer patients to other facilities generally understand the importance and responsibility of reviewing the risks and benefits of each transfer with a patient (or their designee). Similarly, physicians are also familiar with their obligation to explain the risks and benefits and obtain an informed consent prior to procedures or diagnostic testing. However, the risk of intrafacility transport may not be considered with the same significance or may be overlooked altogether.

With advances in medical technology, more diagnostic and therapeutic options can be brought to the ICU bedside, avoiding inherent risks of intrahospital transport. Bedside ultrasonography may provide valuable information, avoiding transport to a CT scanner. Some surgical procedures may also be done at the bedside. A percutaneous dilational tracheostomy can provide for a long-term airway while avoiding transport to the operating room. A bedside diagnostic peritoneal lavage or focused abdominal sonography for trauma (FAST exam) may avert the need for abdominal imaging.

The need for transport is best weighed against the outcome of the test and how it would impact patient care. If a positive or negative test will result in a timely change in therapy, the transport may be justified. However, if no immediate change is anticipated based on the results, or if the transport is considered high risk, then the transport is best avoided. Numerous studies have examined the impact of diagnostic testing outside of the ICU and its influence on patient management. Indeck and colleagues[60] evaluated 103 patient transports for radiographic tests and identified 113 physiologic complications. Only 24% of these transports resulted in therapeutic changes within 48 hours. In a study by Hurst and associates,[63] 66% of the ICU patients who were transported experienced physiologic deterioration, while only 39% of these transports yielded a change in patient management.

COORDINATION OF THE INTRAHOSPITAL TRANSPORT

Hospitalwide guidelines for the transport of patients within the facility can greatly assist in assuring patient safety for transport. Proper planning, training, and equipment minimizes risk. Communication and coordination are keys to the success of a safe intrahospital transport. Hospital security, transport personnel, or ancillary staff should be available to secure elevators as needed. Prior to departing the ICU, ED, or other point of origin, notification given to the destination (e.g., radiology, operating room, etc) will verify the availability to immediately accept the patient upon arrival. If multiple diagnostic studies are required, it may be preferable to undertake one prolonged trip outside the unit rather than several shorter trips. An immediate review of diagnostic studies is also beneficial to facilitate additional films or procedures as needed, while avoiding a second transport.

TRANSPORT DECISION MAKING

In the ideal situation, a dedicated in-hospital transport team with dedicated monitoring equipment and routine medications for resuscitation, intubation, and sedation provides intrafacility transfers. The reality, however, is that in most situations the physicians and nurses managing the patient will need to anticipate patient care requirements during transport to determine the qualified personnel and transport equipment that will be necessary for safety. Except for the vehicle-related considerations found in the decision making for interhospital transport, the process is similar for in-house transport: evaluate the patient, evaluate the medical care required, assess for special requirements (equipment and medication), and consider the personnel (availability, critical care capabilities, and training).

MEDICAL PERSONNEL FOR INTRAHOSPITAL TRANSPORT

In 1993, the Transfer Guidelines Task Force Committee of the Society of Critical Care Medicine, the American College of Critical Care Medicine, and the American Association of Critical Care Nurses recommended that all critical care transports, both intrahospital and interhospital, should be performed by dedicated, specially trained transport teams. While some hospitals have developed dedicated in-house (intrafacility) critical care transport teams, other facilities are utilizing specially trained ICU or ED transport personnel. Similarly to their interhospital counterparts, these individuals have the training and experience for the transport environment, and have the clinical capabilities, transport equipment, and medications to perform these necessary and often complicated transports efficiently and safely. The use of these specialty teams can prevent many transport-related complications, improve patient flow, and reduce delays.[64] Unit-based ICU or ED nurses can remain on their units to continue care for their other patients rather than transporting patients throughout the hospital.

Whether or not a dedicated transport team exists, developing hospital policies and procedures helps to identify what constitutes an appropriate level of transport personnel. The guidelines developed by the Transfer Guidelines Task Force recommend that all transported critically ill patients be accompanied by a minimum of two people, one of whom should be a critical care nurse. They suggest that an accompanying physician is necessary only for unstable patients. Many teaching hospitals will use the patient's primary nurse and a resident physician. The transport may also use a combination of the primary nurse, one or more patient transporters, and a respiratory therapist. Even when the primary providers accompany the patient, it is advantageous for them to have formal transport-related training in order to avoid unnecessary risk to the patient.

Physicians are more often present than for interfacility transport. Smith and associates reported that a physician was present during 40% of the transports, using varied transport personnel depending on the severity of illness.[65] Szem and colleagues followed a standard regimen for transports, regardless of severity of illness, and had a physician present on every transport.[1] These researchers felt that this was an important contributing factor in their low number (5.9%) of transport-related complications. Smith and coworkers[65] on the other hand reported that one third of 125 transports sustained at least one mishap.

Chapter 8
TELEMEDICINE

MICHAEL BRESLOW

KEY POINTS

- *Creating a centralized ICU care system provides a mechanism for implementing 24-hour 7-day intensivist oversight of critically ill patients throughout a network of hospitals.*
- *A major goal of centralizing ICU care is to spread intensivist care over larger numbers of patients, thereby extending both the number of patients managed by an intensivist and the hours of intensivist care. Creating a multidisciplinary remote care team in which ICU nurses and ancillary personnel work in support of the remote intensivist is central to maximizing operating efficiency.*
- *Available data suggest that implementing a remote intensivist management program that supplements on-site physician care can improve clinical outcomes and economic performance. We speculate that dedicated off-site intensivists improve outcomes by closely monitoring patient status when there is no on-site intensivist, thereby ensuring that care plans are adhered to and that new problems are detected and addressed promptly.*
- *The requisite technology includes 2-way audio and high-resolution video links to each patient room, a robust clinical information system that allows off-site physicians to access patient data, technology tools for performing routine care tasks (e.g., creating notes and orders), and a robust and secure broadband wide area network.*
- *Clear definition of roles and responsibilities, detailed elucidation of operating procedures, including how the remote program integrates with on-site physician activities, and ensuring compliance with standard inpatient care policies (e.g., licensure, credentialing, quality assurance, and the Health Insurance Portability and Accountability Act) are essential for a smoothly functioning and effective program.*
- *Centralized ICU care programs as part of a system-wide view of ICU care ensuring consistent 24-hour 7-day intensivist oversight and the use of an information technology backbone, create unique opportunities to standardize care practices, enhance operating effectiveness, and improve outcomes.*

There is wide variation in intensive care unit (ICU) care across U.S. hospitals. Despite data showing improved clinical outcomes with dedicated intensivist staffing[1] and the institution of a variety of best practices,[2] few ICUs are able to implement these care practices broadly and consistently. Fundamental problems in our current health care system make the goal of optimal ICU care nearly unobtainable for most hospitals. Considerable attention has been devoted to the current shortage of intensivists[3] and the high cost of 24-hour 7-day staffing models. Similar focus has been devoted to the difficulty of getting physicians to adopt best practices. While there are behavioral and managerial components to this problem, the lack of real-time prompts and data-based feedback represent equally important obstacles. Even where hospital leadership appreciates the clinical and financial impact of improved ICU care, the path is both costly and difficult. This chapter presents an alternate care paradigm—one that addresses many of the most serious barriers to improving ICU care. There are three core concepts central to this new care model. First, ICU care is viewed as a system-wide problem, where care across multiple institutions is addressed comprehensively, resources are shared across a network of facilities, and care practices are systematically standardized. Second, technology tools and alternate staffing patterns are used to allow intensivists to care for greater numbers of patients. Third, computer applications assist physicians in problem detection, guide their decision making, and provide feedback that helps drive quality improvement initiatives. The vision is for ICU care to become an integrated service across a network of hospitals, to be delivered in a consistent manner, and to achieve the highest level of care possible with existing resources.

Telemedicine and Early Intensive Care Unit Applications

Telemedicine can be defined broadly as the provision of health care services to patients by care providers that are not in physical proximity to the patient. Telemedicine was initially envisioned as a means of providing geographically isolated patients access to quality health care. Early applications, including military and rural health initiatives, focused on establishing adequate connectivity, developing tools that could be used remotely, and demonstrating clinical feasibility. Costs were high and usage was low—primarily because of low population densities in the target locales—and most projects were abandoned when external funding disappeared. One exception was the use of telemedicine for care of prison inmates. There savings of the high cost of patient transport helped to underwrite infrastructure costs. Over the past decade telecommunication costs have fallen markedly and several new uses of telemedicine have appeared, including teleradiology and telepathology. Both employ store-and-forward technology, in which images from multiple sites are transported to a centralized reading facility. Teleradiology probably represents the leading telemedicine application in use today, almost certainly because work volume is high and these centers can be profitable. This application, although potentially representing a more cost-effective way to deliver a service, does not fundamentally improve the quality of health care. While a variety of new programs are being evaluated, most telemedicine initiatives have failed to deliver on the promise of improved access to health care and better outcomes that spawned the concept 20 years ago.

The use of telemedicine for provision of ICU services dates back to the early 1980s. Grundy and associates established an ICU consultative program, in which intensivists provided advice to clinicians at a remote hospital lacking intensivists.[4] While short lived, the clinical teams at both sites subjectively cited value in the program. Almost 15 years later, a team of academic intensivists reported improved outcomes during a 17-week program of continuous intensivist oversight of ICU patients in a 10-bed surgical ICU that did not have dedicated intensivists.[5] This program operated 24 hours 7 days a week and the intensivists had real-time access to bedside monitor and laboratory data, as well as two-way audio-video

connectivity. The remote intensivists worked in support of the on-site team but were credentialed at the remote hospital and had order-writing privileges. Detailed data were collected on all patients cared for during the pilot program and compared to similar data from patients cared for during two 4-month periods 6 and 12 months prior to the program. The Acute Physiology and Chronic Health Evaluation (APACHE) III methodology was used to adjust for changes in disease severity among the study periods. Actual-to-predicted mortality and length-of-stay (LOS) ratios both decreased by 30% during the intervention period, and the incidence of major complications decreased by 40%. A detailed financial analysis showed decreases in the cost of care that paralleled the shortening of ICU LOS. Although only a pilot project, the results suggested that a 24-hour 7-day remote intensivist care program might provide benefits similar to those reported with dedicated on-site intensivist staffing models.

In 1998, following completion of the continuous ICU telemedicine study described above, two of the investigators (including the author of this chapter) started a company to provide remote intensivist monitoring systems to hospitals. The first ICU telemedicine program using this technology was begun in 2000 in two hospitals at Sentara Healthcare, an integrated delivery network (IDN) in Virginia. A total of 36 ICU beds, representing 3 ICUs, were monitored initially. The remote care center was located in commercial office space 8 to 10 miles from the two hospitals, and staffed around the clock by an intensivist, an ICU nurse, and a clerical assistant. This off-site team worked in support of on-site physicians, actively monitored all patients, ensured that care plans were executed, and assisted with management of new problems. The technology infrastructure was provided and installed by the telemedicine vendor and intensivists from the IDN staffed the remote center. A detailed study of clinical and financial outcomes showed a 27% reduction in hospital mortality and decreases in ICU and hospital LOS of 17% and 13%, respectively.[5a] Costs of care decreased by 19%, hospital revenue for ICU patients increased by 7.5% as a result of an increase in ICU throughput, and contribution margin rose by $6 million annually. Of note, the decrease in ICU LOS was attributable to a reduction in the number of long-stay patients, an effect that may indicate fewer complications as a result of improved monitoring and earlier intervention.

The Sentara program has expanded over the past 24 months, and currently includes seven ICUs in four hospitals. Similar systems are in place in two large East Coast academic medical centers, a 29-hospital IDN in California, an eight-hospital system in the Midwest, and in several military facilities (including a 4000 mile remote link from Hawaii to Guam).

Rationale for Intensive Care Unit Telemedicine

Over the past 5 to 10 years, multiple studies have documented superior clinical outcomes in hospitals with dedicated intensivist staffing models.[1] Mortality rate reductions in these studies average >20%. Many of these reports also describe decreases in ICU LOS and resource utilization. Based on the strength of these data, the Leapfrog Group, an organization formed by Fortune 500 companies to establish health care purchasing standards, has called for all nonrural hospitals to implement dedicated intensivist staffing models within the next 1 to 2 years.[6] They project that adoption of this staffing model will result in 50,000 to 170,000 fewer ICU deaths annually in the U.S.[7] A number of other health care quality groups have issued similar recommendations for dedicated-intensivist staffing.[8,9]

Despite compelling evidence that dedicated intensivist staffing models result in better clinical outcomes, fewer than 15% of U.S. hospitals have this staffing in place.[3] The two most commonly cited obstacles to implementing this model are cost and the unavailability of intensivists. A common financial analysis places the salary cost of 4 to 5 intensivists (required for 24-hour 7-day staffing for 1 ICU) at >$1,000,000 annually, a number that exceeds projected professional services reimbursement. However, even when hospitals recognize the financial benefits of improved ICU clinical outcomes and management, a severe national shortage of intensivists makes recruitment difficult. A recently completed manpower study estimates that there are approximately 5500 practicing intensivists in the U.S.[10] Since the overwhelming majority of these intensivists also participate in other clinical and/or academic activities, the number of full-time equivalents (FTEs) is considerably smaller. When viewed in relation to the 30,000 FTEs required for 24-hour 7-day intensivist staffing in all U.S. ICUs, the shortfall is quite daunting. Moreover, projections based on the current pool of trainees suggest that the problem will worsen for many years.

By permitting a single intensivist-led team to provide care to patients in multiple sites simultaneously, telemedicine offers a potential means of leveraging the current pool of intensivists over larger numbers of patients. Central to this model is the creation of a network of ICUs and other high-acuity beds (e.g., stepdown, ED holding, and postanesthetic care unit) and the use of a dedicated team of intensivists and other care providers to supplement on-site care and thereby achieve 24-hour 7-day intensivist care. Viewing the delivery of critical care services from a system-based perspective, rather than the traditional model in which each individual ICU functions autonomously, represents a major shift in how we conceptualize the care of critically ill patients. This change in perspective (and execution) allows resources to be allocated more efficiently, ensures a more uniform level of service across facilities, and it also creates a platform for practice standardization. The use of a centralized intensivist team for the provision of physician services traditionally provided by on-site physicians creates a mechanism for increasing operating efficiency. By using physician extenders and technology tools to increase operating efficiency, this physical redeployment can enable intensivists to care for considerably larger numbers of patients than with traditional on-site physician staffing. Both staffing models and technology tools are covered later in this chapter.

When evaluating the potential for remote ICU care to permit more efficient provision of intensivist services, several important questions arise. Some of these are technology-related—connectivity, reliability, data access, and security—and are addressed in the next section. Others are more operational in nature. How does remote care integrate with on-site activities and how is continuity of care ensured across multiple care providers? This question is not unique to remote care, but one that assumes greater importance given

that 24-hour 7-day intensivist care becomes feasible with this model. These operational issues require new processes and operating procedures. Several solutions developed by early adopters of this new technology are described in a later section of this chapter. The most important questions, however, concern the extent to which intensivist activities can be provided effectively by off-site intensivists. The improvement in clinical and economic outcomes reported with remote care trials suggest a level of efficacy comparable to that reported in studies examining the impact of implementing a dedicated daytime intensivist care model. However, understanding the strengths and weaknesses of this alternate care paradigm will be essential to defining the optimal balance between on-site and remote activities, and optimizing ICU care models moving forward.

At this time there are insufficient data to answer these important questions. However, considering the likely reasons for superior clinical outcomes with dedicated intensivist staffing may provide some useful insights and identify areas for future study. First, intensivists, as a result of their training and clinical activities, have greater familiarity and expertise in managing critically ill patients. This expertise presumably leads to more accurate and timely problem recognition and better management decisions, regardless of whether these activities are provided on-site or remotely. Second, dedicated ICU physicians coordinate the diverse tasks of the care team (consultants, nursing, pharmacy, respiratory, nutrition, etc.), establish priorities, and create a comprehensive care plan. This important activity, setting the care plan, usually occurs at the beginning of each day. Because it is time consuming and entails integrating large amounts of data (including physical exam findings) and communicating with multiple care providers and the patient's family, one might hypothesize that this activity is better performed by on-site physicians. Third, dedicated intensivists monitor each patient's progress throughout the day (altering therapies as needed to ensure that care objectives are met), and detect and respond to new problems promptly. This constant adjustment of care can only occur when intensivists monitor patients continuously, analyze new data as they become available, and respond immediately when changes in therapy become necessary. It is this continuous monitoring of patient status that is at the heart of the dedicated intensivist model. Because of their inherent physiologic instability, ICU patients sustain adverse events and develop complications at rates far exceeding those of other patients. Only through continuous monitoring by highly trained physicians can we ensure that patients progress according to plan and receive appropriate and timely treatment of all problems. We hypothesize that this continuous care function, which requires 24-hour 7-day physician vigilance, can be performed effectively by intensivists regardless of their location, and represents the optimal use of this new technology.

Technology

Effective telemedicine applications must provide off-site care providers with access to the key data required for monitoring clinical status, reliable mechanisms for communicating with on-site personnel, and tools to perform routine tasks such as generating notes and orders. Many of the tools used to enable off-site care will also be deployed in the ICU in order to facilitate integration of remote and on-site activities.

Key ICU telemedicine components include:

- *Two-way audio-video*: Audio-video equipment is used for visual monitoring of patient status and communicating with on-site personnel. Individual connections to each patient room are preferred, although portable devices may be useful in some low-use settings. Desired functionality includes full-motion video (>25 frames per second), remote camera control, automatic aperture control, zoom capability, and synchronization of audio and video switching.
- *Real-time viewing of bedside monitor waveforms and digital readouts*: Vital signs and other physiologic data provide essential information used for monitoring patient status. In addition to digital readouts of heart rate, vascular pressures, and other data, waveform displays are necessary for evaluation of rhythm disturbances and other cardiac anomalies.
- *Radiography and other image viewing*: Although on-site staff will read most radiographic studies, emergency viewing capability is important. High-resolution medical grade scanners can be used for this purpose in hospitals that have not changed over to digitized radiographs.
- *Access to detailed clinical data*: A wide variety of clinical data must be available to the care team, including laboratory, culture, and other test results; medications; vital signs; and other physiologic data (e.g., invasive hemodynamics and input and output, among others). Aggregating these diverse data can be a formidable undertaking, as can organizing and displaying them in user-friendly formats. Successful applications provide considerable value to on-site caregivers and can serve as a platform for knowledge-based applications, such as those described below.
- *Physician notes and orders*: Off-site care providers must be able to both generate notes and orders (the products of their work), and view physician documents created on-site. While many hospitals are evaluating the feasibility of system-wide computerized physician order entry systems, few have these in place. Some system for creating orders and printing them in the ICU is required, preferably one that captures key medication information and provides screening for allergies and drug interactions. Similar tools must be available for creating and viewing physician notes, as these contain key patient data not available elsewhere. The use of computer-based note writing tools is highly recommended, since traditional handwritten notes are very inefficient for information transfer (due to wide variations in content/organization, poor legibility, and lack of portability).
- *Communication tools*: The primary rationale for introducing a centralized care team is to expand intensivist coverage to both greater numbers of patients and more hours of the day (24 hours 7 days a week is optimal). Because of both geographic separation and expanded hours of physician coverage, specific tools to ensure rapid and effective communication between care teams is essential. Dedicated phone lines ensure that on-site personnel can access the remote team rapidly during emergencies, while the audio-video system allows effective in-room communication. Efficient and effective physician-to-physician communication is equally important. Although traditional verbal sign-out rounds can be used to outline treatment goals, delineate

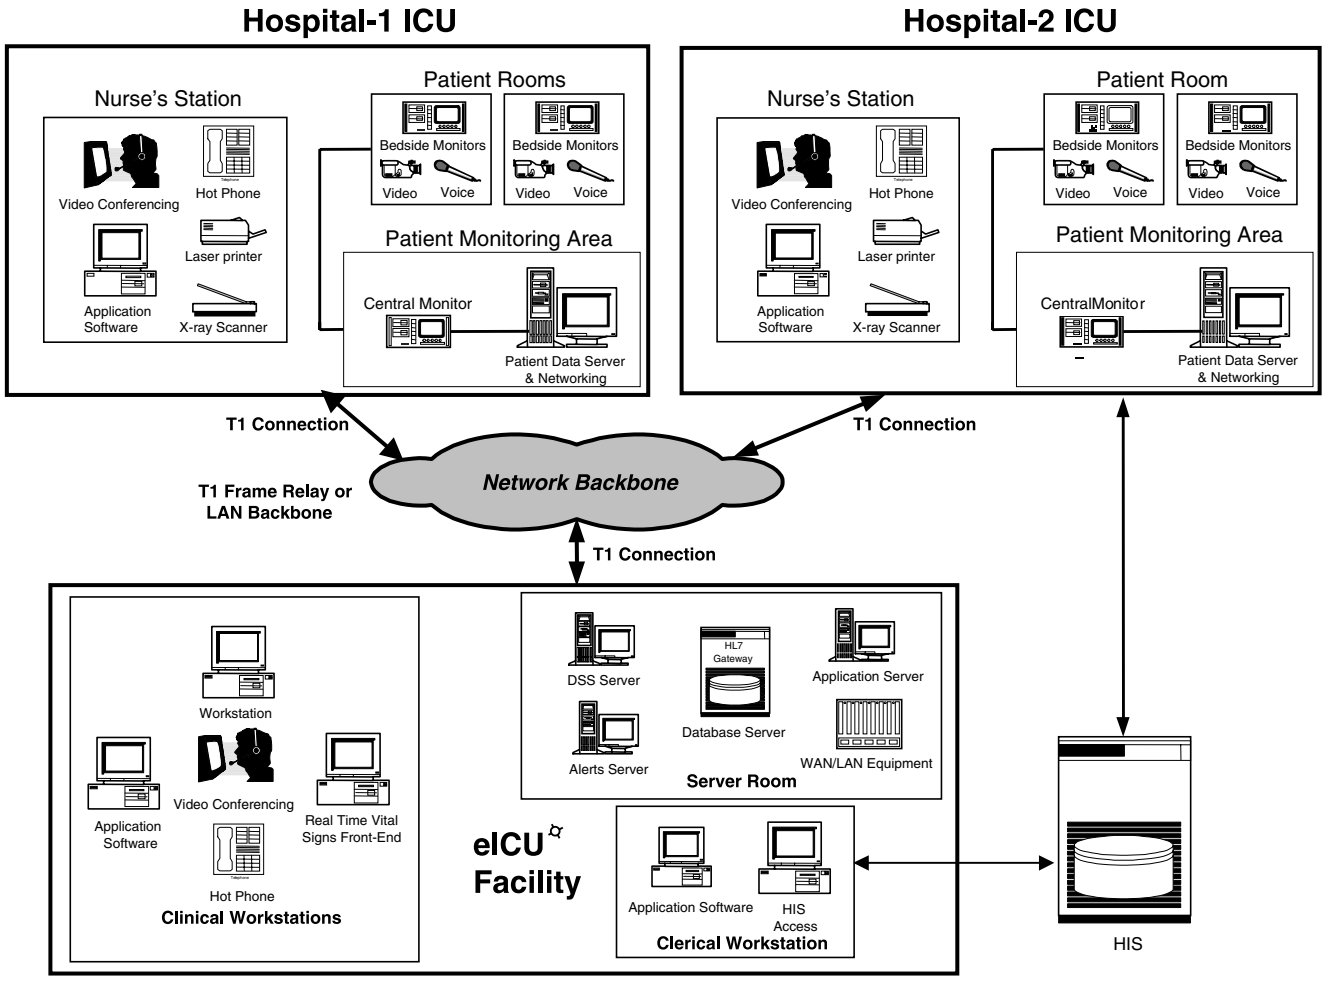

FIGURE 8-1 Schematic diagram showing remote care architecture.

key tasks, and communicate ideas and clinical information not appropriate for inclusion in traditional physician notes, they are time-consuming and difficult to coordinate. The use of computer-based applications for transmission of these data offers clear advantages.

- *A wide area network*: A wide area network that connects each ICU (or other high-acuity site) to the centralized monitoring center is necessary to support all the above applications. This network must be reliable (redundancy is desirable), secure, and have sufficient bandwidth to support full-motion video.

Commercial systems in use today also include computer-based decision-support tools and an alerting system that evaluates new clinical data (e.g., labs, physiologic data, and medications) and flags potential problems. These tools facilitate problem recognition and assist both remote and on-site physicians with decision making. Figure 8-1 shows a schematic representation of a remote care system.

Establishing the technology platform to support a centralized ICU care center is a complex undertaking. While some required functionality may be available in existing ICU or hospital applications, the entire system must function as an integrated whole. The diverse components must be simple to use and support routine ICU care processes. A dysfunctional technology infrastructure will limit the number of patients the remote care team can manage, thus undermining one of the key reasons for centralizing this function. On the other hand, installing a comprehensive patient care system that supports physician workflow, facilitates problem detection, standardizes practice patterns, and improves decision making can provide real benefits. Such systems can also bring value to on-site intensivists and help improve the safety and efficiency of their activities.

Operational Considerations

Establishing a remote ICU management program changes the care paradigm at several different levels. First, a host of new procedures must be introduced to support off-site care. Areas that must be addressed include credentialing, clinical processes, communication, documentation, training, and quality review. However, implementing a remote ICU program entails fundamental changes in ICU management—adopting a system-wide approach to ICU care, moving to 24-hour 7-day intensivist oversight, and standardizing care processes. Migrating to this alternate care paradigm provides substantial benefits, but requires strong institutional leadership and experience in implementing new clinical programs. Establishing clear goals, identifying champions and local leaders, creating appropriate incentives, and aggressively managing

the change process are essential to achieving high levels of success.

Although centralized ICU care programs are still relatively new, the accumulated experience of the sites in current operation have generated considerable useful information. A brief summary of their experience in several key areas follows.

- *Staffing*: All programs to date have targeted reaching 35 to 50 networked beds within a short time frame. This represents a comfortable number of monitored patients for a physician/nurse team, and it also is of sufficient scale to justify the operating expenses of the remote center. As additional beds are added, more staff are required. Although experience is limited, it appears that a second physician will be needed when the number of networked beds approaches 100. Nonintensivists may be able to function as the second physician since they will be working in tandem with the intensivist. ICU fellows and acute care nurse practitioners may prove to be valuable additions to the care team. Because the remote care program supplements, rather than replaces, on-site clinical activities, the program will require the addition of new physicians and nurses. Although some individuals may prefer to work in the remote center exclusively (or may need to because of disabilities, such as latex allergy), most physicians and nurses prefer to divide their time between on-site and remote care. Many hospital systems have multiple groups of intensivists, sometimes representing different private practice teams, and other times representing different medical specialties (e.g., medical intensive care unit, surgical intensive care unit, or neurologic intensive care unit). Creating a structure in which all groups are able to participate in the remote care program simplifies staffing of the remote center and helps to build support for the project. It also increases the breadth of experience, fosters collaboration, and helps with standardizing practice patterns. Where ICU care is highly specialized, open discussion of care practices for different populations and formal back-up procedures for complex specialty cases are important.
- *Financial structure*: Third party reimbursement for telemedicine professional services is very limited at this time. As a result, all current ICU telemedicine programs are funded by the participating hospitals. Hospitals recognize cost savings from reduced ICU and hospital LOS and lower daily ancillary cost expenditures, and they also are able to create additional ICU capacity as a result of the decrease in ICU LOS. Initial data suggest that these financial benefits exceed the implementation and operating costs of the program, including the salary costs of the intensivists and other care team members. Salary levels must be appropriate for the market and sufficient to entice physicians to work nights and weekends.
- *Remote center operations*: The remote team consists of physicians, nurses, and clerical personnel, as well as dedicated administrators. It is important to clearly define the roles and responsibilities of each member of the team. This requires developing procedures for how all key tasks are to be performed (e.g., rounding, data gathering, and communications). Assembling a multidisciplinary team consisting of hospital administrators, program administrators, ICU team members (physicians and nurses), and stakeholders from other areas that interface with the ICU (e.g., pharmacy and ED) ensures broad representation and is recommended. Once remote care processes have been defined, they need to be documented and understood by all. Formal training programs must be developed so that each participant is familiar with the technology and the clinical procedures. Back-up plans must be developed in the event of technical problems (e.g., network failure) and to deal with common problems. The more effective the planning process, the smoother the operation will be.
- *Integration with on-site activities*: The remote care team functions in support of the on-site physicians. In most ICUs the attending of record (or on-site intensivist) will review all data at least once a day, coordinate communication with all members of the team (nurses, consultants, respiratory therapy, etc), and establish the care plan. When that individual leaves the ICU (the time of day will vary depending on the staffing model), the remote team assumes responsibility for executing the care plan, making adjustments to ensure that goals are met, monitoring patients for new problems, and intervening where needed. The smooth transfer of responsibility embodied in this model requires effective communication between the on-site and remote teams. The computer-based applications required for off-site care, if deployed in the ICU, can provide a convenient forum for this information transfer. In this way the thoughts and plans of the attending of record are available to the remote intensivist, and the assessments and interventions of the off-site intensivist are immediately apparent to the on-site physicians when they return to the ICU. However, in order to get the requisite buy-in from busy ICU clinicians, effort must be devoted to ensuring that the on-site care team understands both the value provided by the remote team and the importance of effective communication. It is similarly important that the remote intensivist notify the attending of record when important decisions arise during off hours.
- *Oversight*: As should be evident from the above discussion, implementing a system-wide remote ICU care program is a major undertaking. A new operating center must be established, staff must be hired/recruited and trained, and a complex set of operating procedures need to be developed. ICU staff will need to be trained and physicians that admit to the ICU will require education as well. Assembling an experienced leadership team is essential to the success of the program. Senior hospital executives must clearly enunciate the rationale and vision of the program. Dedicated project leaders must be appointed, usually an intensivist physician and a remote center manager. These individuals should have the requisite skills for the job and have protected time to devote to the project. In addition, a broad-based program oversight committee should meet regularly to review problems, modify operating procedures, and track program progress. This committee, in conjunction with senior hospital leadership, should establish yearly goals for the program and track progress against these.

Regulatory Issues

There are a number of regulatory issues that must be considered when implementing a remote ICU care program. First, off-site intensivists are providing patient care. Although most remote care programs cover a limited geographic region, some may cross state lines, and physicians in the remote

center must be licensed to practice medicine in each state that has hospitals within the network. Physicians also will need to be credentialed at each participating hospital. A few hospitals have developed special credentials for this purpose. The second important area concerns ensuring patient confidentiality. The recently issued federal security guidelines (part of the Health Insurance Portability and Accountability Act; HIPAA) outline general principles for protecting patient data and confidentiality. These have clear implications for remote ICU care, including keeping transmitted data secure, and instituting appropriate security policies at the remote site. Most hospitals include consent for remote care as part of their hospital admission consent process.

The Leapfrog Group has indicated that hospitals may use remote intensivist monitoring in order to meet their intensivist standard. They suggest that this may increase the feasibility of implementing dedicated intensivist coverage. They have defined several key features for a remote management program,[11,12] including:

- An on-site intensivist must review patient data and set the daily care plan.
- The tele-intensivist must provide care during all hours that there is not an intensivist on-site. He or she must be physically at the remote care site and have no concurrent responsibilities.
- Clinical data must be available to the remote intensivist, including laboratory results, medications, and notes, among others.
- The remote care system must be robust (>98% uptime) and secure (HIPAA compliant).
- The remote intensivist must be able to visualize the patient and communicate with on-site personnel, so camera resolution and bandwidth must be sufficient to assess breathing.
- The program must adhere to written standards, including at a minimum: (1) critical care certification, (2) state medical licensure, (3) hospital credentialing, (4) quality review of the program, (5) explicit policies defining roles and responsibilities, and (6) a program to educate staff about the program.
- Remote intensivist care must be proactive and include routine review of all patients.
- The workload of the tele-intensivist should not be excessive; he or she should be available within 5 minutes of a request from ICU personnel.
- There should be written procedures to ensure effective communication between the tele-intensivist and the on-site personnel.
- Actions performed by the remote intensivist should be documented and included in the medical record.

Future Directions, Broader Visions

Implementing a remote care program represents a major change in the patient care paradigm. The rationale for this change, as discussed above, is to improve clinical outcomes in our most vulnerable patients. However, there are several intriguing consequences of this new model. First, critical care is viewed as a system-wide priority and intensivists are viewed as the key resource. By elevating both the prominence of critical care and the importance of intensivists, centralized care programs should have a beneficial impact on the specialty. Second, conceptualizing critical care at the system level should facilitate practice standardization, which will further improve clinical outcomes. Third, the program aspires to continuous intensivist oversight, regardless of time of day. This care model accepts the need for 24-hour 7-day dedicated physician care, and as a result, requires a move to fixed shifts of clinical responsibility. While this change in staffing requires increased focus on processes to ensure continuity of care, it should improve quality of life for intensivists and address a major factor contributing to early burnout and choosing alternate career options. Fourth, remote care depends on the introduction of technology systems that are actually used to care for patients. This technology infrastructure creates opportunities to use information systems to improve the care process. Automated alerts can reduce errors, detailed information on practice patterns can be used to drive performance improvement initiatives, computerized decision support tools can ensure ready access to current knowledge, and time-saving computer applications can improve physician efficiency and effectiveness. It is worth noting that the promise of these smart systems can be realized because there is a physician monitoring all critically ill patients at all times, in contrast to other monitoring paradigms, because the physician doing the monitoring has the clinical skills to analyze the incoming alerts, and he or she is empowered to initiate a response. Finally, because the program views critical care as a system-wide service, operating efficiency can be optimized and resources can be used more effectively. As a result, this re-engineering of ICU patient care can both save lives and have major financial benefits for the hospital.

Centralized ICU care is still in its infancy. As experience increases we can look forward to an improved understanding of which elements of the program have the greatest effect on outcomes, and which functions are best performed by on-site physicians. Efficacy needs to be confirmed in different environments (academic, community, and rural) and with different on-site staffing models. Considerable uncertainty exists regarding preferred off-site staffing models, particularly as the size of the ICU network increases. Operating procedures need to be refined and new systems developed for training both on-site personnel and the remote team. Almost certainly the technology infrastructure will evolve, and this should both simplify establishing a remote program and increase operating efficiency. Like many new technologies, increased experience will enhance efficacy and expose weaknesses. It is important to recognize that the supporting technology enables new systems of care. As such, the success in different sites will depend on the diligence of the clinicians responsible for providing patient care. The potential looks promising and it should be exciting to follow the evolution of this care model moving forward.

Chapter 9

PREPAREDNESS FOR CATASTROPHE

JEFFREY G. WALLS
J. CHRISTOPHER FARMER

KEY POINTS

- *The intensive care unit medical director should play an active role in each hospital's disaster planning.*
- *The Joint Commission on Accreditation of Healthcare Organizations requires that each hospital develop, implement, and regularly test a disaster plan.*
- *A hazard vulnerability analysis should be conducted by each hospital to identify threats to care of patients specific to its region.*
- *Preparation should coordinate all community resources and not be focused on a single ICU or hospital.*
- *Each ICU medical director should identify his or her role within the emergency command structure (typically the hospital emergency incident command system).*
- *Back-up methods of communication such as walkie-talkies should be acquired and tested to ensure reliable communication between the ICU and the hospital command center.*
- *A pool of potential volunteer ICU medical personnel should be identified prior to a disaster and mechanisms put into place to provide emergency credentialing.*
- *An active disaster education program should be created to keep all ICU personnel up to date.*
- *Participation in realistic disaster exercises is important to identify problems within each hospital's plan and to reinforce education.*

Hospitals today are faced with a daunting task: to prepare for community disasters that could bring a large number of injured or ill patients to their doorsteps. Since September 11, 2001, the threats to a community and its hospitals seem endless. In addition to the terrible events surrounding the World Trade Towers collapse, a more insidious attack occurred in the form of anthrax delivered through the mail. Health care workers have died as a result of severe acute respiratory syndrome (SARS), which represents an emerging, highly contagious infectious disease. Natural disasters have wreaked havoc on numerous health care facilities, and have jeopardized patient well-being.

During a disaster, hospitals serve as a refuge for the injured and ill. Unfortunately, the ability of health care organizations to prepare for these would-be crises is jeopardized by current financial constraints. To many hospital administrators, maintaining facility solvency at their current rate of reimbursement is the real threat, while expending funds for disaster preparedness seems less essential. Hospitals must operate in a fiscally efficient manner, operating near full capacity. The ability of a typical hospital system to absorb large numbers of injured patients during an emergency either acutely, or over a more prolonged period of time, is extremely limited. More importantly, there has been little outside financial support to fund hospital disaster preparedness efforts.

First responders (police, fire department, and EMS) remain the primary focus for most ongoing disaster preparedness efforts. However, as mandated by the Joint Commission on Accreditation of Healthcare Organizations (JCAHO), all hospitals must have a functional disaster plan. As we learned during the recent SARS dilemma, the intensive care unit (ICU) is a key element of a hospital's response to large-scale incidents. In addition to emerging infectious diseases, trauma, bioterrorism, chemical attack, and radiation-induced injury are possible occurrences. Unfortunately, there is little written in the medical literature about the effects on structure and function of an ICU during a disaster.[1,2] As one example, during a biological weapons attack or an outbreak of a highly contagious disease, the ICU physician will be called on to recognize the syndrome and initiate the appropriate investigation and therapy. Therefore, the ICU medical director must be intimately involved with the hospital disaster committee to ensure the optimal use of this limited resource, and to ensure that the proper training and equipment are accomplished and available. The purpose of this chapter is to educate the intensivist on the general components of a hospital disaster plan, to detail where an intensive care unit fits into the hospital preparedness plan, and to review what predisaster preparation initiatives an ICU should conduct.

Definitions

The definition of a *disaster* is imprecise. Many different definitions are published, and an appropriate definition should be broad enough to be applicable to most situations. Frederick C. Cuny defines disaster as "a situation resulting from an environmental phenomenon or armed conflict that produced stress, personal injury, physical damage, and economic disruption of great magnitude."[3] By this definition, a disaster includes a wide range of events and outcomes. A disaster can occur outside the hospital or inside the facility, and can be the result of a naturally-occurring phenomenon, an unintentional accident, or an intentional act. A mass casualty incident (MCI) occurs when the requirements to care for multiple casualties overwhelm the normal capacity of the health care system.

Hospital Requirements for Disaster Preparedness

Given recent events, it is self-evident that hospitals must be prepared for an MCI. In the U.S., the standards for hospital accreditation as set forth by the JCAHO[4] (revised standards effective January 1, 2001) serves as a foundation for understanding the minimal components required in disaster preparation. The JCAHO standards include three components:

1. Environment of care (EC) standard EC.1.4 requires a hospital to develop a management plan that addresses the response to emergencies affecting the EC.
2. EC standard EC.2.4 requires the hospital to implement the emergency management plan.
3. EC standard EC.2.9.1 requires the hospital to execute the plan by participating in emergency management drills.

Copyright © 2005, 1998, 1992 by The McGraw-Hill Companies, Inc. Click here for terms of use.

The development of a hospital disaster plan must address four phases of emergency management: mitigation, preparedness, response, and recovery. *Mitigation* refers to the identification of potential emergencies that could affect a hospital, and implementing a plan to support the most vulnerable areas. The JCAHO also requires that a hazard vulnerability analysis (HVA) be conducted. An HVA is a formal assessment of the potential threats to the normal delivery of health care. This analysis should include plans for internal disasters such as fire and loss of power, as well as external disasters that could result in large numbers of patients coming to a hospital. To assist a hospital to evaluate their vulnerabilities, the American Society for Healthcare Engineering has developed a hazard vulnerability assessment tool that is available through their website.[5]

Preparedness is self-explanatory, and includes obtaining supplies and equipment, making arrangements with vendors and outside medical facilities to enable the urgent acquisition of supplies, and educating and preparing the hospital staff through literature, lectures, and drills. *Response* includes the predetermined actions of the medical staff in the event of a disaster, and the actions that management takes to initiate the plan, set up the command structure, and initiate communications with first responders. *Recovery* focuses on returning to normal operations and restoring needed services.

Coordinating Intensive Care Unit and Hospital Plans with the Community

A hospital emergency response plan must be coordinated with community emergency management planning. After the HVA has been accomplished for both the hospital and the community, there should be coordination between organizations regarding which potential hazards are given hierarchical planning priority. The flooding disaster of the Texas Medical Center (TMC) in Houston in June 2001 underscores the need for specific plans for operations and evacuation of hospitals at risk, and the need for a coordinated community response. This was especially true for all critical care functions within the TMC complex. JCAHO standard EC.1.4 highly recommends that hospitals within a geographic area know and share the names, roles, and contact numbers of all leaders in their local/regional emergency command structure. Resources such as hospital personnel staffing should be closely coordinated so that no person is committed to two facilities at one time.

The incident command system (ICS) is a leadership structure that was envisioned to alleviate the traditional problems of poor communications and poor planning during a disaster. It was originally developed in 1970 in response to problems experienced in the management of wildfires in Southern California. During a multiple casualty event, every hospital must be closely linked with the community's command structure. It is helpful for the hospital and ICU leadership to understand the basic premises of the ICS in order to function within it more effectively. The ICS is built on the following basic principles:

1. Common terminology.
2. Modular organization with a unified command structure starting with an incident commander. The incident commander will delegate duties to different functional areas as the situation unfolds. These functional areas will have written consolidated action plans following established strategic objectives.
3. Integrated communications.
4. Manageable span-of-control in which the number of individuals that report to a supervisor is established at a range of three to seven.
5. Predesignated incident facilities with areas for command post, search and rescue, decontamination, transport, and the press.
6. Comprehensive resource management.[6]

During a disaster, the subordinate leaders/representatives under the incident commander would likely include the fire department, emergency medical systems, public health organizations, law enforcement, and environmental agencies. Each of these functions is expected to keep a representative at the central command center. The on-site grouping of each of these liaison representatives dramatically improves communication and coordination of responders. A hospital should know in advance who to contact within the community command structure in order to obtain information about incoming casualties, who to convey information to regarding available hospital capabilities, and who to communicate with about the ongoing needs of their facility. The official point of contact for most hospitals will likely be the emergency medical systems commander.

Developing a Hospital Command Structure

A version of the ICS has been adapted for hospitals and is called the hospital emergency incident command system (HEICS).[7] Utilizing this system provides a seamless interface with the community command structure. Many hospitals are utilizing some form of the HEICS, and the HEICS document contains a proposed hospital command structure (Fig. 9-1). Job action sheets are provided that clearly define the responsibilities for each team member within the command structure. An intensivist may be asked to fill one of several roles. One proposed responsibility for the medical director of the ICU during a time of mass casualties would be as the medical care director. The medical care director coordinates patient care throughout the hospital and would optimize utilization of ICU beds and capability that becomes such a limited resource during surges in numbers of high acuity patients. The HEICS also defines the role of the critical care unit leader, who may be a nursing supervisor or a physician. An example of the associated job action sheet is provided (Fig. 9-2).

Finally, it is important to develop plans for maintaining ICU security during a disaster, as well as a means of communicating the status of patients with families and members of the media. Plans for securing the ICU should be made in cooperation with the safety and security officer identified within the HEICS. Ideally, a single point of entry into the ICU should be established with security present to control access. ICU personnel should be instructed to communicate with the media only with the approval of the public information officer or liaison officer. The public information officer should be consistently updating the media and families of victims and provide appropriate accommodations for them as they

CRITICAL CARE UNIT LEADER

Positioned Assigned To:

You Report To: _____(In-Patient Areas Supervisor)

OperationsCommand Center: _____ Telephone: _____

Mission:	Supervise and maintain the critical care capabilities to the best possible level to meet the needs of in-house and newly admitted patients.	
Immediate	____	Receive appointment from In-Patient Areas Supervisor.
	____	Read this entire Job Action Sheet and review organizational chart on back.
	____	Put on position identification vest.
	____	Receive briefing from In-Patient Areas Supervisor with other In-Patient Area unit leaders.
	____	Assess current critical care patient capabilities. Project immediate and prolonged capabilities to provide services based on known resources. Obtain medical staff support to make patient triage decisions if warranted.
	____	Develop action plan in cooperation with other In-Patient Area unit leaders and the In-Patient Areas Supervisor.
	____	Request the assistance of the In-Patient Areas Supervisor to obtain resources if necessary.
	____	Assign patient care teams as necessary; obtain additional personnel from Labor Pool.
Intermediate	____	Identify location of Discharge Area; inform patient transportation personnel.
	____	Contact Safety & Security Officer of security and traffic flow needs in the critical care services area(s). Inform In-Patient Areas Supervisor of action.
	____	Report equipment/material needs to Materials Supply Unit Leader. Inform In-Patient Areas Supervisor of action.
Extended	____	Ensure that all area and individual documentation is current and accurate. Request documentation/clerical personnel from Labor Pool if necessary.
	____	Keep In-Patient Areas Supervisor, Immediate Treatment, and Delayed Treatment Unit Leaders apprised of status, capabilities, and projected services.
	____	Observe and assist any staff who exhibit signs of stress and fatigue. Report concerns to In-Patient Areas Supervisor. Provide for staff rest periods and relief.
	____	Review and approve the area document's recordings of actions/decisions in the Critical Care Area(s). Send copy to the In-Patient Areas Supervisor.
	____	Direct non-utilized personnel to Labor Pool.
	____	Other concerns:

FIGURE 9-2 Critical care unit leader job action sheet. (*Courtesy of the California Emergency Medical Services Authority*.)

wait. This will maximize patient confidentiality and avoid intrusiveness due to lack of information or curiosity.

Communications with the Hospital Command Structure

During a disaster, traditional forms of communication between the various departments of the hospital may become useless. Traditional telephone lines, cellular communications, and pager systems may fail or become overburdened during a time of community crisis. The hospital disaster plan should include an alternative form of communication within the hospital between vital departments and the hospital command center. An ICU must be able to relay bed and personnel availability to the hospital incident commander and must be able to receive information about incoming critically ill patients. Several hospitals now have dedicated walkie-talkie units to facilitate communication during a disaster.[8,9] These backup communication systems should be tested as part of any disaster exercise and must be properly maintained.

Determining Intensive Care Unit Capacity for Care

If a mass casualty event occurs, hospital leaders must be able to calculate the current capacity of their facility, and the

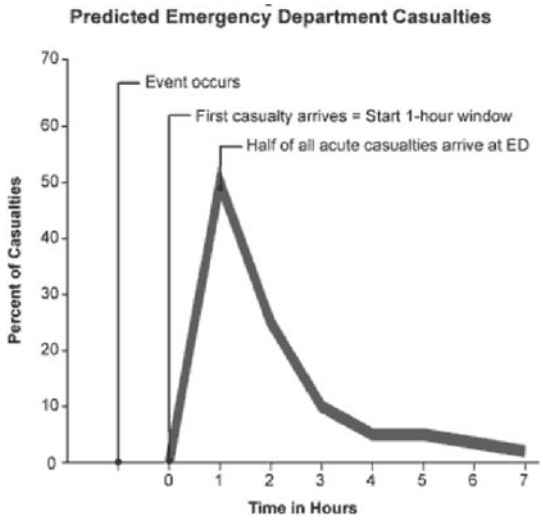

FIGURE 9-3 The expected total number of casualties can be predicted by the number arriving within the first hour. (*Courtesy of the Centers for Disease Control and Prevention.*)

incremental number of patients that can be accepted for care. It is estimated that the capacity of a hospital to care for an emergency patient load is approximately 20% of the total bed capacity.[10] However, this may represent an overestimation of the ability to care for severely injured patients requiring critical care in a sudden mass casualty event. The actual number of trauma teams needed to resuscitate and stabilize critically injured patients may be a truer determinant of capacity. The total number of patients that can be accepted can then be ascertained, once the percentage of critically injured patients is known.[11] The Centers for Disease Control and Prevention (CDC) offers a webpage that provides a mass trauma casualty predictor and predictor of hospital capacity to care for critical casualties. Generally, 50% of all casualties will arrive within the first hour (Fig. 9-3). Of those patients, approximately 33% will be critical casualties. The hospital's capacity to care for these casualties will be determined by the number of available operating rooms staffed with surgery teams.[12]

In some circumstances, the requirement for medical care during an emergency response outstrips availability. In this circumstance, a form of disaster care rationing may be needed. The process of *triage*, a word coming from the French *trier* (to sort, to select), may be required to manage many casualties, and has been incorporated as part of the ICS. Triage sorts the patients, following established guidelines, in order to prioritize their initial management, as well as their evacuation to other facilities, according to the available resources and the type of incident.

Few hospitals maintain a sufficient number of empty beds for "surge capacity" due to cost constraints and the efficiency requirement to operate at or near full capacity. In the event of an emergency, a hospital plan should be in place to define a process for transferring existing ICU patients to other facilities. Agreements with neighboring hospitals should be established to accept predisaster ICU patients in transfer. Restrictions on out-of-ICU vasopressors or mechanical ventilation may need to be temporarily suspended to allow more stable ICU patients to be transferred to a hospital ward.

Not all disasters involve multiple traumas arriving at the hospital over a defined period of time. A bioterrorist act or an epidemic of an emerging infectious disease such as SARS would likely place strain on an ICU's capacity for care over a much more prolonged period. An infectious disease outbreak may mandate that a hospital protect its own employees and other patients first, thereby potentially limiting the capacity to care for all patients requiring critical care. It would be prudent to designate one hospital and ICU in a community or region as the isolation hospital where all confirmed or suspected contagious patients are admitted. This would both consolidate resources in one facility and limit exposure of other patients. The requirements for isolation will depend on the organism involved. Both smallpox and SARS patients would optimally be placed in isolation rooms with negative pressure relative to the surrounding area.[13] In most hospitals this resource is limited, and should be considered in determining capacity for care.

The vaccination of health care workers against smallpox has been controversial due to concerns about side effects from the vaccine and reimbursement of health care costs for those workers who become ill. There are many obvious benefits of having ICU and ancillary personnel who have been vaccinated taking care of patients with smallpox. Hospital personnel safety, limitation of the potential spread of the disease, and confidence of the health care team all would greatly benefit by a pre-exposure vaccine program.

Augmenting Resources During a Disaster

Previously, hospitals planned for a disaster assuming that outside assistance would not be available for up to 72 hours postevent.[1] This remains true in many countries; therefore appropriate supplies should be stockpiled in hospitals, pharmacies, and ICUs to sustain relief efforts until help is projected to arrive. As a response to this concern, in 1999 the CDC and the Department of Health and Human Services (HHS) established the National Pharmaceutical Stockpile. The purpose of this program is to resupply essential medical materiel such as drugs, antidotes, and surgical supplies, to any area of the country within 12 hours in the event of a national emergency. Included in these supplies are critical care-related materials such as mechanical ventilators. These assets were successfully deployed during the World Trade Center disaster. Effective in March 2003, the program became known as the Strategic National Stockpile (SNS), and is managed jointly by the Department of Homeland Security (DHS) and the HHS. To receive supplies from the SNS, the affected state's governor must directly request them from the DHS or the CDC.[14]

Professional organizations are also organizing volunteer personnel to help augment local staffing in the event of a disaster. As one example, the Society of Critical Care Medicine is cataloging the skills that each of its members possesses, and whether these individuals are willing to volunteer to help in times of disaster. In addition, the federal government has responded by creating the USA Freedom Corps as a way to organize volunteers. As a part of the USA Freedom Corps, the Medical Reserve Corps (MRC) is a group of locally organized medical volunteers that would serve in a time of disaster to augment existing medical staff. This program is sponsored by the HHS, and its primary role is to facilitate the establishment of these local organizations.[15] Provisions should be made

by hospitals to establish a process for emergency credentialing of professional volunteers during times of crisis. State or national licensure bodies could also improve access to help by allowing physicians and nurses who are licensed in one state or region to practice medicine in another under emergency conditions.[16]

Education

A vital component of ICU preparedness is ongoing medical education that emphasizes clinical situations likely to be seen during a disaster. However, for busy clinical professionals, medical preparedness training does not compete favorably with traditional continuing medical education requirements. Clinicians have limited time and budgets to accomplish these training demands. External funding sources are negligible at this time. As a result, most clinicians lack sufficient knowledge of disaster response. To address this shortfall, the Society of Critical Care Medicine has developed a succinct disaster medicine course that is designed to either accompany their Fundamentals of Critical Care Support Course, or the material can be taught as a separate 5- to 6-hour course. The course is entitled Fundamentals of Disaster Management, and will be accompanied by a seven-chapter handbook. The American Medical Association has recently endorsed two multiday course offerings called Basic Disaster Life Support and Advanced Disaster Life Support. These courses will offer a more substantial exposure to medical disaster training.

It is beyond the scope of this chapter to provide details on the care of patients who may present to a hospital after a disaster. In today's environment, this can be overwhelming due to the large number of different threats that can face a community. The local hazard vulnerability analysis (HVA) will serve as an initial assessment of which topics should be emphasized. In this way, medical communities can target specific educational goals and then limit training to these highest priorities/risks, at least as a starting point.

The American College of Emergency Physicians has issued an executive summary from their task force on the education and training of its members on the care of casualties of nuclear, biological, or chemical incidents.[17] This summary includes a review of six available training courses, and found that none met all the objectives established by the task force. The primary barriers identified to obtaining the educational goals outlined were access to adequate training and ability to retain the knowledge once learned. Therefore the only acceptable method of improving educational retention is to conduct exercise training that involves a broad cross-section of health care professionals in the community.

Training

JCAHO (EC.2.9.1) currently requires a hospital's disaster plan to be tested twice a year, with the tests occurring at least 4 months apart, but not more than 8 months apart. Furthermore, they suggest that if a hospital is formally designated in the community as a disaster receiving station, then at least one drill per year should include simulated patients. One of these drills should also be conducted as part of a community-wide exercise that addresses likely emergencies, again using the HVA as a guide.[4]

The federal government has assigned a more imminent priority to disaster exercises since the terrorist attacks of September 11, 2001. As one example, the Department of Homeland Security conducted a week-long, $16 million dollar exercise in both Seattle and Chicago in May 2003. This exercise involved a simulated chemical, biologic, and "dirty bomb" attack. The scope of those involved in the exercise ranged from elected civic leaders and other decision makers, to hospitals and health care professionals. Unfortunately, these exercises tend to rediscover the same medical lessons. Specifically, elected civic leader decision making substantially impacts observed medical outcomes. Education and training of civic leaders regarding medical issues can be insufficient. Because of the common focus of these activities on prehospital events, critical care professionals should become actively involved in the planning and participate in these exercises. All medical personnel should know their roles within the HEICS, and then train for disaster in those roles.

In summary, several points should be repeated for emphasis:

1. The current breadth and depth of health care professional education in disaster response has much room for improvement.
2. Our current health care system is underfunded to improve disaster educational standards to optimal levels.
3. Health care professionals are very busy, and have limited time available to devote to disaster medical education.
4. Numerous high-quality courses and training programs are currently available. Further improvement is desirable.
5. Much of our current medical educational focus is on prehospital issues; critical care is required to ensure an effective response to disaster.
6. Effective medical training and education must include elected civic leaders.
7. JCAHO standards and a sensible HVA can be used to target and prioritize the most pressing disaster medical educational needs of a community.

Chapter 10

PREVENTING MORBIDITY IN THE ICU

DEBORAH COOK
GRAEME ROCKER

KEY POINTS

- *Effective preventive health care interventions based on evidence from rigorous randomized trials are increasing.*
- *Nonetheless, preventive strategies are applied suboptimally in many settings, particularly in the intensive care unit (ICU).*
- *Potential reasons such strategies are not more broadly employed include clinician habit, lack of awareness of (or resistance to) new information, reliance on physiologic outcomes rather than on clinically important outcomes when interpreting evidence, and lack of self-efficacy of physicians who question whether the benefits observed in the research setting will be realized in the practice setting.*
- *Another important, but underappreciated, reason for insufficient or delayed uptake of effective preventive strategies is the absence of reinforcements for preventive behavior in general.*
- *A working environment that facilitates the implementation of preventive strategies is a powerful facilitator of change. A crucial first step in trying to improve preventive care in the ICU is to do an environmental scan to understand the practice of the unit and to characterize the culture of the unit.*
- *The most effective strategies to implement behavioral change are interactive education rather than passive education, audit and feedback, reminders (manual or computerized), and involvement of local opinion leaders.*

Importance of Preventive Interventions in the ICU

Effective preventive health care interventions based on evidence from rigorous randomized trials are increasing. Application of such randomized trial evidence in practice has great potential to decrease the morbidity and mortality rates of inpatients and outpatients. However, preventive strategies are applied suboptimally in many settings, particularly in the intensive care unit (ICU). This poses a serious problem because critically ill patients are at high risk of death not only from the condition that necessitated their admission to the ICU but also from the complications of critical illness.

Examples of well-documented underuse of interventions that have been demonstrated to decrease morbid complications of critical illness in randomized trials include prevention of venous thromboembolism,[1] prevention of hyperglycemia,[2] and prevention of pneumonia.[3] Other interventions proved to prevent ICU mortality in patients with acute lung injury and sepsis such as lung protective ventilation strategies, use of corticosteroids, and activated protein C are also variably applied in practice, although mortality-reducing interventions are not the focus of this chapter.

In this chapter, we (a) present key clinical and behavioral issues relevant to preventive care for critically ill medical and surgical patients, (b) illustrate the gap between the evidence and its practical application, (c) underscore lost opportunities for prevention of morbidity by using several study designs, and (d) suggest strategies for improved analysis of, and increased attention to, prevention in the ICU.

Reasons for Inattention to Prevention in the ICU

The reasons clinicians fail to attend to prophylactic strategies supported by randomized trials may mirror those reasons that clinicians fail to apply valid evidence in practice, and the reasons that clinicians do not follow high-quality practice guidelines. Assuming that the evidentiary basis for the preventive strategy is valid and thus worth considering, there are many potential reasons for underuse of primary, secondary, or tertiary prevention, including clinician habit, lack of awareness of (or resistance to) new information, reliance on physiologic outcomes rather than on clinically important outcomes when interpreting evidence,[4] and lack of self-efficacy of physicians who question whether the benefits observed in the research setting can be realized in the practice setting.[5]

Another important, but underappreciated, reason for insufficient or delayed uptake of effective preventive strategies is the absence of reinforcements for preventive behavior in general. This is true particularly in comparison to treatment strategies. Clinicians do not experience direct and immediate feedback about the benefit of prophylactic interventions because they are designed to prevent the occurrence of future adverse events. In contrast, therapeutic interventions usually result in short-term, ongoing feedback about treatment responsiveness. In behavioral terms, the reinforcement for clinicians applying preventive strategies, as distinct from treatment strategies, is often covert and delayed, rather than overt and immediate.[6]

In addition, a factor recently recognized to contribute to inattention to preventive care, which is unrelated to cognitive or behavioral attributes of clinicians, is the lack of systems support to facilitate prevention. The ICU setting poses unique but not insurmountable barriers to preventive care, due to the multidisciplinary complex care of critically ill patients, and the need for fast-paced decision making. Multidisciplinary care has been postulated to result in improved outcomes for critically ill patients, but it can also lead to lack of clarity about responsibility for ministration of preventive care.[7] We discuss these ICU environmental factors in more detail below with respect to prevention of venous thromboembolism and hyperglycemia.

Effective Prevention in the ICU: Do an Environmental Scan

A working environment that facilitates the implementation of preventive strategies is a powerful facilitator of change. A crucial first step in improving preventive care in the ICU is to do an environmental scan. The ICU environment can be scanned quantitatively and qualitatively to help understand which preventive strategies require attention.

A recent qualitative study examining environmental factors that increase β-blocker use to prevent mortality for patients with myocardial infarction illustrates this.[8] Investigators conducted semi-structured interviews with eight cardiologists, four internists, two emergency physicians, 15 nurses, 11 quality-management staff, and five senior administrators in eight U.S. hospitals. Six factors were found to increase β-blocker use: setting goals, administrative support, clinician support, design and implementation of improvement initiatives, use of data, and contextual factors. From this study, we learn which environmental influences encourage the prescription of β blockers, and we may emulate successful strategies in our own environment for other preventive strategies. Investigations of this genre have been conducted to understand pneumonia-prevention strategies.[7]

Other approaches such as self-administered surveys can help us to understand the use of preventive strategies for care of acute lung injury and acute respiratory distress syndrome.[9] Surveys can indicate the information sources in the environment that are considered to inform practice, the availability of specific preventive interventions, and perceived reasons for local practice patterns.

Effective Prevention in the ICU: Understand Current Behavior

The second step toward optimal prevention of morbidity in the ICU is to take a scientific approach to evaluating whether effective prophylactic strategies are being applied in practice, and whether they are achieving the desired patient outcome. Casual interviews rarely provide valid data about preventive care. More credible data about compliance with effective preventive interventions can be obtained through formal surveys of stated practice and structured personal interviews.

However, surveys of stated practice have a universal limitation that must be kept in mind: they do not necessarily reflect actual practice. For example, in a self-administered survey, Canadian ICU clinicians stated that patients of older age with severe illness acuity and serious chronic comorbidity were most likely to undergo withdrawal of life support.[10] Subsequently, however, an observational study of actual practice demonstrated that rather than age, illness severity, and organ dysfunction, the four strongest determinants of ventilator withdrawal were inotrope or vasopressor dependency, perceived patient preferences to limit life support, and physician predictions of ICU survival rate and future cognitive function.[11] There are no substitutes for comprehensive audits, rigorous surveillance strategies, and observational studies to document practice patterns. To be valid, these strategies should be blinded so that clinicians remain unaware that their management is being observed, to avoid the inevitable practice change associated with this awareness (the Hawthorne effect). Although the foregoing example concerns end-of-life care, the design feature of blinding is very important for observational studies evaluating whether optimal prevention is being applied in the ICU.

Qualitative research methods such as focus groups, document analysis, and in-depth interviews, as we found when exploring pneumonia prevention strategies in the ICU, are even more powerful for their insights about *when, where, why, how, and by whom* preventive care is administered[7] than *whether* it is administered.[12]

Effective Prevention in the ICU: Adopt Effective Behavior-Change Strategies

It is now well understood that knowing the research evidence about health care interventions that decrease rates of morbidity and mortality does not ensure that it is used in practice. The research evidence about effective behavior-change strategies can be extremely helpful to improve preventive care. The behavior-change strategies that are most likely to enhance the faithful application of diagnostic, preventive, and therapeutic interventions have been summarized in the Cochrane Collaboration Systematic Review by Bero and colleagues,[13] which has been comprehensively updated by Grimshaw and associates.[14] Although few studies in these reviews focused exclusively on preventive interventions, there are useful signals from this literature. For example, the Cochrane Review clearly shows that passive dissemination of information is generally ineffective; it seems necessary to use specific strategies to encourage implementation of research-based recommendations and to ensure changes in practice. The most effective strategies are interactive education rather than passive education, audit and feedback, reminders (manual or computerized), and involvement of local opinion leaders.

To ensure that preventive care interventions are applied in practice, a behavioral program could be instituted that is specifically adapted to the ICU setting. A portfolio of behavior-change strategies may be desirable, some of which could be common and some of which may be different, to promote each preventive intervention. Further research on the relative effectiveness of different strategies specifically for preventive care and specifically for the ICU setting is needed. Studies on the cost effectiveness of behavioral-change strategies to promote prevention would also be useful. In the following sections of this chapter, we illustrate some behavior-change strategies using two examples in the ICU setting: prevention of venous thromboembolism and prevention of hyperglycemia.

PREVENTION OF VENOUS THROMBOEMBOLISM IN THE ICU

Venous thromboembolism (VTE) is a common complication of serious illness, conferring considerable morbidity and mortality in hospitalized patients. Patients with deep venous thrombosis (DVT) are at risk of subsequently developing pulmonary embolism (PE), which may be fatal if untreated. In the ICU setting, patients with DVT are significantly more likely to have PE,[15] and patients with DVT have a longer duration of mechanical ventilation ($p = 0.02$), ICU stay ($p = 0.005$), and hospitalization ($p < 0.001$) than do patients without DVT.[16] Critically ill patients can rarely communicate their symptoms, making it unlikely that patient self-reported symptoms will prompt intensivists to pursue the diagnosis of VTE; moreover, the physical examination is insensitive to detect DVT. Clinically unsuspected DVT and PE are frequently found at autopsy on critically ill patients.[17] In summary, VTE is a good example of an ICU-acquired morbidity that can be silent but potentially deadly.

There are only two published randomized trials testing heparin for VTE prophylaxis in medical and surgical ICU patients.[18,19] One double-blind single-center trial allocated 119 medical-surgical ICU patients at least 40 years of age to unfractionated heparin 5000 U twice daily or placebo subcutaneous injections.[18] Using serial fibrinogen leg scanning for 5 days, the rates of DVT were 13% in the heparin group and 29% in the placebo group (relative risk = 0.45, $p < 0.05$). Rates of bleeding and PE were not reported. This trial demonstrated that unfractionated heparin is better than no prevention (the number of patients needed to prophylax with 5000 U twice daily of subcutaneous heparin to prevent one DVT is four). A multicenter trial by Fraisse and colleagues randomized 223 patients with an acute exacerbation of chronic obstructive pulmonary disease requiring mechanical ventilation for at least 2 days to 3800 or 5700 IU of the low-molecular-weight heparin nadroparin once daily or placebo.[19] Patients were screened with weekly duplex ultrasounds and after clinical suspicion of DVT, and venography was attempted in all patients. Rates of DVT were 16% in the nadroparin group and 28% in the placebo group (relative risk = 0.67, $p < 0.05$). A similar number of patients bled in each group (25 vs. 18 patients, respectively; $p = 0.18$). Although patients were not screened for PE, no patients developed PE during the trial. This trial demonstrated that nadroparin is better than no prevention (the number of patients needed to prophylax with nadroparin to prevent one DVT is eight).

Although there are only two published randomized trials of thromboprophylaxis in medical-surgical ICU patients, randomized trials have been conducted in other populations for three decades and have clearly shown the effectiveness of anticoagulant VTE prophylaxis. Accordingly, anticoagulant thromboprophylaxis is universally recommended for critically ill patients except those with contraindications.[20] However, compliance with this recommendation for thromboprophylaxis is not what it should be.

COMPLIANCE WITH THROMBOPROPHYLAXIS

Several prospective single-center utilization reviews of VTE prophylaxis have provided evidence about the use of VTE prophylaxis in ICU practice. For example, thromboprophylaxis was prescribed in 33% of 152 medical ICU patients in one study[21] and in 61% of 100 medical ICU patients in another.[22] In contrast, in a medical-surgical ICU in which a clinical practice guideline was in place, VTE prophylaxis was prescribed for 86% of 209 patients.[23] In medical-surgical ICU patients, after excluding those receiving therapeutic anticoagulation and for whom heparin was contraindicated, only 63% of 96 received unfractionated heparin.[24]

In a multicenter 1-day cross-sectional utilization review of surgical ICU patients, unfractionated heparin was the predominant choice, and two methods of VTE prophylaxis were prescribed in 23% of patients.[25] Prophylaxis with unfractionated or low-molecular-weight heparin was significantly less likely for postoperative ICU patients requiring mechanical ventilation than for patients weaned from mechanical ventilation later in their ICU course (odds ratio = 0.36). Use of intermittent pneumatic compression devices was significantly associated with current hemorrhage (odds ratio = 13.5) and risk of future hemorrhage (odds ratio = 19.3).

In summary, the use of effective VTE prophylaxis ranges widely, according to the foregoing utilization reviews. One inference from this health services research is that insufficient attention is paid to thromboprophylaxis in the ICU setting. However, when prophylaxis is prescribed, clinicians appear to risk stratify, that is, patients with more VTE risk factors are more likely to receive prophylaxis than are patients with fewer risk factors. The dynamic competing risks of bleeding and thrombosis during critical illness underscore the individual risk:benefit ratios in critically ill patients.

Two studies evaluating implementation strategies to enhance appropriate VTE prophylaxis are relevant to the ICU setting. One three-armed multicenter randomized trial of 3158 surgical patients requiring VTE prophylaxis evaluated the impact of education versus education plus quality improvement.[26] Both interventions significantly improved appropriate VTE prophylaxis rates compared to the control group. In a time series study of 1971 orthopedic patients, a computer-decision support system significantly increased the rate of appropriate VTE prophylaxis prescribing from 83% to 95%.[27] Interestingly, each time that the computer-decision support was removed, practice patterns reverted to those observed previously. In a before-after single-center study, our group demonstrated how appropriate anticoagulant thromboprophylaxis increased from 65%[24] to 95%[28] after the introduction of a thromboprophylaxis practice guideline implemented by using interactive multidisciplinary educational in-services, ongoing verbal reminders to the ICU team, daily computerized nurse recordings of thromboprophylaxis, weekly graphic feedback to individual intensivists on prophylaxis adherence, and publically displayed graphic feedback on group performance. However, no randomized trials have formally tested individual behavior-change strategies for thromboprophylaxis in the ICU, in contrast with this multimethod approach. Fortunately, published thromboprophylaxis rates for critically ill patients appear to be increasing over time.[1]

PREVENTION OF HYPERGLYCEMIA IN THE ICU

The adverse consequences of acute hyperglycemia have been highlighted in numerous observational studies. A meta-analysis of 15 observational studies showed that, after myocardial infarction, diabetic patients with glucose values of 6.1 to 8.0 mmol/L had a fourfold higher risk of death than did patients without diabetes who had lower glucose values.[29] Among diabetic patients with glucose values of 10.0 to 11.0 mmol/L, the risk of death was increased twofold. After stroke, a meta-analysis of 32 observational studies among nondiabetic patients found that acute hyperglycemia with values of 6.1 to 8.0 mmol/L was associated with a threefold relative risk increase in hospital mortality and an increased risk of poor functional recovery in nondiabetic patients after stroke.[30]

To test the hypothesis that outcomes could be improved in patients with lower blood glucose during acute illness, the Insulin Glucose Followed by Subcutaneous Insulin Treatment in Diabetic Patients with Acute Myocardial Infarction (DIGAMI) study randomized 620 patients with diabetes and myocardial infarction to two different intervention strategies. Patients were allocated to intensive metabolic treatment with insulin plus glucose infusion followed by

multidose insulin treatment or to standard treatment. Investigators found a significantly lower mortality rate in the intensive treatment group at 1 year[31] and at 3 years.[32] In diabetic patients, the adverse consequences of chronic hyperglycemia are well known. The Diabetes Control and Complications Trial (DCCT), which enrolled 1441 patients with type 1 diabetes, demonstrated that patients who had intensive insulin management had significantly less retinopathy, nephropathy, and neuropathy than did those managed conventionally.[33] Similarly, the UK Prospective Diabetes Study (UKPDS) of 3867 patients with type 2 diabetes showed that intensive glucose control with oral hypoglycemic agents or insulin to achieve a target fasting glucose level below 6 mmol/L resulted in significantly fewer microvascular complications than did conventional management.[34]

In addition to the foregoing findings, emerging evidence suggests that acute hyperglycemia has adverse consequences for ICU patients. During critical illness, stress hyperglycemia occurs due to production of excessive counter-regulatory hormones (glucocorticoids, catecholamines, growth hormones, and glucagon), effects of cytokines, insulin resistance, and pre-existing diabetes. Building on the results of the DCCT[33] and UKPDS[34] in diabetic patients and those of the DIGAMI trial in patients with and without diabetes,[31] a recent landmark randomized trial of 1548 critically ill patients demonstrated that patients allocated to a target of euglycemia (4.4 to 6.1 mmol/L) as compared with higher glucose values (10.0 to 11.1 mmol/L) had a significantly lower infectious morbidity rate, less renal failure, less polyneuropathy of the critically ill, and lower ICU and hospital mortality rates regardless of whether they had diabetes.[35]

Compliance with Euglycemia

Human behavior is partly determined by beliefs and attitudes. To determine the beliefs and attitudes held by ICU clinicians about prevention of hyperglycemia, we recently conducted a multicenter survey of ICU physicians and nurses.[2] The goals were to understand (a) perceived thresholds for clinically important hyperglycemia and hypoglycemia in ICU patients, (b) glucose measurement concerns in the critical care setting, and (c) strategies that clinicians would find most useful to help achieve optimal glucose management in the ICU.

ICU clinicians reported their perception that the clinically important threshold for hyperglycemia was 10 mmol/L for diabetic and nondiabetic ICU patients. Avoidance of hyperglycemia was judged most important for diabetic patients (88%), patients with acute brain injury (85%), a recent seizure (74%), advanced liver disease (64%), and acute myocardial infarction (64%). Physicians expressed more concern than nurses about avoiding hyperglycemia in patients with acute myocardial infarction ($p = 0.0004$). We conclude that randomized trial evidence showing the benefit of euglycemia in preventing morbidity and mortality in critically ill patients has not decisively influenced practice in these centers.

In summary, a recent randomized trial in critically ill patients associated euglycemia with lower morbidity and mortality rates than with higher glucose values. This work follows a consistent body of evidence about the importance of euglycemia to achieve optimal patient outcomes in other acute settings. Nevertheless, clinicians in our multicenter survey[2] did not consistently report application of this evidence in practice. Lack of clinician awareness of the ICU trial[35] is unlikely; however, other plausible explanations include the short time since publication of this trial, uncertainty about the application of these results to noncardiac surgery patients or patients with short ICU stays, the challenge of achieving euglycemia in the ICU, concern about unrecognized hypoglycemia in critically ill patients, and a desire for more confirmatory evidence. Principles of behavior change mentioned earlier, and worth repeating, are that changing clinician behavior does not follow passive dissemination of information. The most effective strategies are interactive education, reminders, audit and feedback, and actively implemented, locally developed guidelines and protocols.[14] Further, in the ICU, strategies to improve glycemic control may be more effective by using a collaborative and interdisciplinary approach, rather than relying on a physician-led initiative. Meanwhile, pending the completion of future randomized trials in heterogeneous ICU populations, a shift toward tighter glucose control requires being aware of ICU clinicians' beliefs and attitudes. Addressing these beliefs and attitudes could enhance the success of future clinical, educational, and research efforts to modify practitioner behavior and thereby improve the outcomes for critically ill patients.

supporting the preventive interventions, (b) attributes of the preventive interventions themselves, and (c) existing strategies to enhance their uptake. We illustrate this analytic approach by comparing and contrasting two preventive interventions for mechanically ventilated patients: semirecumbency for pneumonia prevention (vs. supine positioning),[36] and stress ulcer prophylaxis with histamine-2 receptor antagonists (vs. other drugs or placebo).[37]

Figure 10-1 illustrates how the evidentiary basis for these two preventive interventions differs. The body of research in support of histamine-2 receptor antagonists for stress ulcer prophylaxis is much larger in terms of number of randomized trials, and the data are older and better known[38] than the body of evidence supporting semirecumbency for pneumonia prevention.[36,39–41] Figure 10-2 illustrates how the interventions themselves differ. Whereas semirecumbency is a complex, continuous, behavioral intervention potentially influenced by many alternative body positions, stress ulcer prophylaxis is a discrete, twice- or thrice-daily, simple pharmacologic intervention. Figure 10-3 illustrates that existing uptake strategies supporting stress ulcer prophylaxis are multiple, including publications, educational documents, presentations, computer-decision supports, and practice guidelines; in addition, the most powerful uptake strategy is operant: the well-oiled machine of industry detailing. In contrast, uptake strategies for semirecumbency are more limited in scope and effectiveness.

Although we cannot prove a causal relation between this conceptual analysis and the high penetrance of stress ulcer prophylaxis[42,43] as compared with a low penetrance of semirecumbency,[7,12] such a relation may be deduced.

Conclusions

In this chapter, we have emphasized preventive strategies that are grounded in evidence from randomized controlled trials and acknowledged that not all clinical questions in the ICU are best answered using the randomized controlled-trial approach. As we have illustrated, several other study designs can provide high-quality data that inform clinicians about preventive interventions that benefit patients, families, and staff.

Decreasing preventable morbidity (and, of course, mortality) should be among our top priorities in the ICU. Achieving these goals requires a multifaceted approach. It begins with an understanding of why clinicians fail in practice to use prophylactic strategies that are supported by valid evidence. Next, a scientific environmental scan can help to identify which preventive strategies are underused and require attention. An array of effective behavior-change strategies is desirable in the ICU setting. The ICU may be ideally suited to approaches such as population-specific practice guidelines, academic detailing by ICU pharmacists, and computer-assisted reminders. We must be mindful that these behavior-change strategies may require adaptation to the structure, function, and culture of each ICU. By adopting, yet locally adapting, effective behavior-change strategies, we can take essential steps to minimize lost opportunities for effective prevention in the ICU setting. If we fail, the commitment to research made by patients and their families in prior prevention trials will not be honored and will not benefit patients currently under our care.

Chapter 11

NUTRITION IN THE CRITICALLY ILL

DAREN K. HEYLAND
STEVE A. MCCLAVE

KEY POINTS

- *Nutrients and gastrointestinal structure and function are linked to the pathophysiology of infection, organ dysfunction, and survival in critically ill patients.*
- *Nutrition support may both positively and negatively influence the morbidity and mortality of critically ill patients.*
- *When considering nutrition support in critically ill patients, enteral nutrition (EN) should be used in preference to parenteral nutrition (PN).*
- *Strategies to optimize delivery of EN (e.g., starting EN early, use of a feeding protocol with a high threshold of gastric residual volume, use of prokinetic agents, and use of small bowel feeding) and minimize the risks of EN (e.g., elevation of the head of the bed) should be considered.*
- *When initiating EN, PN should not be used in combination with it.*
- *For most patient populations in critical care in whom EN is not possible or feasible, standard therapy (IV fluid resuscitation without artificial nutrition support) is preferable to PN for the first 7 to 10 days.*
- *When PN is indicated, strategies that maximize the benefit (e.g., supplementing with glutamine) and minimize the risks of PN (e.g., hypocaloric dose, withholding lipids, continued use of EN, and the use of intensive insulin therapy to achieve tight glycemic control) should be considered.*

Nutrition support is considered an integral component of standard supportive care in the critically ill patient. In humans, during stress associated with trauma, sepsis, or other critical illness, there is high consumption of various nutrients by the gastrointestinal tract, immune cells, kidneys, and other organs. Requirements for and losses of these nutrients may outstrip synthetic capacity, leading to an erosion of body stores and depletion of proteins and other key nutrients. Historically, in an attempt to mitigate such deficiencies and preserve lean body mass, traditional nutrition (protein, calories, vitamins, etc) has been provided to critically ill patients. The relative merits of nutrition were evaluated in the context of protein-calorie economy (weight gain, nitrogen balance, muscle mass and function, etc). In this chapter we take a broader view of the benefits and risks of nutrition support. The benefits of nutrition support in general include improved wound healing, a decreased catabolic response to injury, enhanced immune system function, improved GI structure and function, and improved clinical outcomes, including a reduction in complication rates and length of stay with accompanying cost savings.[1] Independent of their effects on nutritional status of the patients, key nutrients such as glutamine, arginine, and omega-3 fatty acids may also have favorable direct effects on organ function and clinical outcomes of critically ill patients. Thus nutrition support may be considered a specific therapeutic intervention by which the critically ill patient's disease course may be altered, leading to a more favorable outcome.

There is considerable evidence linking nutrition (and lack thereof) and GI function to the pathogenesis of infection and organ failure in critical illness.[2] Failure to obtain enteral access and to provide nutrients via the enteral route results in a proinflammatory state mediated by macrophages and monocytes. Oxidative stress is increased, severity of illness is exacerbated, and the likelihood of infectious morbidity, multiorgan failure, and prolonged length of stay is increased.[3–5] In contrast, the provision of enteral nutrition results in higher levels of secretory IgA in biliary tract secretions, greater preservation of gut-associated lymphoid tissue, less bacterial translocation, and greater preservation of upper respiratory tract immunity, all of which translates into improved clinical outcomes for critically ill patients.[1]

However, providing nutrients and nutrition support is not without adverse effects or risks. Acquired infection, particularly ventilator-associated pneumonia (VAP), is a major problem for critically ill patients, resulting in increased morbidity, mortality, and health care costs.[6,7] Gastric atony and the use of intragastric enteral feeds appear to increase the risk of gastric colonization and subsequent pneumonia.[8,9] Gastric colonization plays a significant role in the contamination of tracheal secretions and in the development of nosocomial pneumonia via a mechanism of gastroesophageal regurgitation and pulmonary microaspiration.[10] Parenteral nutrition has been associated with gut mucosal atrophy, overfeeding, hyperglycemia, adverse effects on immune function, an increased risk of infectious complications, and increased mortality in critically ill patients.[11] While providing supplemental glutamine to seriously stressed critically ill patients may increase their chances of survival,[12] depending on the circumstances, providing arginine to the same patients may increase their mortality.[13] Therefore, nutrition support must be viewed as a double-edged sword, and strategies that maximize the benefits of nutrition support while minimizing the associated risks need to be considered in formulating clinical recommendations.

In developing such recommendations, the patient populations to which these recommendations will be applied must also be considered. Studies of nutrition support in non–critically ill patient populations may not be generalizable to critically ill patients. For example, the treatment effect of PN in elective surgery patients is significantly different than the treatment effect of PN in critically ill patients.[11]

Even within subpopulations of critically ill patients, differences in outcome between the two routes of providing nutrition support are more likely to be seen with greater severity of illness. For example, the correlation between the importance of maintaining gut integrity and greater disease severity was demonstrated by a study evaluating septic complications in trauma patients, randomized at the time of surgery, to PN or to enteral tube feeding.[14] In patients with high Abdominal Trauma Index (ATI) scores (>24), the incidence of septic complications was greater in the PN group than the group on enteral tube feeding (47.6% vs. 11.1%, $p < 0.05$). For those patients with moderate illness and lower ATI scores (<24), there was no significant difference in the incidence of septic

complications between the parenteral and enteral groups (29.2% vs. 20.8%, p = NS).[14] Furthermore, in studies of EN versus PN in acute pancreatitis, faster resolution of the inflammatory response and significant differences in clinical outcomes (reduced septic morbidity and overall complications in the EN group) were seen in studies in which there were more patients with severe pancreatitis compared to studies with a lower proportion of patients with severe pancreatitis.[15–17]

In this chapter, we will discuss the relationships among nutrition, GI structure and function, immune function, and outcomes in critical illness. Upon this theoretical foundation, we will propose recommendations favoring the use of enteral nutrition over parenteral nutrition. Whereas PN may be life-sustaining in patients with a disrupted GI tract, PN has only a minor role in the ICU patient population with an intact GI tract. In most patient populations in the critical care setting when EN is not feasible, standard therapy (IV fluid resuscitation without artificial nutritional support) is actually preferable to PN for the first 7 to 10 days. Regardless of the route of nutrition support, we will suggest strategies that maximize the benefits and minimize the risks of both PN and EN.

Relationship of the Gastrointestinal Tract, Immune System, and Ischemia/Reperfusion Injury

The GI tract is the largest immune organ in the body, containing 65% of immune tissue overall and up to 80% of the immunoglobulin-producing tissues of the body.[4,5] In the fed state, the normal motility, villous microanatomy, rich blood supply, and epithelial intercellular tight junctions contribute to the overall integrity and barrier function of the GI tract. In response to luminal nutrients, propulsive contractions assist in controlling the concentration of luminal bacteria and the secretion of bile salts, mucus glycoproteins, and secretory IgA retard bacterial adhesion to gut epithelial cells and subsequent translocation.[18,19] The healthy gut acts as an important antigen-sensing organ, in which bacterial antigen is sampled and processed by the M cells, ultimately stimulating the release and maturation of a population of pluripotential stem cells or naïve CD4 helper T lymphocytes.[20,21] These cells will migrate out from the Peyer patches, through the mesenteric lymph nodes and thoracic duct, and into the systemic circulation as a mature line of B- and T-cell lymphocytes. A proportion of these cells generated in the maturation of the pluripotential stem cells migrate out as mucosal-associated lymphoid tissue (MALT) to distant sites such as the lungs, genitourinary tract, breast, and lacrimal glands.[18–21] Those that return to the enteric mucosa are known as gut-associated lymphoid tissue (GALT).[19–21] In some situations, instead of seeing an increase in aspiration pneumonia in response to enteral feeding of critically ill patients, clinicians may instead see a reduced incidence of pneumonia[14] due to maintenance of MALT in the lung by the trophic effects of luminal nutrients on the intestinal immune components.[19–21]

In a situation of even brief disuse, gut integrity may deteriorate. In contrast to the fed state, fasting leads to villous atrophy, diminished blood flow, and loss of intercellular tight junctions. This opens paracellular channels, allowing translocation of bacteria or other gut-derived factors such as endotoxin.[18] Without nutrient-induced stimulation of secretory IgA and bile salts, bacteria are more easily able to adhere to epithelial cells, promoting even greater translocation of bacteria and entry of their secretory products (e.g., endotoxin).[18] Lack of enteral nutrients may result in a reduction in the mass of GALT and antigen-processing and buildup of MALT at distant sites.

The most important aspect of gut disuse may be the diminished blood supply to the gut, which predisposes to regional ischemia/reperfusion injury.[22] The generation of superoxide radicals in response to ischemia/reperfusion may promote mucosal macrophage activation.[22,23] Macrophages, primed and activated at the level of the gut, may migrate to distant sites such as the liver, lung, and kidney. In such sites they may mediate tissue injury, resulting in the generation of oxidative species.[23] Macrophage activation is a key step linking gut functional compromise with more systemic factors that adversely affect patient outcome.[23,24] Activated macrophages also initiate the arachidonic acid cascade. Generation of prostaglandin E_2 suppresses delayed hypersensitivity reaction, generates superoxide radicals, and leads to an increased susceptibility to sepsis. Generation of leukotriene B_4 leads to chemotaxis and edema and the systemic inflammatory response syndrome (SIRS). Thromboxane A_2, another product of this cascade, leads to vasoconstriction and thrombosis. This event, in turn, promotes physiologic shunts and multiple organ failure.[23,25]

The overall tone of the systemic immune response may be modulated at the level of the gut. The dendritic macrophage cells act as antigen-presenting cells (APCs), which release cytokines and activate the naïve CD4 T cells (Th0). The specific cytokines that are generated ultimately affect the differentiation pathway of these lymphocytes[26] (Fig. 11-1). With gut disuse and fasting, contractility is decreased, which promotes bacterial overgrowth. Bacteria or viruses tend to generate a Th1 inflammatory response (while chronic parasitic infections are more likely to generate Th2 responses).[27] As bacterial antigen passes through M cells across the epithelium of the intestine, an initial response is elicited from the macrophages and dendritic cells,[26,28] (Fig. 11-2) releasing interleukin-12 (IL-12) and stimulating the naïve T cells to differentiate into the Th1 subset. This Th1 response represents cellular immunity, and results in the further release of other inflammatory cytokines, such as interleukin-2 (IL-2), interferon-γ (IFN-γ), and tumor necrosis factor-α (TNF-α). Th1 responses are associated with increased inflammation and are essential for a successful defense against infections. However, uncontrolled Th1 responses can result in self-injury. Feeding, on the other hand, may generate a different cytokine response and thus a different immune environment. Feeding is associated with oral tolerance, which represents a Th3 subset and is generated in the presence of interleukin-4 (IL-4), IL-10, and transforming growth factor-β (TGF-β), which tend to have immunosuppressive effects.[26] This immune environment allows ingestion of protein antigen from food without eliciting an inflammatory response. The production of IL-4 also stimulates a change in naïve T cells (Th0) into the Th2 subset.[26] Differentiation into Th2 lymphocytes represents humoral immunity, and causes further release of IL-4, interleukin-6 (IL-6), and interleukin-10 (IL-10). The Th2 response tends to curb or check the Th1 inflammatory response. Th2 responses are essential to prevent self-injury caused by inflammation.

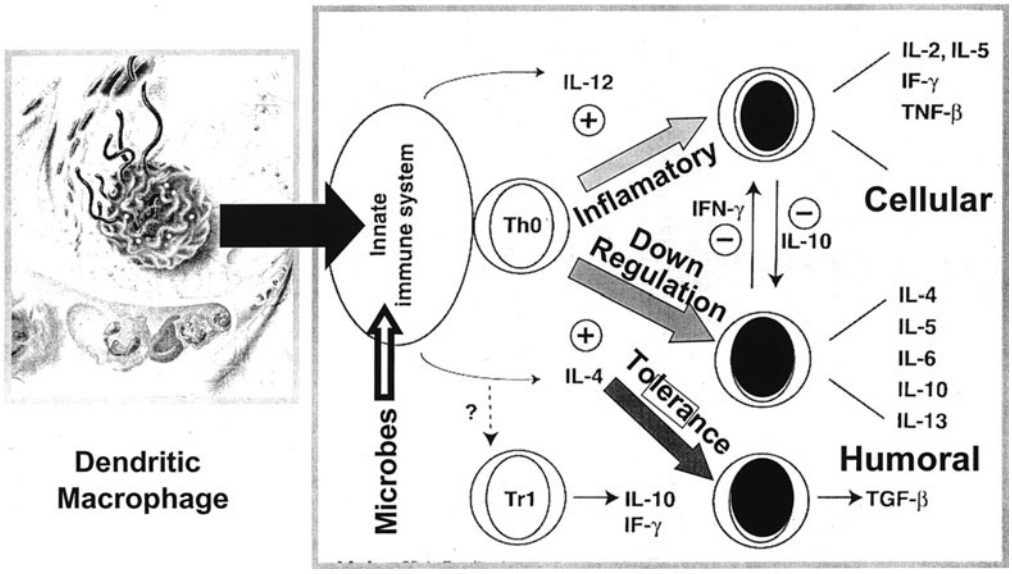

FIGURE 11-1 Antigen processing immune function by the gut.

However, excessive regulation of inflammatory responses by Th2 cytokines can lead to increased immune suppression. This may cause anergy to skin test antigens, impaired antibody production, and diminished phagocytosis, rendering patients susceptible to additional infectious morbidity and mortality.[29]

These immune responses usually occur simultaneously, in effect competing with each other to set the overall immune environment, and may be responsible for the pattern of clinical response seen in critical illness. Initially the Th1 inflammatory response predominates, the intensity of which is determined in part by the injury itself. Almost immediately, the compensatory Th2 response is stimulated. At the point at which this compensatory Th2 response predominates over the initial Th1 response, the patient may pass into a period of relative immune suppression, characterized by anergy, hyporesponsiveness of T lymphocytes, and a diminished overall immune responsiveness.[1] Theoretically, any feeding by the enteral route early in the patient's disease process helps maintain gut integrity, promote motility, and minimize bacterial overgrowth in the small bowel, all of which may diminish the early gut-derived Th1 inflammatory response. As the patient progresses into the period of moderate immunosuppression, they are particularly at risk for late complications arising from aspiration or bacterial translocation, such as multiorgan failure and sepsis.[30] It is during this period of moderate immunosuppression that immune-enhancing formulas may have their greatest role in supporting the immune response, improving bactericidal activity, and reducing deleterious outcomes.

The Importance of Maintaining Gastrointestinal Integrity

Loss of gut structural integrity has been documented in humans, but it probably occurs as a late complication only with protracted disuse. A prospective study evaluating the effects of enteral feeding versus PN in patients with pancreatitis compared these patients against a control group without pancreatitis.[31] A segment of jejunum was resected at surgery to evaluate the effect of enteral feeding on mucosal integrity and architecture.[31] The control group maintained on enteral feeding had essentially normal villi. Pancreatitis was associated with villous atrophy in the experimental arm, but the effect was minimized in the enteral nutrition group. Those patients with pancreatitis placed on PN had the greatest villous atrophy. Longer periods of gut disuse completely transformed the mucosal architecture, resulting in a flattened featureless surface.[31]

Much more clinically important is the loss of functional integrity, which in some patients occurs over a very short period of time. With loss of functional integrity, the tight junctions between the intestinal epithelial cells open up, the gut becomes "leaky," and the patient experiences systemic bacterial challenge (through release of endotoxin and other gut-derived factors) and an exaggerated stress response with increased severity of disease.[18] In a prospective randomized trial, Windsor and colleagues showed that patients with pancreatitis maintained on enteral tube feeding had no change in IgM antibodies to endotoxin over a week of enteral feeding.[16] In contrast, controls placed on PN and gut disuse demonstrated a significant increase in IgM antibodies to endotoxin of 25% in response to a week of parenteral feeding ($p < 0.05$).[16] In a second study, increased gut permeability (measured by enteric absorption and urinary excretion of polyethylene glycol) and systemic endotoxemia correlated significantly with greater disease severity in patients with acute pancreatitis.[32] In a prospective randomized trial, normal healthy volunteers randomized to PN and gut disuse for 7 days demonstrated an exaggerated stress response to a standard IV challenge of *E. coli* endotoxin, as evidenced by higher glucagon, epinephrine, tumor necrosis factor, and C-reactive protein levels and greater muscle catabolism compared to a study group receiving a week of enteral feeding.[33] In two studies in patients with acute pancreatitis, significantly faster resolution of the SIRS response and "resolution of the disease process" (resolution of pain, decreasing amylase, and successful advancement to oral diet) was seen in patients randomized to EN compared to those placed on PN.[16,34]

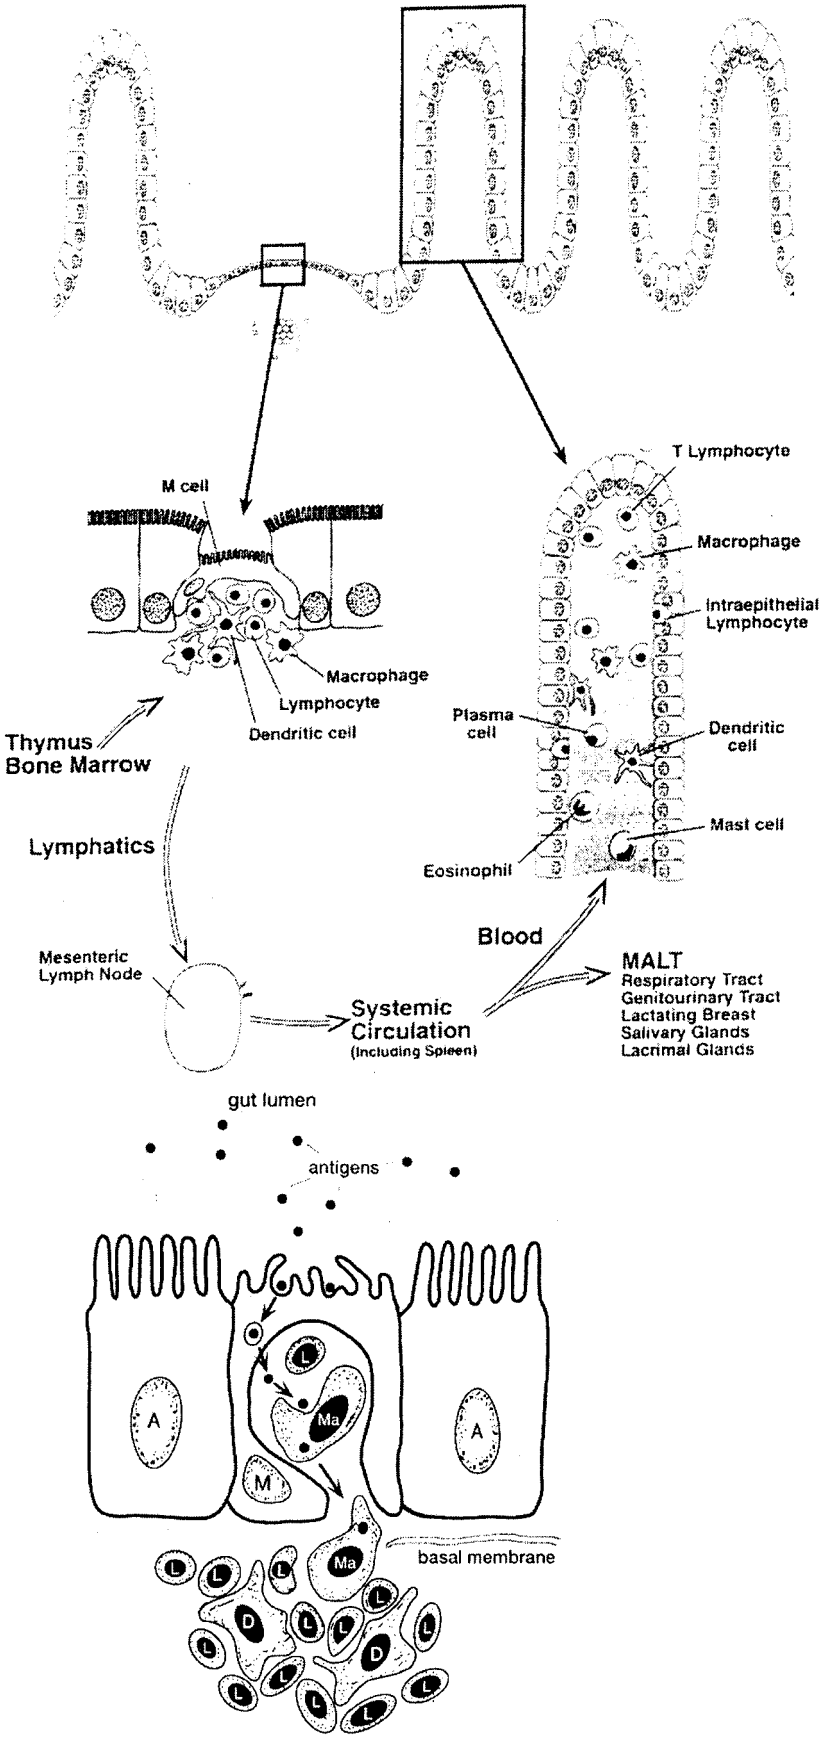

FIGURE 11-2 Pattern of immune response involving CD4 helper T cells.

Consistent with the theoretical evidence presented, there are 13 studies of critically ill patients with surgery, trauma, and medical illnesses, that evaluated the benefits of EN compared to PN. Compared to PN, EN was associated with a significant reduction in infectious complications (RR 0.61; 95% confidence intervals [CIs] 0.44, 0.84; $p = 0.003$).[35] No significant differences were seen in mortality between groups. *Thus in general, by feeding via the enteral route, we can expect to reduce the infectious complications associated with nutrition support in critically ill patients without adversely affecting survival.*

READINESS FOR ENTERAL NUTRITION

At the bedside, clinicians fail to recognize the relationship between gut structure and function and adverse patient outcome, primarily because there is significant delay in the development of complications that arise from poor management decisions related to enteral therapy. If mistakes are made with oxygen delivery, hypoxemia ensues immediately and the patient may deteriorate within minutes. If mistakes are made with volume resuscitation, there is a degree of delay, and problems arising from decreased vascular volume, hypoperfusion, and increasing azotemia may not develop for 12 to 24 hours. If no effort is made to maintain gut integrity, the complications that arise as a result may not develop for 3 to 5 days. At that point, when nosocomial infections occur or organs begin to fail, the clinician does not connect the development of these complications with management decisions made 5 days before with regard to enteral nutrition. In fact, only in prospective randomized trials can it be determined that had gut integrity been maintained, there might have been a decrease in the number of nosocomial infections, the number of organs failing, and the overall length of stay in the ICU prior to discharge.

Initial Bedside Evaluation

The initial nutritional assessment that leads to the initiation of enteral tube feedings differs from the sequential monitoring that takes place as the patient continues to receive feeding. Low visceral proteins (such as albumin, transferrin, and prealbumin) on initial evaluation provide valuable prognostic information, accurately identifying those patients with the greatest degree of physiologic stress, severity of illness, and highest mortality.[36] Weight as percentage of ideal body weight, usual body weight, or as degree of recent weight lost, identify patients with possible underlying malnutrition that was present prior to the event causing the current hospital admission.[36] Determining risk for deterioration in nutrition status on initial evaluation may be facilitated by use of current scoring systems designed for certain patient populations. An Acute Physiology and Chronic Health Evaluation (APACHE) II score $\geq$10 in critically ill patients, an ATI score $\geq$24 in trauma patients, and presence of $\geq$3 Ranson criteria in patients with pancreatitis identify those patients with severe degrees of critical illness who are at high risk for rapid deterioration in nutritional status, with low likelihood for early advancement to oral diet, and in greatest need for aggressive enteral nutritional support.[14,37–39]

Determination of caloric requirements is very important on the initial nutritional evaluation, helping to set the goal (number of required calories) of nutritional support. Caloric requirements are best determined using simple equations (25 to 30 kcal/kg per day) or by specific measurement via indirect calorimetry. A dose-response effect in which the provision of 55% to 60% of the required number of calories *over the first 48 to 72 hours* to achieve a therapeutic effect has been suggested by several studies.[40–43] In a prospective study, burn patients who consumed an average of 64% of their goal calories showed no increased gut permeability and remained uninfected throughout their hospital course. In contrast, those who became infected consumed an average of only 40% of their goal calories, and showed evidence of significantly increased gut permeability.[40] Therefore, prolonged use of "trickle or trophic feeds," providing 10 to 30 mL/h, may be insufficient to adequately maintain gut integrity and translate into improved clinical outcomes.

ACHIEVING ACCESS

Unfortunately, obtaining enteral access early in the course of the critical illness may be very difficult. With greater severity of illness, patients become more prone to ileus with gastroparesis, high residual volumes, and intolerance of gastric feeds. Early on, the hypermetabolic response, SIRS, high doses of narcotic analgesics, and electrolyte abnormalities may potentiate gastroparesis. Compounding the problem is the fact that disuse of the gut reduces the secretion of prokinetic hormones such as gastrin, bombesin, and motilin.[18,19]

The ability to obtain enteral access may be vital to the success of nutritional support in the critically ill patient. Each institution needs specialists who have the skills to place tubes at the appropriate levels of the GI tract, with techniques that can usually be done at the bedside with minimal or no sedation. A number of techniques have been described for blind postpyloric placement at the bedside, which in the hands of a dedicated nurse, dietitian, or intensivist should be successful in >85% of cases.[44] In cases in which blind bedside placement is unsuccessful or deeper jejunal placement is required (such as in patients with severe acute pancreatitis), enteral access to the small bowel may require endoscopic or fluoroscopic placement. For these latter patients, transport out of the ICU should be avoided to prevent an increased risk of mishaps (e.g., cardiopulmonary arrest, new dysrhythmias, or loss of central IV line access) and pulmonary aspiration.[45–47]

ASSESSING TOLERANCE

Physical examination by the clinical nutritionist may be the most important element of monitoring the patient on enteral tube feeding. Abnormalities on physical exam usually reflect segmental abnormalities in contractility of the GI tract. Bloating, abdominal distention, hyperresonance, and increased residual volumes may signify delayed gastric emptying. In patients placed on nasogastric drainage, output of >1200 mL/d may indicate relative gastroparesis. Contractility of the colon may be assessed by passage of stool and gas. The presence of bowel sounds is a poor indicator of contractility in the small bowel, as evidenced by the fact that nasogastric suction will reduce its detection. Studies performed on the postoperative return of bowel function or contractility have provided valuable findings for the clinician. Invariably, contractility in the stomach stops initially, followed next by colonic contractility. Small bowel function or contractility appears to be retained the longest.[48] In most critically ill patients

(particularly patients with trauma), who on baseline evaluation have grossly abnormal physical exams, tolerance to enteral tube feeding may be defined by slight decreases in abdominal distention and abdominal discomfort in the absence of high gastric residual volumes, metabolic acidosis, third-spacing of fluids, or a worsening clinical condition. These findings on serial physical examinations determine whether the position of the feeding tube needs to be changed (i.e., placing the tip of the tube lower down in the GI tract at or below the ligament of Treitz), whether a tube with simultaneous aspirating and feeding capabilities needs to be added, or whether the feeds need to be temporarily discontinued.

Strategies to Maximize the Benefits and Minimize the Risks of Enteral Nutrition

TIMING OF ENTERAL NUTRITION

While enteral feeding is the preferred route of nutrient administration, how soon it should be started after an acute injury or insult is not clear. In critically ill patients, there were eight randomized controlled trials comparing early EN (i.e., that started within 24 to 48 hours of admission to the ICU) to some form of delayed nutrient intake (i.e., delayed EN or oral diet).[49] When results from these studies were aggregated, early EN was associated with a trend towards a reduction in mortality (RR 0.52; 95% CIs 0.25, 1.08; $p = 0.08$) when compared to delayed nutrient intake. Three studies reported infectious complications.[50–52] When these were aggregated, early EN was associated with a trend towards a reduction in infectious complications (RR 0.66; 95% CIs 0.36, 1.22; $p = 0.19$) when compared to delayed nutrient intake. No differences in length of stay were observed between groups. All seven studies that reported nutritional end points showed a significant improvement in the groups receiving early EN (e.g., improvements in calorie intake, protein intake, percentage of goal achieved, and better nitrogen balance achieved). There were no differences in other complications between the groups.

Although the results lack statistical significance, they do suggest a large improvement in clinical outcome and a significant increase in nutrient delivery associated with early enteral feeding. However, before endorsing the concept of early enteral feeding, one must consider the potential risks of such a strategy. Two recent nonrandomized studies suggest that early enteral feeds delivered into the stomach may be associated with increased complications.[53,54] In contrast, Taylor and colleagues combined an aggressive early feeding protocol with the use of small bowel feedings and documented that head-injured patients fed aggressively, compared to standard (slower) provision of EN, not only had better nutritional status, but also had fewer complications and a more rapid recovery from their illness.[42]

Synthesizing these discordant results, it would seem that early EN may be associated with improved clinical outcomes when done in such a way that maximizes the benefits and minimizes the risks (see below). Furthermore, it should be noted that the goal of early EN, while critically ill patients are still early in the acute phase of their illness, is to provide enough critical nutrients to the gut to modulate the disease process and enhance gut barrier structure and function, not to meet their caloric requirements as soon as possible. Thus for some patients with evidence of inadequate oxygen delivery, specific nutrients (e.g., glutamine and antioxidants) may be required in the first few days of critical illness. If patients are still on high-dose inotropes to maintain adequate blood pressure, the risk of providing EN may outweigh the benefits, and EN should be held until patients are weaning off pressor agents. As the patient enters the more stable, chronic phase of their illness (after 7 to 10 days), preserving lean body mass, stimulating protein synthesis, and minimizing nutritional deficits, rather than maintaining GI structure and function, become the primary goals.

REDUCING RISK OF ASPIRATION

It is important on initial evaluation to assess the patient's risk for aspiration on EN. Aspiration may occur from the antegrade passage of contaminated oropharyngeal secretions or the retrograde passage of contaminated gastric contents into the larynx. Regurgitation occurs more frequently than aspiration.[55] A number of risk factors have been identified that increase risk of aspiration in the ICU.[56] While it is difficult to quantify or stratify degree of risk among these factors, a simple categorization differentiates major risk factors for which change in management strategy may be needed, versus additional minor risk factors that may not warrant specific change in therapeutic course. *Major risk factors* include documented previous episode of aspiration, decreased level of consciousness (including sedation or increased intracranial pressure), neuromuscular disease, structural abnormalities of the aerodigestive tract, need for endotracheal intubation, overt vomiting or regurgitation, need for prolonged supine position, and persistently high gastric residual volumes.[56] *Additional risk factors* include presence of a nasoenteric tube, noncontinuous or bolus intermittent feeding, abdominal/thoracic surgery or trauma, delayed gastric emptying, poor oral care, advanced age, inadequate nursing staff, large bore feeding tube, malpositioned enteral tube (back into the esophagus), or transport out of the ICU.[1,56] Strategies to prevent aspiration in patients receiving nutrition support who have significant risk factors, as outlined below, should be utilized to minimize the risks associated with EN in this setting.

ROLE OF SMALL BOWEL FEEDING

A number of strategies may be employed to maximize the delivery of EN while minimizing the risks of gastric colonization, gastroesophageal regurgitation, and pulmonary aspiration (Table 11-1). By delivering enteral feeds into the small bowel, beyond the pylorus, the frequency of regurgitation and aspiration, as well as the risk of pneumonia, is decreased while at the same time nutrient delivery is maximized.[57] There are seven randomized trials that evaluated the effect of route of feeding on rates of ventilator-associated pneumonia (VAP).[58] When these results were aggregated, there was a significant reduction in VAP associated with small bowel feedings (RR 0.76; 95% CIs 0.59, 0.99) compared to gastric feeding. Therefore, the converse is also true. In some patients intragastric feeding may be associated with inadequate delivery of nutrition, increased regurgitation, pulmonary aspiration, and pneumonia, particularly if patients are cared for in the supine position.

TABLE 11-1 Summary of Strategies to Optimize the Benefits and Minimize the Risks of Enteral Nutrition and Total Parenteral Nutrition

Enteral Nutrition	Total Parenteral Nutrition
Initiate early, within 24–48 hours of admission	Hypocaloric dose
Use small bowel feedings	Do not use lipids for short term use (<10 days)
Elevate head of the bed	Tight control of blood sugars
Use motility agents	Supplement with glutamine
Use feeding protocol that enables consistent evaluation of gastric residual volumes and specifies when feeds should be interrupted	Continue to trickle concentrated amounts of enteral nutrition if able
Use concentrated feeding formulae in cases of intolerance	
Consider formulae with immune additives	

The clinical implications of these findings are influenced by the inherent difficulties in obtaining small bowel access. Given that some patients will tolerate intragastric feeds, it seems more prudent to reserve small bowel feeds for patients at high risk for intolerance to EN (due to use of inotropes, continuous infusion of sedatives, paralytic agents, high gastric residual volumes, or patients with high nasogastric drainage) or at high risk for regurgitation and aspiration (nursed in prolonged supine position).

BODY POSITION

While several studies document that elevation of the head of the bed is associated with less regurgitation and pulmonary aspiration, only one randomized controlled trial compared the frequency of pneumonia in critically ill patients assigned to semirecumbent or supine position.[59] Drakulovic and colleagues demonstrated that providing EN into the stomach in patients kept in the supine position was associated with a much higher risk of pneumonia compared to feeding patients with the head of the bed elevated to 45° (23% vs. 5%, $p < 0.05$). Thus, a simple maneuver (i.e., elevating the head of the bed to 30° to 45°) can reduce the risks associated with enteral feedings.

MOTILITY AGENTS

Gastrointestinal prokinetic agents improve gastric emptying, improve tolerance to enteral nutrition, reduce gastroesophageal reflux and pulmonary aspiration, and therefore may have the potential to improve outcomes in critically ill patients.[60] While no study has demonstrated an impact from use of these agents on clinical outcomes, their low probability of harm and favorable feasibility and cost considerations warrant their use as a strategy to optimize nutritional intake and minimize regurgitation. Since cisapride is no longer available and due to the concerns of bacterial resistance with the use of erythromycin, metoclopramide is probably the drug of choice. It can be prescribed with the initiation of enteral feeds or reserved for patients who experience persistently high gastric residuals. It can be discontinued after four doses if there is no benefit observed, or after tolerance to EN is no longer a problem clinically. Reducing narcotic dosages and potentially reversing their effect at the level of the gut by infusing naloxone through the feeding tube, and switching from bolus intermittent feeds to continuous infusion may also be effective in improving gastric function and tolerance to EN, while reducing risk of aspiration.[56] Methods not recommended solely to reduce risk of aspiration include switching to PN, adding acid to the enteral formula, switching from a large bore to a small bore nasoenteric tube, or converting a nasogastric tube to a percutaneous endoscopic gastrostomy tube.[56]

FEEDING PROTOCOLS

Several observational studies document that EN is frequently interrupted for high gastric residual volumes, procedures, nausea and vomiting, and other miscellaneous reasons.[61] Over the duration of ICU stay, this may result in inadequate delivery of EN to a critically ill patient and the associated complications of inadequate nutrition. Nurse-directed feeding protocols or algorithms have been shown to increase the amount of EN delivered on a daily basis.[62] Instituting a feeding protocol in ICUs that provides specific instructions on the patient's management related to EN to the bedside nurse has the potential to improve nutrient delivery and decrease complications.

ROLE OF IMMUNE STIMULANTS AND ANTIOXIDANTS

An additional strategy to maximize the benefits of enteral nutrition is to consider using products supplemented with specific nutrients that modulate the immune system, facilitate wound healing, and reduce oxidative stress. Enteral formulas developed to such an extent contain selected substrates such as glutamine, arginine, and omega-3 fatty acids, as well as selenium, vitamins E, C, and A, and beta-carotene in supraphysiologic concentrations. Unfortunately, with the possible exception of glutamine, the nutrients by themselves have not been adequately studied in critically ill patients, so their individual efficacy remains unknown. Nevertheless, these nutrients have been combined together and marketed as an immune-enhancing diet. We use the term *immunonutrition* as a general term to describe all these enteral products, but attempt to make summary recommendations based on the specific nutrients by themselves.

ARGININE

Supplementing arginine in the diet has a variety of biologic effects on the host[63,64] (Fig. 11-3). L-arginine is an active secretagogue that stimulates the release of growth hormone, insulin growth factor, and insulin, all of which may stimulate protein synthesis and promote wound healing. Conversion of arginine to ornithine by arginase provides two further functions. This pathway enables shuttling of nitrogen to urea, and ornithine is utilized in polyamine synthesis (which is involved in deposition of hydroxyproline, collagen, and the laying down of connective tissue to heal wounds). Arginine has also been shown to have significant immunostimulatory effects. Arginine has a trophic effect on the thymus gland that promotes the production and maturation of T lymphocytes. In the nitric oxide synthase pathway, the precursor arginine may contribute to improved bacterial killing.[63]

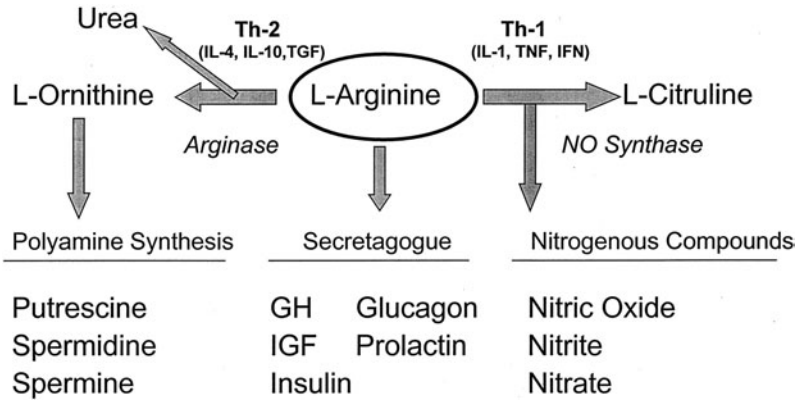

FIGURE 11-3 Arginine metabolic pathways.

Of interest is the fact that the arginase pathway is driven by a Th2 cytokine profile, mediated by further release of IL-4, IL-10 and TGF-β.[64] The Th2 cytokine profile has the effect of reducing the overall inflammatory immune response. In contrast, the nitric oxide synthase pathway is mediated by a Th1 cytokine profile, and is perpetuated by further release of IL-1, TNF, and IFN-γ.[64] This pathway has the capability of promoting the inflammatory response and inducing the formation of nitric oxide. Increased levels of nitric oxide may exert a negative inotropic and chronotropic effect on the cardiovascular system, and promote vasodilation (which may contribute to the hypotension and shock associated with sepsis syndrome). Nitric oxide in larger amounts may act as a mitochondrial toxin and inhibit several steps in the oxidative phosphorylation chain. Nitric oxide may also damage gut epithelium, increasing bacterial translocation and reducing overall gut integrity.[63] Nitric oxide can also have nonspecific cytotoxic effects of inhibiting growth or killing cells indiscriminately.[63]

Clinical Review

There are no randomized studies of pure arginine supplementation in critically ill patients that evaluate clinically important outcomes. All studies in critically ill patients have combined arginine with other immune-modulating nutrients. When the results of these 15 trials were aggregated, there was no effect on mortality (RR 1.05; 95% CIs 0.82, 1.35; $p = 0.7$), no overall effect on infectious complications (RR 0.94; 95% CIs 0.76 to 1.16; $p = 0.6$), and a trend towards reduction in hospital length of stay (weighted mean difference –3.5; 95% CIs –8.8, 1.9; $p = 0.20$). The presence of significant statistical heterogeneity across studies weakens the estimate of effect on length of stay.

Concerns have been expressed that based on the scientific rationale presented above, arginine-containing products may worsen outcomes in critically ill septic patients.[65] There are now three reports in the literature of excess mortality associated with critically ill septic patients who received arginine-supplemented diets.[66–68] In contrast, Galban and colleagues[69] demonstrated an increase in survival associated with arginine-supplemented diets in critically ill patients with infection. However, in this study, it was apparent that all the treatment benefit was in the least sick patients (baseline APACHE II score <15). The effect of arginine-containing products on critically ill patients with a high severity of illness remains unanswered. To the extent that in sepsis endotoxin exposure and cytokine activation have led to elevated levels of inducible nitric oxide synthesis, supplemental arginine may lead to the production of excessive amounts of nitric oxide, shock, and early death. Thus arginine-supplemented specialized diets should not be used in critically ill patients who are clearly septic. If a critically ill patient receiving an arginine-supplemented diet develops sepsis, the arginine-containing diet should be discontinued. Which subpopulations of critically ill patients benefit from these diets remains to be elucidated.

OMEGA-3 FATTY ACIDS

Omega-3 fatty acids may be provided in the form of fish oil or canola oil. These agents do not have direct stimulatory effects, but instead have an indirect effect by modifying phospholipids in cell membranes throughout the body.[70] Omega-6 fatty acids are involved in the cyclooxygenase pathway, generating prostaglandin E_2 (PGE_2) and leukotriene B_4 (LTB_4) from arachidonic acid. These are proinflammatory cytokines that lead to immune suppression and nosocomial infection, SIRS, and organ dysfunction. Through diet supplementation, omega-3 fatty acids compete with the omega-6 fatty acids for incorporation into cell membranes. Upon activation of the cyclooxygenase pathway, omega-3 fatty acids instead lead to the formation of PGE_3 and LTB_5. These compounds have $^1/_{10}$ the biologic activity of the PGE_2 and LTB_4 series, and as a result have a much less immunosuppressive effect.[70] Borage oil is unique as an omega-6 fatty acid, because it is metabolized to the PGE_1 series. PGE_1 possesses both anti-inflammatory and antiproliferative (reduced thrombosis) properties, and will attenuate the biosynthesis of arachidonic acid metabolites.[71]

Clinical Review

The only study of omega-3 fatty acids was conducted in patients with acute lung injury (ALI)/acute respiratory distress syndrome (ARDS).[72] The pathophysiology of this syndrome is thought be related to the release of arachidonic acid–related metabolites from inflammatory cells. Gadek and colleagues performed a multicenter, randomized, double-blind, clinical trial to evaluate whether a diet supplemented with eicosapentaenoic acid, docosahexanoic acid (DHA), borage oil, and antioxidants (Oxepa, Ross Products, Columbus, OH) would have a favorable effect on markers of inflammation in the lung and an improvement in clinical outcomes.[72] In this study, 146 patients meeting the standard definition of ARDS with evidence of active pulmonary inflammation as indicated by fluid from a bronchoalveolar lavage (BAL) that contained a

neutrophil count >10%, were randomized to the experimental diet or a high-fat, low carbohydrate control feed.

In the subset of "evaluable" patients, those who received the experimental diet had higher plasma levels of dihomogamma linolenic acid, eicosapentaenoic acid, and an increased eicosapentaenoic/arachidonic acid ratio. With respect to the clinically important outcomes, patients fed the experimental diet experienced a reduction in days receiving supplemental oxygen (13.6 vs. 17.1; $p = 0.078$), required significantly fewer days of ventilatory support (9.6 vs. 13.2; $p = 0.027$), and less time in the ICU (11.0 vs. 14.8; $p = 0.016$), and had fewer new organ failures (10% vs. 25%; $p = 0.018$). There was also a trend towards a reduction in mortality associated with the experimental diet (16% vs. 25%; $p = 0.17$).

This study confirms that short-term administration of dietary lipids in critically ill patients can modify fatty acid levels with a resultant favorable effect on neutrophil recruitment in the lung and subsequent clinical outcomes. However, given that a high-fat diet in itself may be harmful,[73] the use of a high-fat control formula and the requirement for a BAL to identify patients with a high degree of neutrophils limits the applicability of these findings to clinical practice. Furthermore, it is difficult to attribute the beneficial effects of the experimental diet to fatty acid composition when it was combined with antioxidants as well.

GLUTAMINE

The amino acid glutamine plays a central role in nitrogen transport within the body, is a fuel for rapidly dividing cells (particularly lymphocytes and gut epithelial cells), is a precursor to glutathione, and has many other essential metabolic functions. As noted previously, plasma glutamine levels drop during critical illness, and lower levels of glutamine have been associated with immune dysfunction[74] and increased mortality.[75] Human studies suggest that glutamine supplementation maintains gastrointestinal structure[76] and is associated with decreased intestinal permeability compared to standard PN.[77,78] In humans, glutamine-supplemented formulas have resulted in improved nitrogen balance,[79] and higher intramuscular glutamine levels.[80] Glutamine plays a crucial role in enhancing immune cell function[81] with no elevation in proinflammatory cytokine production.[82,83]

There have been several randomized trials of perioperative or critically ill adults reporting on clinically important outcomes.[84] When the results of these trials were aggregated, a significant reduction in mortality (RR 0.78; 95% CIs 0.61 to 0.99; $p = 0.04$), a trend towards a reduction in infectious complications (RR 0.89; 95% CIs 0.73 to 1.08; $p = 0.2$), and no overall effect on length of stay (LOS in days –1.30; 95% CIs – 4.77, 2.17; $p = 0.5$) were observed.[85] Subgroup analysis suggested that with respect to mortality and infectious complications, the majority of the treatment effect observed was associated with parenteral glutamine in patients receiving PN compared to enteral glutamine supplementation. The majority of glutamine provided enterally will be metabolized in the gut and liver, and therefore may not have a systemic effect. The only study that demonstrated a mortality effect with enteral glutamine was a small study in burn patients.[86] In a study of trauma patients, enteral feeds supplemented with glutamine were associated with a trend towards a reduced rate of infection compared to control feeds (20/35 [57%] vs. 26/37 [70%], $p = 0.24$).[87]

Therefore, for critically ill patients requiring PN, we recommend parenteral glutamine supplementation as long as the patient remains on PN. For patients with major burns or trauma, enteral diets supplemented with glutamine could be considered. Recommendations about glutamine supplementation (enteral or parenteral) in other critically ill patient populations fed enterally are premature and warrant further study.

ANTIOXIDANT VITAMINS AND TRACE MINERALS

While there is a putative beneficial role of reactive oxygen species in modulating cell signaling (redox signaling), and thus regulating proliferation, apoptosis, and cell protection, oxygen-derived radicals may cause cellular injury by numerous mechanisms, including destruction of cell membranes through the peroxidation of fatty acids, disruption of organelle membranes such as those covering lysosomes and mitochondria, degradation of hyaluronic acid and collagen, and disruption of enzymes like Na^+,K^+-ATPase or $alpha_1$-proteinase inhibitor.

To protect tissues from oxygen free radical–induced injury, the body maintains a complex endogenous defense system that consists of a variety of extra- and intracellular antioxidant defense mechanisms. The first line of intracellular defense is comprised of a group of antioxidant enzymes such as superoxide dismutase, catalase, glutathione peroxidase, and glutathione reductase, including their metal cofactors selenium, copper, and zinc. When these enzymatic antioxidants are overwhelmed, oxygen free radicals (OFRs) are free to react with susceptible target molecules within the cell (i.e., unsaturated fatty acids of the cell membrane). Thus there is a need for a second line of defense scavenging OFRs by means of nonenzymatic antioxidants that are either water soluble, such as glutathione and vitamin C, or lipid soluble, such as vitamin E and beta-carotene.[88]

In critical illness, oxidative stress arises when the balance between protective antioxidant mechanisms and the generation of reactive oxygen species (ROS) is disturbed. This imbalance may be caused by excess generation of ROS by means of ischemia/reperfusion injury, inflammation, infection, and toxic agents (chemotherapy or drugs), or by low antioxidant capacity (secondary to comorbid illnesses, malnutrition, and excessive losses such as in the case of burns). Many studies have demonstrated low plasma and intracellular concentrations of the various antioxidants in critically ill patients, and the clinical consequence of these low endogenous stores of antioxidant levels is increased morbidity and mortality.[89–91]

Most of the immune formulas are fortified with vitamins and minerals that have increased antioxidant capabilities. Vitamins A, E, and C, and the trace mineral selenium have antioxidant capabilities and are added in different amounts to the various formulas. The exact doses of these components have not been standardized.

Single Antioxidant Nutrients

SELENIUM ALONE Selenium is an important co-factor in glutathione enzymatic function and has favorable effects on cellular immune function. In critically ill patients, there have been only a few randomized controlled trials looking at the effects of selenium supplementation alone.[92–95] In a poorly designed trial of 17 patients with acute necrotizing pancreatitis, parenteral supplementation of 500 μg of selenium was

associated with a significant reduction in ICU mortality (0% vs. 89%).[93] In a prospective randomized trial, Zimmermann and colleagues reported a reduction in mortality (15% vs. 40%) after IV administration of 1000 μg of sodium selenite for 28 days in patients with SIRS compared to placebo.[94] However, no difference in mortality or pneumonia was seen in critically ill trauma/surgical patients given IV selenium supplementation (2.9 μmol/d) compared to placebo.[92] In a trial of 42 patients with SIRS, subjects that received a higher dose of parenteral selenium (535 μg/d $\times$ 3 days, 285 μg/d $\times$ 3 days, 155 μg/d $\times$ 3 days, and 35 μg/d thereafter) versus a lower dose (35 μg/d) had a trend towards reduced hospital mortality (33% vs. 52%; $p = 0.13$).[95] When the results from the four trials that compared supplementation of selenium alone to standard were aggregated,[92–95] selenium was associated with a trend towards a reduction in mortality (RR 0.52; 95% CIs 0.21, 1.30; $p = 0.16$).[85]

ZINC ALONE Zinc is an essential trace element necessary for normal protein metabolism, membrane integrity, and the function of more than 200 metalloenzymes including enzymes involved in oxidative capacity. In a randomized, prospective, double-blinded controlled trial in severely head injured, ventilated patients, those receiving a higher zinc supplement (12 mg elemental zinc via PN for 15 days, then progressing to 3 months of oral zinc) had a trend towards a reduction in mortality ($p = 0.09$) when compared to those receiving a placebo (2.5 mg elemental zinc).[96]

Combined Antioxidant Nutrients

Many randomized controlled trials have chosen to administer a combination of antioxidants via various routes of administration, thereby making it impossible to attribute the outcomes to a specific nutrient. When 11 trials of single and combined antioxidants were aggregated, overall antioxidants were associated with a trend towards a reduction in mortality (RR = 0.73; 95% CIs 0.47, 1.12; $p = 0.15$) and no effect on infectious complications (RR = 0.94; 95% CIs 0.63, 1.40; $p = 0.8$).[97] Thus, for critically ill patients, selenium supplementation in combination with other antioxidants (vitamin E/alpha tocopherol, vitamin C, N-acetylcysteine, and zinc) may be beneficial, but insufficient data currently exist to support clinical recommendations.

ROLE OF PARENTERAL NUTRITION

Several trials and meta-analyses have evaluated the treatment effect of parenteral nutrition in the last few years, and none has shown a positive result, while some have suggested increased harm associated with PN in the critically ill patient.[11,98,99] We have already stated that EN is used preferentially to PN. However, to optimize the delivery of nutrients, some prescribe PN at the same time EN is initiated, to provide nearly all required calories and protein immediately. Then, as EN becomes successfully established, PN is reduced and eliminated. There are five randomized trials that address the clinical benefits of such a strategy in critically ill patients.[100] All five studies reported on mortality and the aggregated results demonstrated a trend towards an increased mortality associated with the use of combination EN and PN (RR 1.27; 95% CIs 0.82 to 1.94; $p = 0.3$). In one study, there was a significant increase in mortality associated with supplemental PN.[101] Supplemental PN was not associated with a difference in the incidence of infections (RR 1.14; 95% CIs 0.66 to 1.96; $p = 0.6$), had no effect on hospital stay (standardized mean difference 0.12; 95% CIs 0.45, 0.2; $p = 0.5$), and had no effect on ventilator days. Thus there appears to be no clinical evidence to support the practice of supplementing EN with PN when EN is initiated. If anything, there appears to be a signal of excess harm.

What about the patient who has been started on EN, and after several days is only tolerating inadequate amounts of EN? Does PN have a role in this patient population? The preferred approach is to continue with EN and standard IV therapy. However, at some point (probably between 7 and 14 days postinjury) the risk from further deterioration of nutritional status outweighs the risk of providing PN, due to the cumulative effect on immune function, continued losses to the lean body mass, and development of specific key nutrient deficiencies in the critically ill patient receiving inadequate nutritional support by EN. This time frame may be considerably shortened in patients at tremendously increased risk for deterioration of nutritional status due to the presence of large open wounds, enteric fistula, or short bowel syndrome. Unfortunately, there are no randomized trials to guide practitioners as to when PN should be initiated in patients tolerating inadequate amounts of EN. While the results of our previous reviews suggest that PN is associated with no clinical benefit or increased harm, prolonged starvation (more than 14 days) is equally associated with poor outcomes.[102]

In summary, PN has a very limited role in the critical care setting. PN should not be started in critically ill patients until all strategies to maximize EN delivery (such as the use of small bowel feeding tubes and motility agents) have been attempted. Waiting 2 weeks in someone tolerating inadequate amounts of EN is probably too long, but practitioners will have to weigh the safety and benefits of initiating PN in patients not tolerating EN on an individual case-by-case basis.

MAXIMIZING THE BENEFITS AND MINIMIZING THE RISKS OF PARENTERAL NUTRITION

If PN is associated with harm in critically ill patients, it may be due to a variety of potentially avoidable pathophysiologic mechanisms, including overfeeding, the immunosuppressant effects of lipids, hyperglycemia, absence of key nutrients like glutamine, and the association of gut disuse and systemic inflammation. Understanding these potential mechanisms can guide practitioners when they use PN to use it in such a way that its benefits are maximized and its risks are minimized.

Role of Hypocaloric Parenteral Nutrition

Because of the degree of insulin resistance so commonly observed in stressed critically ill patients, providing large amounts of dextrose intravenously results in hyperglycemia and predisposes critically ill patients to risk of infection. Other attendant complications associated with overfeeding carbohydrates include hepatic steatosis, hypertriglyceridemia, and hypercapnia. This has given rise to the notion of hypocaloric or hypoenergetic PN as a strategy to minimize complications associated with PN. There are only two small studies that have evaluated the effect of hypocaloric feeding in critically ill patients. To achieve a hypocaloric dose of PN, Choban and associates[103] reduced both carbohydrates and lipids in morbidly obese critically ill patients, while McCowen and colleagues[104] withheld lipids in a heterogeneous group

of patients, including critically ill patients. Only one study reported infectious complications, and in that study[104] hypocaloric feeding was associated with a trend toward a reduction in infectious complications ($p = 0.2$). There were no significant differences in mortality or length of stay between groups in either study. Given the lack of positive treatment effect from standard PN, minimizing the dose of PN seems reasonable until further data emerge to prove the contrary.

Parenteral Lipids

There are several reports that demonstrate that intravenous lipids may adversely affect immune status and clinical outcomes.[105,106] The results of previously described meta-analysis of PN[11] suggest that the adverse effects of lipids may negate any beneficial effect of nonlipid parenteral nutritional supplementation. There are two studies reviewed that compared the use of lipids to no lipids in parenteral nutrition.[104,107] A significant reduction in pneumonia (48% vs. 73%; $p = 0.05$), catheter-related sepsis (19% vs. 43%; $p = 0.04$), and a significantly shorter stay in both ICU (18 vs. 29 days; $p = 0.02$) and hospital (27 vs. 39 days; $p = 0.03$) was observed in trauma patients not receiving lipids compared to those receiving lipids.[107] In the McCowen study mentioned previously, the group that received no lipids (hypocaloric group) showed a trend towards a reduction in infections (29% vs. 53%; $p = 0.2$). No difference in length of stay was seen in this study, and it did not report on ventilator days. Combining these two studies, the meta-analysis done showed a significant reduction in infections in the group that received no lipids (RR 0.63; CIs 0.42 to 0.93; $p = 0.02$) and no difference in mortality (RR 1.29; CIs 0.16 to 10.7; $p = 0.8$).

It is unknown what the effects of long-term fat-free parenteral nutrition would be, and there is a paucity of data in malnourished patients. Given these caveats, lipid-free PN is probably best indicated for those patients requiring PN for a short time (<10 days), where the risk of fatty acid deficiency would be minimal. This recommendation cannot be extrapolated to those who have an absolute contraindication to EN and need PN for a longer duration.

Tight Glycemic Control

Hyperglycemia, which occurs more often with PN than EN, is associated with increased infectious complications. Van den Berghe and associates[108] compared intensive insulin therapy (target range 4.4 to 6.1 mmol/L) vs. conventional treatment (10.0 to 11.1 mmol/L) in critically ill patients receiving nutrition support. This was a large study (n = 1548) of surgical ICU patients (predominantly elective cardiovascular surgery) with a relatively low APACHE II score (median 9). Study patients were started on a glucose load (200 to 300 g/d) and then were advanced to PN, combined PN/EN, or EN after 24 hours of admission. Intensive insulin therapy was associated with a lower incidence of sepsis ($p = 0.003$), a trend towards a reduction in ventilator days, and a reduced ICU ($p < 0.04$) and hospital mortality ($p = 0.01$), compared to conventional insulin therapy. From this study, one can infer that intensive insulin therapy to achieve tight glycemic control may be associated with improved clinical outcomes in critically ill patients. The corollary to this is that high glucose loads in patients who are insulin resistant is associated with excess complications and increased mortality, which can be reduced by insulin. Whether insulin has any therapeutic effects in patients who do not receive such high glucose loads, or whether these results apply to other medical, sicker ICU patients is unknown. Despite these limitations, in the absence of further studies, patients prescribed PN should receive intensive insulin therapy to obtain tight glycemic control. This can best be accomplished by using an insulin protocol or nomogram.[109]

Supplementation with Glutamine

Perhaps the lack of treatment effect of PN relates to the lack of key nutrients necessary for repair and recovery following critical illness. As noted previously, there are data that suggest that PN supplemented with glutamine is associated with increased survival in seriously ill hospitalized patients.[12] It is difficult to provide high-dose free glutamine intravenously to critically ill patients due to problems with limited solubility and stability, especially in critically ill patients with volume-restricted conditions. However, recent advances in parenteral glutamine delivery have overcome some of these challenges, making the provision of bioavailable glutamine practical, even at higher doses.[110] The treatment effect is likely greatest when high-dose (>0.2 g/kg per day) glutamine is given parenterally to patients with gastrointestinal failure (and thus prescribed PN). Whether parenteral glutamine has a beneficial effect on patients receiving enteral nutrition is unknown.

Use of Enteral Nutrition in Patients on Parenteral Nutrition

The adverse effect of PN may be related to the absence of nutrients in the bowel. The gastrointestinal mucosa is metabolically very active and the lack of enteral nutrients (as in the case of PN) would result in mucosal atrophy, increased permeability, bacterial overgrowth, translocation of bacteria and/or gut-derived factors that activate the immune system, atrophy of the gut-associated lymphoid tissue, and increased production of proinflammatory cytokines.

An observational study suggested that low-volume EN is associated with less toxicity compared to PN alone.[111] Clearly our recommendation is that EN is used preferentially to PN, but in the patient who is not tolerating adequate amounts of EN over a prolonged period of time, if PN is going to be used, we suggest that attempts to provide EN be continued until EN is successful and the PN can be discontinued.

Summary and Conclusions

An opportunity exists for aggressive enteral nutritional support to favorably alter a patient's course through critical illness. The window of time to start enteral feeding and/or key nutrients to resuscitate the metabolically active gastrointestinal tract is variable in duration depending on the specific disease process; the opportunity may involve a time frame as limited as several hours or as long as 2 to 3 days. During this period, provision of enteral nutrients in a way that maximizes the benefits and minimizes the risks (see Table 11-1) has the capability to maintain gut integrity, minimize permeability, reduce oxidative stress and macrophage activation, and ultimately improve patient outcome through reduced infectious morbidity, organ failure, length of hospitalization, and even mortality. There is a limited role for PN, and when it is used it

should similarly be used in a way that maximizes the benefits and minimizes the risks (see Table 11-1).

Chapter 12

INTRAVASCULAR DEVICES

JOHN F. McCONVILLE
JOHN P. KRESS

KEY POINTS

- *The subclavian approach is preferred for placement of central venous catheters (CVCs).*
- *Real-time ultrasound may reduce the mechanical complications associated with CVC insertion.*
- *Chlorhexidine-based skin antiseptic solutions reduce the incidence of catheter-related bloodstream infections as compared with povidone-iodine.*
- *Almost 50% of hospital-acquired bloodstream infections are caused by staphylococcal species.*
- *CVCs should not be replaced nor exchanged over a guidewire on a routine basis.*

Central venous catheters (CVCs) have become an integral part of delivering care in the modern ICU. In fact, the Centers for Disease Control and Prevention (CDC) estimates that in U.S. ICUs there are 15 million CVC days per year (total number of days patients are exposed to CVCs).[1] Indications for placement of CVCs include invasive hemodynamic monitoring, administration of vasoactive drugs, administration of caustic agents (e.g., chemotherapy), administration of parental nutrition, renal replacement therapy, large-bore venous access for rapid administration of fluids, and long-term venous access. This chapter focuses on the use of CVCs in the ICU setting. Thus long-term tunneled catheters used for hemodialysis and peripherally inserted central catheters (PICCs) will not be discussed.

Placement of CVCs

The clinical presentation often dictates the type of catheter to be inserted. For example, a patient with a hemodynamically significant gastrointestinal hemorrhage may require only a single-lumen, large-bore CVC for volume resuscitation in addition to a peripheral IV, whereas a neutropenic patient with septic shock may require a triple-lumen CVC in order to administer vasoactive drugs and antibiotics simultaneously. Importantly, most evidence suggests that the number of catheter lumens does not affect the rate of CVC infectious complications.[2,3] Once the type of catheter has been selected, an anatomic site for insertion needs to be determined. The optimal anatomic location for insertion of CVCs has been a matter of debate for many years. In 2001, Merrer and colleagues[4] published a study of 289 patients who were randomized to have their CVCs inserted in either the femoral or subclavian vein. Patients with femoral vein catheters had a dramatically higher incidence of infectious complications (19.8% versus 4.5%; $p < 0.001$) and thrombotic complications (21.5% versus 1.9%; $p < 0.001$) as compared with patients with subclavian catheters. The overall sum of mechanical complications (i.e., arterial puncture, pneumothorax, hematoma or bleeding, and air embolism) was similar between the two groups. To date, there are no randomized trials comparing subclavian versus internal jugular catheters with regard to infectious complications, although observational studies suggest a lower rate of infectious complications with subclavian catheters and a similar rate of mechanical complications.[5,6] As a result of these and other studies,[7] the CDC recommends that, if not contraindicated, the subclavian vein should be used for the insertion of nontunneled CVCs in adult patients in an effort to minimize infection risk.

Approaches to Insertion of CVCs

INFRACLAVICULAR SUBCLAVIAN APPROACH

Prior to the insertion of an infraclavicular subclavian CVC, a small rolled-up towel should be placed between the shoulder blades to move the vascular structures to a more anterior position. After the subclavian area has been sterilely prepped and draped (see below) and local anesthesia has been administered, the patient should be placed in the Trendelenburg position. The arm should be positioned at the patient's side so that the shoulder, clavicle, and sternal notch are aligned and perpendicular to the sternum. The subclavian vein arises from the axillary vein and travels beneath the clavicle and inferior to the subclavian artery prior to joining the internal jugular vein and forming the brachiocephalic vein. Thus the clavicle provides a good anatomic landmark for the insertion of a subclavian CVC. The skin and periosteum of the clavicle should be infiltrated with a local anesthetic (e.g., lidocaine 1%). Following administration of local anesthesia, the skin should be entered with a 16-gauge introducer needle 1 to 2.5 cm below the inferior edge of the clavicle and 2 to 4 cm lateral to the midpoint of the clavicle. Once the needle is directly underneath the clavicle, it should be advanced toward the sternal notch, making sure that the needle remains in the plane immediately below the clavicle. If no blood return is obtained, then the needle should be pulled back and directed more cephalad. Slight backpressure should be placed on the plunger of the syringe any time the needle is advanced or withdrawn so that blood return can be visualized when the vessel is cannulated. After the vessel has been accessed, the modified Seldinger technique is used to complete the insertion of the CVC. Inexperienced operators often have difficulty knowing when the needle is directly underneath the clavicle and are appropriately fearful of puncturing the visceral pleura. Thus we often use a slightly different approach when supervising an inexperienced operator. Once the skin is entered, the operator is instructed to find the clavicle with the tip of the introducer needle. After the edge of the clavicle is reached and more local anesthesia is given in the area, the introducer needle is removed slightly (1 cm) and redirected in a more posterior direction by pushing down on the syringe and needle as a unit with the nondominant hand. This prevents the inexperienced operator from advancing the needle at a steep angle toward the underlying visceral pleura of the lung while attempting to locate the posterior border of the clavicle. Once the needle is "walked down" the bone and is positioned underneath the clavicle, it is then redirected toward the sternal

notch and advanced slowly while applying backpressure to the syringe (Fig. 12-1).

INTERNAL JUGULAR APPROACH

If the patient's anatomy (e.g., scar from previous vascular access) or a coagulation disorder prevents use of the subclavian vein, then the internal jugular vein should be used for placement of a CVC. The central approach to placing an internal jugular catheter uses the triangle formed by the two heads of the sternocleidomastoid muscle and the medial portion of the clavicle as the anatomic landmark. Typically, the internal jugular vein is lateral to the carotid artery, and both vessels run through the triangle beneath the sternocleidomastoid muscle. After the patient has been sterilely prepped and draped and local anesthesia has been administered, the patient is placed in the Trendelenburg position, and the head is rotated slightly toward the contralateral side such that carotid artery can be palpated in the apex of the triangle. The nondominant hand is used to lightly palpate the carotid artery, with careful attention paid to not place too much pressure on the skin because this can alter the position of the internal jugular vein. An 18- or 20-gauge "finder needle" often is used to locate the vessel prior to using the introducer needle (16 gauge). This finder needle should enter the skin at the apex of the triangle and be advanced at an angle of 60 degrees above the plane of the skin. If the nondominant hand is able to delineate the course of the common carotid artery, then the needle should be advanced along a similar line just lateral to the carotid artery because both vessels are contained within the carotid sheath. If the carotid artery cannot be palpated with the nondominant hand, then the needle should enter the skin at the apex of the triangle at a 60-degree angle to the skin and be advanced in the direction of the ipsilateral nipple. If the needle is inserted 3 cm without achieving good blood return, then it should be pulled back slowly while applying constant backpressure to the plunger of the syringe and redirected more medially before being slowly advancing again. After the vessel has been cannulated, the modified Seldinger technique is used to complete insertion of the CVC (Fig. 12-2).

POSTERIOR INTERNAL JUGULAR APPROACH

The posterior internal jugular approach is an alternative to the central internal jugular approach that may be used if there is concern that the patient will not be able to tolerate a procedure-related pneumothorax (high positive end-expiratory pressure and/or high F_{IO_2} requirements). The puncture site is posterolateral to the sternocleidomastoid muscle and immediately cephalad to where the sternocleidomastoid is crossed by the external jugular vein. The needle should be directed beneath the muscle and advanced in an anterior and inferior direction toward the sternal notch. If blood return is not obtained, the needle should be pulled back and redirected slightly more posterior until venous blood is obtained. Because unintentional carotid artery puncture is more

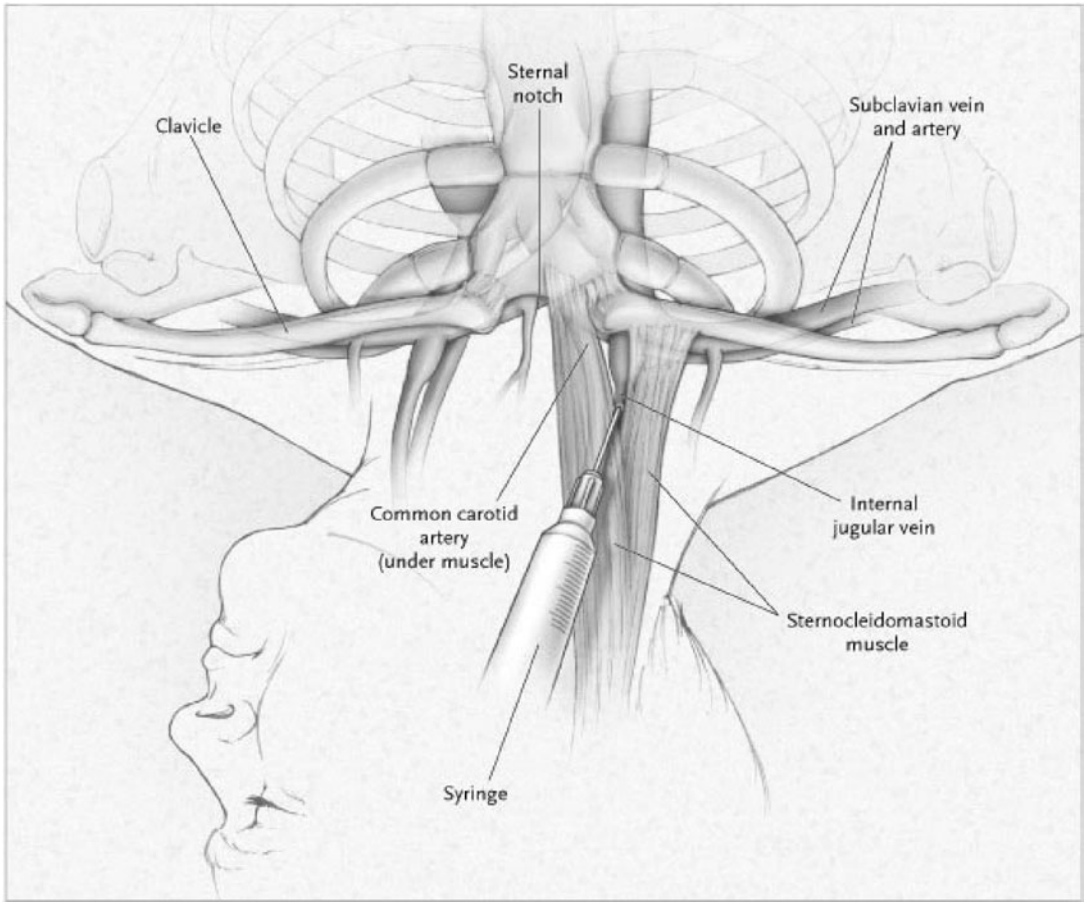

FIGURE 12-2 Insertion of an internal jugular CVC. See text for description. ***(Used with permission from McGee and Gould.[6]***

Copyright © 2003 Massachusetts Medical Society. All rights reserved.)

likely with this approach, a "finder needle" should be used prior to cannulation with a large-bore needle.

ULTRASOUND-GUIDED PLACEMENT

Ultrasound guidance to assist in the placement of CVCs is a subject of controversy. Mansfield and colleagues[29] reported that ultrasound guidance did not affect the rate of complications or failures in 821 patients randomized to standard insertion procedures with anatomic landmark guidance versus ultrasound guidance for subclavian vein catheterization. It is noteworthy that this study used ultrasonography to locate the subclavian vein but did not use real-time ultrasound guidance for the actual venipuncture. In contrast, several studies have compared the use of real-time ultrasound with the use anatomic landmarks during the insertion of both subclavian and internal jugular CVCs. These studies showed decreased failure rates, decreased complication rates, and an increased rate of successful catheter placement on the first attempt with the use of real-time ultrasound.[30,31] A recent review of CVC complications reported a 6% to 10% incidence of mechanical complications with the insertion of subclavian and internal jugular CVCs.[6] Given the frequent use of CVCs in the ICU and the risk of mechanical complications, it seems prudent to use real-time ultrasound during the insertion of CVCs if it is available, especially for patients with coagulation disturbances or unclear anatomic landmarks.

Infectious Complications of CVCs

Catheter-related infections (e.g., bloodstream infection, catheter colonization, or an exit-site infection) are thought to arise via several different mechanisms: Skin flora from the insertion site can migrate down the external surface of the catheter, the catheter hub can become infected with repeated manipulation, or hematogenous seeding of the catheter tip can result from a distant source of bacteremia.[22] CVC-related infections are the most common cause of nosocomial bacteremia in critically ill patients.[14] The incidence of hospital-acquired CVC-associated bloodstream infections is collected by the CDC's National Nosocomial Infection Surveillance System (NNIS) and is expressed as the number of bloodstream infections (BSI) per 1000 CVC-days. From 1992 to 2001, the rate of CVC-related bloodstream infections in adult ICUs ranged from 2.9 to 5.9 per 1000 catheter-days.[15] Diagnosis of a CVC-related BSI requires clinical symptoms of bacteremia (fever >38°C, chills, or hypotension) without another apparent source and isolation of an organism from a peripheral blood culture with either a semiquantitative or quantitative culture of a catheter segment that yields the same organism and

antibiotic sensitivities as the organism cultured from blood. In the semiquantitative culture method, the catheter segment is rolled on a culture plate and considered positive if there are greater than 15 colony-forming units (CFUs) of an organism. In the quantitative method, the catheter is processed in broth and sonicated, followed by plating the broth on a culture plate. A positive culture requires growth of greater than 10^3 CFUs.[16] CVC-related BSI should be distinguished from catheter colonization, which only requires a positive semiquantitative or quantitative culture from a catheter segment. In addition to BSI and catheter colonization, a CVC can develop an exit-site infection, defined as erythema, tenderness, induration, or purulence within 2 cm of the catheter exit site.[16]

The majority of pathogens causing CVC-related bloodstream infection are skin flora, which suggests migration of bacteria down the catheter as the mechanism of infection. A study of 297 pulmonary artery catheters found that 80% of infected catheters showed concordance with organisms cultured from the skin at the insertion site.[5] According to NNIS data from 1992 to 1999, approximately 50% of hospital-acquired bloodstream infections were caused by staphylococcal species. The most common organisms isolated were coagulase-negative staphylococci (37%), *Staphylococcus aureus* (13%), enterococcus (13%), gram-negative rods (14%), and *Candida* spp. (8%).[15] Given the frequency and cost associated with treating catheter-related infections, there has been a great deal of research into reducing the rate of these infections. Several interventions implemented at the time of catheter insertion have been shown to reduce the rate of catheter-associated infections.

SKIN PREPARATION

The use of antiseptic skin preparations prior to sterile draping and percutaneous placement of CVCs is a routine part of the procedure. Although povidone-iodine is the most commonly used skin antiseptic agent in the United States, a recent meta-analysis reported a 50% reduction in catheter-related bloodstream infections with the use of chlorhexidine-based solutions rather than povidone-iodine (risk ratio 0.49, 95% confidence interval [CI] 0.28–0.88).[19] This meta-analysis included several different types of chlorhexidine gluconate solutions for the insertion of central venous, peripheral venous, peripheral arterial, and pulmonary artery catheters. Subset analysis indicated that most of the benefit appeared to come from the chlorhexidine gluconate alcohol solutions rather than chlorhexidine gluconate aqueous solutions. Additionally, a subsequent meta-analysis determined that the use of chlorhexidine for central catheter site care resulted in a 0.23% decrease in the incidence of death and savings of $113 per catheter used.[20] Finally, it should be noted that there are little data about whether antibiotic resistance emerges with the use of antiseptic solutions.

MAXIMAL STERILE BARRIERS

Meticulous attention to sterile technique is of paramount importance during the placement of CVCs. The use of maximal sterile barriers likely decreases the incidence of inadvertent contamination of gloves, guidewires, and other equipment in the CVC kit. The technique of employing maximal sterile barriers, including a full body sterile drape, sterile gloves and long-sleeved gown, and nonsterile cap and mask, has been shown to reduce the incidence of CVC-related infections. Mermel and colleagues[5] found that pulmonary artery catheters (PACs) placed in the ICU with the use of maximal sterile barrier precautions developed fewer infections (15.1% versus 24.6%, $p < 0.01$) when compared with PACs placed in the operating room without maximal sterile barrier precautions. Raad and colleagues[21] found that the time to occurrence of catheter-related bloodstream infection was lengthened in cancer patients who had CVCs and peripherally inserted CVCs inserted with maximal sterile barriers as compared with patients who had catheters inserted with sterile gloves and a small sterile field ($p < 0.05$). Another study investigated the impact of a 1-day course taken by first-year resident physicians on infection control practices and hands-on instruction for several common procedures (arterial puncture and placement of arterial lines and CVCs). Subsequently, the documented use of full-size sterile drapes increased from 44% to 65%, and the rate of catheter-related infections decreased from 4.51 infections per 1000 patient-days before the first course to 2.92 infections per 1000 patient-days 18 months after the course. This decrease in catheter-related infections was associated with an estimated cost savings of $63,000.[22]

ANTIMICROBIAL CATHETER TREATMENT

Another approach to reducing the incidence of catheter-related infections is the use of catheters treated with antimicrobial agents. Catheters coated with chlorhexidine and silver sulfadiazine and minocycline and rifampin are currently available for clinical use. Compared with conventional catheters, these antimicrobial-treated catheters are associated with significant reductions in catheter-related bacteremia.[23,24] A study by Maki and colleagues[25] comparing conventional triple-lumen polyurethane catheters with catheters coated with chlorhexidine and silver sulfadiazine reported both a reduction in catheter colonization and a nearly fivefold reduction in bloodstream infection. A recent randomized trial of minocycline and rifampin versus chlorhexidine and silver sulfadiazine catheters, however, found a significant decrease in the incidence of catheter-related BSI in the group of patients using minocycline and rifampin (0.3% versus 3.4%, $p < 0.002$).[26] There are several possible reasons for the differences between the two catheters. The minocycline and rifampin catheters had antibacterial substances both outside and inside the catheters, as opposed to the chlorhexidine catheters, which were only externally coated. Importantly, neither study reported hypersensitivity reactions to the catheters, and neither reported the occurrence of infections by organisms with resistance to the antimicrobial agents. A newer chlorhexidine and silver sulfadiazine catheter with antiseptic located on both the internal and external surfaces is now available, and studies comparing this new catheter with the minocycline and rifampin catheter are underway. While the exact role of the catheters remains the subject of some debate, a cost-benefit analysis suggests that antiseptic catheters are beneficial if an institution's rate of catheter-related bacteremia is 3 infections per 1000 catheter-days.[25]

CATHETER EXCHANGE OVER A GUIDEWIRE

In order to avoid mechanical complications of placing a new CVC, a strategy of inserting a sterile guidewire through an

existing catheter, removing the catheter, and inserting a new sterile CVC over the guidewire is employed frequently. Since the existing catheter is not sterile, contamination of the new catheter is a concern with this technique. There have been several studies comparing scheduled catheter exchange over a guidewire and scheduled replacement of a CVC at a new site every 2 days, 3 days, 7 days, or as needed. In a meta-analysis, Cook and colleagues[27] found trends toward higher catheter colonization (relative risk [RR] 1.26, 95% CI 0.87–1.84) and catheter-related bacteremia (RR 1.72, 95% CI 0.89–3.33) associated with exchange over a guidewire. Additionally, prophylactic catheter replacement was not found to reduce catheter colonization or catheter-related bacteremia as compared with replacement of the catheter on an as-needed basis. In fact, the CDC strongly recommends that CVCs should *not* be replaced or exchanged over a guidewire on a routine basis[15] (category 1B recommendation: strongly recommended for implementation and supported by some experimental, clinical, or epidemiologic studies and a strong theoretical rationale). However, most authorities recommend wire exchange for suspicion of infection or mechanical catheter dysfunction. If infection is suspected, the catheter should be cultured on removal, and the new catheter should be removed if the culture of the old catheter is positive (>15 CFUs by the roll-plate method). Catheters with inflamed or purulent entry sites should be removed, and a new catheter should be inserted into a new site[6,28] (Fig. 12-3).

Mechanical Complications of CVCs

Lefrant and colleagues[32] reported their experience with subclavian vein catheterization over a 5-year period. Seven hundred and seven patients in a surgical critical care unit had subclavian vein catheterization attempted, with 562 successful procedures (79.5%). For the remaining 145 catheterizations, there were 67 failed procedures (overall failure rate of 9.5%). By multivariate analysis, more than one attempted venipuncture was the only independent risk factor for failed catheterization and immediate complications (e.g., arterial puncture, pneumothorax, misplacement of catheter). Elderly patients (>77 years of age) were more likely to have immediate complications but not failed catheterization. It is noteworthy that the operator's level of training and experience (junior, but not senior, residents were supervised by a critical care anesthesiologist) did not affect outcomes in the study, suggesting that adequately supervised physicians in training can perform CVC placement safely. Based on their observations, the authors recommended no more than two attempts at subclavian vein catheterization before aborting the procedure, with consideration of attempting at a different anatomic site. Contralateral attempts to cannulate the internal jugular or subclavian vein should be preceded by a chest radiograph to rule out pneumothorax, however, prior to proceeding.

ARTERIAL PUNCTURE/BLEEDING

Accidental arterial puncture is a well-recognized complication of CVC placement. The incidence of this complication in published reports ranges from 0% to 15%.[8–10] Complications arising from accidental arterial puncture include mediastinal hematoma formation, hemothorax, tracheal compression and possible asphyxiation, and retroperitoneal hemorrhage. A recent meta-analysis comparing internal jugular versus subclavian catheter placement noted a higher incidence of arterial puncture with internal jugular catheter attempts.[10] Although arterial puncture occurs more frequently with internal jugular attempts, the carotid artery is more readily compressible compared with the subclavian artery, which makes this approach more attractive in patients with coagulation disturbances. Most complications of accidental arterial puncture occur with dilation and subsequent placement of large-bore catheters into an artery. Several case reports and small series have acknowledged this important complication.[11–13] Traditional means of confirming arterial versus venous puncture of a blood vessel (e.g., bright red color, pulsatile blood return) may be unreliable in hypotensive, hypoxemic patients frequently encountered in the ICU. Transduction of the pressure waveform with intravenous extension tubing before dilation and placement of a large-bore catheter may reduce the occurrence of this complication. One may use tubing filled with sterile saline and attached to a three-way stopcock. After a vessel is entered, this tubing is connected to the needle while it is in the vessel, the tubing is elevated, and movement of the column of saline is analyzed to reflect either a venous or arterial waveform. Alternatively, the guidewire can be placed through the needle into the vessel using the modified Seldinger technique. Subsequently, a small, short catheter (e.g., 18- or 20-gauge 2-in intravenous catheter) can be placed over the wire into the vessel and the wire removed. The saline-filled, intravenous extension tubing can be attached to the catheter in the vessel to confirm a venous or arterial waveform. After confirmation of a venous waveform, the guidewire is replaced through this small intravenous catheter, the catheter is removed, and the procedure is finished. If unintentional arterial cannulation occurs, the small catheter is removed from the artery, and pressure is held at the site. Such a small catheter is much less likely to cause serious complications compared with a dilator and large-bore catheter. In our teaching hospital, we stress the importance of placing sterile intravenous extension tubing on the sterile field before the procedure is started so that a venous waveform can be confirmed prior to dilation and insertion of the catheter.

Bleeding complications from both arterial and venous punctures are exacerbated dramatically in patients who are thrombocytopenic or in those with coagulation disturbances. Unfortunately, such problems are common in critically ill patients. Those with platelet counts below 50,000/μL or those with an international normalized ratio (INR) above 2 probably should have catheters placed at a site with compressible vessels (e.g., internal jugular or femoral vein) unless the clotting problem can be corrected. The external jugular vein is an alternative that should be considered in those with clotting disturbances because it is a superficial vein that is easily compressible.

PNEUMOTHORAX

Pneumothorax is another important mechanical complication of CVC placement. The reported incidence of this complication ranges from 0% to 4.5%. Although some studies have reported a higher incidence of pneumothorax with subclavian catheter placement, a recent meta-analysis did not describe differences in the incidence of this complication when

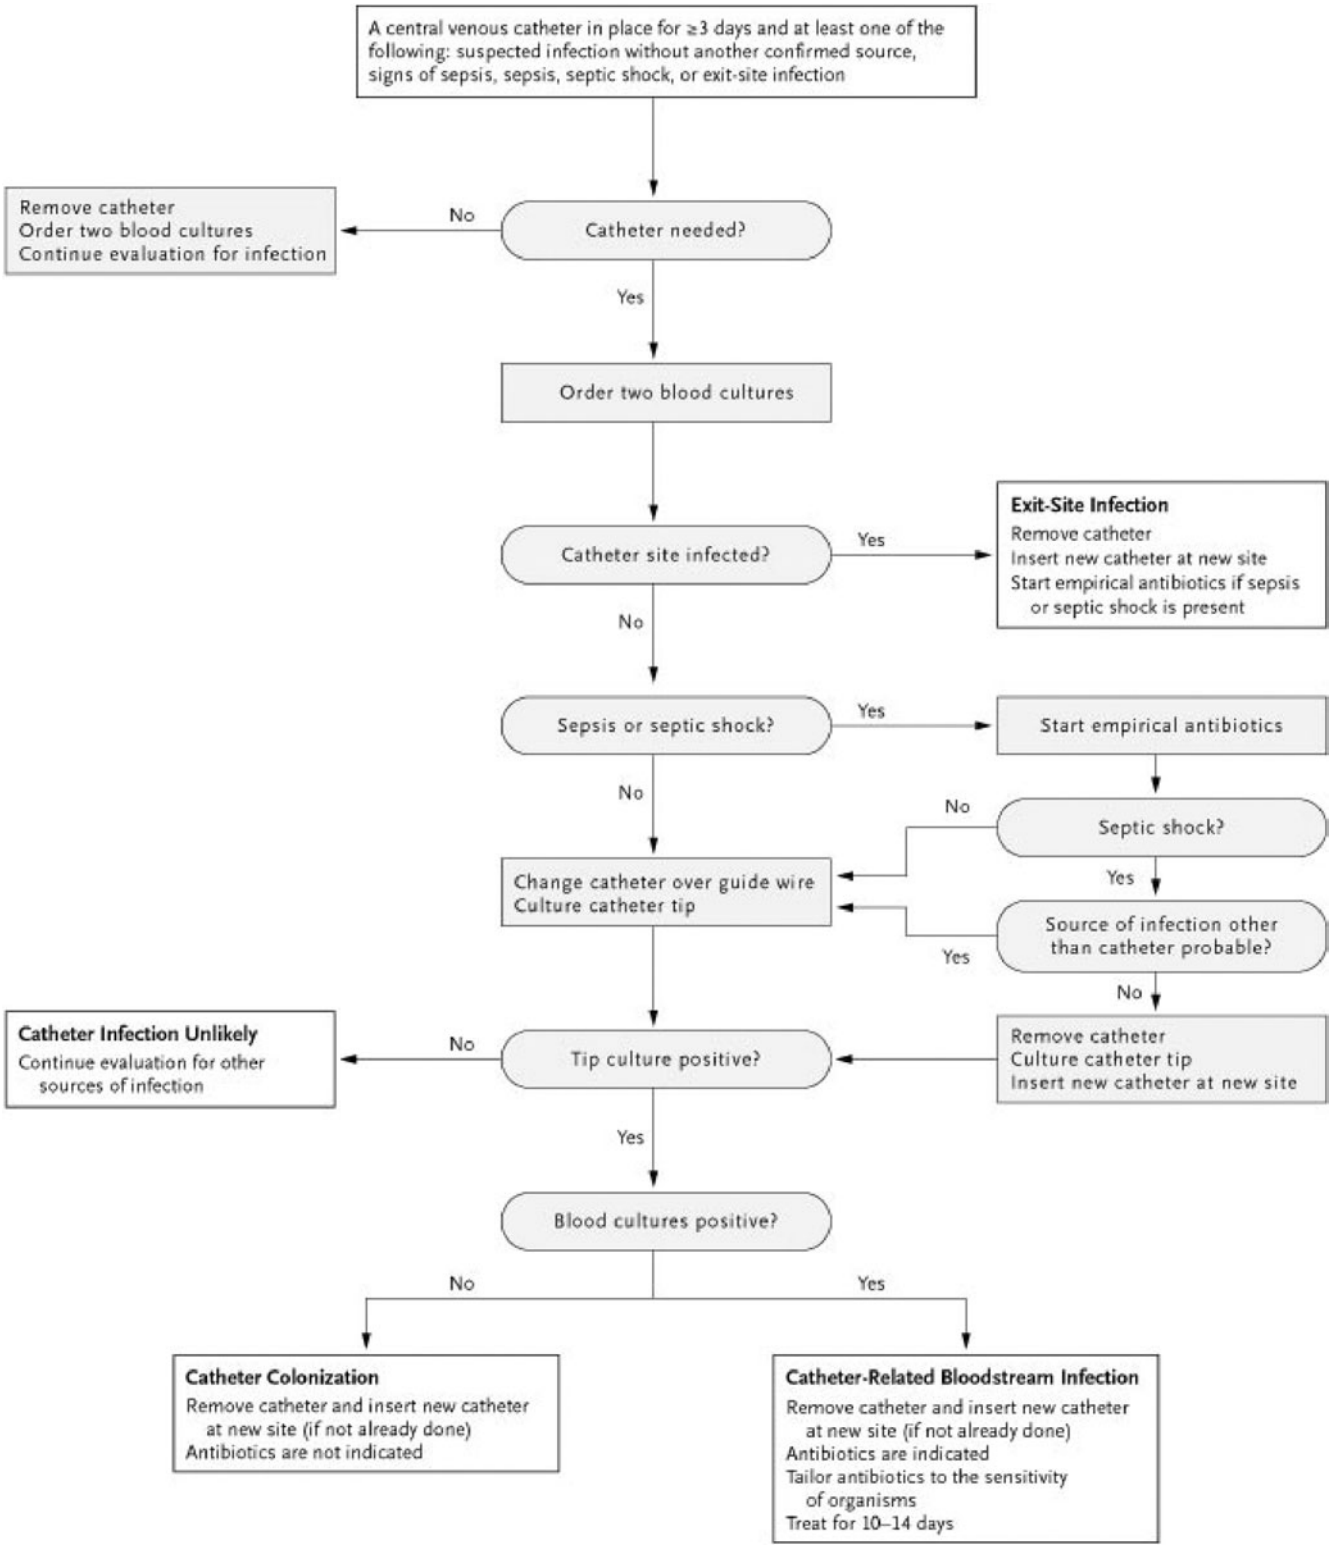

FIGURE 12-3 Management of suspected CVC infection. See text for description. ***(Used with permission from McGee and Gould.[6]***

internal jugular and subclavian approaches were compared.[10] Although many pneumothoraces occurring after CVC placement may not require treatment,[33] patients undergoing positive-pressure ventilation should have the pneumothorax evacuated. The use of small-caliber pleural catheters is effective as an alternative to conventional tube thoracostomy in evacuating simple iatrogenic pneumothoraces[34]; however, since this therapy has not been tested extensively in patients undergoing positive-pressure ventilation, tube thoracostomy remains the treatment of choice in this situation.

THROMBOTIC COMPLICATIONS

Catheter-related venous thrombosis is a relatively common complication, occurring in between 2% to 66% of catheters.[5,39] Catheter-related venous thrombosis may manifest as either a fibrin sleeve around the catheter or a thrombus that adheres to the wall of the vein that is typically asymptomatic. Because CVCs injure the endothelium and expose the venous intima, the coagulation system can become activated, resulting in thrombus formation. Difficulty with insertion of the line appears to increase the incidence of thrombosis, presumably owing to a greater degree of local venous trauma.[40] There is some evidence that *in an ICU setting* a subclavian vein CVC is less likely to develop a catheter-related thrombosis than an internal jugular vein CVC.[41] Timsit and colleagues[41] used color Doppler ultrasound just before or within 24 hours of catheter removal to determine the frequency of catheter-related thrombosis associated with 208 CVCs placed in the ICU (catheters in place for 9.35 ± 5.4 days). A catheter-related internal jugular or subclavian vein thrombosis occurred in 42% (95% CI 34–49) and 10% (95% CI 3–18), respectively. The overall rate of thrombus formation was 33%, and an internal jugular CVC increased the risk of thrombus formation by a factor of four (RR 4.13 [95% CI 1.72–9.95]). Importantly, this study also determined that the risk of catheter-related sepsis was 2.62-fold higher when thrombosis occurred ($p = 0.011$). These findings contradict two studies that examined the incidence of complications in more *permanent tunneled catheters* and found a decreased incidence of venous stenosis and thrombus formation in the internal jugular group as compared with the subclavian group.[42,43] Finally, the femoral vein is the least desirable anatomic location with regard to the risk of venous thrombosis. Merrer and colleagues[4] reported that 25 of 116 (21.5%) patients randomized to femoral vein catheterization had ultrasound-detected venous thrombosis. This differed dramatically from those randomized to subclavian vein catheterization, in whom 2 of 107 (1.9%) had venous thrombosis ($p < 0.001$).[4]

CATHETER OCCLUSION

Occlusion of a CVC is another mechanical complication that occurs, particularly when catheters have been in place for extended periods of time. Thrombosis at the tip of the catheter may lead to this problem. Other reasons for CVC occlusion include precipitation of incompatible medications, a problem that can be avoided by careful attention to medication compatibility. Patients may suffer occasionally from the "pinch-off syndrome," in which a subclavian catheter is compressed between the clavicle and the first rib.[17] This complication usually occurs in long-term indwelling catheters; however, a narrow space between the clavicle and the first rib sometimes can interfere with successful placement of subclavian catheters, particularly those of large bore. CVCs placed for extended time periods have been reported to break and embolize to the right side of the heart or pulmonary artery, requiring radiologic or surgical removal.[17,33]

CATHETER MISPLACEMENT

Most CVC placements in critically ill patients are performed without direct real-time visualization of the catheter. Typically, a chest radiograph is obtained after the procedure to ensure proper catheter position and to assess for evidence of a pneumothorax. Malpositioned catheters can then be repositioned correctly. Ideally, thoracic CVCs should terminate in the superior vena cava. Catheters occasionally may terminate in subclavian or jugular vein, as well as in the azygous, internal mammary, or pericardiophrenic vein, which may result in vascular injury and even perforation. When the tip of a catheter is positioned in the right atrium or right ventricle, perforation and subsequent cardiac tamponade may result.[35,36] In order to avoid complications when CVCs are positioned in cardiac chambers, it is recommended that the tip of the catheter lie proximal to the angle between the trachea and the right mainstem bronchus.[37] Ultrasonic examination after CVC placement may provide an alternative means of assessing adequacy of catheter placement.[44]

AIR EMBOLISM

When there is a communication between the great veins and the atmosphere, air may enter into the venous system. This potential complication is particularly relevant when considering the large-bore venous catheters used frequently in critically ill patients. Dysfunctional one-way valves or uncapped catheters may allow air to enter the venous system when intrathoracic pressure is subatmospheric during inspiration. Another problem is the possibility of venous air embolism during catheter removal, when a communication from the skin to a great vein may occur temporarily. Use of the Trendelenburg position and bioocclusive dressings may prevent this problem.[38]

Conclusion

In conclusion, intravascular catheters are necessary routinely for the management of critically ill patients. Mechanical, infectious, and thrombotic complications contribute considerable morbidity and mortality to these vulnerable patients. Recent evidence suggests that the subclavian vein may be the most desirable anatomic location for CVC placement; however, thrombocytopenia or coagulation disturbances—common problems in critically ill patients—may preclude this approach in some patients. It is encouraging that evidence to guide the appropriate management of CVCs is accumulating. Such evidence should allow clinicians to use these potentially lifesaving devices effectively while minimizing complications associated with their use.

Chapter 13

CLINICAL USE OF THE PULMONARY ARTERY CATHETER

JAMES W. LEATHERMAN
JOHN J. MARINI

KEY POINTS

- *Recent randomized trials found that use of a pulmonary artery catheter (PAC) did not influence the mortality of high-risk surgical patients or critically ill patients with shock or acute respiratory distress syndrome (ARDS).*
- *Insertion of a PAC is associated with a low incidence of serious complications. Of potentially greater risk to the patient than insertional complications are errors in recording and interpreting hemodynamic data that lead to faulty clinical decisions. Several studies have shown that there are serious deficiencies in the understanding of basic aspects of hemodynamic monitoring among physicians and nurses who use the PAC.*
- *Incomplete wedging can lead to marked overestimation of the actual pulmonary artery wedge pressure (Ppw) and always should be suspected when the measured Ppw exceeds the pulmonary artery diastolic pressure (Ppad). However, with pulmonary hypertension, incomplete wedging may be present despite a positive Ppad–Ppw gradient and should be suspected when the latter markedly narrows in comparison with previous values.*
- *Careful inspection of the PAC waveforms may be helpful in the diagnosis of underlying cardiac disorders: Acute mitral regurgitation results in prominent v waves in the Ppw tracing, pericardial tamponade is characterized by equalization of the Ppw and right atrial pressure (Pra) and by blunting of the y descent in the atrial waveform, tricuspid regurgitation often leads to a broad cv wave and a prominent y descent, and both constrictive pericarditis and restrictive cardiomyopathy result in prominence of both the x and y descents in the atrial waveform.*
- *Over the range of values most often seen in the ICU, neither the Pra nor the Ppw provides a reliable indicator of the adequacy of preload and of fluid responsiveness. However, the change in Pra with a spontaneous breath may be a useful indicator of fluid responsiveness in that failure of the Pra to fall with inspiration predicts that the patient is unlikely to benefit from a fluid challenge.*
- *Positive end-expiratory pressure (PEEP) causes the measured Ppw to overestimate transmural left atrial pressure; the effect of PEEP on transmural pressure can be quantified by calculating the percentage of alveolar pressure that is transmitted to the pleural space during a positive-pressure breath. Active expiration also causes the measured Ppw to overestimate transmural pressure and usually results in much greater errors than does applied PEEP.*
- *Thermodilution cardiac output ($\dot{Q}_T$) can be measured by the intermittent bolus method or continuously with a modified catheter. Several noninvasive and minimally invasive methods of measuring $\dot{Q}_T$ are also available.*
- *Venous oxygen saturation in the pulmonary artery (Sv_{O_2}) or superior vena cava (Scv_{O_2}) serves as a global indicator of the adequacy of O_2 delivery relative to tissue O_2 demands.*

Although the pulmonary artery catheter (PAC) has been in use for more than 30 years,[1] its value in management of critically ill patients remains controversial. Different studies have concluded that use of the PAC is associated with increased mortality,[2,3] has no effect on mortality,[4,5] or decreases major morbidity.[6,7] Several prospective, randomized studies have been initiated within the last few years in an effort to better define the impact of the PAC on patient outcome.[8] Three trials have been completed, and none found an impact of the PAC on mortality.[9–11] The appropriateness of these trials has been questioned,[8,12,13] and it has been suggested that efforts instead should be directed toward improvement of the standard of practice through intensive educational efforts, institution of more stringent accreditation policies, and evaluation of newer monitoring techniques before proceeding with expensive and time-consuming randomized clinical trials.[8,12,13] The latter view is based in part on evidence that ICU nurses and physicians who use the PAC may have significant deficiencies in knowledge about some of the most fundamental aspects of hemodynamic monitoring,[14,15] raising concern that the value of the PAC may be difficult to assess if data are not collected and interpreted optimally.[16]

We believe that carefully designed prospective clinical trials may provide some guidance regarding appropriate use of the PA catheter but are unlikely to clarify with certainty whether an individual patient who is critically ill and hemodynamically unstable will benefit from the information available from a PAC. At least for the time being, ICU physicians should continue to assess the benefits and risks of catheterization on a case-by-case basis, including in the decision analysis the applicability of alternative, less invasive methods of hemodynamic assessment.[17,18] We share the view that the PAC is an "occasionally useful tool" that can be of value in guiding therapy of selected critically ill patients, especially when empirical therapeutic trials have proven unsuccessful or are considered hazardous.[19] Implicit in this view, however, is the understanding that hemodynamic data must be collected accurately by ICU nurses and must be interpreted by physicians who are knowledgeable about cardiopulmonary pathophysiology. Faulty clinical decisions based on inaccurate or misinterpreted data may be a greater risk to the patient than the procedure per se. This chapter reviews clinical use of the PAC in the ICU, with particular emphasis on principles of data acquisition and interpretation and on the practical application of PAC-derived data in guiding therapy. Where appropriate, comparisons between the PAC and alternative methods of hemodynamic assessment will be discussed.

Indications

There are no absolute indications for PA catheterization. However, a PAC sometimes may aid in the diagnosis and management of a number of common clinical conditions (Table 13-1). These include cardiogenic and distributive

TABLE 13-1 Clinical Uses of Bedside Pulmonary Artery Catheterization

Condition	Primary Data Sought
DIAGNOSTIC USES	
Pulmonary edema	Ppw
Shock	$\dot{Q}_T$ and SVR; Ppw; Sv_{O_2}
Oliguric renal failure	Ppw, $\dot{Q}_T$
Perplexing lactic acidemia	$\dot{Q}_T$, Sv_{O_2}
Pulmonary hypertension	Ppa and PVR, Ppad versus Ppw
Cardiac disorders:	
Ventricular septal defect	Step-up in O_2 saturation (RA to PA)
RV infarction	Pra ≥ Ppw
Pericardial tamponade	Pra = Ppw; blunted *y* descent
Tricuspid regurgitation	Broad *cv* wave, Kussmaul's, deep *y* descent
Constrictive pericarditis	Pra = Pw, Kussmaul's; deep *y* descent
Narrow-complex tachyarrhythmia	Mechanical flutter waves (Pra waveform)
Wide-complex tachyarrhythmia	Cannon *a* waves (Pra waveform)
Lymphatic carcinoma	Aspiration cytology
Caloric requirements	V_{O_2} (by Fick equation)
MONITORING USES	
Assess adequacy of intravascular volume:	
Hypotension	
Oliguria	
High-risk surgical patient	
Assess effect of change in Ppw on pulmonary edema	
Assess therapy for shock	
Cardiogenic (vasodilator, inotrope)	
Septic (volume, vasopressor, inotrope)	
Hypovolemic (volume)	
Assess effects of PEEP or $\dot{Q}_T$ in ARDS	

shock, severe acute respiratory distress syndrome (ARDS), pulmonary edema of uncertain etiology, oliguric renal failure, perplexing lactic acidosis, and unexplained pulmonary hypertension. Preoperative insertion of a PAC also has been advocated for patients undergoing cardiac surgery and for high-risk patients undergoing major noncardiac operations. However, one large prospective study found no benefit to routine placement of a PAC before cardiac surgery and concluded that catheterization should be deferred until there was a clear indication for invasive monitoring.[20] A large prospective, randomized trial involving high-risk surgical patients found no benefit to the use of a goal-oriented hemodynamic approach based on data obtained from a PAC.[10] Anticipatory placement of a PAC because a patient *might* become unstable would not seem to be justified in most instances. Rather, placement of a PAC usually should be reserved for circumstances in which important questions about underlying pathophysiologic derangements cannot be answered confidently by less invasive means. In this regard, it is interesting to note that the controversial study linking PAC use to increased mortality found that the risk of the PAC appeared to be greatest in less critically ill patients who had the highest likelihood of survival on entry into the ICU.[2]

Patients for whom a PAC might be considered often can be managed effectively with alterative methods for assessing preload, cardiac output ($\dot{Q}_T$), and cardiac contractility.[17,18,22] The decision to proceed with invasive hemodynamic monitoring should be influenced by a variety of factors, including an assessment of procedural risk, the level of confidence in clinical assessment, and especially by the availability and expertise with alternative noninvasive techniques. For example, the etiology of unexplained hypotension may become obvious when echocardiography reveals severe depression of left ventricular contraction, acute pulmonary hypertension with right ventricular failure, hypovolemia with inspiratory collapse of the vena cava, or pericardial tamponade, potentially obviating the need for insertion of a PAC to establish a diagnosis.[22] On the other hand, patients with multiple and complex hemodynamic derangements that are likely to change over time, e.g., septic shock with multiorgan dysfunction, potentially may benefit from continuous hemodynamic monitoring with a PAC.

Complications

Complications of PAC insertion include those related to achieving vascular access and those resulting from the catheter itself (Table 13-2). Only catheter-related complications will be considered here.

Both atrial and ventricular tachyarrhythmias can develop as a result of catheter insertion.[23–25] Ventricular ectopy during passage through the right ventricle (RV) is not uncommon but almost always ceases as soon as the catheter tip passes through the pulmonic valve. Sustained ventricular tachycardia is unusual, and ventricular fibrillation is rare; in two large series, only 1.3% and 1.5% of patients required antiarrhythmic therapy, chest thump, or cardioversion.[23,24] Given the low incidence of sustained ventricular tachycardia, prophylactic administration of lidocaine is not recommended. Ongoing ischemia, shock, hypoxemia, electrolyte disturbances, acidosis, and/or high endogenous catecholamine levels may increase the risk of ventricular tachycardia. Arrhythmogenic factors should be eliminated before catheter insertion, when possible, and time in the RV should be kept to a minimum.

Transient right bundle branch block has been reported to occur in 0.05% to 5% of catheterizations.[25] Although generally of little consequence, even transient right bundle branch block is obviously of major concern if the patient already has left bundle branch block. However, a study of 82 patients with

TABLE 13-2 Complications of Pulmonary Artery Catheterization

Complications related to central vein cannulation
Complications related to insertion and use of the PAC
Tachyarrhythmias
Right bundle branch block
Complete heart block (pre-existing left bundle branch block)
Cardiac perforation
Thrombosis and embolism
Pulmonary infarction due to persistent wedging
Catheter-related sepsis
Pulmonary artery rupture and pseudoaneurysm
Knotting of the catheter
Endocarditis, bland and infective
Pulmonic valve insufficiency
Balloon fragmentation and embolization

left bundle branch block found no episodes of complete heart block during PAC insertion, and the two episodes of complete heart block that occurred while the catheters were in place were ascribed to the underlying disease rather than to the catheter.[26] It is not necessary to place a prophylactic transvenous pacemaker when a PAC is inserted into patients with left bundle branch block, but an external pacemaker should be at the bedside.

Clinically silent thromboses occur commonly at the site of PAC insertion, and PAC-associated clots can form occasionally in the heart or pulmonary artery.[23,27] In a recent prospective, randomized study, pulmonary emboli occurred more often in patients randomized to a PAC, but the incidence of pulmonary embolism in the PAC group was only 1.6%.[10] In a second large study, none of the 335 patients randomized to a PAC developed clinically evident pulmonary embolism.[11] Pulmonary infarction related to peripherally placed catheters is also infrequent, with an incidence of 0% to 1.4% in a large series.[25] Even when infarction does occur, it is often evidenced only by a new radiographic abnormality beyond the catheter tip without apparent clinical deterioration. In brief, clinically significant thromboembolism and infarction attributable to the PAC appear to be quite uncommon.

Pulmonary artery rupture and pseudoaneurysms can occur as a direct result of PAC-induced vascular injury. Pulmonary artery rupture, the most serious complication of pulmonary artery catheterization, usually is heralded by the abrupt onset of frank hemoptysis and carries a mortality rate of up to 50%.[25] Fortunately, this complication is rare, being observed in 0.06% and 0.2% of catheterizations in two large series.[23,24] Pulmonary hypertension, cardiopulmonary bypass, and anticoagulation place the patient at increased risk for morbidity and mortality from pulmonary artery rupture.[25] It has been suggested that pulmonary hypertension may favor distal migration of the catheter tip on balloon deflation, permitting vascular rupture when the balloon is reinflated.[28] In some cases, rupture occurs with the first reinflation. Avoidance of distal catheter placement and of balloon overinflation may reduce the risk of pulmonary artery rupture. Pseudoaneurysms can develop as a result of nonlethal pulmonary artery rupture, posing a significant risk of subsequent hemorrhage that may prove fatal.[29] The possibility of a false aneurysm should be considered whenever self-limited hemoptysis occurs after manipulation of the PAC. The diagnosis can be made by dynamic computed tomographic (CT) scanning or by angiography. Prompt treatment by coil embolization may prevent subsequent aneurysm rupture.[29]

A number of unusual complications of pulmonary artery catheterization have been reported (see Table 13-2). However, a review of nine large series found that major complications are quite uncommon.[25] A different "complication" associated with use of the PAC—erroneous recording and interpretation of hemodynamic data that results in bad clinical decisions and adverse patient outcome—may be much more frequent than these procedural risks. The remainder of this chapter will focus on the principles of data acquisition and their physiologic relevance to caring for the critically ill.

Pressure Monitoring

PRESSURE MONITORING SYSTEM

Essential system components required for pressure monitoring include a fluid-filled catheter and connecting tubing, a transducer to convert the mechanical energy from the pressure wave into an electrical signal, and a signal-processing unit that conditions and amplifies this electrical signal for display (Fig. 13-1). Two primary features of the pressure monitoring system determine its dynamic response properties: natural resonant frequency and damping coefficient.[30,31] Once

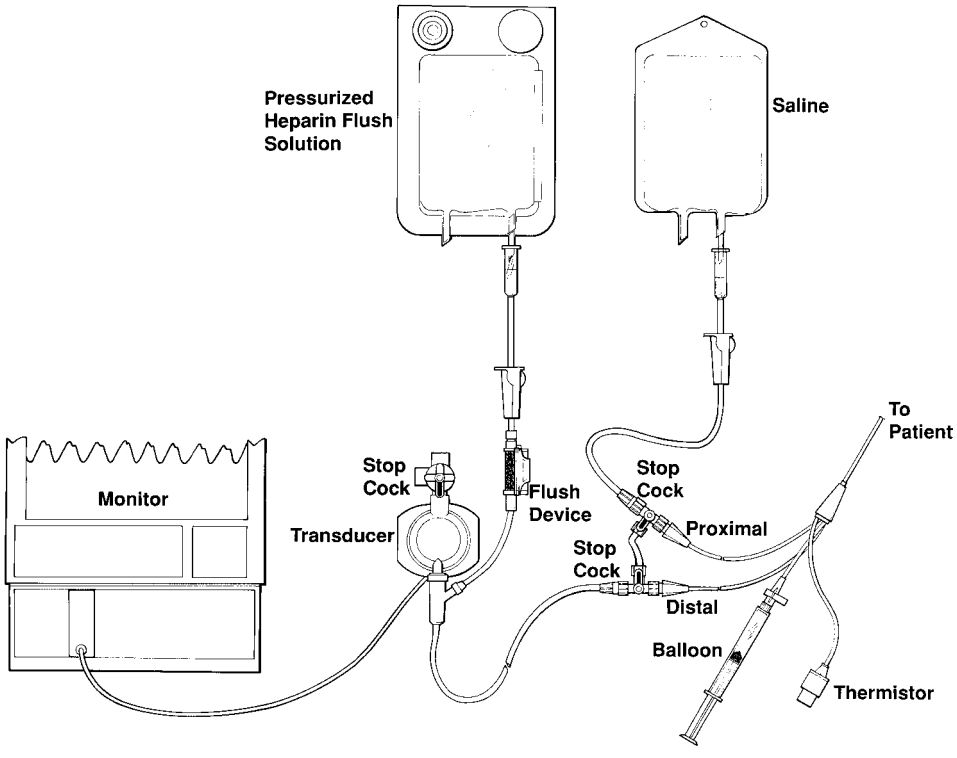

FIGURE 13-1 Standard four-lumen pulmonary artery catheter with pressure tubing, heparinized flush, transducer, and signal-processing unit (monitor). Pulmonary arterial or right atrial pressure can be displayed by stopcock adjustment.

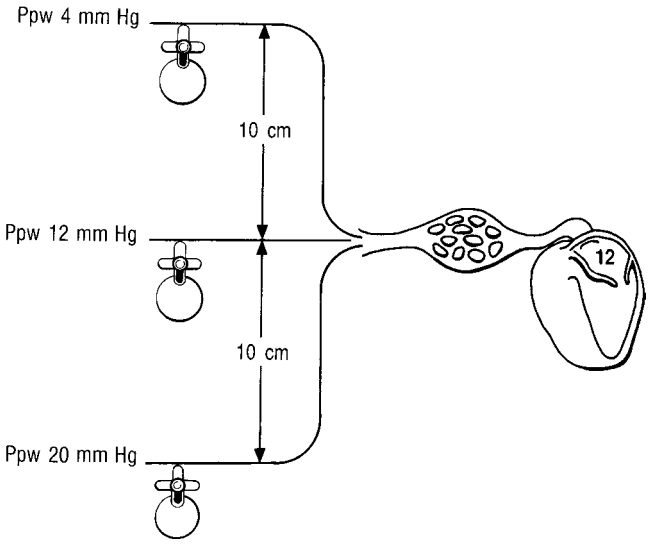

FIGURE 13-2 Effect of transducer malposition on pressure measurement. In this example, left atrial and wedge pressures are 12 mm Hg. Once the transducer has been zeroed at the left atrial level (see text), movement of the transducer above or below the left atrial plane will result in erroneous pressure measurement (10 cm $H_2O \sim 8$ mm Hg).

perturbed, each catheter-transducer system tends to oscillate at a unique (natural resonant) frequency determined by the elasticity and capacitance of its deformable elements. An undamped system responds well to the low-frequency components of a complex waveform, but it exaggerates the amplitude of components near the resonant value. Modest damping is desirable for optimal fidelity and for suppression of unwanted high-frequency vibration (*noise*); however, excessive damping smoothes the tracing unnaturally and eliminates important frequency components of the pressure waveform (see below).

For the hydraulic monitoring system to display accurate pressures, it is essential that the system be *zeroed* (balanced) at the phlebostatic axis (i.e., midaxillary line, fourth intercostal space). Body angle is not crucial, so one can zero the transducer with the orthopneic patient upright or semiupright. Once the transducer has been zeroed, however, movement of the transducer relative to the heart will cause the recorded pressure to underestimate or overestimate, respectively, the true value (Fig. 13-2). Because the pulmonary circuit is a low-pressure vascular bed, small errors in transducer position

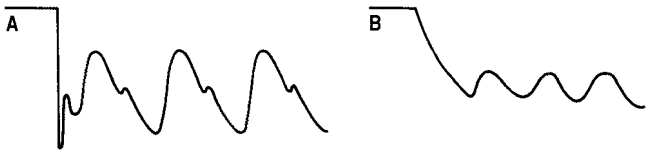

FIGURE 13-3 Rapid-flush test. *A*. Appropriately damped system. *B*. Overdamped system.

may be clinically significant. The transducer converts mechanical energy from the fluid-filled tubing into an electrical signal that is then amplified and displayed. The quality and cost of transducers vary considerably. The plastic disposable transducers used in the ICU are sufficiently accurate for routine clinical purposes.[32]

CATHETER INSERTION

The standard 7F PAC includes four essential elements: (1) a distal lumen for measurement of pressure in the pulmonary artery and for sampling of blood to determine mixed venous oxygen saturation (Sv_{O_2}), (2) a proximal lumen whose orifice is 30 cm from the catheter tip for measuring right atrial pressure (Pra) and infusing fluids, (3) a lumen to introduce air for balloon inflation, and (4) a thermistor at the catheter tip to enable estimation of $\dot{Q}_T$ by thermodilution (see Fig. 13-1). Various catheter modifications are available, including an additional lumen for infusion of fluids, a fiberoptic system to continuously assess Sv_{O_2}, a heating coil and modified thermistor to allow continuous measurement of $\dot{Q}_T$, a rapid-response thermistor that permits measurement of right ventricular ejection fraction, and a pacing electrode.

In the ICU, the PAC usually is inserted via the internal jugular or subclavian vein. A femoral approach may require fluoroscopy, although one study reported a surprisingly high success rate of 90% with nonfluoroscopic insertion via the femoral vein.[33] Before insertion, the proximal and distal lumens are connected to the appropriate pressure tubing, balloon integrity is tested, and a rapid-flush test is performed to assess the dynamic responsiveness of the pressure monitoring system (Figs. 13-3 and 13-4). Although the proximal and distal ports can be connected to separate transducers, more often a single transducer is connected to the distal port, and the proximal port is connected to a separate infusion of intravenous fluid (see Fig. 13-1). Use of a "bridge" and stopcocks permits monitoring of Pra when desired. The stopcocks should be checked before insertion to be sure that the monitor

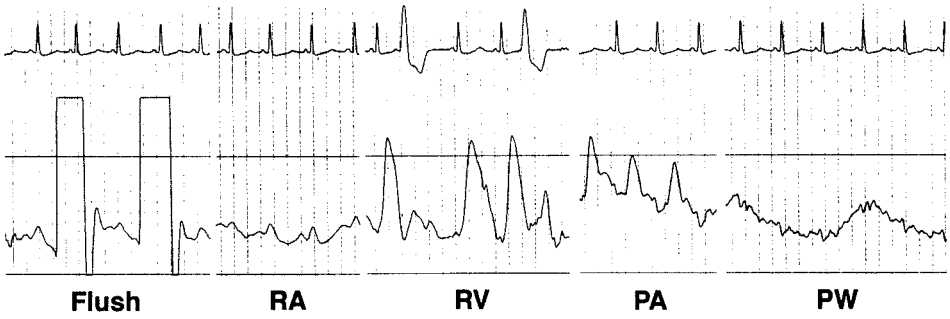

FIGURE 13-4 Waveform transition as catheter is advanced from the right atrium (RA) to the wedge (PW) position. The rapid flush test before insertion reveals good dynamic responsiveness. Passage from the right ventricle (RV) into the pulmonary artery (PA) is evidenced by a rise in diastolic pressure, and catheter wedging is evidenced by a fall in pressure and the appearance of an atrial waveform. Note the ventricular ectopy when the catheter is in the RV.

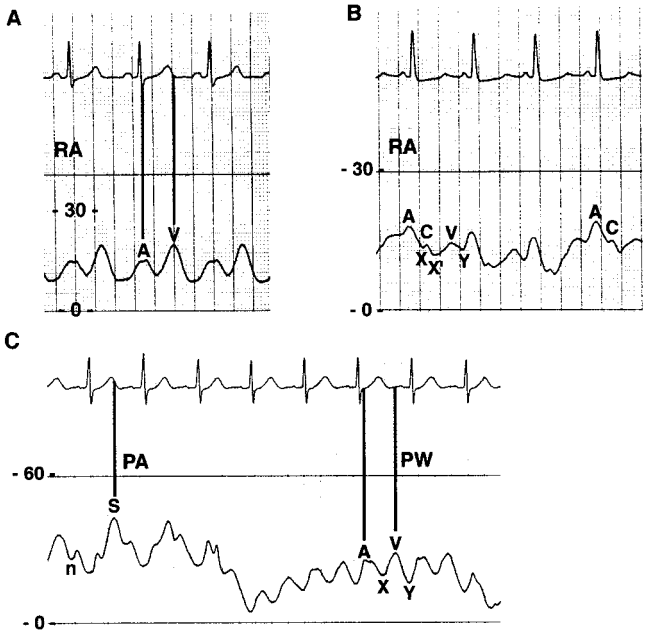

FIGURE 13-5 Pressure waveforms recorded simultaneously with an electrocardiographic lead. *A*. Right atrial (RA) tracing showing timing of *a* and *v* waves and *x* and *y* descents. *B*. RA tracing with visible *c* wave. *C*. Pulmonary artery (PA) tracing showing systolic wave (*s*); wedge (PW) tracing showing *a* and *v* waves and *x* and *y* descents. Note the difference in timing of the PA and PW pressure waves with respect to the electrocardiogram. (Scale is in millimeters of mercury.)

displays pressure from the distal lumen. Inadvertent recording from the proximal lumen will result in an unusually long length of catheter being inserted without achieving an RV tracing. This pitfall also should be suspected if the displayed pressure is initially near zero and then suddenly increases (proximal lumen enters the introducer) or if ventricular ectopy (tip in RV) is noted while the monitor displays a Pra waveform.

The RV should be reached within 30 to 40 cm from the internal jugular or subclavian entry sites. After entering the RV, insertion of an additional 10 to 15 cm of catheter is usually sufficient to reach the pulmonary artery. Feeding excessive catheter while the tip is in the RV should be avoided to prevent coiling and possible knotting within the RV. Entry into the pulmonary artery is reflected by an abrupt rise in diastolic pressure (see Fig. 13-4). The catheter is then advanced gradually until a pulmonary artery occlusion (wedge) pressure (Ppw) is signaled by a transition to an atrial waveform and a fall in mean pressure (Figs. 13-4 and 13-5).

A number of factors may interfere with recognition of characteristic waveforms during catheter insertion. Severe hypovolemia or other causes of decreased stroke volume reduces the pulmonary artery pulse pressure and the difference between mean pulmonary artery pressure (Ppa) and Ppw, potentially creating difficulties in determining whether a valid Ppw tracing has been achieved. With pericardial tamponade or RV infarction, the right ventricular end-diastolic pressure (RVEDP) approaches pulmonary artery diastolic pressure (Ppad), making the transition from RV to pulmonary artery sufficiently difficult to appreciate that fluoroscopy may be required to confirm catheter position.[34] Large swings in intrathoracic pressure may create major problems with waveform interpretation. If the patient is mechanically ventilated, elimination of large respiratory excursions with sedation (or temporary paralysis) may aid in delineation of the tracing and will enhance reliability of the measurements obtained.[35] Another problem is excessive catheter "whip" caused by "shock transients" being transmitted to the catheter during RV contraction in hyperdynamic states (Fig. 13-6). Overdamping occurs when air bubbles, clots, fibrin, or kinks diminish transmission of the pulsatile pressure waveform to the transducer, resulting in a decrease in systolic pressure and an increase in diastolic pressure. An overdamped Ppa tracing may be mistaken for a Ppw, leading to unnecessary retraction of a properly positioned catheter. A simple bedside test for overdamping is the "rapid flush" test[30] (see Fig. 13-3). Because of the length and small gauge of the catheter, very high pressures are generated near the transducer when the flush device is opened. An appropriately damped system will show a rapid fall in pressure with an "overshoot" and prompt return to a crisp pulmonary artery tracing on sudden closure of the flush device. In contrast, an overdamped system will generate a tracing that demonstrates a gradual return to the baseline pressure without an overshoot (see Fig. 13-3).

FIGURE 13-6 Catheter whip. Prominent excursions in the pulmonary artery tracing are due to "shock transients" transmitted directly to the catheter from the contracting right ventricle. (Scale is in millimeters of mercury.)

PAC-DERIVED PRESSURES

The properly positioned PAC provides access to pressures from three sites: right atrium (Pra), pulmonary artery (Ppa), and pulmonary vein (Ppw). Each of these pressures will be discussed sequentially in relationship to its determinants, waveform characteristics, and factors that commonly confound its interpretation. Subsequently, clinical use of PAC-derived pressure data will be discussed.

RIGHT ATRIAL PRESSURE (Pra)

In sinus rhythm, the Pra waveform is characterized by two major positive deflections (*a* and *v* waves) and two negative deflections (*x* and *y* descents) (see Fig. 13-5). A third positive wave, the *c* wave, is sometimes seen. The *a* (atrial) wave is due to atrial systolic contraction. The *a* wave is followed by the *x* descent as the atria undergo postsystolic relaxation and the atrioventricular junction moves downward during early ventricular systole. When visible, a *c* wave due to closure of the atrioventricular valves interrupts the *x* descent. When a *c* wave is seen, standard nomenclature dictates that the initial descent is termed *x* and the second descent is termed *x′*[34] (see Fig. 13-5). After the *x* descent, the *v* (ventricular) wave is generated by passive filling of the atria during ventricular systole. The *y* descent reflects the reduction in atrial pressure as the tricuspid valve opens (see Fig. 13-5).

In order to evaluate pressure waveforms adequately, it is essential to use a two-channel recorder that allows simultaneous recording of cardiac electrical activity and pressure. An electrocardiographic lead that clearly demonstrates atrial electrical activity should be chosen. Analysis of the atrial pressure tracing begins with identification of the electrical P wave. The first positive-pressure wave to follow the P wave is the *a* wave. The right atrial *a* wave usually is seen at the beginning of the QRS complex, provided that atrioventricular conduction is normal (see Fig. 13-5). When visible, the *c* wave follows the *a* wave by an interval equal to the electrocardiographic PR interval (see Fig. 13-5). The peak of the right atrial *v* wave normally occurs simultaneously with the T wave of the electrocardiogram, provided that the QT interval is normal (see Fig. 13-5).

Normal Pra is approximately 2 to 8 mm Hg.[34] In the absence of left ventricular (LV) dysfunction, the Pra is typically 2 to 5 mm Hg lower than the Ppw.[36] However, the Ppw may be markedly higher than the Pra in patients who have either systolic or diastolic LV dysfunction.[37] Conversely, the Pra may exceed the Ppw in patients with RV failure due to increased pulmonary vascular resistance (PVR) or RV infarction. In the absence of tricuspid stenosis or regurgitation, mean Pra approximates RVEDP. However, there is only a modest correlation between Pra and right ventricular end-diastolic volume (RVEDV), and the Pra required for optimal filling varies among patients.[38,39] Besides being an indicator of RV filling pressure, Pra also represents the downstream pressure for venous return. Normally, the decrease in intrathoracic pressure during a spontaneous breath produces a reduction in Pra, increasing the gradient for venous return from extrathoracic veins. When the right atrium is at its limits of distensibility, however, Pra will not fall with inspiration and may even rise (Kussmaul's sign). The response of Pra to a spontaneous breath may provide insight into the adequacy of volume expansion (see below).[39]

PULMONARY ARTERY PRESSURE (Ppa)

The pulmonary artery waveform has a systolic pressure wave and a diastolic trough (see Fig. 13-5). A dicrotic notch due to closure of the pulmonic valve may be seen on the terminal portion of the systolic pressure wave, and the pressure at the dicrotic notch closely approximates mean Ppa.[40] Like the right atrial *v* wave, the pulmonary artery systolic wave typically coincides with the electrical T wave (see Fig. 13-5). The pulmonary artery diastolic pressure (Ppad) is recorded as the pressure just before the beginning of the systolic pressure wave.

Ppa is determined by the volume of blood ejected into the pulmonary artery during systole, the resistance within the pulmonary vascular bed, and the downstream (left atrial) pressure. Normal values for Ppa are as follows: systolic, 15 to 30 mm Hg; diastolic, 4 to 12 mm Hg; and mean, 9 to 18 mm Hg.[34] The normal pulmonary vascular network is a low-resistance circuit with enormous reserve, so large increases in cardiac output ($\dot{Q}_T$) do not cause pressure to rise significantly. This large capillary reserve normally offers such slight resistance to runoff during diastole that the difference between the Ppad and the Ppw (the Ppad–Ppw gradient) is 5 mm Hg or less. Increased pulmonary vascular resistance (PVR) causes the Ppad–Ppw gradient to widen, whereas an increase in left atrial pressure results in a proportional rise in the Ppad and Ppw.[41,42] Therefore, the Ppad–Ppw gradient is used to differentiate pulmonary hypertension due to increased PVR from pulmonary venous hypertension.

An increased $\dot{Q}_T$ alone will not cause pulmonary hypertension. However, in the setting of increased vascular resistance, the degree to which Ppa increases will be influenced by the $\dot{Q}_T$. Pulmonary hypertension may result from the combination of a modest increase in vascular resistance and a major increase in $\dot{Q}_T$ due to sepsis, cirrhosis, agitation, fever, or other factors. The relative contributions of blood flow and the pulmonary vasculature to the increase in Ppa can be assessed by measuring $\dot{Q}_T$ by thermodilution and calculating PVR ($PVR = [P_{pa} - P_{pw}]/\dot{Q}_T$). It should be appreciated, however, that interpretation of the PVR is confounded by the fact that the pulmonary vascular bed behaves like a Starling (variable) resistor; PVR increases as flow ($\dot{Q}_T$) decreases, and the calculated PVR must be interpreted with respect to the $\dot{Q}_T$ at the time the measurement is made.[43] For example, a fall in $\dot{Q}_T$ owing to hemorrhage may produce a rise in calculated PVR even though the pulmonary vascular bed has not been affected directly; the PVR then may normalize once the $\dot{Q}_T$ returns to its baseline value. Conversely, calculated PVR may decrease solely due to an increase in $\dot{Q}_T$. The latter may be particularly relevant when assessing the response to vasodilators that affect both the pulmonary and systemic vascular beds. With decreased $\dot{Q}_T$, a rise in calculated PVR that is accompanied by an increase in driving pressure within the pulmonary circuit (Ppa–Ppw) would clearly indicate active pulmonary vasoconstriction, whereas a reduction in driving pressure at increased $\dot{Q}_T$ would provide unequivocal evidence of vasodilation.[44]

PULMONARY ARTERY WEDGE PRESSURE (Ppw)

The Ppw tracing contains the same sequence of waves and descents as the right atrial tracing. However, when the atrial waveform is referenced to the electrocardiogram, the mechanical events arising in the left atrium will be seen later than

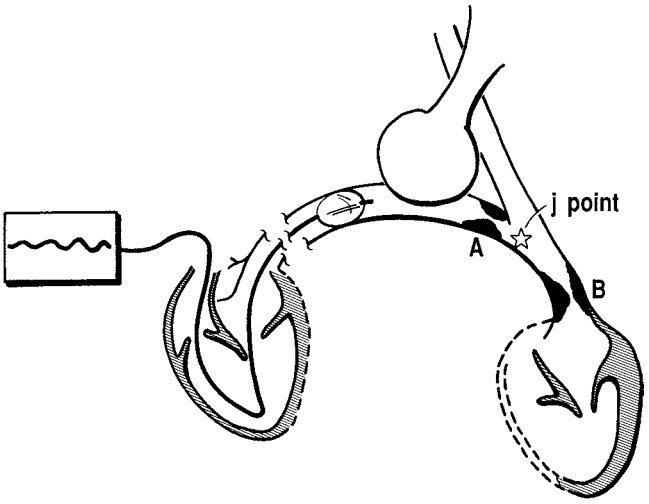

FIGURE 13-7 Principle of the wedge pressure (Ppw) measurement. When the inflated balloon obstructs arterial inflow, the catheter will record the pressure at the junction of the static and flowing venous channels, the j point. An obstruction distal (*B*) to the j point will cause the Ppw to overestimate left atrial pressure (Pla). With obstruction proximal (*A*) to the j point (e.g., veno-occlusive disease), the Ppw accurately reflects Pla but greatly underestimates pulmonary capillary pressure. *(Used with permission from O'Quinn and Marini.[30])*

those in the right atrium because the left atrial pressure waves must travel back through the pulmonary vasculature and a longer length of catheter. Therefore, in the Ppw tracing, the *a* wave usually appears after the QRS complex, and the *v* wave is seen after the T wave (see Fig. 13-5). Thus the systolic pressure wave in the pulmonary artery tracing *precedes* the *v* wave of the Ppw tracing when referenced to the electrocardiogram. An appreciation of the latter relationship is critical when tracings are being analyzed to ensure that balloon inflation has resulted in a transition from an arterial (Ppa) to an atrial (Ppw) waveform and to detect the presence of a "giant" *v* wave in the Ppw tracing (see below).

The Ppw is obtained when the inflated catheter obstructs forward flow within a branch of the pulmonary artery, creating a static column of blood between the tip of the catheter and the point (junction, or j point) in the pulmonary venous bed where it intersects with flowing blood (Fig. 13-7). Since the fully inflated catheter impacts in segmental or lobar pulmonary arteries, the j point is usually located in medium to large pulmonary veins. If the catheter were to be advanced with the balloon only partially inflated (or uninflated), obstruction to flow would occur in a much smaller artery, and the j point accordingly would move upstream to the smaller pulmonary veins. Since there is normally a resistive pressure drop across the small pulmonary veins, the Ppw recorded with a distal uninflated catheter will be slightly higher than the Ppw obtained with a fully inflated catheter.[45] Owing to resistance in the small pulmonary veins, the Ppw will underestimate the pressure in the pulmonary capillaries (see below), but the absence of any appreciable resistive pressure drop across the larger pulmonary veins dictates that the Ppw will reliably reflect left atrial pressure (Pla).

For the Ppw to accurately represent Pla, it is essential that the tip of the inflated catheter lie free within the vessel lumen,

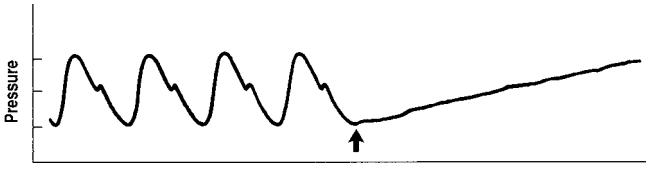

FIGURE 13-8 Overwedging. Arrow indicates time of balloon inflation.

and the inflated balloon must completely interrupt forward flow within the obstructed artery. Obstruction to flow at the catheter tip can lead to *overwedging*, whereas failure of the balloon to seal the vessel lumen results in a *partial* or *incomplete* Ppw. Overwedging is recognized by a progressive rise in pressure during balloon inflation and usually results from the balloon trapping the tip against the vessel wall. In such cases, the continuous flow from the flush system results in a steady buildup of pressure at the catheter tip, or at least as high as required to cause compensatory leakage from the trapped pocket (Fig. 13-8). If overwedging occurs, the deflated catheter should be retracted before reinflating the balloon to achieve a more suitable Ppw tracing and to prevent possible vessel injury.

An incomplete Ppw tracing occurs when the inflated balloon does not completely interrupt forward flow, resulting in a recorded pressure that is intermediate between mean Ppa and Ppw. As a result, the measured Ppw will overestimate the true value, potentially leading to serious errors in patient management. In the absence of pulmonic valve insufficiency or prominent *a* or *v* waves that increase its mean value, the Ppw should be equal to or less than the Ppad. Therefore, incomplete wedging always should be suspected if the Ppw exceeds the Ppad.[46] However, incomplete wedging also can occur despite the presence of a positive Ppad–Ppw gradient. Incomplete wedging occurs often in patients with pulmonary hypertension whose increased pulmonary vascular resistance results in a marked increase in the Ppad–Ppw gradient. In this setting, the measured Ppw can increase significantly above the true value owing to incomplete wedging yet still remain less than the Ppad, giving the impression that a reliable Ppw has been obtained[47] (Fig. 13-9). When this occurs, the measured Ppad–Ppw gradient will decrease in comparison with previous values. With pulmonary hypertension, incomplete wedging should be suspected when the Ppad–Ppw narrows unexpectedly or when at the time of insertion a normal Ppad–Ppw gradient is found when a widened gradient would be suspected (e.g., severe ARDS)[47] (Fig. 13-10). Another clue to incomplete wedging is provided by a pressure waveform that is more consistent with Ppa than Ppw (see Fig. 13-9). Incomplete wedging can result from a catheter that is too proximal, in which case advancement of the inflated catheter may be corrective. Alternatively, a catheter that is too distal, perhaps with its tip at a vascular branch point, also can lead to incomplete wedging. This circumstance is suggested by measuring a lower (more accurate) Ppw when the balloon is only partially inflated.[47] In this case, retraction of the deflated catheter before full balloon inflation may yield a more accurate Ppw and potentially reduce the risk of vessel injury due to distal catheter placement.

One method that has been suggested to confirm the reliability of the Ppw is aspiration of highly oxygenated

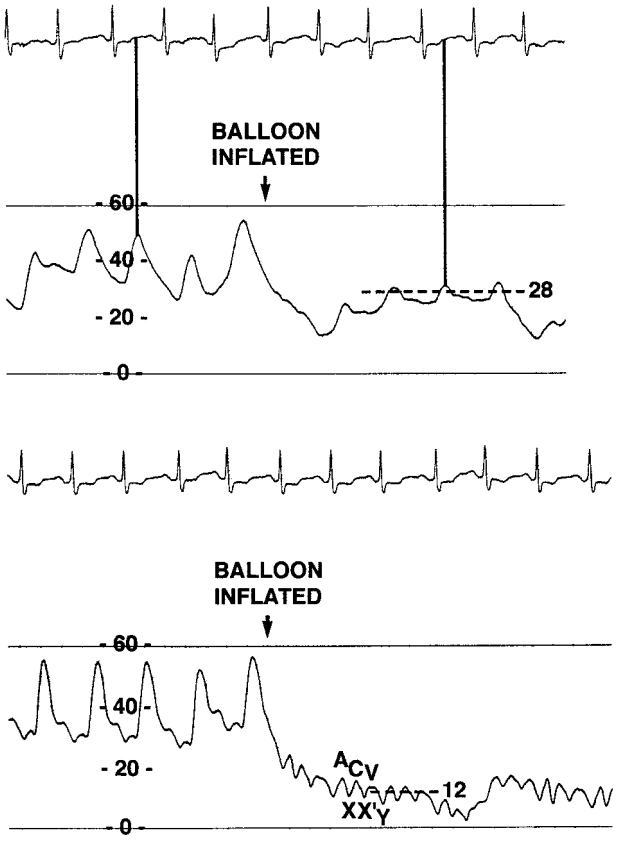

FIGURE 13-9 Incomplete wedge pressure (Ppw). (*Above*) With balloon inflation, there is a fall in pressure to a value that approximates pulmonary artery diastolic pressure (Ppad). However, the clinical setting (severe ARDS) is usually associated with a large Ppad–Ppw gradient. Review of the tracings reveals that there is a single positive wave coinciding with the electrocardiographic T wave after balloon inflation, a pattern inconsistent with a left atrial waveform. (*Below*) Waveforms after catheter has been retracted and balloon reinflated. Now there is a large Ppad–Ppw gradient, and the tracing after balloon inflation is consistent with a left atrial waveform. (Scale is in millimeters of mercury.)

blood from the distal lumen of the inflated catheter.[48] However, there are several important considerations when using the Pa_{O_2} of aspirated blood to confirm a wedge position. First, failure to obtain highly oxygenated blood in the Ppw position could occur if the catheter tip is located in a vessel whose capillary bed supplies an area of markedly reduced alveolar ventilation.[30,49] Second, it is recommended that an initial 15 to 20 mL of "dead space" blood be withdrawn and discarded before the sample for analysis is obtained so as to reduce the likelihood of obtaining a false-negative result when the inflated catheter has truly wedged.[49] Finally, a false-positive result (i.e., high O_2 saturation in aspirated blood when the catheter is not wedged) can occur if the sample is aspirated too quickly. It is recommended that the sample be aspirated at a rate no faster than 3 mL/min.[49]

RESPIRATORY INFLUENCES ON THE Ppw

The Ppw is an intravascular pressure, but it is the *transmural* pressure (intravascular minus pleural, Ppw − Ppl) that represents the distending pressure for cardiac filling and the hydrostatic component of the Starling forces that govern transcapillary fluid movement. During normal breathing, the lung returns to its relaxed volume at end expiration, with alveolar pressure being atmospheric and Ppl being slightly negative. The Ppw therefore should be measured at end expiration, the point in the respiratory cycle when juxtacardiac (pleural) pressure can be estimated most reliably (Fig. 13-11). Either a strip recording or the cursor method should be used to record the end-expiratory Ppw because digital readouts that average over the respiratory cycle may overestimate or underestimate Ppw.

Even when strip recordings are used, there may be inaccuracies in identifying the end-expiratory Ppw.[14] In one study, agreement among a group of critical care physicians who interpreted the same pressure recordings was only moderate.[50] A recent study found considerable interobserver variability among ICU nurses and physicians who were asked to record the Ppw from the same strip recordings. The most important factor contributing to interobserver variability was the presence of a large amount of respiratory variation.[51] Furthermore, a brief educational program did not improve the agreement among observers.[52] These data highlight some of the ongoing educational deficiencies among ICU physicians and nurses regarding some of the most basic aspects of hemodynamic monitoring and support the need for more intensive instruction, as proposed in the recent report by the Pulmonary Artery Consensus Conference Organization (PACCO).[53]

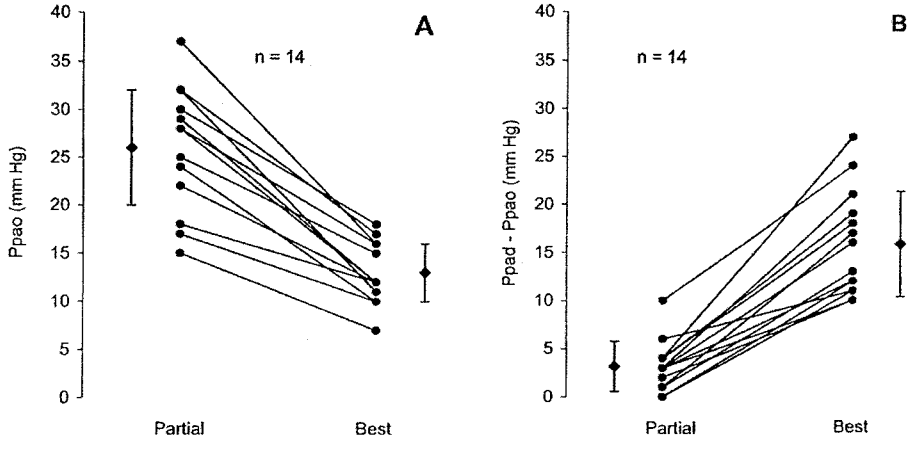

FIGURE 13-10 Effect of partial wedging on the measured pulmonary artery occlusion (wedge) pressure (Ppao) (*A*) and the pulmonary artery diastolic pressure (Ppad)–Ppao gradient (Ppad–Ppao) (*B*) in patients with pulmonary hypertension. These patients initially had a large Ppad–Ppao gradient that narrowed unexpectedly, leading to suspicion of partial wedging. Catheter repositioning to obtain a lower, more reliable ("best") Ppao resulted in a marked fall in the measured Ppao and a simultaneous increase in the Ppad–Ppao gradient. *(Used with permission from Leatherman and Shapiro.[47])*

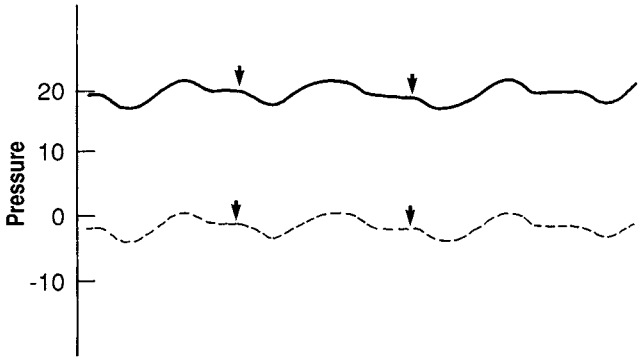

FIGURE 13-11 Effect of varying intrathoracic pressure on the wedge pressure (Ppw). (*Above*) Ppw tracing. (*Below*) Intrapleural pressure (Ppl). In this example, the patient is receiving assisted mechanical ventilation. Arrows indicate end-expiratory pressures. Negative deflections in Ppl and Ppw result from inspiratory muscle activity, and subsequent positive deflections represent lung inflation by the ventilator. At end expiration (*arrow*), the respiratory system has returned to its relaxed state, and Ppl is back to baseline (22 cm H_2O). Transmural wedge pressure remains approximately constant throughout the ventilating cycle. Since Ppl usually is not measured simultaneously with Ppw, however, it is necessary that the Ppw be recorded at a point where Ppl can be estimated reliably (i.e., end exhalation, assuming no active expiratory muscle activity). A digital scan may under- or overestimate transmural pressure depending on whether the pressure is sampled during a period of negative or positive change in Ppl.

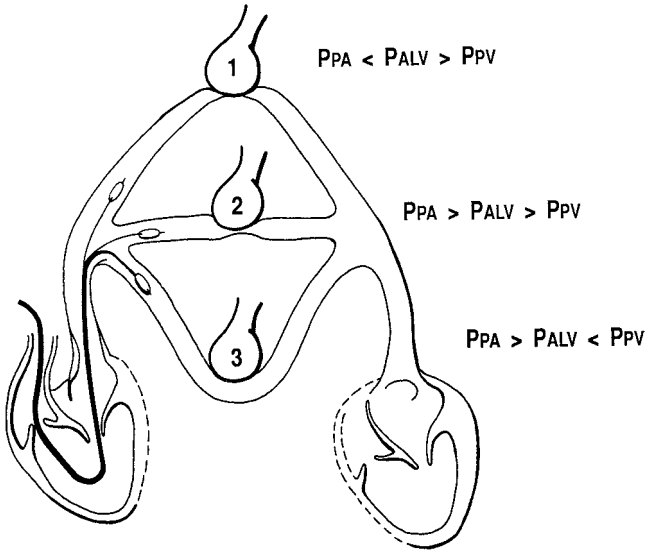

FIGURE 13-12 Physiologic lung zones based on the relationship between pressures in the pulmonary artery (Ppa), alveolus (Palv), and pulmonary vein (Ppv). *(Used with permission from O'Quinn and Marini.[30])*

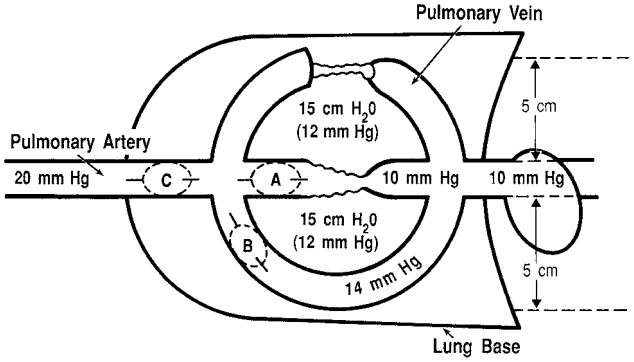
A frequent error in identifying end expiration is the false assumption that during mechanical ventilation the lowest point in the Ppw tracing reflects end expiration. While this may be true during controlled ventilation, inspiratory efforts that trigger mechanical breaths will produce a nadir in the Ppw tracing immediately after end expiration[54] (see Fig. 13-11). Identification of end expiration in the Ppw tracing is aided by the knowledge that expiration is usually longer than inspiration, two exceptions being marked tachypnea and inverse-ratio ventilation. In reality, identification of end expiration in the Ppw tracing should not be difficult so long as the respiratory influences on the Ppw are interpreted in relationship to the patient's ventilatory pattern. When confusion occurs, a simultaneous airway pressure tracing may help to identify the end of expiration.

Even when the Ppw is reliably recorded at end expiration, the measured value will overestimate the transmural pressure if intrathoracic pressure is positive at that point in the respiratory cycle. Positive juxtacardiac pressure at end expiration may result from the increase in lung volume that results from applied positive end-expiratory pressure (PEEP) or auto-PEEP or from increased intraabdominal pressure due to active expiration or the abdominal compartment syndrome. In the latter two circumstances, lung volume is not increased. Whatever the cause, increased juxtacardiac (pleural) pressure at end expiration should be taken into account when Ppw is used in clinical decision making.

APPLIED PEEP AND AUTO-PEEP

PEEP may influence the Ppw in one of two ways. First, the positive alveolar pressure conceivably could compress the pulmonary microvasculature sufficiently that there is no longer a continuous column of blood between the catheter tip and left atrium, resulting in a Ppw that reflects *alveolar* rather than pulmonary venous pressure. Second, even when PEEP does not interfere with the reliability of the Ppw as an indicator of pulmonary venous pressure, it nonetheless may result in increased juxtacardiac pressure so that the measured Ppw overestimates transmural pressure (Pla – Ppl).

In theory, the lung can be divided into three physiologic zones based on the relationship of pressures in the pulmonary artery (Ppa), alveolus (Palv), and pulmonary vein (Ppv)[30] (Fig. 13-12). This model would predict that the catheter tip must be in zone 3 (Ppv > Palv) at end expiration for the Ppw to provide a reliable estimate of left atrial pressure (Pla), and this would not be the case if PEEP was greater than Pla. However, in the great majority of instances the Ppw will reflect Pla reliably even when PEEP exceeds the latter.[55–58] Several factors may help to explain this apparent paradox. First, regardless of the values of PEEP and Pla, as long as there is a patent vascular channel between the catheter tip and the left atrium, the Ppw should reflect Pla. Since flow-directed catheters often place themselves below the level of the left atrium, local Ppv will be higher than Pla, encouraging vascular patency.[59] Even when the catheter tip lies at or above the atrial level, there may still be a branch of the occluded artery extending below the left atrium that prevents the wedged catheter from recording Palv[60] (Fig. 13-13). Finally, damaged lungs may not transmit Palv as fully to the capillary bed as normal lungs. In a dog model of unilateral lung injury, agreement between Ppw and Pla in the injured lung was excellent up to a PEEP of 20 cm H_2O, whereas Ppw overestimated Pla in the uninjured lung at a PEEP above 10 cm H_2O[55] (Fig. 13-14). A clinical study involving patients with ARDS found good agreement between the Ppw and left ventricular end-diastolic pressure (LVEDP) even at a PEEP of 20 cm H_2O.[56] Since high levels of applied PEEP generally are restricted to patients with ARDS, the Ppw is likely to reflect Pla reliably even when high-level PEEP is required.



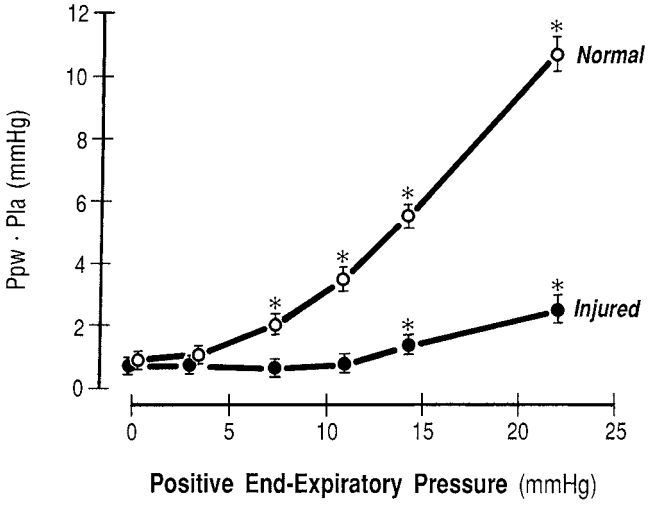


FIGURE 13-13 Reliability of the end-expiratory wedge pressure (Ppw) as a measure of pulmonary venous pressure (Ppv) during application of positive end-expiratory pressure (PEEP). With the balloon inflated, forward flow into the vessel is interrupted, and the catheter will record the higher of the two downstream pressures, Ppv or Palv. In this example, Ppv at the left atrial level is less than Palv. In catheter position *A*, the downstream Ppv is less than Palv, and the latter will be recorded. In position *B*, the catheter is below the left atrium, and local Ppv in this channel exceeds Palv, preserving vascular patency. Thus a reliable Ppw (10 mm Hg) will be recorded. In position *C*, the catheter is located at left atrial level, but it is situated more proximally than in *A*. Since a branch of the occluded vascular segment remains patent, an accurate Ppw (10 mm Hg) will be recorded. *(Used with permission from Culver.[60])*

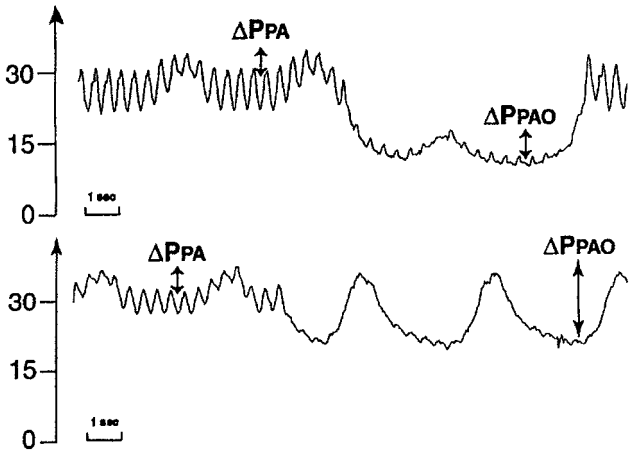
Although uncommon, a non-zone 3 condition should be considered when the Ppw tracing does not possess characteristics of an atrial waveform and the end-expiratory Ppw approximates PEEP. In this circumstance, a simple bedside method of ensuring a zone 3 condition may be useful.[57] This technique involves a comparison of the change in pulmonary artery systolic pressure (ΔPpas) and change in Ppw (ΔPpw)

FIGURE 13-14 Effect of lung injury on accuracy of the wedge pressure (Ppw) as an estimate of left atrial pressure (Pla). At high levels of PEEP, Ppw overestimates Pla in the uninjured lung but accurately predicts Pla in the injured lung. Thus lung injury favors a zone 3 condition, even though PEEP may exceed Pla significantly. *(Used with permission from Hassan et al.[55])*



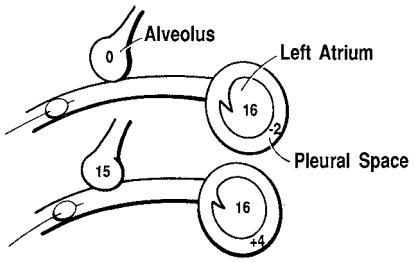


FIGURE 13-15 Changes in pulmonary artery systolic pressure (Ppas) and pulmonary artery occlusion (wedge) pressure (Ppao) during a positive-pressure breath. In the top figure, Ppao tracks with changes in pleural pressure, ensuring a zone 3 condition. In the bottom figure, the Ppao tracks the larger change in alveolar pressure, indicating that a zone 3 condition may not be present. *(Used with permission from Teboul et al.[57])*

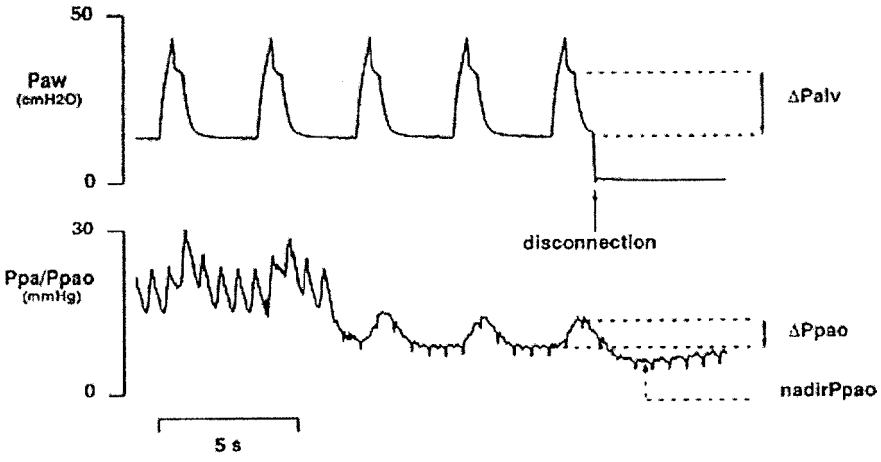
during a controlled ventilator breath (Fig. 13-15). Since the former reflects the increment in Ppl during a positive-pressure breath, a ratio of ΔPpas/ΔPpw close to unity would indicate that the ventilator-induced rise in Ppw also results from change in Ppl, thereby ensuring a zone 3 condition. In contrast, ΔPpw will exceed ΔPpas if the Ppw tracing tracks the larger pressure change within the alveoli, in which case a zone 3 condition may not be present.[57] Over 90% of patients with ARDS have a ΔPpas/ΔPpw close to unity (0.7 to 1.2), even at a PEEP of 20 cm H_2O.[57] In those few instances when Ppw tracks Palv during inspiration, a zone 3 condition could still be present at end expiration, when alveolar pressures are lowest. In brief, data from several sources strongly indicate that the end-expiratory Ppw nearly always will represent the downstream vascular pressure (Ppv, Pla) in ARDS, even when high levels of PEEP are required. Concern that the Ppw instead may be representing Palv should be limited to those rare instances in which the Ppw tracing has an unnaturally smooth appearance that is uncharacteristic of an atrial waveform, the end-expiratory Ppw is close to 80% of the applied PEEP (because mm Hg ~ 0.8 × cm H_2O), and the ΔPpw is significantly greater than ΔPpas during a controlled ventilator breath.

Even though PEEP seldom interferes with the reliability of the Ppw as a measure of Pla, it does cause the Ppw to overestimate the actual *transmural* pressure by increasing Ppl at end expiration (Fig. 13-16). The effect of PEEP on Ppl is determined by two factors: the PEEP-induced increase in lung volume and chest wall compliance. The degree to which lung volume increases in response to PEEP is inversely related to lung compliance.[30,61] Decreased chest wall compliance (e.g., increased intraabdominal pressure or morbid obesity) enhances the fraction of PEEP transmitted to the pleural space, whereas reduced lung compliance (e.g., ARDS) may blunt PEEP transmission. One study found that the percentage of PEEP transmitted to the pleural space (as estimated

PEEP cm H_2O	Pleural Pressure mmHg	Intracardiac Pressure mmHg	Transmural Pressure mmHg
0	-2	16	18
15	+4	16	12

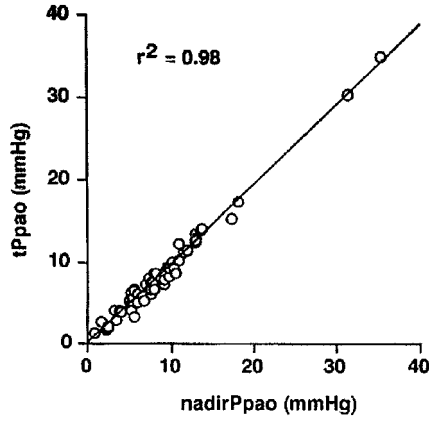
FIGURE 13-16 The effect of positive end-expiratory pressure (PEEP) on transmural pressure. In this example, 50% of PEEP is transmitted to the juxtacardiac space (15 cm $H_2O \sim 12$ mm Hg). The same wedge pressure of 16 mm Hg corresponds to greatly different effective transmural filling pressures.

with an esophageal balloon) in ARDS varied from 24% to 37%.[62] However, changes in esophageal pressure may underestimate the actual changes in juxtacardiac pressure when the heart and lungs are both expanded.[63,64] Thus in individual patients it may be difficult to estimate the actual juxtacardiac pressure reliably and hence the transmural pressure (Ppw − Ppl) with PEEP.



Two methods for measuring transmural pressure on PEEP have been described. The first employs a brief ventilator disconnection, during which time the Ppw falls rapidly to a nadir and then subsequently rises due to altered ventricular loading conditions. It has been shown that the nadir Ppw within 2 to 3 seconds of PEEP removal closely approximates the transmural pressure while on PEEP.[65] Although this technique potentially yields a more accurate estimate of transmural pressure, it may encourage alveolar derecruitment and hypoxemia in patients with severe ARDS. In addition, the nadir method will not be reliable in patients with auto-PEEP owing to airflow obstruction because their intrathoracic pressure falls very slowly after ventilator disconnection. The second technique, which does not require ventilator disconnection, uses the *transmission ratio* of ΔPpw/ΔPalv during a controlled ventilator breath to calculate the percent of alveolar pressure that is transmitted to the pleural space.[66] (In zone 3, ΔPpw should reflect the change in pleural pressure, and ΔPalv is defined as plateau pressure-PEEP.) The Ppl on PEEP is then estimated by multiplying PEEP by the transmission ratio, allowing calculation of transmural pressure (Ppw − Ppl)[66] (Fig. 13-17*A*). In one study, estimates of transmural pressure using the latter technique were virtually identical to those obtained by the nadir method in patients on PEEP who did not have dynamic hyperinflation[66] (see Fig. 13-17*B*). As noted earlier, the nadir method is unreliable for estimating transmural pressure in patients with airflow obstruction and auto-PEEP, whereas the technique involving calculation of the transmission ratio retains its validity in this patient population.[66] Even though these techniques may provide valid estimates of transmural pressure, it is unclear whether they contribute positively to patient management. In clinical decision making, use of the Ppw should not focus excessively on its absolute value. Rather, *change* in the Ppw with therapeutic interventions and their correlation with relevant end points (e.g., blood pressure, Pa_{O_2}, $\dot{Q}_T$, and urine output) are of greater importance, and such changes can be assessed without correcting the measured Ppw for the effects of PEEP.

Auto-PEEP may create greater difficulties in use of the Ppw than applied PEEP for several reasons. First, hemodynamically significant auto-PEEP may be occult. Second, because auto-PEEP usually occurs in the setting of chronic obstructive pulmonary disease (COPD) with normal or increased lung compliance, a larger component of the alveolar pressure may be transmitted to the juxtacardiac space. Third, the absence of parenchymal lung injury may promote non-zone 3 conditions. As noted earlier, estimates of transmural pressure based on the ΔPpw/ΔPalv ratio are more reliable than the nadir Ppw technique in patients with auto-PEEP owing to airflow obstruction.[66] From a practical standpoint, the potential hemodynamic significance of auto-PEEP can be determined easily by assessing whether a 30- to 45-second interruption of positive-pressure ventilation leads to an increase in blood pressure and $\dot{Q}_T$.[67] Although this maneuver usually also results in a lower Ppw, an unchanged Ppw does not exclude the presence of hemodynamically significant auto-PEEP because a large increase in venous return could offset the reduction in juxtacardiac pressure.



ACTIVE EXPIRATION

When the abdominal expiratory muscles remain active throughout expiration, the resulting increase in juxtacardiac pressure causes the end-expiratory Ppw to overestimate transmural pressure[35,68–70] (Fig. 13-18). Although initially described in spontaneously breathing patients with COPD, this problem also occurs in the absence of obstructive lung disease and in mechanically ventilated patients.[35,70] Since the pressure generated by the abdominal expiratory muscles is transmitted directly to the pleural space and is not "buffered" by the lungs, active exhalation typically causes the end-expiratory Ppw to overestimate transmural pressure to a much greater extent than does the application of PEEP.[70] With active exhalation, it is common for the end-expiratory Ppw to overestimate transmural pressure by more than 10 mm Hg.[35,70] Failure to appreciate the effect of active exhalation on the measured Ppw may result in inappropriate treatment of hypovolemic patients with diuretics or vasopressors on the basis of a misleadingly elevated Ppw.

When respiratory excursions in the Ppw tracing are due entirely to inspiratory muscle activity, the end-expiratory Ppw will remain unaffected. However, respiratory excursions that exceed 10 to 15 mm Hg increase the likelihood of active expiration.[35] Inspection of the Ppw tracing may provide a clue to active expiration if pressure rises progressively during exhalation. However, an end-expiratory plateau in the Ppw tracing does not exclude positive intrathoracic pressure due to tonic expiratory muscle activity.[69,70] Abdominal palpation may be useful in detecting muscle activity that persists throughout expiration. In mechanically ventilated patients, sedation (or even paralysis) may be used to reduce or eliminate expiratory muscle activity.[35,70] In the nonintubated patient, recording the Ppw while the patient sips water through a straw sometimes helps to eliminate large respiratory fluctuations. An esophageal balloon also can be used to

FIGURE 13-17 *A.* (*Above*) **Airway pressure (Paw) during volume-cycled ventilation with an inspiratory pause. The change in alveolar pressure (ΔPalv) resulting with each tidal breath is the plateau pressure minus PEEP. (*Below*) There is an identical change in pulmonary artery pressure (Ppa) and pulmonary artery occlusion (wedge) pressure (Ppao) with each tidal breath, indicating that the catheter is in zone 3, and the ΔPpao therefore reflects the change in pleural pressure. Transmural Ppao is calculated by the transmission-ratio method as transmural pressure = measured Ppao − 0.8 (ΔPpao/ΔPalv) × PEEP. (PEEP, in cm H_2O, is converted to mm Hg by multiplying by 0.8.) *B.* Also shown is the nadir Ppao measured 2 to 3 seconds after ventilator disconnection. Correlation between determinations of the on-PEEP transmural Ppao by the transmission-ratio method (tPpao) and the nadir method (nadir Ppao). *(Used with permission from Teboul et al.[66])***

FIGURE 13-18 Effect of vigorous respiratory muscle activity on end-expiratory wedge pressure (Ppw). *A.* Patient on mechanical ventilation is observed at the bedside to be making vigorous inspiratory and expiratory efforts. The Ppw measured at end exhalation (*arrow*) is 25 mm Hg. *B.* In order to obtain a reliable Ppw, respiratory muscle activity is temporarily eliminated with a short-acting paralyzing agent. The Ppw is now measured at 8 mm Hg.

provide a better estimate of transmural pressure.[68] In circumstances where prominent respiratory muscle activity cannot be eliminated and esophageal pressure is unavailable, transmural pressure often is better estimated by the Ppw measured midway between end inspiration and end expiration.[70] However, the latter is not true in all instances,[70] and it may be most appropriate simply to recognize that an accurate estimate of transmural pressure may not be possible in this situation.

CLINICAL USE OF PRESSURE MEASUREMENTS

There are three principal uses of PAC-derived pressures in the ICU: (1) diagnosis of cardiovascular disorders by waveform analysis, (2) diagnosis and management of pulmonary edema, and (3) evaluation of preload.

ABNORMAL WAVEFORMS IN CARDIAC DISORDERS

Unfortunately, physicians and nurses sometimes focus solely on the numbers generated by the pressure monitoring system without carefully assessing the pressure waveforms. Analysis of pressure waveforms may prove valuable in the diagnosis of certain cardiovascular disorders, including mitral regurgitation, tricuspid regurgitation, RV infarction, pericardial tamponade, and limitation of cardiac filling due to constrictive pericarditis or restrictive cardiomyopathy.

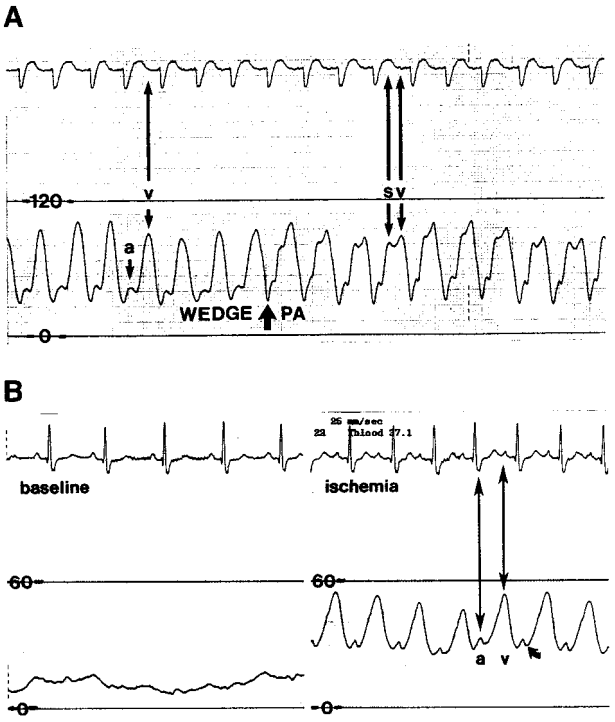

FIGURE 13-19 *A.* **Acute mitral regurgitation with a giant *v* wave in the pulmonary wedge tracing. The pulmonary artery (PA) tracing has a characteristic bifid appearance due to both a PA systolic wave and the *v* wave. Note that the *v* wave occurs later in the cardiac cycle than the PA systolic wave, which is synchronous with the T wave of the electrocardiogram.** *B.* **Intermittent giant *v* wave due to ischemia of the papillary muscle. Wedge tracings are from the same patient at baseline and during ischemia. (Scale is in millimeters of mercury.)** ***(Used with permission from Sharkey.[34])***

Acute mitral regurgitation most often is due to papillary muscle ischemia or rupture. When the mitral valve suddenly becomes incompetent, an unaccommodated left atrium accepts blood from the left ventricle during systole, producing a prominent *v* wave (Fig. 13-19). A large *v* wave gives the Ppa tracing a bifid appearance owing to the presence of both a pulmonary artery systolic wave and the *v* wave (see Fig. 13-19). When the balloon is inflated, the tracing becomes monophasic as the pulmonary artery systolic wave disappears (see Fig. 13-19). A giant *v* wave is confirmed most reliably with the aid of a simultaneous recording of the electrocardiogram during balloon inflation. Although the pulmonary artery systolic wave and the left atrial *v* wave are generated simultaneously, the latter must travel back through the pulmonary vasculature to the catheter tip. Therefore, when the pressure tracing is referenced to the electrocardiogram, the *v* wave will be seen later in the cardiac cycle than the pulmonary artery systolic wave (see Fig. 13-19). In the presence of a giant *v* wave, the Ppad is lower than the mean Ppw, and the mean pressure may change only minimally on transition from Ppa to Ppw, giving the impression that the catheter has failed to wedge. This impression may lead to insertion of excess catheter, favoring distal placement that could lead to pulmonary infarction or to rupture of the artery on balloon inflation.

A large *v* wave leads to an increase in pulmonary capillary pressure, often with resulting pulmonary edema. When mitral insufficiency is due to intermittent ischemia of the papillary muscle, giant *v* waves may be quite transient (see Fig. 13-19). Failure to appreciate these intermittent giant *v* waves may lead to a mistaken diagnosis of noncardiogenic pulmonary edema because the Ppw will be normal between periods of ischemia.

Large *v* waves are not always indicative of mitral insufficiency. The size of the *v* wave depends on both the volume of blood entering the atrium during ventricular systole and left atrial compliance.[71,72] Decreased left atrial compliance may result in a prominent *v* wave in the absence of mitral regurgitation. Conversely, when the left atrium is markedly dilated, severe valvular regurgitation may give rise to a trivial *v* wave, especially when there is coexisting hypovolemia.[72] The important effect of left atrial compliance on the size of the *v* wave was demonstrated by a study that simultaneously evaluated the height of the *v* wave and the degree of regurgitation, as determined by ventriculography.[72] One-third of patients who had large *v* waves (>10 mm Hg) had no valvular regurgitation, and a similar percentage of patients with severe valvular regurgitation had trivial *v* waves.[72]

Hypervolemia is a common cause of a prominent *v* wave. When the left atrium is overdistended, it operates on the steep portion of its compliance curve; i.e., small changes in volume produce large changes in pressure (Fig. 13-20). As a result, passive filling from the pulmonary veins can lead to a prominent *v* wave, and the latter may be quite large if $\dot{Q}_T$ is increased. With hypervolemia or intrinsic reduction in left atrial compliance, the *a* wave also may be prominent, provided that the underlying rhythm is not atrial fibrillaton. Following diuresis, the *a* and *v* waves become less pronounced. Another cause of a large *v* wave is an acute ventricular septal defect because the increased pulmonary blood flow enhances filling of the left atrium during ventricular systole. Thus both papillary muscle rupture (or dysfunction) and acute ventricular septal defect (VSD) can be associated with prominent *v* waves, and these two complications of myocardial infarction usually must be differentiated by other means (see below).

Tricuspid regurgitation most often is due to chronic pulmonary hypertension with dilation of the right ventricle. With tricuspid regurgitation, there is often a characteristically broad *v* (or *cv*) wave in the central venous (right atrial) tracing (Fig. 13-21). The *v* wave of tricuspid regurgitation generally is less prominent than the *v* wave of mitral regurgitation, probably because the systemic veins have a much greater capacitance than do the pulmonary veins. One of the most consistent findings in the Pra tracing of patients with tricuspid regurgitation is a steep *y* descent. The latter often becomes more pronounced with inspiration (see Fig. 13-21). Kussmaul's sign, an increase in Pra with inspiration, also is observed commonly in patients with severe tricuspid regurgitation.

RV infarction may complicate an inferoposterior myocardial infarction. Common findings include hypotension with clear lung fields, Kussmaul's sign, positive hepatojugular reflux, and a Pra that equals or even exceeds the Ppw. The Pra tracing in RV infarction often reveals prominent *x* and *y* descents, and these deepen with inspiration or volume loading.[34] With RV infarction, the RV and pulmonary artery pulse pressures narrow, and with RV failure, the RVEDP may approximate the Ppad (Fig. 13-22). This, together with the frequent presence of tricuspid regurgitation, may lead to difficulties in bedside insertion of the PAC, and fluoroscopy may be required.[34] In the setting of a patent foramen ovale,

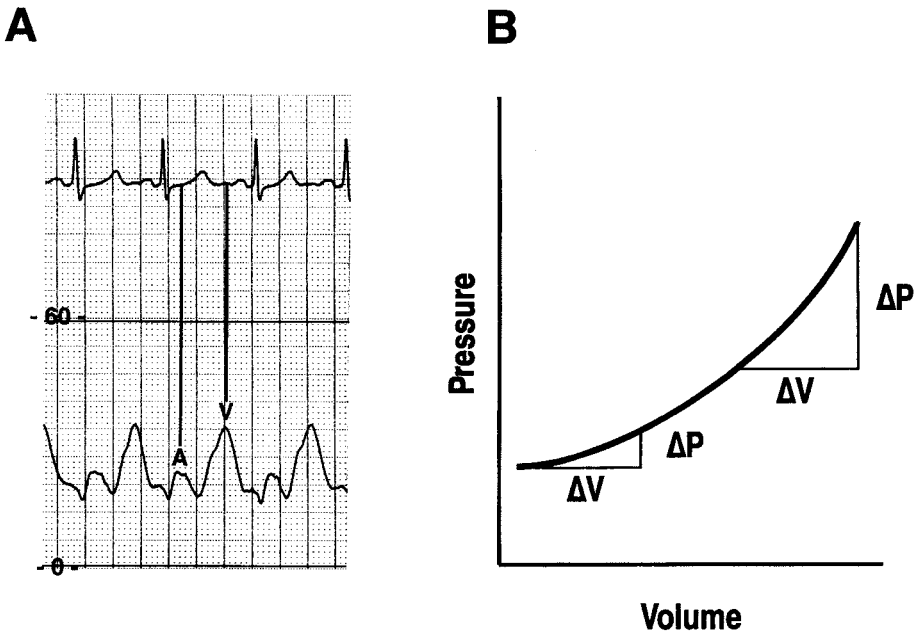

FIGURE 13-20 ***A.*** **Prominent** *v* **wave. The echocardiogram showed only trace mitral regurgitation.** ***B.*** **Left atrial pressure-volume relationship. The same degree of passive filling during diastole (ΔV) produces a much larger change in pressure (ΔP) when the left atrium is overdistended and is operating on the steep portion of the compliance curve. This explains the presence of a large** *v* **wave with hypervolemia.**

patients with RV infarction may develop significant hypoxemia due to a right-to-left atrial shunt. Profound hypoxemia with a clear chest radiograph and refractory hypotension also would be consistent with major pulmonary embolus. The hemodynamic profiles of these two disorders are different, however, in that massive pulmonary embolism is characterized by a significant increase in the Ppad–Ppw gradient, whereas the latter is unaffected by RV infarction.[41]

Pericardial tamponade is characterized by an increase of intrapericardial pressure that limits cardiac filling in diastole. With advanced tamponade, intrapericardial pressure becomes the key determinant of cardiac diastolic pressures, resulting in the characteristic *equalization* of the Pra and Ppw. Intrapericardial pressure is a function of the amount of pericardial fluid, pericardial compliance, and total cardiac volume. The *x* descent is preserved in tamponade because it occurs in early systole when blood is being ejected from the heart, thereby permitting a fall in pericardial fluid pressure. In contrast, the *y* descent occurs during diastole when blood is being transferred from the atria to the ventricles, during which time total cardiac volume and intrapericardial pressure are unchanged. As a result, there is little (if any) change in Pra during diastole, accounting for the characteristically blunted *y* descent of pericardial tamponade[73] (Fig. 13-23). Attention to the *y* descent may prove to be quite useful in the differential diagnosis of a low $\dot{Q}_T$ with near equalizaton of pressures. An absent *y* descent dictates that echocardiography be performed to evaluate for possible pericardial tamponade, whereas a well-preserved *y* descent argues against this diagnosis.

Constrictive pericarditis and restrictive cardiomyopathy have similar hemodynamic findings. Both disorders may be associated with striking increases in Pra and Ppw due to limitation of cardiac filling. In restrictive cardiomyopathy the Ppw usually is greater than the Pra, whereas in constrictive pericarditis the right and left atria exhibit similar pressures. In contrast to pericardial tamponade, the *y* descent is prominent and often is deeper than the *x* descent. The prominent *y* descent is due to rapid ventricular filling during early dias-

FIGURE 13-21 Tricuspid regurgitation. A broad *v* **(or** *cv***) wave and prominent** *y* **descent are apparent in the right atrial tracing. Note that inspiration leads to accentuation of the** *y* **descent and that mean right atrial pressure increases slightly (Kussmaul's sign).**

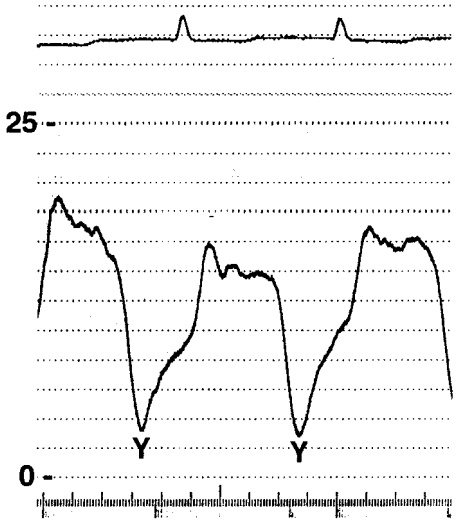
tole, with sharp curtailment of further filling during the later portion of diastole (Fig. 13-24).

DIAGNOSIS AND MANAGEMENT OF PULMONARY EDEMA

The Ppw is used commonly to aid in the differentiation of cardiogenic and noncardiogenic pulmonary edema. For uninjured lungs, the expected Ppw threshold for hydrostatic pulmonary edema is approximately 22 to 25 mm Hg. (A higher threshold is common if the Ppw has been chronically elevated.) When capillary permeability is increased, however, pulmonary edema occurs at a much lower Ppw. Indeed, one generally accepted criterion for ARDS has been a Ppw < 18 mm Hg. It is important to appreciate, however, that an isolated Ppw reading does not reliably predict whether pulmonary edema occurred on the basis of increased capillary pressure (Pcap) alone or on the basis of altered permeability, especially when recorded after a therapeutic intervention. Acute hydrostatic pulmonary edema occurs frequently despite normal intravascular volume on the basis of an acute decrease in LV compliance resulting from ischemia or accelerated hypertension. By the time a PAC is placed, the acute process often has resolved, resulting in a normal or even reduced Ppw, depending in part on what type of therapy (e.g., diuretics or vasodilators) has been given. In this circumstance, maintaining the Ppw ≤ 18 mm Hg over the next 24 hours should lead to marked clinical and roentgenographic improvement if pulmonary edema had been due to elevated Pcap prior to catheter insertion. Conversely, lack of improvement or worsening would suggest altered permeability as the etiology of pulmonary edema. One must be careful, however, when hydrostatic pulmonary edema is due to intermittent elevations in Ppw due to myocardial ischemia. Transient ischemia-related elevations in Ppw may be missed by intermittently recording Ppw (see Fig. 13-19), potentially leading to an erroneous diagnosis of ARDS. Some bedside monitors store pressure data from the previous 12 to 24 hours, and inspection of a graphic display of the stored data may be useful in detecting transient elevations in Ppa that occur during periods of intermittent ischemia. Just as patients with hydostatic pulmonary edema may have a normal Ppw, patients whose pulmonary edema is due primarily to increased permeabililty may have an increased Ppw due to volume expansion.[74] In brief, the pathogenesis of pulmonary edema formation should not be based solely on Ppw, and clarification of the underlying mechanism may require a period of careful clinical and radiologic observation.

Ppw, the pressure in a large pulmonary vein, represents a very low-end estimate of the average pressure across the fluid-permeable vascular bed. Normally, about 40% of the resistance across the pulmonary vascular bed resides in the small veins[75] (Fig. 13-25). When pulmonary arterial and venous resistances are normally distributed, the Gaar equation

FIGURE 13-24 Constrictive pericarditis. Right atrial tracing (obtained in the cardiac catheterization laboratory) reveals a very prominent *y* descent. Lack of a prominent *x* descent may be due to atrial fibrillation. Paper speed is 50 mm/s.



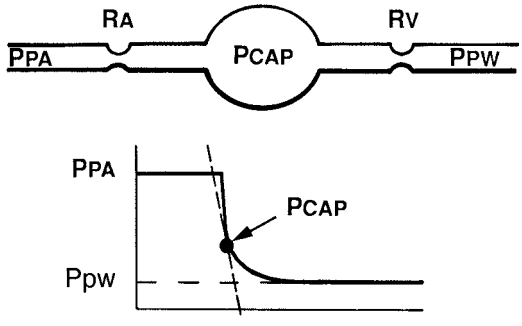


FIGURE 13-25 Pulmonary vascular resistance (PVR) is due to precapillary arteriolar resistance (Ra) and postcapillary venous resistance (Rv). Normally, it is estimated that 60% of total PVR is due to Ra and 40% is due to Rv. The inflection point during decay from the pulmonary artery (mean) to the wedge tracing approximates capillary pressure (Pcap).

predicts Pcap by the formula Pcap = Ppw + 0.4(Ppa − Ppw).[75] Since the driving pressure (Ppa − Ppw) across the vascular bed is normally very low, Pcap will be only a few millimeters of mercury above Ppw. However, a significant pressure drop from Pcap to Ppw could occur under conditions of increased venous resistance, increased $\dot{Q}_T$, or both. For example, the markedly increased venous resistance of pulmonary veno-occlusive disease results in clinical evidence of increased Pcap (e.g., pulmonary edema, Kerley B lines) despite a normal Ppw.[76] Other clinical conditions that selectively increase venous resistance are not well defined.

A number of techniques for determining Pcap have been described.[77–79] The transition from a Ppa to a Ppw waveform after balloon occlusion includes an initial rapid decay and a subsequent slower decay (see Fig. 13-25). In experimental animals, the inflection point between the rapid and slow components has been shown to represent Pcap, as measured by isogravimetric or simultaneous double-occlusion (arterial and venous) techniques.[77] Estimates of Pcap from visual inspection of pressure tracings after balloon occlusion has been used in humans.[78,79] One study concluded that Pcap was on average 7 mm Hg higher than the measured Ppw in patients with ARDS.[78] In this study, the estimated Pcap and the calculated Pcap by the Gaar equation were highly correlated, implying that arterial and venous resistances are increased equally in ARDS.[78] It should be appreciated, however, that it may be difficult to determine Pcap confidently by inspection of the pressure tracing following balloon occlusion.[80] Furthermore, even if an accurate estimate of Pcap can be obtained, it is unclear how this would have any practical advantage over the Ppw in guiding fluid management. The important point is that Ppw is a low-range estimate of Pcap; the true value of the latter lies somewhere between Ppa and Ppw. It follows that increases in the driving pressure across the microvasculature caused by increases in $\dot{Q}_T$ have the potential to exacerbate edema formation.

Downward manipulation of Ppw by diuresis or ultrafiltration will reduce Pcap and may benefit gas exchange markedly in patients with ARDS. There is no minimum value for Ppw below which removal of intravascular volume is contraindicated, provided that $\dot{Q}_T$ is adequate. If the clinical problem is severely impaired gas exchange requiring high $F_{I_{O_2}}$ or high PEEP, then a trial of Ppw reduction is reasonable as long as $\dot{Q}_T$ and blood pressure remain within acceptable limits. As with all therapeutic manipulations, clinically relevant end points (e.g., Pa_{O_2}, blood pressure, and $\dot{Q}_T$) should be assessed before and after Ppw reduction.

ASSESSMENT OF PRELOAD

When afterload and intrinsic contractility are held constant, the forcefulness of ventricular contraction is determined by end-diastolic fiber length (preload).[81] The most commonly used indicators of preload are Ppw and Pra.[82] Indeed, one of the principal reasons for developing the PAC was to have a bedside method of assessing LV preload.[1] In order to assess preload reliably, the Ppw must accurately reflect LVEDP, and LVEDP must correlate well with left ventricular end-diastolic volume (LVEDV). Under most circumstances, the Ppw provides a close approximation of LVEDP. Exceptions include an overestimation of LVEDP by the mean Ppw with mitral stenosis or mitral regurgitation with a very large *v* wave and

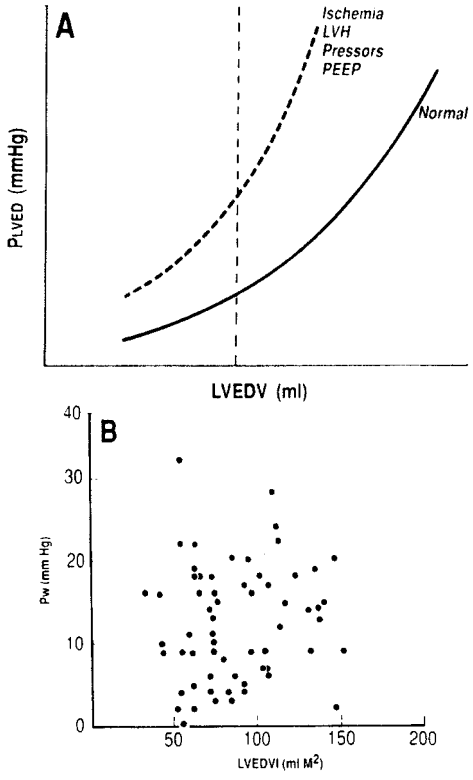

FIGURE 13-26 ***A.*** **Pressure-volume (compliance) relationship of the left ventricle (LV). Ischemia, LV hypertrophy, and high doses of pressors may decrease LV compliance. Positive end-expiratory pressure (PEEP) increases juxtacardiac pressure and may increase ventricular interdependence owing to an increased right ventricular afterload. These factors result in a lower left ventricular end-diastolic volume (LVEDV) at a given left ventricular end-diastolic pressure (PLVED), necessitating a higher PLVED (and thus a higher wedge pressure, Pw) to achieve optimal preload (as compared with normal individuals).** ***B.*** **Simultaneous measurements of LVEDV index (LVEDVI) and Pw in a diverse group of critically ill patients. The poor correlation between LVEDVI and Pw is apparent.** ***(Adapted from Raper and Sibbald, Chest 89:427, 1986.)***

underestimation of LVEDP by the mean Ppw when diastolic dysfunction or hypervolemia causes the LVEDP to increase markedly with atrial systole ("atrial kick").[30] (With a large *v* wave, LVEDP is best estimated by the pressure just before the onset of the *v* wave; with a prominent *a* wave, LVEDP is best estimated by the pressure at the *z point,* just after the peak of the *a* wave.)[81] Unfortunately, even though the mean Ppw is usually equivalent to LVEDP, factors that alter LV compliance (e.g., hypertrophy or ischemia) or change juxtacardiac pressure (e.g., PEEP or active exhalation) may profoundly influence the relationship between LVEDP and LVEDV (Fig. 13-26*A*). It is not surprising, therefore, that among different patients, an equivalent LVEDV may be associated with widely varying Ppw[83] (see Fig. 13-26*B*).

The optimal Ppw (for preload) can be defined as the Ppw above which there is minimal increase in stroke volume. In normal individuals, optimal Ppw is often 10 to 12 mm Hg.[84] During resuscitation from hypovolemic or septic shock, the optimal Ppw is usually ≤14 mm Hg,[85] whereas in acute

myocardial infarction it is often between 14 and 18 mm Hg.[86] However, these target values certainly are not valid in all cases. By measuring stroke volume at different Ppw values, a cardiac function curve can be constructed, thereby defining optimal Ppw for an individual patient. This may be particularly useful in patients who also have established or incipient ARDS because a Ppw above the optimal value will increase the risk of worsening oxygenation without offering any benefit with regard to $\dot{Q}_T$. It should be appreciated, however, that the relationship between Ppw and $\dot{Q}_T$ may change as a consequence of alterations in LV compliance, myocardial contractility, or juxtacardiac pressure and therefore may need to be redefined if clinical status changes.

A clinically relevant test of the utility of the Ppw is its ability to predict the hemodynamic response to a fluid challenge when hypotension, oliguria, or tachycardia leads to uncertainty about the adequacy of preload. Studies that have examined the utility of the Ppw in predicting fluid responsiveness have been reviewed recently.[18] Seven of nine studies found that the Ppw was no different in fluid responders and nonresponders, and analysis by receiver operating characteristic (ROC) curves in two studies indicated that the Ppw was not particularly useful as a predictor of fluid responsiveness.[87,88] One study did find a significant inverse relationship between Ppw and fluid-induced change in stroke volume, but the degree of correlation was only moderate.[89] Although these data suggest a major limitation of the Ppw as an indicator of preload, it is clear that there must be a Ppw above which volume expansion almost always would be futile and a Ppw below which a positive response to fluid virtually is certain. To define these cutoff Ppw values confidently, however, would require a large study in which individual values for Ppw and fluid-induced change in stroke volume are reported for each patient, with a wide range of Ppw values being examined. Individual values for Ppw and fluid-induced change in stroke volume were reported in two studies.[89,90] Although no patient with a Ppw >18 mm Hg had a positive response to fluid and all patients with a Ppw <8 mm Hg were fluid responders, the number of patients within these Ppw domains was too small to draw any firm conclusions about the usefulness of these cutoff values.[89,90] Furthermore, in the great majority of patients who had a Ppw between 8 and 18 mm Hg there was no apparent relationship between Ppw and fluid response. In brief, while the Ppw is used often in clinical practice as an indicator of the adequacy of preload, most of the evidence to date would suggest that it has limited utility in predicting fluid responsiveness, at least over the range of values encountered most often in the ICU.

Overall, the data for Pra were quite similar to those described for the Ppw, in that three of five studies found no difference between the Pra values of responders and nonresponders,[18] and in one of the studies that did find a difference, there was only a modest inverse correlation between Pra and the fluid-induced change in stroke volume.[89] Although there does not appear to be an appreciable difference in the predictive value of the Pra and the Ppw with regard to fluid response for most patients, it might be anticipated that the Pra would be inferior to the Ppw in a population of patients with severe isolated LV dysfunction related to acute myocardial infarction or other causes.[37] Conversely, in patients with severe RV dysfunction and preserved LV function, the Pra may be more relevant than the Ppw.[91]

Although Ppw and Pra are used most widely in guiding fluid therapy in the ICU,[18,82] measurements of cardiac volumes also have been used to predict fluid responsiveness.[89,92–94] A modified PAC with a rapid-response thermistor permits simultaneous measurement of RV ejection fraction (RVEF) and stroke volume, from which RV end-diastolic volume (RVEDV) can be calculated. Several studies have compared the Ppw and RVEDV as predictors of fluid responsiveness.[89,92,93] One study found the RVEDV to be superior to the Ppw and suggested that either a positive or negative response to fluid could be predicted reliably when the RVEDV index was less than 90 or greater than 138 mL/m^2, respectively.[93] However, a subsequent study found that these threshold values for RVEDV index were unreliable and that both the Ppw and Pra predicted the response to fluid better than RVEDV.[89] It is not clear that the RVEDV is any better than the Ppw (or Pra) at predicting fluid responsiveness.

Left ventricular end-diastolic area (LVEDA), measured by transesophageal echocardiography, is another potential indicator of fluid responsiveness. Two studies found that LVEDA was significantly lower in responders than in nonresponders and that LVEDA was superior to Ppw as a predictor of fluid responsiveness.[87,90] However, there was considerable overlap in the LVEDA values between groups, and analysis using ROC curves demonstrated minimal utility of LVEDA in predicting the fluid response of individual patients.[87] Another study found that the Ppw was a better predictor of fluid response than LVEDA during cardiac surgery.[95] In addition, a recent study of patients in septic shock also found the LVEDA to be of minimal value in predicting the response to volume expansion.[96]

In contrast to the static indicators of preload mentioned earlier, methods that rely on the dynamic response to respiratory changes in intrathoracic pressure have performed somewhat better at predicting fluid response. One method is based on the presence or absence of a reduction in Pra during a spontaneous breath.[39] When Pra decreased with inspiration, a positive response to fluid was likely (although not inevitable). Conversely, when a spontaneous breath did not produce a fall in Pra, $\dot{Q}_T$ remained unchanged or decreased after a fluid challenge.[39] In this study, neither the Ppw nor the Pra discriminated responders from nonresponders.[39] A follow-up study confirmed that patients with an inspiratory decrease in Pra had a much greater probability of responding to fluid than did patients whose Pra did not change with inspiration.[97] A second method is based on the change in arterial pressure from inspiration to expiration during controlled positive-pressure ventilation.[88] In a study involving septic patients with circulatory failure, the respiratory variation in arterial pulse pressure was much greater in responders than in nonresponders, and a threshold value was found that discriminated these two groups with a high degree of accuracy.[88] A second study that used a modification of this technique also found the respiratory variation in arterial pressure to predict the response to fluid much better than the Ppw or LVEDA in patients with sepsis.[87] Although more investigations are needed to confirm these studies, methods that rely on the dynamic response to respiratory changes in intrathoracic pressure ultimately may

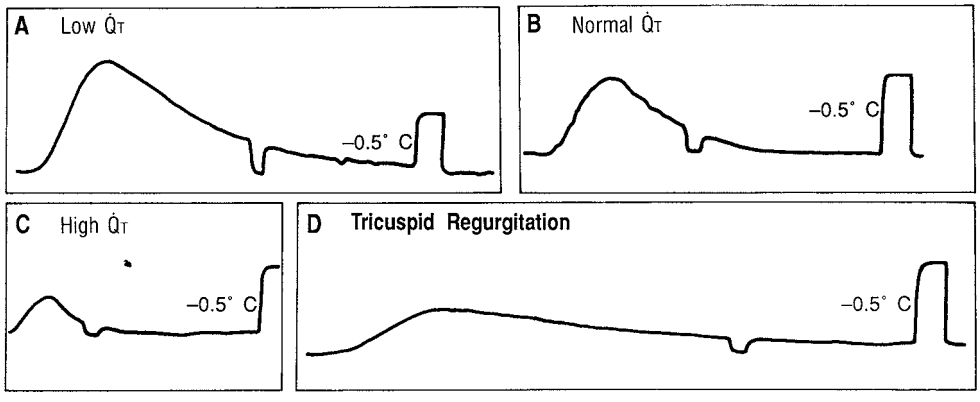
prove to be better indicators of the adequacy of preload than static indicators such as the Ppw, Pra, RVEDV, and LVEDA.[18]

Cardiac Output

PRINCIPLES OF MEASUREMENT

The thermodilution technique for measuring $\dot{Q}_T$ is an indicator-dilution method in which the indicator is thermal depression (cold). Cold fluid is injected through the proximal lumen of the PAC and, after mixing thoroughly in the RV with venous blood returning from the periphery, passes into the pulmonary artery, where a thermistor at the tip of the catheter senses dynamic changes in temperature. The Stewart-Hamilton formula relates $\dot{Q}_T$ to temperature change over time:

$$\dot{Q}T = \frac{V(TB - TI) \times K_1 \times K_2}{\int TB(t)dt}$$



where V is injected volume, TB is blood temperature, *TI* is injectate temperature, $\int TB(t)dt$ is change in blood temperature as a function of time, and K_1 and K_2 are computational constants. The numerator contains known constants or measured values, whereas the denominator is the area beneath the time-temperature curve derived by computer integration of the thermistor signal. Although it would seem that increasing the strength of the signal by cooling the injectate should enhance the accuracy and reproducibility of thermodilution $\dot{Q}_T$ ($\dot{Q}_{Td}$), studies have shown that iced and room-temperature injectates usually are similar in effect as long as careful attention to technique is employed.[98]

Errors may occur if the wrong computational constant is entered into the computer or if either the volume or the recorded temperature of the injectate is incorrect. In addition, the temperature-time curve should be inspected for irregularities. A valid curve shows a rapid early ascent to a peak value and then smoothly returns to the thermal baseline within 10 to 15 seconds of injection (Fig. 13-27). Inadequate blending of injectate with blood, prolonged (>4 s) or uneven injection, thermistor contact with the vessel wall, or abrupt changes in heart rate may result in a grossly irregular curve, and the data should be discarded. The measured $\dot{Q}_{Td}$ may vary significantly depending on the phase of the respiratory cycle at which the injection is begun.[99] Timing of injection may be less important when the respiratory rate is high because the duration of injection will span the entire respiratory cycle. The average of three to five randomly spaced injections probably gives the best overall measure of $\dot{Q}_T$.

Certain conditions can render $\dot{Q}_{Td}$ an unreliable estimate of net systemic $\dot{Q}_T$. Since individual measurements are made over a few cardiac cycles, major irregularities in cardiac rhythm during the period of injection could affect the extent to which $\dot{Q}_{Td}$ reflects average $\dot{Q}_T$ over a longer period. Left-to-right shunts (e.g., atrial septal defect or ventricular septal defect) increase the ratio of pulmonary to systemic $\dot{Q}_T$, causing $\dot{Q}_{Td}$ to seriously overestimate systemic $\dot{Q}_T$. The effect of tricuspid regurgitation on the reliability of $\dot{Q}_{Td}$ is controversial. In two studies, $\dot{Q}_{Td}$ significantly underestimated $\dot{Q}_T$ measured by the Fick method or continuous-flow Doppler in patients with severe tricuspid regurgitation.[100,101] In contrast, other investigators found that tricuspid regurgitation had no discernible impact on the agreement between simultaneous measurements of $\dot{Q}_{Td}$ and Fick-derived $\dot{Q}_T$.[102,103] Given the uncertainty regarding accuracy of $\dot{Q}_{Td}$ in individual patients with significant tricuspid regurgitation, it may be advisable to measure $\dot{Q}_T$ with an alternative method (see below) when significant tricuspid regurgitation is diagnosed by inspection of the Pra tracing (see above), by echocardiography, or by a characteristically attenuated time-temperature thermodilution curve (see Fig. 13-27).

Continuous monitoring of $\dot{Q}_{Td}$ is possible with a modified PAC that contains a 10-cm-long thermal filament that transfers heat directly to the blood using a pseudorandom binary sequence.[104] The amount of heat applied is safe, and the upper limit of temperature attained within the filament is 44°C. Temperature change is detected at the catheter tip and is cross-correlated with the input sequence to produce a thermodilution washout curve. The displayed $\dot{Q}_T$ value is an average of the last 10 separate determinations over the previous 6 to 8 minutes.[104] Several studies have compared measurements of $\dot{Q}_{Td}$ by the continuous and bolus injection methods.[104–106] Reported agreement between methods appears good, with observed differences of little clinical significance. An in vitro study in which flow was controlled found both the bolus

FIGURE 13-27 Thermodilution curves in patients with (*A*) low $\dot{Q}_T$, (*B*) normal $\dot{Q}_T$, (*C*) high $\dot{Q}_T$, and (*D*) tricuspid regurgitation. The notch on each curve represents the end of data processing. The remainder of the curve is extrapolated. *(Used with permission from Sharkey.[34])*

and continuous thermodilution methods to be reliable, but the continuous method was more accurate when flow was very low (<3 L/min).[106] A recent study of patients with a left ventricular assistance device that allowed an independent intravascular measurement of $\dot{Q}_T$ also found the continuous cardiac output to be reasonably accurate.[107] Although the clinical impact of continuous $\dot{Q}_{Ttd}$ monitoring is uncertain, it could have potential utility when $\dot{Q}_T$ is likely to undergo marked fluctuations either spontaneously or in response to therapy. From a practical standpoint, it may be more convenient to use the continuous thermodilution method when frequent assessments of $\dot{Q}_T$ are desired during titration of inotropic or vasodilator agents or with incremental application of PEEP.

ALTERNATIVE METHODS OF MEASURING $\dot{Q}_T$

Several noninvasive or minimally invasive alternatives to the thermodilution technique for measuring $\dot{Q}_T$ have been introduced to clinical practice recently. These methods include pulse contour analysis of the arterial pressure waveform, esophageal Doppler analysis of aortic blood flow, thoracic electrical bioimpedance, the indirect Fick method employing partial carbon dioxide rebreathing, and a transpulmonary thermodilution technique.[17] Because all methods have limitations, there is no "gold standard" for measuring $\dot{Q}_T$. However, for logistic reasons, assessment of these less invasive methods generally has been done by comparison with the PAC-based bolus thermodilution technique as the reference technique. The partial CO_2 rebreathing technique, a method applicable to intubated patients, is entirely noninvasive and has shown good agreement with the bolus thermodilution method in some studies. However, although the issue currently remains unsettled, there has been some concern regarding accuracy of this technique in the setting of severe lung injury (where CO_2 shunting occurs) or when there is variability in tidal volume due to spontaneous breaths, potentially limiting its general applicability in the ICU.[17,108] Esophageal Doppler measurements of $\dot{Q}_T$ generally have shown good concordance with those obtained by bolus thermodilution, including investigations performed in critically ill patients with sepsis.[109,110] To achieve reliable results with this method, it is important that nurses who perform the procedure receive sufficient training to achieve proficiency.[111] Thoracic electrical bioimpedance has been evaluated in numerous studies. A meta-analysis of over 150 studies concluded that while it may be useful for trend analysis, this method is probably not reliable enough for diagnostic purposes.[112] Bioimpedance methodology may be less accurate when there is significant pulmonary or peripheral edema or in the setting of large pleural effusions, possibly limiting its utility in the ICU.[17] A recent study suggested that advances in technology have made the current systems more reliable than earlier versions.[113] In contrast to the standard bolus thermodilution technique using a PAC, which measures right-sided $\dot{Q}_T$, the transpulmonary thermodilution technique measures left-sided $\dot{Q}_T$ by injection of a cold injectate intravenously and detection of the change in temperature in the arterial system.[17,114,115] The agreement between these two methods has been reasonably good, with the transpulmonary technique values being somewhat higher, possibly due to loss of indicator (cold) in the lung.[17] Pulse contour analysis of the arterial pressure waveform to measure stroke volume was developed 20 years ago.[17] Most studies comparing the pulse contour and bolus thermodilution methods of measuring $\dot{Q}_T$ have shown excellent correlation.[17,116] The standard pulse contour device must be calibrated with a $\dot{Q}_T$ value measured independently, such as by the transpulmonary thrermodilution technique. An alternative method of calibration is an indicator dilution technique in which lithium chloride is the indicator.[117] The lithium pulse contour method has been shown to correlate very well with the bolus thermodilution technique, and in one study the coefficient of variation for multiple measurements was significantly less for the former method.[118]

CLINICAL USE OF $\dot{Q}_{Ttd}$

Combining $\dot{Q}_{Ttd}$ with measurement of systemic and pulmonary pressures allows calculation of vascular resistances: systemic vascular resistance (SVR) = (Pa − Pra)/$\dot{Q}_T$ and pulmonary vascular resistance (PVR) = (Ppa − Ppw)/$\dot{Q}_T$. To assess the appropriateness of $\dot{Q}_T$ to body mass, $\dot{Q}_{Ttd}$ is divided by body surface area (BSA) to calculate cardiac index. Unlike flow ($\dot{Q}_T$), pulmonary and systemic pressures are not dependent on body size. Therefore, to avoid misinterpretation due to variation in body mass, it is also appropriate to compute indices of systemic and pulmonary vascular resistance by using cardiac index rather than $\dot{Q}_T$ in the resistance calculations.

Assessment of $\dot{Q}_{Ttd}$ and SVR may be particularly helpful in the assessment of hypotension, oliguria, and unexplained lactic acidosis. Measurement of $\dot{Q}_{Ttd}$ is of particular value in the management of septic shock and ARDS. Septic hypotension often is due primarily to excessive arterial vasodilation, but decreased venous return and myocardial dysfunction may contribute to the hemodynamic derangement. By assessing the relative contribution of $\dot{Q}_T$ and SVR to systemic hypotension, the clinician may be able to apply fluid, vasopressor, and inotropic therapy more rationally. In ARDS, a fall in blood pressure could result from hypovolemia, LV dysfunction, pneumothorax, pulmonary emboli, increasing PVR from ARDS, a change in applied PEEP, or dynamic hyperinflation, all of which produce hypotension through a decrease in $\dot{Q}_T$. Evaluation would consist of measurement of intravascular and airway pressures, perhaps along with obtaining a chest x-ray, electrocardiogram, or echocardiogram. On the other hand, these conditions would be of little concern if it were known that $\dot{Q}_T$ remained unchanged, indicating that the fall in blood pressure was due entirely to a reduction in SVR.

Sepsis is the most common cause of hypotension with a low SVR, but other conditions may produce a similar hemodynamic profile. Severe hypotension resulting from excessive arterial vasodilation can occur as a result of acute adrenal insufficiency, thiamine deficiency (beriberi), severe pancreatitis, or poisoning with a variety of drugs or toxins (e.g., nitrates, calcium channel blockers, aspirin, and tricyclic antidepressants). Systemic arteriovenous fistulas, as occur with cirrhosis, also lead to a high $\dot{Q}_T$–low SVR hemodynamic profile, albeit usually with normal blood pressure. Failure to include noninfectious processes in the differential diagnosis of a high $\dot{Q}_T$–low SVR state may result in misdiagnosis of life-threatening, treatable conditions.[119]

The hemodynamic response to a fluid challenge, inotropes, vasodilators, or alterations in PEEP is often assessed in part by measuring changes in $\dot{Q}_{Ttd}$. Critically ill patients may undergo significant spontaneous fluctuations in tissue O_2 de-

mand and $\dot{Q}_T$ throughout the day. Therefore, determinations of $\dot{Q}_{Ttd}$ ideally should be made immediately before and after a specific intervention. Even when assessment is optimal, the normal variability in measured $\dot{Q}_{Ttd}$ may confound the response to an intervention. A study involving hemodynamically stable patients found that measured $\dot{Q}_{Ttd}$ varied by an average of 7.7% over a period of 1 hour.[120] Therefore, the clinician must observe a change in measured $\dot{Q}_{Ttd}$ of at least 10% to 15% before concluding that the observed response was actually due to a specific intervention.[120,121]

Mixed Venous Oxygen Saturation

Mixed venous oxygen saturation (Sv_{O_2}) is the O_2 saturation of blood in the pulmonary artery after the venous effluent from various organs has been mixed thoroughly in the RV. The Sv_{O_2} can be measured intermittently by slowly withdrawing a sample of blood from the distal port of the unwedged PAC or continuously with a fiberoptic PAC that measures O_2 saturation by reflectance oximetry.[122] Intermittent sampling of Sv_{O_2} is accomplished by discarding the initial 3 mL of blood and then withdrawing a sample very slowly so as to avoid contamination with capillary blood. The Sv_{O_2} should be measured by co-oximetry because the steep slope of the O_2 dissociation curve in the venous range means that small errors in measurement of Pv_{O_2} may result in substantial errors in calculation of Sv_{O_2}.

Ordinarily, the O_2 saturation is lower in the superior vena cava than in the inferior vena cava, but the reverse is true in shock due to redistribution of blood flow away from splanchnic, renal, and mesenteric beds.[123,124] Thus the oxygen saturation of blood obtained from a central venous catheter in the superior vena cava (Scv_{O_2}) will overestimate Sv_{O_2} in shock. Although the absolute values of Sv_{O_2} and Scv_{O_2} may differ, they tend to track together with changing hemodynamic conditions.[124] Furthermore, it has been argued that a low Scv_{O_2} in the setting of shock may be clinically relevant because it implies an even lower Sv_{O_2}.[124]

Oxygen delivery is the product of $\dot{Q}_T$ and arterial O_2 content, the latter being determined by the hemoglobin and arterial O_2 saturation (Sa_{O_2}). The body's O_2 consumption (V_{O_2}) is determined by the underlying metabolic activity of tissues and normally is independent of O_2 delivery.[125] Thus, as O_2 delivery falls, so too will Sv_{O_2} (Fig. 13-28). Therefore, measurement of Sv_{O_2} helps to assess the adequacy of O_2 delivery in relationship to tissue O_2 requirements. Under normal conditions, the $Sa_{O_2} - Sv_{O_2}$ difference is 20% to 25%, yielding an Sv_{O_2} of 65% to 75% when arterial blood is well oxygenated. An Sv_{O_2} in the normal range may be associated with very different levels of $\dot{Q}_T$ depending on underlying aerobic metabolism. For example, a "low" $\dot{Q}_T$ of 3 L/min may be entirely appropriate if metabolic activity is reduced, in which case the Sv_{O_2} would be normal. However, the same $\dot{Q}_T$ in association with a decrease in Sv_{O_2} would suggest inadequacy of either intravascular volume or cardiac function. Similarly, a low Sv_{O_2} despite a normal (or increased) $\dot{Q}_T$ indicates that the latter is inadequate to meet increased metabolic demands for O_2. In essence, the Sv_{O_2} helps to define the appropriateness of measured $\dot{Q}_T$.

Increased Sv_{O_2} may be seen in a variety of conditions. In sepsis, Sv_{O_2} is often normal, but in some cases there is extreme

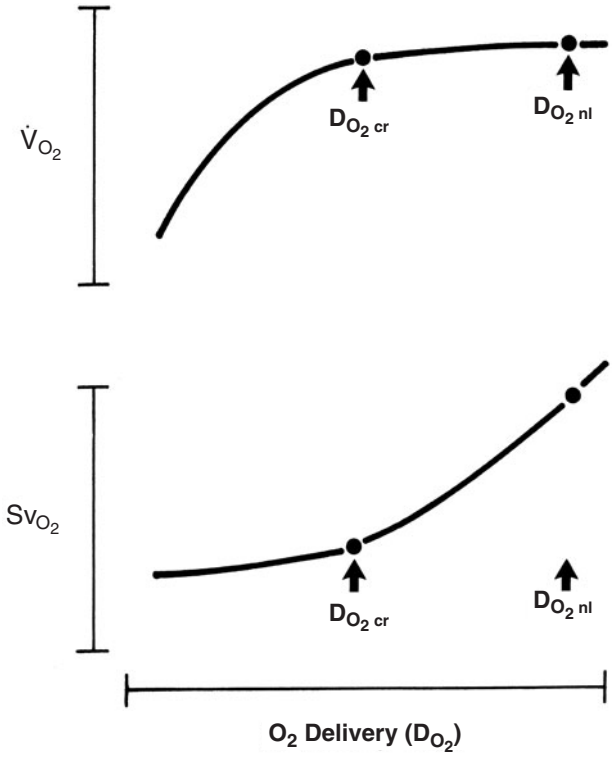


FIGURE 13-28 (*Upper panel*) Relationship between oxygen delivery (D_{O_2}) and oxygen consumption ($\dot{V}_{O_2}$). (*Lower panel*) Relationship between D_{O_2} and mixed venous O_2 saturation (Sv_{O_2}). Normally, $\dot{V}_{O_2}$ is independent of D_{O_2} until D_{O_2} falls to a critical value (D_{O_2cr}), at which point further reductions in D_{O_2} lead to reduced $\dot{V}_{O_2}$. Above D_{O_2cr}, the Sv_{O_2} and D_{O_2} are linearly related, but below D_{O_2cr}, the Sv_{O_2} does not change markedly as D_{O_2} falls (as long as Sa_{O_2} does not change).

peripheral vasodilation, and $\dot{Q}_T$ increases disproportionately to metabolic demands, resulting in an increase in Sv_{O_2}. Cirrhosis is one of the more common causes of a markedly increased Sv_{O_2}, with values occasionally in excess of 85%. A number of vasodilating agents and left-to-right cardiac shunts also result in an increase in Sv_{O_2}. Lastly, agents that interfere with mitochondial cytochrome activity (e.g., cyanide) may produce striking elevations in Sv_{O_2} owing to the inability of tissues to use O_2.

Continuous measurement of Sv_{O_2} with a fiberoptic PAC has been advocated as a useful technique for early detection of inadequate $\dot{Q}_T$ relative to tissue O_2 demand. If hemoglobin and Sa_{O_2} remain unchanged, then a reduction in Sv_{O_2} would predict either a primary reduction in $\dot{Q}_T$ or a rise in tissue O_2 requirement that is unmet by a compensatory increase in $\dot{Q}_T$. Theoretically, continuous Sv_{O_2} monitoring could lead to more rapid detection of hemodynamic instability than simple monitoring of blood pressure and heart rate, but it is unclear whether it has a significant impact on patient care.[126–128] Perhaps the most rational use of the fiberoptic PAC is in the management of patients with cardiac dysfunction, in whom rapid changes in $\dot{Q}_T$ may be expected to occur on the basis of the underlying disease process or in response to pharmacologic interventions. This would be particularly true when measurement of $\dot{Q}_{Ttd}$ has been documented to be erroneous in the setting of significant tricuspid regurgitation or as a re-

sult of markedly variable heart rhythm. In the latter circumstances, Sv_{O_2} assumes primary importance as an indicator of $\dot{Q}_T$, and continuous monitoring might prove more convenient than intermittent sampling from the catheter's distal lumen.

CLINICAL USE OF Sv_{O_2}

Use of the Sv_{O_2} may be a pivotal indicator of the adequacy of hemodynamic support. A low Sv_{O_2} in the absence of severe hypoxemia often indicates a deficiency of oxygen delivery relative to tissue O_2 needs and the need for augmentation of $\dot{Q}_T$ with volume loading or inotropic support or with red blood cell transfusion if anemia is present.[129] In contrast, a normal or high Sv_{O_2} does not necessarily indicate adequacy of oxygen delivery (as in sepsis), but the need to further augment $\dot{Q}_T$ in this setting is controversial.[129] A number of studies have evaluated the use of Sv_{O_2} in critical illness, but few have addressed important end points such as mortality or major morbidity. One randomized study reported decreased morbidity after cardiac surgery when therapy was targeted to achieve an Sv_{O_2} greater than 70% and a lactate level of less than 2 mg/dL.[130] In contrast, another study involving a more heterogeneous group of critically ill patients in the ICU found no clear benefit to goal-directed hemodynamic therapy based on the Sv_{O_2}.[131] However, it has been argued that the potential benefits of Sv_{O_2}-based hemodynamic resuscitation may be greater during the *early* management of critically ill patients.[124] While placement of a PAC to measure Sv_{O_2} is impractical during initial resuscitation, a recent study evaluated the use of vena caval O_2 saturation (Scv_{O_2}) obtained from central venous catheters placed in the emergency department in the early management of patients with severe sepsis.[132] Patients whose resuscitation was targeted to achieve an Scv_{O_2} of greater than 70% had significantly lower mortality than those randomized to conventional therapy based on mean arterial pressure and central venous pressure.[132]

Miscellaneous Diagnostic Applications of the PAC

Although the PAC is used primarily to aid in the management of fluids and vasoactive drug therapy during critical illness, it has additional applications that may be useful occasionally. These include microvascular cytology,[133] evaluation of arrhythmias,[34] detection of intracardiac shunts,[34] and determination of caloric requirements.[134,135]

Microvascular cytology of blood drawn through the distal port of the wedged PAC has been used to diagnose lymphangitic carcinoma.[133] It is unlikely that this technique will replace transbronchial biopsy as the initial diagnostic approach for this condition. However, very breathless patients with suspected lymphangitic carcinoma may tolerate insertion of a PAC better than bronchoscopy, and those with bleeding tendencies cannot undergo transbronchial biopsy safely.

Narrow-complex, regular tachyarrhythmias at a rate of 140 to 180 beats per minute are common in the ICU. It is sometimes difficult to differentiate atrial flutter from sinus tachycardia and paroxysmal supraventricular tachycardia, even with the aid of a 12-lead electrocardiogram. Although the response to adenosine is often the best way to define the underlying atrial rhythm, in some cases atrial flutter also may be diagnosed by

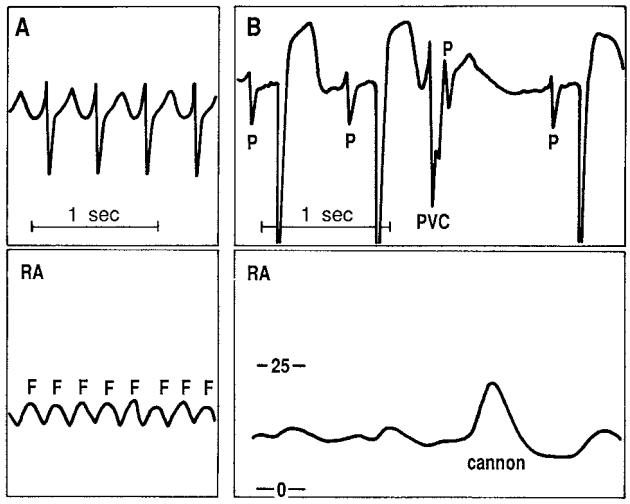

FIGURE 13-29 ***A.*** **Surface electrocardiogram indicates a narrow-complex tachycardia (*top*) of uncertain nature. Simultaneous right atrial (RA) pressure tracing (*bottom*) shows mechanical flutter waves (*F*) at a rate exactly twice that of the ventricular response, indicating atrial flutter with a 2:1 block.** ***B.*** **Premature wide complex (PVC) beat (*top*) is defined as ventricular in origin by the presence of a cannon *a* wave in a simultaneous RA pressure tracing.** ***(Used with permission from Sharkey.[34])***

inspection of the Pra tracing[34] (Fig. 13-29*A*). The Pra tracing also may be of value in defining wide-complex premature beats as ventricular in origin if clear-cut cannon *a* waves are seen[34] (see Fig. 13-29*B*).

Intracardiac left-to-right shunts can occur between atria or ventricles. One of the more serious complications of myocardial infarction is acute perforation of the ventricular septum. Postinfarction ventricular septal defect is not diagnosed reliably by clinical examination. A ventricular septal defect is associated with a step-up in O_2 saturation from the right atrium to the pulmonary artery. In addition, the patient may be in shock despite a normal (or elevated) $\dot{Q}_{T_{td}}$ because the latter measures right-sided rather than systemic flow. Both a ventricular septal defect and acute mitral regurgitation may present as postinfarction pulmonary edema with a new systolic murmur. A step-up in O_2 saturation from the right atrium to the pulmonary artery occasionally occurs in acute mitral regurgitation due to reflux of pulmonary venous blood into the pulmonary artery, and a ventricular septal defect occasionally produces a large *v* wave.[34] Differentiation of ventricular septal defect from acute mitral regurgitation by pressure waveform and O_2 saturation criteria could prove difficult, but Doppler echocardiography should clarify the diagnosis.

Fick-derived measurement of the volume of oxygen consumed (V_{O_2}) may be used to help guide nutritional support. Caloric needs are a function of overall metabolic activity, which in turn can be assessed by measuring V_{O_2}. Resting energy expenditure (REE) is the caloric intake required to meet ongoing metabolic demands. The Fick-derived estimate of REE is as follows: REE (kcal/d) = $V_{O_2} \times 7.0$, or REE = $\dot{Q}_T \times Hb \times (Sa_{O_2} - Sv_{O_2}) \times 95$.[134] Prediction of REE by the Fick method, using PAC-derived data while assuming a respiratory quotient of 0.85, has been shown to correlate reasonably well with measurement of REE by indirect calorimetry.[135] While placement of a PAC solely for the purpose of assessing

caloric needs would be inappropriate, it may be reasonable to use the available data to help guide nutritional support when a catheter is already in place.

Chapter 14

PAIN CONTROL, SEDATION, AND USE OF MUSCLE RELAXANTS

BRIAN GEHLBACH
JOHN P. KRESS

KEY POINTS

- *Sedatives and analgesics used commonly in the care of critically ill patients often exhibit pharmacokinetics and pharmacodynamics that are significantly different when compared with studies of their use in other arenas, such as the operating room. Knowledge of these differences is crucial to designing a sedation protocol for the critically ill patient.*
- *While the administration of sedatives and analgesics to the critically ill patient is indicated for a variety of conditions ranging from relief of suffering to facilitation of lung protective strategies of mechanical ventilation, continued reassessment of the need for and means of providing sedation is necessary to prevent the prolongation of mechanical ventilation.*
- *Intravascular catheters, endotracheal intubation, suctioning, immobility, and underlying illnesses all may cause pain in the critically ill patient. While physical remedies always should be tried—e.g., repositioning a patient to alleviate arthritic pain—most patients require intravenous narcotics at least initially. Thus adequate sedation begins with adequate analgesia.*
- *Regional pain control techniques, such as with epidural catheter–administered anesthetics or opiates, can be highly effective at achieving pain control in the postoperative patient. The placement and removal of such catheters require correction of any underlying coagulation abnormalities in order to reduce the risk of epidural hematoma.*
- *The evaluation of sedation adequacy can only be performed at the bedside and is facilitated by the use of a validated sedation scale, such as the Richmond Agitation-Sedation Scale, along with a protocol for the systematic assessment and administration of sedatives and analgesics.*
- *Although both continuous and intermittent bolus strategies for sedative administration have been advocated, the two strategies have not been compared directly in a large, randomized, controlled trial. Regardless of the approach used, most patients require larger doses of sedatives—sometimes in excess of drug manufacturer guidelines—in the initial 48 hours than subsequently. Thus the level of sedation must be reassessed continuously and a protocol for downward titration of sedation applied.*
- *If continuous administration is used, daily sedative interruption is recommended to prevent drug accumulation, allow the performance of a neurologic examination, and permit reassessment of the need for sedation. If resedation is required, restarting the infusion at half the previous dose, with subsequent titration as necessary, is a useful strategy for systematic downward titration.*
- *Prolonged (>24 h) neuromuscular blockade should be used as a last resort owing to the high incidence of neuromuscular complications associated with this practice in critically ill patients. In particular, the administration of these agents in combination with high-dose corticosteroids is discouraged.*

Administration of analgesics and sedatives is commonplace in the ICU. Unfortunately, many early studies of analgesic and sedative medications were performed in the operating room, a setting very different from the ICU. The clinician must recognize the diverse and often unpredictable effects of critical illness on the pharmacokinetics and pharmacodynamics of sedatives and analgesics. Failure to recognize these effects may lead to inadequate or excessive sedation. Sedatives and analgesics may cause prolonged alterations in mental status and may mask the development of coincident complications of critical illness. Data studying the effects of analgesia and sedation in the ICU have accumulated in the last decade and have had important influences on this aspect of critical care. As outcomes data have become available, analgesia and sedation practices driven by protocol guidelines have emerged.

Indications for Sedation and Analgesia

Analgesia and sedation needs vary widely in ICU patients. Although nonpharmacologic means such as comfortable positioning in bed and verbal reassurance should be considered initially, treatment with analgesic and sedative agents frequently is needed. An effective approach to the use of analgesics and sedatives in critically ill patients begins with an understanding of the various indications for their use in this setting. Effective *analgesia* is extremely important and is discussed in detail in a later section of this chapter. *Dyspnea* is common in ICU patients and may be a source of distress. Excessive coughing may contribute to patient-ventilator dyssynchrony. Opiates may alleviate dyspnea and coughing, particularly in intubated patients. *Excessive oxygen consumption* (V_{O_2}) and related *carbon dioxide production* (V_{CO_2}) may be detrimental in patients with respiratory failure or shock, and restoration of the delicate balance of oxygen delivery and consumption is important in the management of these patients. Oxygen consumption in intubated patients who are agitated can be reduced by 15% after administration of sedatives and opiates.[1] For those with shock or severe hypoxemic respiratory failure, this reduction in oxygen consumption may be important for cardiopulmonary stability. The importance of *amnesia* during critical illness is not well understood. Although it may seem intuitive that amnesia for the period of critical illness is desirable, data supporting this notion are lacking. Certainly it seems logical that amnesia for short periods (e.g., during unpleasant interventions such as bronchoscopy) may be desirable; however, there are some data suggesting that complete amnesia for prolonged periods (e.g., for the entire period of mechanical ventilation) may be detrimental.[2–4] As discussed later, it is certain that complete amnesia is mandatory during the administration of neuromuscular blocking agents. *Delirium*—an acutely changing or fluctuating mental status, inattention, disorganized thinking, and an altered level of consciousness that may or may not be accompanied by agitation—is common in ICU patients.[5] Some patients may manifest an aggressive type of delirious

Copyright © 2005, 1998, 1992 by The McGraw-Hill Companies, Inc. Click here for terms of use.

behavior. This delirium may occur as a result of medications, sepsis, fevers, encephalopathy (e.g., hepatic or renal), paranoia, or withdrawal syndromes (alcohol, tobacco, or illicit drugs). Agitated delirium often responds well to neuroleptic medications such as haloperidol.[6] More commonly, ICU patients exhibit a hypoactive, quiet form of delirium. There is no currently established pharmacologic therapy for hypoactive delirium, although sedative medications are likely to exacerbate rather than alleviate the problem.

Analgesia

It is undeniable that pain is a common experience for most ICU patients.[7–9] Failure to recognize that pain frequently leads to agitation may lead to inappropriate administration of nonanalgesic sedatives. Accordingly, an aggressive approach to managing pain has been strongly recommended by published consensus opinions regarding sedation in the ICU.[6,10] Addressing analgesic needs frequently poses a challenge to the critical care clinician. The ability to discern pain accurately may be difficult because many clinical parameters such as changes in vital signs are sensitive but not specific indicators. There are numerous reasons for pain in the ICU patient. While causes such as surgical incisions or trauma may be obvious, other causes such as endotracheal suctioning or invasive catheters may be less apparent. Other causes of pain include pain from preexisting diseases (e.g., vertebral compression fractures from multiple myeloma), endotracheal tubes, and prolonged immobility during bed rest.[7,11]

Pain may result in many adverse effects, including increased endogenous catecholamine activity, myocardial ischemia, hypercoagulability, hypermetabolic states, sleep deprivation, anxiety, and delirium.[12] Adequate analgesia may diminish some of these detrimental effects.[13]

It is sobering to note that pain is treated inadequately in many different medical care settings,[14] including the critical care unit.[15,16] Ineffective communication with patients is sometimes at the root of this problem because delirium in the ICU is a common occurrence.[5] Concern over addiction to opiates,[17] adverse cardiopulmonary effects of analgesics, and arbitrary limits placed on drug doses may be other reasons for inadequate analgesia in the ICU.

Certainly, the assessment of pain in critically ill patients can be challenging. As mentioned earlier, even the recognition of pain in these patients may be impaired by communication problems because many are intubated and/or delirious. Tools to categorize pain, such as scales or scoring systems, may be beneficial. In general, simpler scales are more effective because communication for many ICU patients is limited. The Visual Analogue Scale (VAS) has been found to have very good reliability and validity,[18,19] although it has not been evaluated specifically in critically ill patients. This scale is a self-report measure of pain intensity that typically consists of a 10-cm line on paper with verbal anchors ("no pain" and "severe pain") on the ends. A similar scale is the Numeric Rating Scale. This scale also consists of a horizontal line with numeric markings 1 and 10 anchoring either extreme of the pain intensity scale.[20,21] It may be preferred because it can be completed by writing, speaking, or hand gestures and may be better across various age groups.[6]

Previous studies have shown that benzodiazepines may enhance the analgesic effects of opiates[22,23] and that opiate requirements are decreased in patients sedated with benzodiazepines rather than propofol.[1,24] Notwithstanding this interesting observation, it is imperative that sedative agents are not used in the place of analgesics.

Although nonpharmacologic analgesic strategies are worth considering, they are frequently ineffective in dealing with pain in ICU patients. Nevertheless, malpositioning of invasive catheters (e.g., endotracheal tube impinging on the main carina) is a problem that may be remedied easily. Likewise, optimal patient positioning in bed may relieve at least in part low back pain, pain from chest tubes, etc. Despite appropriate attention to nonpharmacologic approaches, most patients require administration of some pharmacologic agents, with opiates being the mainstay of therapy. Strategies for administration include continuous infusions and intermittent dosing strategies. Among the intermittent dosing strategies are scheduled intermittent opiate administration, administration on an "as needed" or prn basis, and patient-controlled analgesic (PCA) strategies. Strategies given "as needed" are discouraged because of fluctuations between inadequate and excessive analgesia that are seen frequently. Intravenous rather than intramuscular injection is the preferred route of administration because intramuscular injections themselves may be painful, and absorption of a drug given intramuscularly is frequently sporadic in critically ill patients. Patients alert enough to respond to their own pain needs may benefit from PCA strategies. Transdermal opiates may be continued in patients who are chronically receiving such medications; however, absorption is often unreliable during critical illness. Therefore, this route should not be used for treating acute pain in the ICU; conversion to transdermal medications toward the end of a bout of critical illness is sometimes a reasonable approach. Clearly, intravenous injection remains the preferred route.

Opiate withdrawal can be seen in patients receiving opiates for extended periods when the drugs are discontinued suddenly. Patients who abuse opiates are at risk for this when hospitalized during critical illness. The signs and symptoms seen in withdrawal are mostly nonspecific and include pupillary dilation, sweating, lacrimation, rhinorrhea, piloerection, tachycardia, vomiting, diarrhea, hypertension, yawning, fever, tachypnea, restlessness, irritability, increased sensitivity to pain, nausea, cramps, muscle aches, dysphoria, insomnia, symptoms of opioid craving, and anxiety.[25] The lack of specificity for many of these signs and symptoms may make it difficult to establish a diagnosis of opiate withdrawal in critically ill patients. Patients without previous illicit drug use also may experience opiate withdrawal when pharmacologically administered opiates given for extended periods are stopped suddenly. Whether downward titration of opiate doses or regular interruption of opiate administration can prevent this is not known. One study of trauma/surgical ICU patients reported a 32% incidence of withdrawal in patients receiving opiates and/or sedatives who were in the ICU for more than 1 week.[25] Those manifesting withdrawal received higher opiate and benzodiazepine drug doses than their counterparts who did not experience withdrawal. The role of long-acting opiates such as methadone to overcome this problem has not been studied.

REGIONAL TECHNIQUES FOR ANALGESIA

EPIDURAL ANALGESIA

Regional analgesic techniques may be effective strategies, particularly for postoperative analgesia. Epidural administration of pharmacologic agents is an alternative approach to systemic administration. Local anesthetics may be used to block sensory nerve transmission. Autonomic nerves are more sensitive to local anesthetics than sensory nerves. Therefore, loss of sympathetic vascular tone is common with epidural local anesthetics. Motor nerves are most resistant to epidural local anesthetics.

Ideally, an epidural catheter is placed at the spinal level that is at the same level as the pain source. For example, thoracic epidural catheters frequently are used for patients undergoing thoracic surgical procedures to optimize the ability to cough and deep breathe after surgery. Although any local anesthetic may be used, bupivacaine is the most commonly used drug because of its long duration of action and preferential blockade of sensory over motor neurons. A relatively dilute, high-volume concentration of local anesthetic is preferred (e.g., bupivacaine 0.125% to 0.25%) because of spread over a wider dermatomal distribution. However, recent studies have reported that high-concentration, low-volume dosing regimens may produce similar analgesia and patient satisfaction but less profound motor block and improved hemodynamic stability.[26] Continuous infusions of local anesthetic are typically used, which may provide effective analgesia for days.

Side Effects

Although central neuroaxial blockade is an extremely effective analgesic technique, side effects such as hypotension may limit its use in critically ill patients. Inevitably, there is some sympathetic blockade with administration of local anesthetics for central neuroaxial block. The resulting venodilation and increase in venous capacitance produces a relative hypovolemia. Accordingly, patients are routinely given crystalloid prior to administration of epidural (or spinal) local anesthetics. Obviously, patients with hemodynamic instability (e.g., septic or hemorrhagic shock) may not tolerate decreases in sympathetic tone. Sympathetic blockade at a high level may block outflow from the so-called cardiac accelerator fibers at the T1–T4 levels. The resulting bradycardia may further compromise hemodynamic stability. Drugs for treating hemodynamic instability after central neuroaxial blockade include ephedrine (alpha and beta agonist, 5 to 10 mg), epinephrine (10 to 100 μg), and atropine (0.4 mg). Genitourinary blockade (parasympathetic S2–S4) with resulting urinary retention is problematic occasionally in patients without bladder catheters.

Complications

Epidural hematoma formation is a rare but potentially devastating complication of central neuroaxial blockade. Although exact cutoff values precluding this approach in patients with coagulation disturbances are not known, platelet counts less than 50,000/μL or international normalized ratios above 2 generally are considered absolute contraindications. There is controversy regarding lesser degrees of coagulation abnormalities because of the lack of outcomes data; however, a conservative approach—where a normal coagulation state is required—is typically adhered to by most clinicians. The use of prophylactic heparin has been linked to epidural or spinal hematoma formation.[27] Such case reports have led to recommendations that when prophylactic or low-molecular weight heparin (LMWH) is used perioperatively, neuroaxial block should be delayed for 10 to 12 hours after the last dose.[28] Indeed, most recommend leaving existing epidural catheters in place in patients with coagulation abnormalities until these problems are corrected. In 1997, the Food and Drug Administration (FDA) issued a public health advisory regarding reports of epidural or spinal hematomas with the concurrent use of LMWH and spinal-epidural anesthesia or lumbar puncture.[29] Fortunately, the incidence of complications from epidural anesthesia is extremely low. A study of over 4000 patients scheduled for abdominal or abdominothoracic surgery reported a predicted maximum risk for permanent neurologic complications from epidural placement of 0.07%.[30] An epidural hematoma may be difficult to detect in a critically ill patient. New motor deficits and back pain are the most common early signs. Ideally, an awake, interactive patient is preferred so that serial neurologic examinations can be performed, facilitating early detection.

Epidural catheter infection is another rare complication. Avoiding placement of catheters through inflamed or infected skin is mandatory and certainly will reduce this complication risk. Careful, frequent assessments of skin entry sites and catheter dressings are an important part of the care of these catheters. Some clinicians advise against placement of these catheters in patients with bacteremia or sepsis, although there is some controversy surrounding this recommendation owing to a paucity of outcomes data. Exact guidelines for the use of epidural analgesia in critical illness have not been established. Indeed, it is clear that there is wide practice variation regarding the use of this technique in critically ill patients.[31]

NEUROAXIAL OPIATE ANALGESIA

Opiates also are used frequently for neuroaxial analgesia. The presence of opiate receptors in the spinal cord was noted over 25 years ago,[32,33] and spinal opiate-mediated analgesia is currently a mainstay of regional anesthesia. Opiate receptors found on the dorsal region of the spinal cord (substantia gelatinosa) mediate analgesia. Analgesia is profound and prolonged with water-soluble opiates such as morphine. Lipid-soluble opiates such as fentanyl have a more rapid onset than morphine but a shorter duration. A single dose of epidural fentanyl may last 2 to 4 hours, whereas a single dose of epidural morphine typically lasts 16 to 24 hours. Accordingly, fentanyl usually is given by continuous infusion through epidural catheters. Neuroaxial opiates also can be given by intrathecal routes. Much smaller doses are needed when opiates are given intrathecally—typically 10 percent of the epidural dose is adequate. Opiates given by neuroaxial routes produce effective analgesia with less alteration in mental status than systemic opiates. The analgesia tends to be distributed dermatomally in the region of the spinal cord where the drug is administered when lipid-soluble drugs such as fentanyl are used. On the other hand, water-soluble drugs such as morphine tend to move rostrally regardless of the

spinal cord level of injection. Importantly, when lipid-soluble neuroaxial opiates are used, the injection site must be at the same level as the pain source (e.g., thoracic epidural after thoracic surgery). There is controversy over the benefits of epidural versus intravenous fentanyl analgesia. Some studies have reported similar outcomes when these two strategies are compared,[34] whereas others have reported more effective analgesia with thoracic epidural fentanyl.[35,36] In thoracic surgery patients, epidural fentanyl has been associated with better preservation of respiratory function compared with intravenous fentanyl. These salutary effects may be related to the catheter being located near the source of pain.

Sedation

While pain is certainly a cause for anxiety in most ICU patients, many patients suffer from anxiety despite adequate analgesia. It is obvious that a state of critical illness and dependence on others for care can invoke anxiety. Accordingly, sedation strategies must recognize and respond to this problem.

ASSESSING ADEQUACY OF SEDATION

Assessing adequacy of sedation can be difficult because of its subjective nature. Several sedation scales such as the Ramsay Sedation Score[37] (Table 14-1), the Sedation Agitation Scale (SAS),[38] and most recently, the Richmond Agitation-Sedation Scale (RASS)[39] (Table 14-2) have been developed. The Ramsay scoring system is the most frequently referenced in clinical investigations of sedation. While it has the benefit of simplicity, it does not effectively measure quality or degree of sedation with regard to the goals outlined earlier[40] and has never been validated objectively.[41] Sedation scales such as the Sedation Agitation Scale and the Richmond Agitation-Sedation Scale have been tested extensively for validity and reliability.[38,39,42] The RASS is perhaps the most extensively evaluated scale. It has been validated for ability to detect changes in sedation status over consecutive days of ICU care, as well as against constructs of level of consciousness and delirium. Furthermore, this scale has been shown to correlate with doses of sedative and analgesic medications administered to critically ill patients. As such, the RASS and SAS are preferable over the traditional Ramsay Sedation Score.

The evaluation of sedation adequacy remains an individual bedside maneuver. The nurse's input is critical because he or she often will notice changes from an optimal level of sedation. Armed with validated sedation scales, clinicians may strive to administer sedatives and analgesics to more concrete, reportable levels. Ideally, one would prefer a patient whose indications for sedation as outlined earlier are met yet who remains fully communicative with bedside caregivers. Such a state of sedation correlates with a Ramsay score of 2 or 3, a Sedation Agitation Scale score of 3 or 4, or a RASS score of 0 or –1.[37–39] This state of being awake and communicative while sedatives are still infusing is achievable in some patients. However, in many patients the stress of critical illness precludes such a condition, and patients may require sedation and analgesia to a point where constant communication is not possible.

Recently, the Bispectral Index Monitor, a device that processes the raw electroencephalogram (EEG) signal into a discreet scaled number from 0 (absence of cortical activity) to 100 (fully awake), has been evaluated as a tool to monitor sedation in the ICU setting. Some have found this device to reliably detect a patient's level of consciousness under general anesthesia,[43] although others have questioned the overall utility of this device for preventing awareness.[44] Preliminary data suggest a reasonable correlation between the bispectral index and the sedation agitation scale,[45] as well as the RASS[42]; however, this device has not been evaluated extensively in the ICU and awaits more extensive validation before its role in the critical care setting is established.[6]

Recently, the occurrence of delirium in mechanically ventilated ICU patients has been shown to be associated with higher six-month mortality even after adjusting for severity of illness and the use of sedatives or analgesic medications.[45a] How to decrease the risk of delirium in critically ill patients, and the impact of such a strategy on overall outcome, is not known. The Confusion Assessment Method for diagnosing

TABLE 14-1 Ramsay Sedation Score

1. Patient anxious and agitated or restless or both
2. Patient cooperative, oriented, and tranquil
3. Patient responds to commands only
4. Patient asleep, shows brisk response to light glabellar tap or loud auditory stimulus
5. Patient asleep, shows sluggish response to light glabellar tap or loud auditory stimulus
6. Patient asleep, shows no response to light glabellar tap or loud auditory stimulus

TABLE 14-2 Richmond Agitation-Sedation Scale

Score	Term	Description
+4	Combative	Overtly combative/violent; danger to staff
+3	Very agitated	Pulls/removes tubes or catheters; aggressive
+2	Agitated	Nonpurposeful movement; not synchronous with ventilator
+1	Restless	Anxious, but movements not aggressive/violent
0	Alert and calm	
−1	Drowsy	Sustained awakening (>10 s) with eye contact, to voice
−2	Light sedation	Briefly awakens (<10 s) with eye contact, to voice
−3	Moderate sedation	Movement to voice, but no eye contact
−4	Deep sedation	No response to voice; movement to physical stimulation
−5	Unarousable	No response to voice or physical stimulation

Procedure:
Observe patient. Calm? (score zero) Does patient have restless or agitated behavior? (1 to 4)

delirium has been modified for the ICU (the CAM-ICU) and has been validated (see chapter 62).[45b]

STRATEGIES FOR ADMINISTERING SEDATIVES IN THE ICU

Since no single drug can achieve all the indications for sedation and analgesia in the ICU, a combination of drugs, each titrated to specific end points, is a more effective strategy. This may allow lower doses of individual drugs and reduce problems of drug accumulation. In the ICU, sedatives and analgesics almost always are administered by the intravenous route. Both continuous infusion and intermittent bolus techniques have been advocated. While continuous infusions of sedatives may reduce rapid fluctuations in the level of sedation, accumulation of drugs resulting in prolongation of mechanical ventilation and ICU stay has been described.[46] Intermittent administration of sedatives and analgesics may increase demands on nursing time, potentially distracting attention away from other patient care issues. Other perceived benefits of continuous sedative infusions include a more consistent level of sedation with greater levels of patient comfort. The convenience of this strategy for both patients and caregivers is likely the greatest reason for its popularity.

Ideally, strategies for sedation and analgesia in critically ill patients should adhere to pharmacokinetic and pharmacodynamic principles. Unfortunately, ICU patients frequently exhibit unpredictable alterations in pharmacology,[47] so precise guidelines for drug administration are not possible. For instance, when "short acting" benzodiazepines[48,49] such as midazolam and lorazepam are administered in the ICU, these drugs accumulate in tissue (especially adipose) stores with a resulting prolonged clinical effect.[24,46,50–52] Other circumstances that confound prediction of the pharmacologic behavior of sedatives and analgesics include altered hepatic and/or renal function,[53] polypharmacy in the ICU with complex drug-drug interactions, altered protein binding, and circulatory instability. The multicompartmental pharmacokinetics typical in critically ill patients defy simple bedside pharmacokinetic profiling. As such, titration of sedatives and analgesics against discernible clinical end points, while imprecise, is the only tool available. Further confounding administration of sedatives in the ICU is the dramatic difference between extremes of sedation. Frequently, oversedated patients are easier to manage than undersedated patients, and in an effort to avoid unmanageable agitation, clinicians may be heavy handed when sedating agitated patients. In the initial stages of critical illness, such as the period immediately following intubation and mechanical ventilation, this may be appropriate; however, maintaining deep levels of sedation after patients are stabilized on mechanical ventilation can lead to the problems of prolonged sedation alluded to earlier.

It is not uncommon for some critically ill patients to require extraordinarily high doses of sedatives to achieve tranquility; such doses may be much greater than quoted in the literature and recommended by drug manufacturers.[54] Indeed, occasional patients may even require pharmacologic paralysis to achieve synchrony with mechanical ventilation.[55]

Recently, evidence-based treatment strategies for many common conditions seen in critical illness have emerged. In the last decade, improved outcomes for critically ill patients with acute respiratory distress syndrome (ARDS),[56] sepsis,[57,58] acute renal failure,[59] status asthmaticus,[60] and cancer[61] all have been reported. As sicker patients continue to demonstrate improved outcomes in the ICU, more aggressive levels of sedation and analgesia may be necessary. This is particularly likely for patients managed with unconventional ventilator strategies (e.g., permissive hypercapnia, low tidal volumes, prone positioning, and pressure-controlled ventilation) because these strategies may be inherently distressing to many patients. For selected patients, deep sedation may be the only practical option.

The use of deep sedation carries a heavy price because the neurologic examination is severely limited in these patients. Ideally, a head-to-toe daily assessment for the presence of organ failure should be routine for every critically ill patient. This is particularly so during resuscitative phases of ICU care, when assessing the adequacy of end-organ perfusion and function is of paramount importance. The mental status examination is an important gauge of brain perfusion. Since brain injury is a devastating complication of critical illness, acute cerebral dysfunction must be detected quickly and corrected, if possible, before permanent injury takes place. The veil of sedation severely handicaps a clinician's ability to serially follow a patient's neurologic condition. Communication and thorough physical examination may detect problems early on and obviate urgent diagnostic studies and therapeutic interventions after a problem has advanced.

A protocol-driven approach to sedation has been shown to alleviate many of the problems mentioned earlier. A protocol directed by bedside nurses can shorten the duration of mechanical ventilation, ICU and hospital length of stay, and the need for tracheostomy[62] (Fig. 14-1). Such protocols ensure adequate analgesia and sedation using frequent assessments of patient needs with goal-directed titration of analgesics and sedatives. Alternatively, a routine protocol of daily interruption of continuous sedative infusions can reduce many of the complications of sedation in the ICU setting, including duration of mechanical ventilation and ICU length of stay[24,24a] (Figs. 14-2 and 14-3). Such a strategy allows patients to spend a substantial portion of their ICU time awake and interactive, potentially reducing the amount of sedative and opiate given, as well as reducing the need for diagnostic studies (e.g., brain CT scan) to evaluate unexplained alterations in mental status.

Such protocol-driven sedation strategies allow a focused downward titration of sedative infusion rates over time, streamlining administration of these drugs and minimizing the tendency for accumulation. Protocol-driven sedation may allow the depth of sedation to be decreased without compromising the stated goals of sedation. This strategy may allow clinicians to minimize sedative accumulation. Initially, the thought of decreasing or stopping sedatives in a critically ill patient who has been agitated may be unsettling. As such, clinicians may sedate patients aggressively early in their ICU course and maintain the same level of deep sedation indefinitely. A daily holiday from sedatives can eliminate the tendency to "lock in" to a high sedative infusion rate, which—while appropriate early in ICU care—may be unnecessary on subsequent days. When sedative infusions are decreased or stopped, tissue stores can redistribute drug

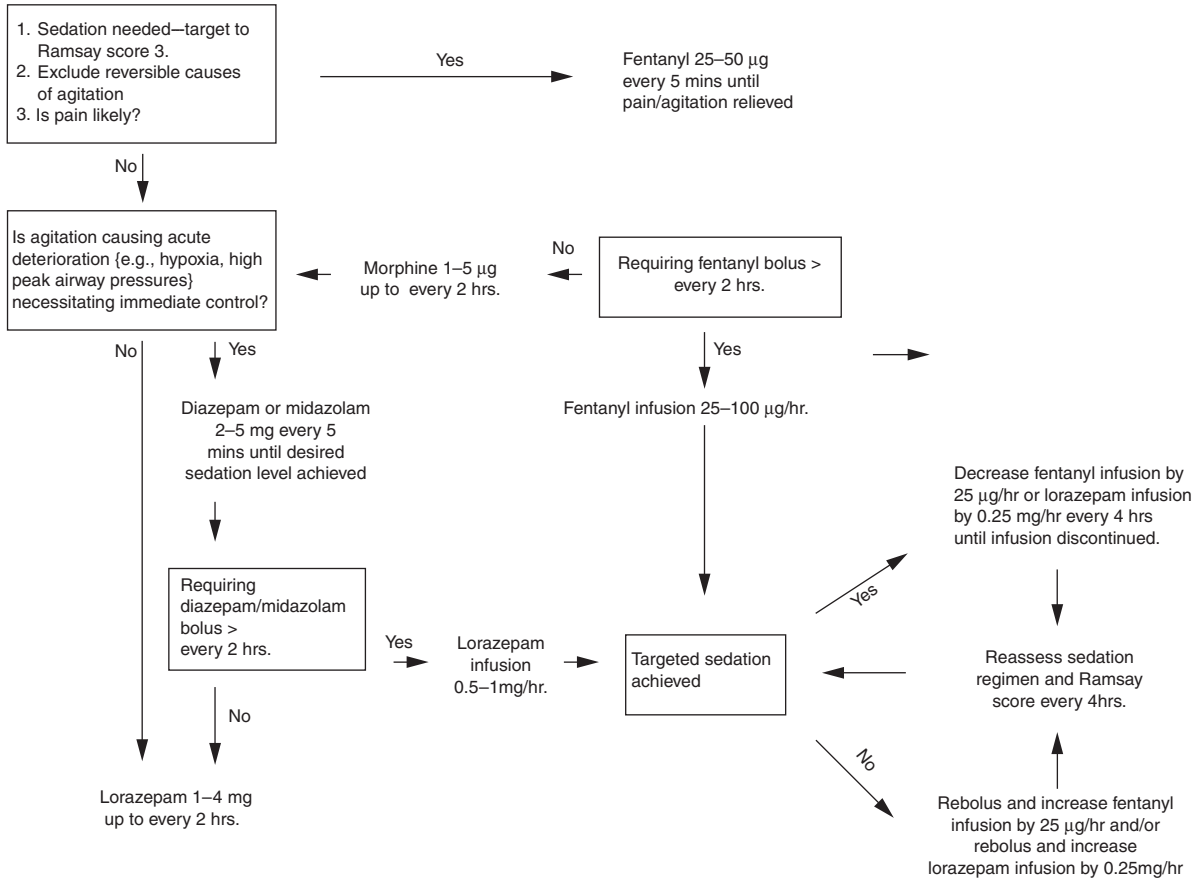

FIGURE 14-1 Protocol for nursing management of sedation during mechanical ventilation. ***(Used with permission from Brook et al.*[62]**)

back into the circulation. The interruption of sedative infusions sometimes may lead to abrupt awakening and agitation. This must be anticipated by the ICU team to avoid complications such as patient self-extubation; if excessive agitation is noted, sedatives should be restarted. Although the attempt at waking and communicating with a patient may fail on a given day, this does not portend inevitable failure on all subsequent days. When awakening patients from sedation, one need only bring patients to the brink of consciousness—able to follow simple commands (i.e., open eyes, squeeze hand,

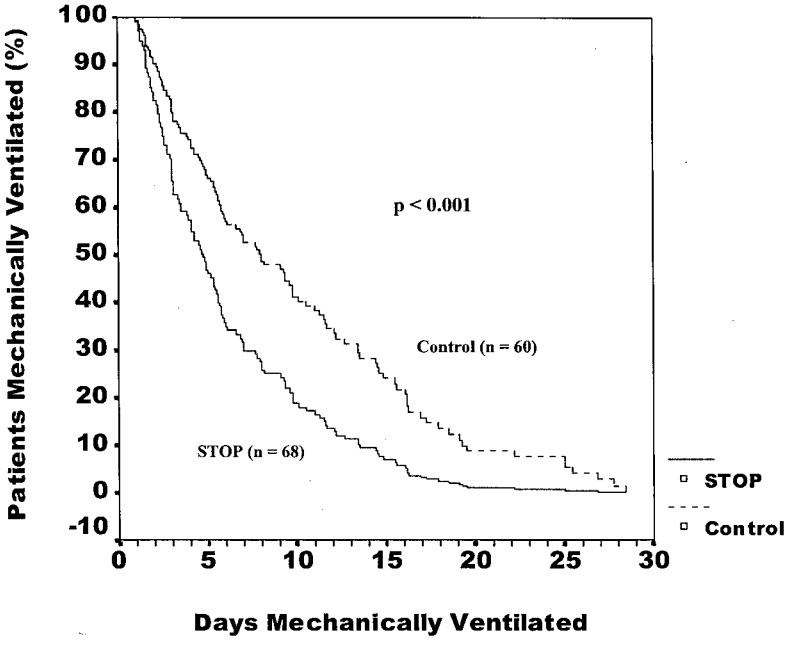

FIGURE 14-2 Kaplan–Meier analysis of the duration of mechanical ventilation, according to study group. After adjustment for base-line variables (age, sex, weight, APACHE II score, and type of respiratory failure), mechanical ventilation was discontinued earlier in the STOP group than in the control group (relative risk of extubation, 1.9; 95 percent confidence interval 1.3 to 2.7; $P < 0.001$).

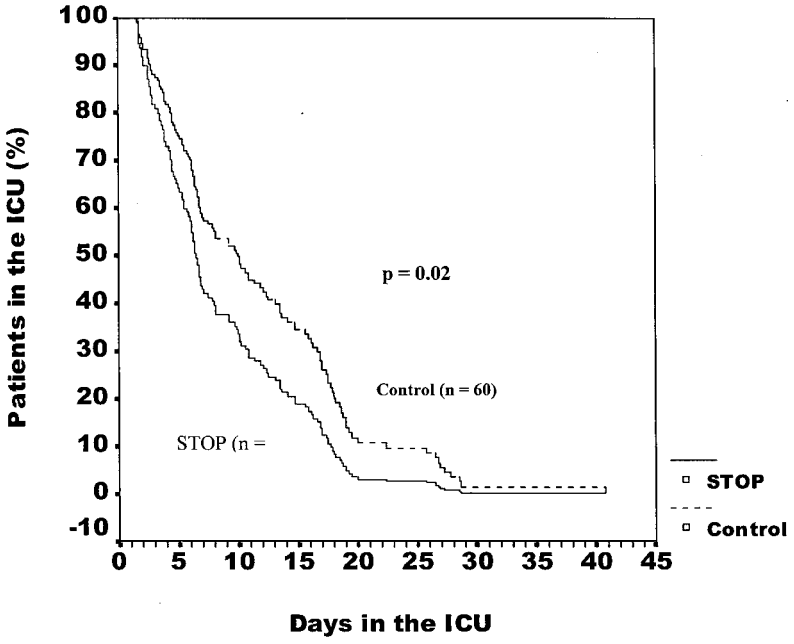

FIGURE 14-3 Kaplan–Meier analysis of the length of stay in the intensive care unit (ICU), according to study group. After adjustment for base-line variables (age, sex, weight, APACHE II score, and type of respiratory failure), discharge from the intensive care unit (ICU) occurred earlier in the STOP group than in the control group (relative risk of discharge, 1.6; 95 percent confidence interval, 1.1 to 2.3; $P = 0.02$).

track with eyes, open mouth/stick out tongue) without precipitating excessive agitation. Once objective signs of consciousness are demonstrated, restarting sedatives as needed is recommended. If after discontinuing the sedative infusion the patient requires resedation, we recommend restarting the infusion at 50 percent of the previous dose. Adjustments from this starting point can be individualized to patient needs.

It is clear that sedatives may have an impact on the duration of mechanical ventilation.[24,62] Protocolized sedation strategies may reduce the duration of mechanical ventilation by allowing earlier recognition of patient readiness to undergo a spontaneous breathing trial. Others have reported previously an important link between a successful spontaneous breathing trial and subsequent liberation from mechanical ventilation.[63,64] The use of a daily spontaneous waking trial, followed, when possible, by a daily spontaneous breathing trial, should be implemented widely in the care of critically ill patients requiring mechanical ventilation.

DRUGS FOR SEDATION OF MECHANICALLY VENTILATED PATIENTS

OPIATES

Opiate receptors are found in the central nervous system, as well as in peripheral tissues. There are several classes of receptors, but the two most clinically important are the mu and kappa receptors. The mu receptors have two subtypes, mu-1 and mu-2. Mu-1 receptors are responsible for analgesia, whereas mu-2 receptors mediate respiratory depression, nausea, vomiting, constipation, and euphoria. The kappa receptors are responsible for such effects as sedation, miosis, and spinal analgesia. Table 14-3 presents a summary of the pharmacologic properties of the opiates.

Pharmacokinetics

The following discussion applies to the intravenous opiates used most commonly in the ICU.

TABLE 14-3 Properties of Commonly Used Opiates

	Morphine	Meperidine	Fentanyl	Methadone
Typical starting dose	2–5 mg	20–50 mg	25–50 μg	5–10 mg
Onset	10 min	3–5 min	0.5–1 min	10–20 min
Duration after single dose	4 h	1–4 h	0.5–1 h	6–24 h
Metabolism	Hepatic	Hepatic	Hepatic	Hepatic
Elimination	Renal	Renal	Renal	Renal
Anxiolysis	+	++	++	+
Analgesia	+ + ++	+ + ++	+ + ++	+ + ++
Hypnosis	No reliable effect	No reliable effect	No reliable effect	No reliable effect
Amnesia	No reliable effect	No reliable effect	No reliable effect	No reliable effect
Sz threshold	No effect	May decrease	No effect	No effect
Reducing dyspnea	+ + ++	+ + ++	+ + ++	+ + ++
CV effect	Venodilation	Venodilation	Venodilation	Venodilation
Respiratory effect	Hypoventilation	Hypoventilation	Hypoventilation	Hypoventilation
Common side effects	N/V, ileus, itching	Seizure, N/V, ileus, itching	N/V, ileus, itching	N/V, ileus, itching

NOTE: + = minimal effect; ++ = mild effect; + + + = moderate effect; + + ++ = large effect; N/V = nausea and vomiting.

MORPHINE Intravenous morphine has a relatively slow onset of action (typically 5 to 10 minutes) owing to its relatively low lipid solubility, which delays movement of the drug across the blood-brain barrier. The duration of action after a single dose is approximately 4 hours. As the drug is given repeatedly, accumulation in tissue stores may prolong its effect. Morphine undergoes glucuronide conjugation in the liver and has an active metabolite, morphine-6-glucuronide. Elimination occurs in the kidney, so effects may be prolonged in renal failure.

MEPERIDINE Meperidine's greater lipid solubility leads to more rapid movement across the blood-brain barrier and a more rapid onset of action, typically 3 to 5 minutes. Because of redistribution to peripheral tissues, its duration of action after a single dose is less than that of morphine (1 to 4 hours). Meperidine undergoes hepatic metabolism and renal elimination. A major problem with the use of meperidine is its metabolite normeperidine, a CNS stimulant that can precipitate seizures, especially with renal failure and/or prolonged use. Since meperidine offers no apparent advantage over other opiates, its side effect of CNS toxicity largely should preclude its use in critically ill patients.

FENTANYL Fentanyl is very lipid soluble, thereby rapidly crossing the blood-brain barrier and exhibiting very rapid onset of action. Its duration of action after a single dose is short (0.5 to 1 hour) because of redistribution into peripheral tissues; however, as with all opiates, accumulation and prolongation of effect can occur when this drug is given for extended periods. Inactive products of hepatic metabolism are excreted by the kidney.

HYDROMORPHONE The onset of action is similar to morphine. The duration of action is likewise similar to that of morphine when given as a single dose. However, the absence of active metabolites makes the duration of effect typically shorter than that of morphine when administered for extended periods.

REMIFENTANIL Remifentanil is a lipid-soluble drug with a rapid onset of action. This drug is unique in that it is metabolized rapidly by hydrolysis by nonspecific blood and tissue esterases. As such, its pharmacokinetic profile is not affected by hepatic or renal insufficiency. It must be given by continuous infusion because of its rapid recovery time. This rapid recovery, typically minutes after cessation of the drug infusion, may prove useful in the management of critically ill patients. To date, the drug has not been studied extensively in the critical care setting. Most studies have been performed in neurosurgical and cardiac surgical settings, and little data are available regarding long-term use of this drug. Remifentanil as a component of general anesthesia may have a role in reducing the need for ICU admissions by allowing extubation in the operating room and preventing the need for postoperative ICU care.[65,66]

Pharmacodynamics

All opiates have similar pharmacodynamic effects and will be discussed without reference to individual drugs except where important differences are present.

CENTRAL NERVOUS SYSTEM The primary effect of opioids is analgesia, mediated mainly through the mu and kappa receptors. Mild to moderate anxiolysis is also common, although less than with benzodiazepines. Opiates have no reliable amnestic properties.

RESPIRATORY SYSTEM Opiates lead to a dose-dependent centrally mediated respiratory depression, one of the most important complications associated with their use. Respiratory depression, mediated by the mu-2 receptors in the medulla, typically presents with a decreased respiratory rate but preserved tidal volume. The CO_2 response curve is blunted, and the ventilatory response to hypoxia is obliterated. An important benefit of these drugs is the relief of the subjective sense of dyspnea frequently present in critically ill patients with respiratory failure.

CARDIOVASCULAR SYSTEM Opiates have little hemodynamic effect on euvolemic patients whose blood pressure is not sustained by a hyperactive sympathetic nervous system. When opiates and benzodiazepines are given concomitantly, they may exhibit a synergistic effect on hemodynamics. The reasons for this synergy are not entirely clear. Meperidine has a chemical structure similar to atropine and may elicit a tachycardia, another reason its use is discouraged in the ICU. All other opiates usually decrease heart rate by decreasing sympathetic activity. Morphine and meperidine may cause histamine release, although it is rarely important in doses typically used in the ICU. Fentanyl does not release histamine.[67] Remifentanil may cause bradycardia and hypotension, particularly when administered concurrently with drugs known to cause vasodilation, such as propofol.

OTHER EFFECTS Other side effects include nausea, vomiting, and decreased gastrointestinal motility. Methylnaltrexone, a specific antagonist of mu-2 receptors in the gut, has been reported recently to attenuate this side effect in humans.[68] The utility of methylnaltrexone in the ICU has not been tested. Other side effects include urinary retention and pruritus. Muscle rigidity occasionally occurs with fentanyl and remifentanil. This is seen typically when high doses of these drugs are injected rapidly and may affect the chest wall muscles, making ventilation impossible. Neuromuscular blockade, typically with succinylcholine, reverses this problem.

BENZODIAZEPINES

Benzodiazepines act by potentiating γ-aminobutyric acid (GABA) receptor complex–mediated inhibition of the CNS. The GABA receptor complex regulates a chloride channel on the cell membrane, and by increasing the intracellular flow of chloride ions, neurons become hyperpolarized, with a higher threshold for excitability. Flumazenil is a synthetic antagonist of the benzodiazepine receptor that may reverse many of the clinical effects of benzodiazepines. Table 14-4 presents a summary of the pharmacologic properties of the benzodiazepines.

Pharmacokinetics

The three available intravenous benzodiazepines, midazolam, lorazepam, and diazepam, are discussed below.

MIDAZOLAM The onset of action of midazolam is rapid (0.5 to 5 minutes), and the duration of action following a

TABLE 14-4 Properties of Commonly Used Benzodiazepines

	Midazolam	Lorazepam	Diazepam
Typical starting dose	1–2 mg	0.5–1 mg	5–10 mg
Onset	0.5–2 min	3–5 min	1–3 min
Duration after single dose	2 h	6–10 h	1–6 h
Metabolism	Hepatic	Hepatic (less influenced by age and liver disease)	Hepatic
Elimination	Renal	Renal	Renal
Anxiolysis	+ + ++	+ + ++	+ + ++

Common side effects	Paradoxical agitation	Paradoxical agitation	Paradoxical agitation

NOTE: + = minimal effect; ++ = mild effect; + + + = moderate effect; + + ++ = large effect.

single dose is short (~2 hours). All benzodiazepines are lipid soluble with a large volume of distribution and therefore are distributed widely throughout body tissues. For all benzodiazepines, the duration of action after a single bolus depends mainly on the rate of redistribution to peripheral tissues, especially adipose tissue. Midazolam undergoes hepatic metabolism and renal excretion. Alpha-hydroxy midazolam is an active metabolite but has a half-life of only 1 hour in the presence of normal renal function.

The kinetics of midazolam change considerably when it is given by continuous infusion to critically ill patients. After continuous infusion for extended periods, this lipid-soluble drug accumulates in peripheral tissues rather than being metabolized. On discontinuing the drug, peripheral tissue stores release midazolam back into the plasma, and the duration of clinical effect can be prolonged.[69] Obese patients with larger volumes of distribution and elderly patients with decreased hepatic and renal function may be even more prone to prolonged effects.

LORAZEPAM Intravenous lorazepam has a slower onset of action than midazolam (~5 minutes) because of its lower lipid solubility, which increases the time required to cross the blood-brain barrier. The duration of action following a single dose is long (6 to 10 hours) and is proportional to the dose given; however, most pharmacokinetic studies are done on healthy volunteers and may not apply to critically ill patients. Lorazepam's longer duration of action is due to lower lipid solubility with decreased peripheral tissue redistribution.

DIAZEPAM The onset of action of intravenous diazepam is short (~1 to 3 minutes). Duration of action following a single dose also is short (30 to 60 minutes) owing to high lipid solubility and peripheral redistribution. Diazepam rarely is given by continuous infusion because it has a long termination half-life. Once the peripheral tissue compartment is saturated, recovery can take several days. Diazepam has several active metabolites that themselves have prolonged half-lives. The metabolism of diazepam depends on hepatic function and is prolonged in liver disease and in the elderly.

Pharmacodynamics

The benzodiazepines have similar effects and will be discussed without reference to individual drugs except where important differences are present.

CENTRAL NERVOUS SYSTEM All benzodiazepines cause a dose-dependent suppression of awareness along a spectrum from mild depression of responsiveness to obtundation. They are potent amnestic agents;[70,71] lorazepam appears to produce the longest duration of antegrade amnesia. All are potent anxiolytic agents. A paradoxical state of agitation that worsens with escalating doses may occur occasionally, especially in elderly patients. All benzodiazepines have anticonvulsant properties.[72]

RESPIRATORY SYSTEM Benzodiazepines cause a dose-dependent, centrally mediated respiratory depression. This ventilatory depression is less profound than that seen with opiates; however, it may be synergistic with opiate-induced respiratory depression. In contrast to opiates (described earlier), the respiratory pattern of a patient receiving benzodiazepines is a decrease in tidal volume and an increase in respiratory rate. Even low doses of benzodiazepines can obliterate the ventilatory response to hypoxia.

CARDIOVASCULAR SYSTEM Benzodiazepines have minimal effects on the cardiovascular system in patients who are euvolemic. They may cause a slight decrease in blood pressure without a significant change in heart rate. Clinically important hypotensive responses usually are seen only in patients who are hypovolemic and/or those whose increased endogenous sympathetic activity is maintaining a normal blood pressure.

PROPOFOL

Propofol is an alkylphenol intravenous anesthetic. The exact mechanism of action is unclear, although it is thought to act at the GABA receptor. It is an oil at room temperature and is prepared as a lipid emulsion.

Pharmacokinetics

Propofol is highly lipid soluble and rapidly crosses the blood-brain barrier. Onset of sedation is rapid (1 to 5 minutes) and depends on whether or not a loading dose is given. Duration of action depends on dose but is usually very short (2 to 8 minutes) owing to rapid redistribution to peripheral tissues.[73,74] When continuous infusions are used, duration of action may be increased, but it is rare for the effect to last longer than 60 minutes after the infusion is discontinued. The drug is metabolized mainly in the liver with an elimination half-life of 4 to 7 hours. Propofol has no active metabolites. Because of its high lipid solubility and large volume of distribution, propofol can be given for prolonged periods without significant changes in its pharmacokinetic profile. The termination of its clinical effect depends solely on redistribution to peripheral fat tissue stores. When the infusion is discontinued, the fat tissue stores redistribute the drug back into the plasma, but usually not to clinically significant levels.

Pharmacodynamics

CENTRAL NERVOUS SYSTEM Propofol is a hypnotic agent that, like the benzodiazepines, provides a dose-dependent suppression of awareness from mild depression of responsiveness to obtundation. It is a potent anxiolytic as well as a potent amnestic agent.[75] Its effect on seizure activity is controversial. Animal studies suggest that it is neither pro- nor anticonvulsant; however, there are case reports of propofol being used to treat seizures, as well as being associated with seizure activity. Propofol has no analgesic properties and should be accompanied by a separate analgesic agent in most, if not all, patients. Failure to recognize this may lead to difficulty keeping patients comfortable, and excessive doses of propofol may be administered.

RESPIRATORY SYSTEM The CO_2 response curve is blunted, and apnea may be seen, especially after a loading dose is given. The respiratory pattern is usually a decrease in tidal volume and an increase in respiratory rate.

CARDIOVASCULAR SYSTEM Propofol can cause significant decreases in blood pressure, especially in hypovolemic patients. This is mainly due to preload reduction from dilation of venous capacitance vessels. A lesser effect is mild myocardial depression.[76,77] Care must be taken in giving this drug to patients with marginal cardiac function; however, since myocardial oxygen consumption is decreased by propofol and the myocardial oxygen supply-demand ratio is preserved, it may be useful in patients with ischemic heart disease.

OTHER EFFECTS Because it is delivered in an intralipid carrier, hypertriglyceridemia is a possible side effect.[78,79] Therefore, triglyceride levels should be checked frequently. If hypertriglyceridemia occurs, the drug should be stopped. Intralipid parenteral feedings should be adjusted according to the propofol infusion rate because there is a significant caloric load from propofol. Strict aseptic technique and frequent changing of infusion tubing are essential to prevent iatrogenic transmission of bacteria and fungi because propofol can support their growth.[80] Dysrhythmias, heart failure, metabolic acidosis, hyperkalemia, and rhabdomyolysis have been reported in both children and adults treated with propofol, especially at high doses (>80 μg/kg per minute in adults).[81]

BUTYROPHENONES (HALOPERIDOL AND DROPERIDOL)

Butyrophenones such as haloperidol and droperidol are used occasionally in the ICU for sedation. These drugs induce a state of tranquility such that patients often demonstrate a detached affect. Butyrophenones appear to antagonize dopamine, especially in the basal ganglia, although their exact site of action is not known.

Pharmacokinetics

HALOPERIDOL After an intravenous dose, onset of sedation usually occurs after 2 to 5 minutes. The half-life is approximately 2 hours but is dose dependent. Dose requirements vary widely, starting at 1 to 10 mg and titrating to effect. Haloperidol undergoes hepatic metabolism.

DROPERIDOL Onset of action is usually 2 to 5 minutes, with a typical starting dose of 0.625 to 2.5 mg. Half-life is approximately 2 hours but is longer when higher doses are used. Droperidol, like haloperidol, is metabolized in the liver.

Pharmacodynamics

CENTRAL NERVOUS SYSTEM Both haloperidol and droperidol produce CNS depression, resulting in a calm, often detached appearance. These drugs are used most commonly in critically ill patients who are acutely agitated and hyperactive. Patients may demonstrate a mental and psychiatric indifference to the environment.[82] Patients also may experience a state of cataleptic immobility. There is no demonstrable amnesia with these drugs. They have no effect on seizure activity. Analgesic effects are minimal with haloperidol; however, droperidol seems to have a significant potentiating analgesic effect when given concomitantly with an opiate. Indeed, droperidol and fentanyl are given occasionally in combination, producing a so-called neuroleptanesthesia. The butyrophenones are the drugs of choice for patients thought to be demonstrating psychotic behavior or agitation resistant to other pharmacologic interventions.

RESPIRATORY SYSTEM Neither haloperidol nor droperidol has any significant effect on the respiratory system when used alone. There are reports of attenuation of respiratory depression in the presence of opiates, but this effect is mild. Droperidol has been shown to maintain the hypoxic pulmonary drive.[83]

CARDIOVASCULAR SYSTEM Haloperidol and droperidol may result in mild hypotension secondary to peripheral α_1 blocking effects. Haloperidol also may decrease the neurotransmitter function of dopamine and lead to mild hypotension by this mechanism. Haloperidol may prolong the QT interval and has been reported to result in torsade de pointes,[84] although this problem is quite rare.

OTHER EFFECTS Extrapyramidal effects are seen occasionally with these drugs but are much less common with intravenous than with oral butyrophenones. When these complications occur, treatment with diphenhydramine or benztropine may be necessary. Neuroleptic malignant syndrome (NMS) occurs rarely and is characterized by "lead pipe" muscle rigidity, fever, and mental status changes. The mechanism of NMS is not fully understood, although some data suggest a central dopaminergic blockade that leads to extrapyramidal

TABLE 14-5 Properties of Other Sedative Agents

NOTE: + = minimal effect; ++ = mild effect; + + + = moderate effect; + + ++ = large effect.

side effects and muscle rigidity with excess heat generation. Bromocriptine, dantrolene, and pancuronium all have been used to treat NMS successfully.[85] Droperidol is a potent antiemetic and sometimes is used for nausea and vomiting associated with general anesthesia or chemotherapy.

OTHER DRUGS USED FOR SEDATION IN THE ICU

Dexmedetomidine[86–88] is a selective α_2 agonist approved for short-term use (<24 hours) in patients initially receiving mechanical ventilation. While patients remain sedated, when undisturbed, they arouse easily with stimulation. This drug is attractive because patients seem to transition from sedated to awake states rather easily, thus facilitating neurologic examinations. The drug has both analgesic and anxiolytic effects. Side effects include bradycardia and hypotension, especially with hypovolemia or high sympathetic tone. Unfortunately, dexmedetomidine has not been studied extensively as an agent for long-term administration to critically ill patients.

Ketamine has a molecular structure similar to phencyclidine. Patients given this drug experience a profound dissociative state. They may keep their eyes open and maintain a protective cough reflex but appear unaware of their surroundings. It is recommended to give this drug slowly over a period of approximately 1 minute. Ketamine causes minimal respiratory depression. There may be amnesia, but this is not a reliable property of the drug. Coordinated but seemingly purposeless movements are seen often. Profound analgesia is seen with ketamine. The common side effect of emergence delirium and severe hallucinations has limited its usefulness for sedation of adult patients in the ICU. This phencyclidine derivative has gained popularity recently as an illicit drug of abuse.

Barbiturates such as thiopental and pentobarbital are potent agents that cause amnesia and unconsciousness. They have little use as sedatives in critically ill patients because of a propensity to cause hemodynamic instability. In addition to this, they are lipid soluble and thus accumulate in peripheral tissues after long-term infusions, leading to prolonged recovery from sedation. These drugs may be used to induce a pharmacologic coma in patients with severe brain injury.

Inhalational anesthetics such as *isoflurane* have been studied in critically ill patients and shown to be safe and effective.[89] These drugs have analgesic, amnestic, and hypnotic properties and may be useful as single agents. Isoflurane undergoes only 0.2% metabolism, being eliminated almost exclusively through the lungs. Technical problems delivering the drug safely through the ventilator at accurate concentrations, as well as difficulty scavenging the exhaled gas, have limited the use of inhalational anesthetics for sedation in the ICU in the United States.

Table 14-5 summarizes pharmacologic properties of other commonly used sedative agents.

Neuromuscular Blocking Agents

The frequency with which neuromuscular blocking agents (NMBs) are used in critically ill patients has decreased significantly over the last 20 years. As reports of complications related to the use of NMBs continue to accrue, intensive care clinicians typically administer these agents only as a last resort. The usual indications for the use of NMBs in the ICU are to facilitate mechanical ventilation in patients with ventilator dyssynchrony despite optimal sedation, to manage tetanus with chest wall rigidity, and to facilitate redistribution of blood flow away from respiratory muscles in patients with acute hypoxemic respiratory failure accompanied by shock. It is mandatory that patients given NMBs be given agents to ensure amnesia while they are pharmacologically paralyzed.

Normally, at the neuromuscular junction, acetylcholine is released from synaptic vesicles at the terminal end of the motor nerve. The acetylcholine binds to the postsynaptic endplate, propagating an electrical signal through the muscle

and leading to muscle contraction. Pharmacologic NMBs bind to the acetylcholine receptor at the terminal end of the motor nerve. These agents can activate the acetylcholine receptor (depolarizing agents) or competitively inhibit the receptor without activating it (nondepolarizing agents). Succinylcholine is the only available depolarizing NMB. In normal individuals, depolarization of skeletal muscle beds leads to release of intracellular potassium, typically resulting in an increase in the serum potassium level of approximately 0.5 mEq/L. Denervation of skeletal muscle from tissue injury as in burns or upper motor neuron lesions may result in more dramatic rises in serum potassium, which may precipitate malignant cardiac dysrrhythmias. Succinylcholine may be used to facilitate endotracheal intubation but is not indicated for ongoing neuromuscular blockade in critically ill patients and will not be discussed further in this chapter. Table 14-6 presents a summary of the pharmacologic properties of the neuromuscular blocking agents.

NONDEPOLARIZING NMBs

A number of nondepolarizing NMBs are available currently. The pharmacology of the ones more commonly used in the ICU will be discussed below.

PANCURONIUM
Pancuronium is an older NMB that is used during general anesthesia, as well as in the ICU. It has an aminosteroidal molecular structure. The drug has a long half-life, with a duration of action of between 60 and 90 minutes after a single intravenous bolus dose of 0.1 mg/kg. Its vagolytic side effect (typically results in an increase in heart rate of ~10 beats per minute), active metabolite (3-hydroxypancuronium), and reliance on renal clearance limit its attractiveness in critically ill patients.

VECURONIUM
Vecuronium also has an aminosteroidal molecular structure but a shorter half-life than pancuronium. After a bolus of 0.1 mg/kg, this drug typically lasts 30 minutes. Fifty percent of the drug is excreted in bile, so prolongation of effect may be seen in patients with liver dysfunction. In addition to this, one-third of the drug is excreted in the kidneys, so accumulation in the setting of renal insufficiency may be seen. The active metabolite 3-desacetylvecuronium may lead to prolongation of effect with repeated dosing, particularly in those with renal failure.[90]

ROCURONIUM
Rocuronium also has an aminosteroidal molecular structure. Unlike the other aminosteroidal nondepolarizing NMBs, rocuronium has a rapid onset of action. It may be used to facilitate endotracheal intubation as a substitute for succinylcholine when the latter is contraindicated (e.g. burns, muscle tissue injury, upper motor neuron lesions). The usual bolus dose is 0.6 to 1.0 mg/kg, with a duration of effect of 30 to 45 minutes, similar to vecuronium. The metabolite, 17-desacetylrocuronium, has minimal neuromuscular blocking activity.

DOXACURIUM
Doxacurium is a benzylisoquinolinium agent with a half-life lasting 60 to 90 minutes. The usual bolus dose is 0.5 to 1.0 mg/kg. The drug is eliminated by renal excretion and has no hemodynamic effects.

ATRACURIUM
Atracurium is a benzylisoquinolinium compound with a duration of action of between 20 and 45 minutes. The initial loading dose is 0.4 to 0.5 mg/kg. The drug usually is given by continuous infusion in the ICU at a dose of 10 to 20 μg/kg per minute. Atracurium is inactivated in plasma by ester hydrolysis and Hofmann elimination, so renal or hepatic dysfunction do not have an impact on its duration of blockade. This feature has made it attractive for use in ICU patients because most patients sick enough to require NMBs suffer from renal or hepatic dysfunction. Atracurium may cause histamine release, and its breakdown product, laudanosine, has been associated with central nervous system excitation and seizures in animal models.

CISATRACURIUM
An isomer of atracurium is cisatracurium, which has a similar pharmacologic profile to atracurium. The initial loading dose is 0.1 to 0.2 mg/kg, and the duration of action is approximately 25 minutes. Like atracurium, this drug is inactivated in plasma by ester hydrolysis and Hofmann elimination. Cisatracurium does not cause histamine release. Because of its short half-life, it requires administration by continuous infusion. The usual dose is 2.5 to 3 μg/kg per minute. This drug is currently one of the most frequently used for neuromuscular blockade in ICU patients.

MONITORING THE LEVEL OF NEUROMUSCULAR BLOCKADE

The depth of neuromuscular blockade is monitored most accurately with use of a peripheral nerve stimulator. This device sends a current between electrodes placed on the skin along the course of a peripheral nerve, most commonly the ulnar nerve. With this setup, the twitches of the adductor pollicus muscle are evaluated to assess depth of neuromuscular blockade. The peripheral nerve stimulator is programmed to deliver four sequential stimuli at 2 Hz. Each stimulus causes release of acetylcholine from synaptic vesicles. In the absence of pharmacologic neuromuscular blockade, the fourth twitch of the adductor pollicus muscle is as strong as the first. However, when neuromuscular receptors are occupied by nondepolarizing NMBs, the strength of the fourth twitch is less than the first, until eventually the muscle does not twitch with the fourth stimulus. This phenomenon is known as *fade.* When 85% to 90% of the neuromuscular receptors are occupied by NMBs, only the first twitch in the train of four is visible. When 70% to 85% of the neuromuscular receptors are occupied by NMBs, between two and four twitches are visible. Typically, two or three of four twitches are sought, and dosing of NMBs is titrated to this goal. Peripheral nerve stimulator use in the ICU has been shown to reduce the amount of drug used and shorten recovery of neuromuscular function and spontaneous ventilation.[91] Another study showed a reduction in the incidence of persistent neuromuscular weakness.[92]

COMPLICATIONS OF NEUROMUSCULAR BLOCKADE

Prolonged weakness after the use of NMBs is the most concerning complication of their use. Categorically, two separate

TABLE 14-6 Properties of Commonly Used Neuromuscular Blocking Agents

	Succinylcholine	Pancuronium	Vecuronium	Rocuronium	Atracurium	Cisatracurium
Type	Depolarizing	Nondepolarizing	Nondepolarizing	Nondepolarizing	Nondepolarizing	Nondepolarizing
Typical loading/ intubation	1.0–1.5 mg/kg	0.1 mg/kg	0.1 mg/kg	0.6–1.0 mg/kg	0.5 mg/kg	0.1–0.2 mg/kg
Continuous infusion? (Dose)	No	No	No	No	Yes (10–20 μg/kg/min)	Yes (2–3 μg/kg/min)
Onset	60 s	3–5 min	3–5 min	1–2 min	3–5 min	3–5 min
Duration after loading dose	7–9 min	60–90 min	30–40 min	30–45 min	20–45 min	25 min
Metabolism	Plasma cholinesterase	Hepatic	Hepatic/biliary	Hepatic	Ester hydrolysis/ Hoffman elimination	Ester hydrolysis/ Hoffman elimination
Elimination		Renal	Renal/biliary	Biliary clearance of parent molecule from plasma		
Active metabolite?	No	Yes	Yes	Yes (minimal)	No	No
CV effect	Supraventricular and ventricular rhythm disturbances with hyperkalemia	Vagolytic—tachycardia	None	None	Histamine release	No histamine release
Common side effects	Hyperkalemia	None	None	None	Histamine release	None

conditions may arise that lead to this problem. As mentioned earlier, accumulation of NMB parent drug or its metabolites is seen with several drugs, particularly with renal and/or hepatic insufficiency. This condition of prolonged recovery from NMBs is defined by an increase in the time to recovery of 50% to 100% longer than predicted by pharmacologic parameters after the drugs are stopped.[93] The second cause of weakness associated with NMBs is acute quadriplegic myopathy syndrome. Patients with this syndrome manifest acute paresis, myonecrosis with increased creatine phosphokinase (CPK) concentration, and abnormal electromyography (EMG). Findings on EMG are consistent with denervation of skeletal muscle (decreased compound motor action potential amplitudes). This may progress to muscle atrophy and even necrosis.

Concerns over complications of NMBs have led to a dramatic decrease in their use in the ICU.[94] This is particularly noteworthy when corticosteroids are used in conjunction with NMBs. Several studies have suggested that this combination is associated with a significant incidence of myopathy.[95,96]

Conclusions

Sedation is an important component of the treatment of critically ill patients who require mechanical ventilation. Directing treatment to specific and individualized goals will ensure that patient needs are met. All currently available sedatives for use in the ICU have limitations. Rather than seeking an ideal drug, strategies of drug administration that focus attention on principles of sedative pharmacology in critical illness should be used. Recognition of the goals of sedation in individual patients will allow rational administration strategies to be implemented in the care of these patients. The use of neuromuscular blocking agents should be reserved for those patients with extreme ventilator dyssynchrony despite optimal sedation, tetanus, and critically reduced oxygen delivery from hypoxemia with shock.

KEY POINTS

- *Most cardiac arrests in the community setting occur as a result of coronary artery disease and cardiac ischemia.*
- *Given the high mortality of cardiac arrest, prevention is crucial.*
- *Cardiopulmonary resuscitation and rapid defibrillation are the keys to successful resuscitation from cardiac arrest.*
- *Advanced Cardiopulmonary Life Support (ACLS) guidelines provide treatment algorithms for the different cardiac rhythms of arrest.*
- *Automatic external defibrillators provide a means for rapid defibrillation by the public.*

Cardiac arrest, defined as the sudden complete loss of cardiac output and therefore blood pressure, is the leading cause of death in the United States and much of the developed world, claiming at least 300,000 lives each year in the United States alone.[1] In the majority of cases, myocardial ischemia in the setting of coronary artery disease represents the underlying etiology of arrest. Conversely, cardiac arrest is the initial presentation of myocardial ischemia in approximately 20% of patients.[2] A wide variety of other processes can lead to cardiac arrest, including septic shock, electrolyte abnormalities, hypothermia, pulmonary embolism, and massive trauma (Table 15-1).

Survival from cardiac arrest remains dismal, even after the introduction of electrical defibrillation and cardiopulmonary resuscitation (CPR) over 50 years ago. In the best cases (witnessed ventricular fibrillation arrest with rapid defibrillation), survival to hospital discharge ranges from 30% to 46%,[3,4] although overall out-of-hospital arrest survival is usually much lower, ranging from 2% to 26%.[5] In large American cities, out-of-hospital arrest survival may be even worse—survival rates of 1.4% and 1.8% have been reported for New York and Chicago, respectively.[6–8] Even after successful resuscitation from cardiac arrest, most patients die within 24 to 48 hours despite aggressive intensive care treatment. Reperfusion injury, a subject of much basic science investigation, is thought to be involved in this postarrest deterioration.[9,10]

Demographic data from multiple studies demonstrate that the mean age of patients who suffer out-of-hospital cardiac arrest is approximately 68 to 70 years, with a slightly higher incidence in men than in women.[1,2,11] Over 70% of these patients experience arrest in the home or other residential location.[12,13] In-hospital cardiac arrest patients exhibit similar demographics, with one survey showing a mean age of 71 years and also somewhat higher incidence in males.[14] There do not appear to be significant survival differences between men and women.[2]

To standardize treatment during cardiac arrest, a number of treatment algorithms have been developed based on laboratory and clinical evidence. These have been compiled into the Basic Life Support (BLS) and Advanced Cardiopulmonary Life Support (ACLS) guidelines published and updated regularly by the American Heart Association's Emergency Cardiac Care Committee,[15] as well as other international resuscitation organizations (International Liaison Committee on Resuscitation).[15] For additional information about ACLS guidelines and their revisions, see the contact information listed in Table 15-2.

Pediatric Cardiac Arrest

The majority of discussion in this chapter pertains to adult cardiac arrest because cardiac arrest in children, fortunately, is much less common. When it occurs, pediatric cardiac arrest more often is secondary to trauma or pulmonary derangements, such as drowning, status asthmaticus, or foreign-body obstruction, rather than due to a primary cardiac arrhythmia.[16] However, ventricular fibrillation does occur in the pediatric population.[17] Guidelines for pediatric resuscitation have been established and are compiled in the Pediatric Advanced Life Support (PALS) manual. For neonates, in whom cardiac arrest is yet another specialized problem, the manual Neonatal Advanced Life Support (NALS) has been developed. While many of the general principles of this chapter also apply to children, readers should refer to these additional texts for more detailed information.[15]

Prevention of Cardiac Arrest

Given the poor prognosis of cardiac arrest, prevention remains the best hope to save lives. To this end, out-of-hospital and in-hospital cardiac arrests require different prevention strategies.

In the outpatient setting, careful attention to coronary artery disease risk factors such as smoking, hypertension, and hypercholesterolemia and aggressive treatment for these conditions can lower the risk of myocardial ischemia and therefore the risk of cardiac arrest. In consultation with their physicians, most patients with multiple cardiac risk factors should be treated with aspirin to lower the probability and severity of myocardial infarction. Patients otherwise at risk for sudden death, such as patients with bouts of ischemic ventricular tachycardia and/or a history of myocardial infarction with subsequently depressed ejection fraction, should be considered for implantable cardioverter defibrillator (ICD) placement (reviewed in refs. 18 and 19). The use of ICD devices remains an area of active investigation and likely will expand as smaller and less expensive devices are developed.

In the in-hospital setting, where sudden ventricular fibrillation/ventricular tachycardia (VF/VT) from coronary events is not the most common mechanism of arrest, prevention requires a different approach. Several studies have demonstrated that hospitalized patients who suffer cardiac arrest frequently exhibit signs and symptoms of destabilization up to 12 hours before they become pulseless.[20,21] These symptoms include vital sign changes such as progressive hypoten-

Myocardial pump failure
Pulmonary embolism
Cardiac tamponade
Ventricular wall rupture
Severe valvular disease
Infiltrative cardiomyopathy
Inflammatory cardiomyopathy
Massive hemorrhage
Postoperative
Trauma
Gastrointestinal bleeding
Hypoxemia/respiratory failure
Pneumonia
Pulmonary embolism
Status asthmaticus
Suffocation, e.g., foreign-body aspiration
Electrolyte derangement
Hyperkalemia
Hypocalcemia
Drug toxicity/overdose
Digoxin
β Blockers
Calcium channel blockers
Tricyclic antidepressants

NOTE: This list is by no means exhaustive; a number of etiologies are grouped by mechanism, although some likely involve multiple mechanisms (e.g., pulmonary embolism causing hypoxemia and right ventricular pump failure). Myocardial ischemia and primary cardiac arrhythmia are the most common underlying pathophysiologic mechanisms in cardiac arrest, especially in out-of-hospital arrest.

sion, tachycardia, hypothermia, or hypoxia. They also include clinical changes such as mental status deterioration or progressive shortness of breath. Therefore, nursing staff should be appropriately vigilant in monitoring for such changes, and physicians should be duly attentive to warning signs from patients and staff. Early stabilization by such measures as intubation, initiation of vasopressor therapy, and/or transfer to an intensive care unit are far more effective than treating cardiac arrest once it has occurred. In Europe, this concept has been formalized into the ALERT course, in which hospital staff and physicians are trained to recognize and treat the early signs of destabilization that may lead to cardiac arrest.[22–24]

Resuscitation Team Organization

It is very important for hospitals, ICUs, and prehospital care systems to establish a clearly delineated team structure for cardiac arrest treatment. In-hospital studies have shown that a well-trained and organized arrest team is an important component in the resuscitation from sudden death.[25] Team members should be ACLS trained and have a specified team leader who will lead the resuscitation efforts. Training should emphasize the need for a hierarchical structure, with the team leader making most treatment decisions, to prevent the confusion that often occurs during cardiac arrest events. It also should be emphasized that response time is critical, such that a resuscitation team should be able to arrive on the scene of a cardiac arrest within minutes to initiate treatment. Recent data demonstrate that groups with best-practice survival from cardiac arrest have mean "call to shock" times (for VF/VT arrest) of 5 minutes or less,[26] and certainly the earlier the response, the more likely a better outcome will be obtained.

Resuscitation efforts during cardiac arrest require activities to be performed quickly, calmly, and in regimented fashion. Rescuer panic and disorganized efforts are counterproductive and can best be avoided by appropriate training before (and debriefing after) events take place. With the growth of medical simulation technology and sophisticated manikins for resuscitation training, it is possible for cardiac arrest teams to rehearse scenarios to supplement education and enhance preparedness.[27,28]

Basic Life Support

The first steps of resuscitation from cardiac arrest involve what is known as Basic Life Support (BLS). These fundamental skills are part of CPR training courses offered to the public by organizations such as the American Heart Association and the American Red Cross. Given the importance of early recognition and care for cardiac arrest, it is incumbent on all medical personnel from ward receptionists to radiology technicians to physicians to maintain BLS training. Health care workers also should encourage the public to obtain these skills, which are often summarized by the ABC's—airway, breathing, and circulation.

Initial Assessment

When a patient is first assessed, it must be determined if the patient is truly unresponsive. Stimulation by squeezing a shoulder or rubbing the sternum is reasonable, and if no movement, eye opening, or verbal response is noted, attention should be turned to the ABC's. The outdated BLS teaching that a patient should be shaken probably should be avoided given that the unresponsive state may be secondary to head and neck trauma. Care should be given to moving a patient as little as possible until this is determined. If a patient is deemed unresponsive, the initial observer immediately should call for help while assessing the ABC's.

Airway

To attempt optimal airway opening, the chin should be lifted, and the jaw should be thrust forward. A quick evaluation of the oropharynx should be performed to look for a foreign body, blood, or other occluding material. Any visualized foreign body should be removed by suction or by careful use of fingers or forceps. After this evaluation, several "rescue breaths" should be delivered via mouth-to-mouth or mask-to-mouth technique. If the chest wall does not rise with these breaths, it is possible that a complete airway obstruction exists, and abdominal thrusts should be performed to attempt airway clearance. If these fail, trained personnel may need to establish a surgical airway via cricothyrotomy.

Breathing

While holding the chin and jaw in the correct position, breaths should be delivered during initial efforts until a more definitive airway can be obtained. In cardiac arrest, this is performed via endotracheal intubation, which is performed routinely by anesthesiologists, emergency physicians, respiratory therapists, and paramedics. If possible, ventilation should be performed with maximal $F_{I_{O_2}}$ via bag-valve-mask until intubation is performed. Pulse oximetry can be used to monitor patient oxygen saturation during this process.

Circulation

The hemodynamic status of the patient should be assessed via palpation of arterial sites. As an approximate rule of thumb, the radial, femoral, and carotid pulses are lost at systolic pressures below 80, 70, and 60 mm Hg, respectively.[15] Therefore, the most sensitive site to assess is the carotid artery. If no pulse can be felt at the carotid, chest compressions should be initiated immediately. Compressions should be performed at a rate of 100 beats per minute and to a depth of at least 1 to 2 in.

Recent studies have demonstrated the importance of "good quality" chest compressions, partially defined by compressions performed at the appropriate rate and depth. This is important in light of the fact that an observational study has shown performance of chest compressions to be grossly suboptimal in practice.[29] Rescuers should pay particular attention to the performance of this skill. Future generations of resuscitation devices may aid this process by monitoring the quality of chest compressions and generating alarms during suboptimal performance. Exciting recent data have suggested that chest compressions may be more important than defibrillation in the initial treatment of cardiac arrest.[30,31] These observations, which might have been considered heretical just several years ago, lend support to an important new paradigm in cardiac arrest, that of the *three-phase model* of cardiac arrest (see discussion later in this chapter).[32] It has been proposed that 90 seconds of CPR be performed before defibrillation,[33] but this recommendation has not been evaluated fully for inclusion in the American Heart Association ACLS guidelines.

Monitoring the adequacy of the circulation during performance of CPR traditionally has been based on palpation of pulses. Capnography is an attractive adjunct to bedside clinical monitoring because the amount of carbon dioxide returned from peripheral tissues and then exhaled from the lung should be a measure of the adequacy of cardiac output. In one prospective, observational study,[33a] 150 consecutive cardiac arrests out of hospital were monitored by end-tidal carbon dioxide levels after intubation. After 20 minutes of advanced cardiac life support, end-tidal carbon dioxide levels averaged 4.4 ± 2.9 mm Hg in nonsurvivors and 32.8 ± 7.4 mm Hg in survivors ($p < 0.001$). A 20-minute end-tidal carbon dioxide value of 10 mm Hg or less successfully discriminated between the 35 patients who survived to hospital admission and the 115 nonsurvivors. While not yet routine, capnography may be useful for both judging the adequacy of resuscitative efforts and offering prognostic information.

While not strictly part of BLS, fluid resuscitation is a crucial adjunct to circulatory support in the initial phases of resuscitation. Intravenous access should be obtained rapidly if it is not already present, and adult patients should receive a rapid infusion of at least 500 to 1000 mL of 0.9% saline or lactated Ringer's solution. In children, the crystalloid infusion should be calculated at 20 mL/kg. The ideal IV access would include a peripheral large-bore (i.e., 14 to 18 gauge) catheter and/or large-bore central catheter (i.e., not a double- or triple-lumen catheter). The optimal site for central line placement in resuscitation is the femoral vein because the chest and neck are busy sites for chest compressions and ventilatory support, respectively, making subclavian or internal jugular approaches impractical unless already present. In children, an intraosseous line may be a convenient approach to initial access.

Ventricular Tachycardia with a Pulse

Ventricular tachycardia (VT) may or may not generate a pulse. Therefore, it is crucial to assess the hemodynamic status before ACLS resuscitative measures are begun. If the patient has a pulse, is conscious, and has only mild complaints of palpitations, mild chest discomfort, weakness, and/or anxiety, immediate electrical cardioversion is not required. On the other hand, if the patient exhibits signs of instability, including syncope, severe chest pain, or marked hypotension, then cardioversion should proceed immediately after appropriate sedation is delivered.

The treatment of VT with a pulse includes intravenous administration of lidocaine or amiodarone and supportive care (oxygen administration and preparation for electrical cardioversion). In cases in which both VT and supraventricular tachycardia with aberrancy cannot be distinguished with certainty, the use of procainamide can be considered because it is appropriate for both conditions. Recurrent VT often requires electrophysiologic evaluation and treatment, including the placement of an implantable cardioverter defibrillator (reviewed in ref. 34).

Ventricular Fibrillation/Ventricular Tachycardia without a Pulse

Ventricular fibrillation and ventricular tachycardia without a pulse (VF/VT) are grouped together because both require the same treatment—immediate defibrillation. In

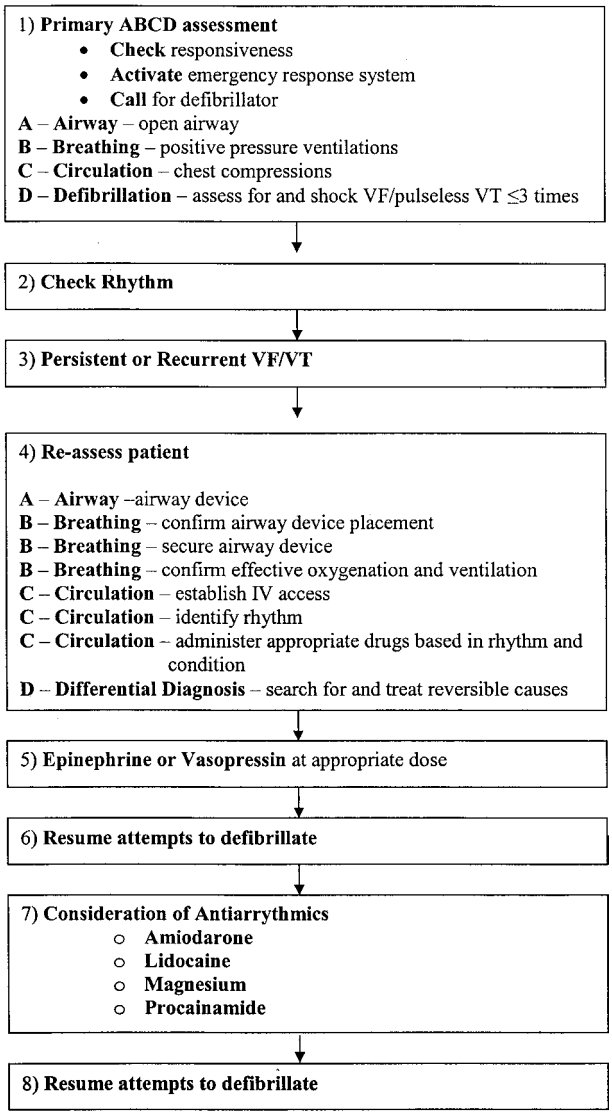

FIGURE 15-1 ACLS algorithm for VF/VT. Perhaps the most important aspect of this algorithm is the need for early defibrillation. ***(Modified from American Heart Association ACLS Manual.)***

fact, defibrillation should precede any other assessment or treatment. Studies have shown consistently that the earlier a patient is defibrillated successfully, the better are the chances for survival.[35] This observation has stimulated the use of automatic external defibrillators (AEDs) in airports and other public locations (see the section on AEDs later in this chapter).

When a patient is found in VF/VT, up to three defibrillatory shocks should be delivered in rapid succession, with a brief pause between each shock to examine the cardiac monitor (see Fig. 15-1 for a VF/VT algorithm). There is no need to feel for a pulse between shocks unless the rhythm has changed. Using standard monophasic defibrillators, the first shock should be delivered at 200 J; the next two shocks can be delivered at 200 J or at 300 and 360 J, respectively, in the energy escalation proposed in the ACLS guidelines. Using biphasic defibrillators (see later in this chapter for a discussion of different defibrillator types), all shocks should be delivered at 150 J or at the energy suggested by the manufacturer.[4]

If a patient remains in pulseless VF/VT immediately after these three shocks, further treatments include assessment of the ABC's and pharmacologic adjuncts. Chest compressions should be initiated immediately, with care taken to ensure compression quality, as discussed previously. Patients should be intubated immediately and ventilated with 100% O_2, with care taken to ensure correct endotracheal tube placement by both auscultation and end-tidal CO_2 detection, if available. If not already performed, IV access should be established. Large-bore (not multilumen) central venous access by the femoral approach is most convenient and practical in this setting if skilled personnel are available. It is often useful to obtain an arterial blood gas sample at this point as well because it will take some time for the results to return to the team in any case. While these steps are taking place, the arrest team leader should rapidly obtain a very brief history from available sources, including nursing staff, family, or physicians caring for the patient. The most important details to obtain are when the patient was last seen with a pulse, what pertinent medical problems the patient has, and what has taken place in the last few hours of patient observation.

In VF/VT arrest, either epinephrine 1 mg IV or vasopressin 40 U IV should be given early, preferably within the first 5 minutes of resuscitation efforts. Vasopressin, a relatively new addition to the ACLS guidelines, has been shown to improve coronary perfusion pressure and possibly improve initial resuscitation compared with epinephrine.[36–38] However, despite some optimism regarding the theoretical advantages of vasopressin over epinephrine, conclusive data showing improved survival to hospital discharge are still lacking.[39] Additionally, high doses of epinephrine (e.g., 3 or 5 mg IV) previously had been hoped to have additional benefit over the standard 1 mg IV dose, but human trials have demonstrated no significant survival benefit.[40–42]

After the administration of epinephrine or vasopressin, another shock at 360 J should be delivered. If the patient remains in VF/VT after this, additional medications can be administered before additional defibrillation attempts. One such pharmacologic option is amiodarone, given as a 300-mg IV bolus. Two studies have shown clearly higher initial survival with amiodarone compared with lidocaine, although lidocaine and amiodarone have yet to show an effect on survival to hospital discharge.[43,44]

Pulseless Electrical Activity

Pulseless electrical activity (PEA) is a state defined by having no detectable pulse despite the appearance of an organized electrical rhythm on cardiac monitoring. This electrical activity may appear as so-called normal sinus rhythm or similar pattern but must be differentiated from pulseless VF/VT, which requires specific treatment (see above). PEA used to be described as "electromechanical dissociation" (EMD), based on the assumption that some pathophysiologic process had separated the normal electrical conduction of the heart from its ability to cause myocardial contraction. Echocardiographic studies of myocardium in PEA, however, demonstrate some degree of visible muscle activity.[45] Thus, the term *EMD* has fallen out of favor compared with the more appropriate PEA.

The initial approach to a patient in PEA is much the same as the approach to patients with other pulseless rhythms

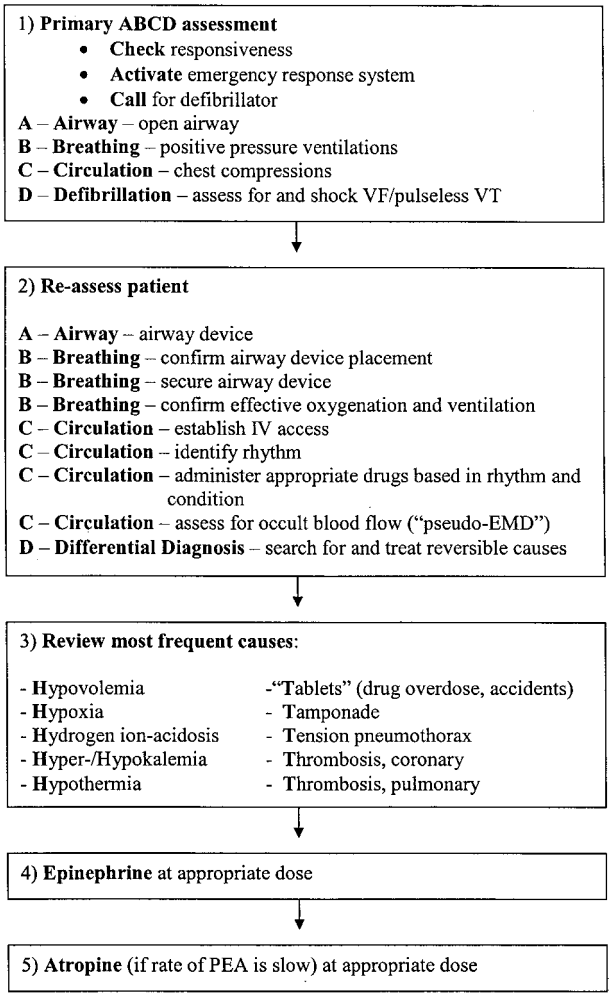

FIGURE 15-2 ACLS algorithm for PEA. Note that this algorithm really serves more as a prompt for differential diagnosis; see Table 15-3 for elaboration of PEA etiologies. ***(Modified from American Heart Association ACLS Manual.)***

(see Fig. 15-2 for a PEA algorithm). CPR should be initiated immediately, a definitive airway should be established, and the patient should be ventilated with 100% O_2. Large-bore central venous access should be established. An arterial blood gas sample should be obtained early, with a request to check hemoglobin and potassium, if possible. A brief history should be taken from staff by the resuscitation team leader regarding the events leading up to the pulseless state. Neck veins should be examined to consider cardiac tamponade, lungs should be auscultated to rule out tension pneumothorax, and if appropriate, the patient's temperature should be taken to evaluate for hypothermia. All patients in PEA should receive epinephrine 1 mg IV early in the resuscitation efforts.

In contrast to VF/VT, there is no specific treatment for PEA per se. There are, however, a number of appropriate therapeutic options depending on the *cause* of PEA. Therefore, a differential diagnosis must be considered quickly (Table 15-3). Intravascular hypovolemia, through either hemorrhage or leakage of fluid from the vascular compartment, is a common cause of cardiac arrest in the hospital setting. A high suspicion for this etiology should be maintained for patients

TABLE 15-3 PEA Differential Diagnosis and Possible Treatments

PEA Etiology	Possible Treatment
Cardiac temponade	Needle pericardiocentesis
Drug overdose	Specific antidotes as required
Hyperkalemia	Administration of calcium, insulin, glucose, bicarbonate
Hypothermia	Rewarming with warm IV fluids, warming blankets
Hypovolemia	Administration of IV fluids, blood, and/or blood products
Hypoxia	Ventilation with 100% O_2
Massive pulmonary embolism	tPA or other thrombolytic agent
Myocardial infarction	Thrombolytic agent or interventional catheterization
Tension pneumothorax	Needle thoracostomy on affected side of chest

NOTE: This list only covers the major common etiologies that might be considered in the treatment of PEA. Hypovolemia and hypoxia are probably the most likely in-hospital factors leading to PEA arrest; myocardial infarction and hypothermia are probably the most common out-of-hospital etiologies.

who recently underwent surgery or for patients known to have a serious infectious process and now may be presenting in septic shock. Hypoxemia is another common cause of PEA, although ventilation with 100% O_2 renders this largely a diagnosis of exclusion. A third common process underlying PEA is hypothermia, which again may be common in postoperative and/or septic patients. Aggressive treatment with warm IV fluids and warming blankets should be undertaken in these patients during resuscitation. Resuscitative efforts should not be terminated until all efforts have been made to warm the patient to normothermia.

Tension pneumothorax also can lead to PEA arrest and should be considered especially in any patient who was mechanically ventilated prior to arrest. Lung auscultation during ventilatory cycles should help to identify this problem. If lung sounds are diminished unilaterally, the endotracheal tube should be pulled back several centimeters to determine if a main stem bronchus intubation was present. If decreased breath sounds persist after this maneuver, a needle thoracostomy should be performed with a 16- to 18-gauge IV catheter in the second intercostal space on the side exhibiting diminished lung sounds.

Another major cause of PEA arrest that deserves some discussion is massive pulmonary embolism, which can lead not only to hypoxemia but also to cardiogenic shock from sudden right ventricular (RV) dysfunction. If the resources are available, rapid echocardiography can be performed during resuscitation efforts to evaluate the size and function of the right ventricle. A markedly enlarged and poorly contracting right ventricle supports the diagnosis of pulmonary embolism. This diagnosis also should be considered for patients with known deep venous thrombosis or possible thrombophilia from disease processes such as malignancy or systemic lupus and for patients who have been hospitalized and/or immobile for at least several days. If pulmonary embolism is strongly suspected, treatment with tissue plasminogen activator (tPA) can be considered. The use of tPA in cardiac arrest remains controversial, however (see discussion of tPA later in this chapter).

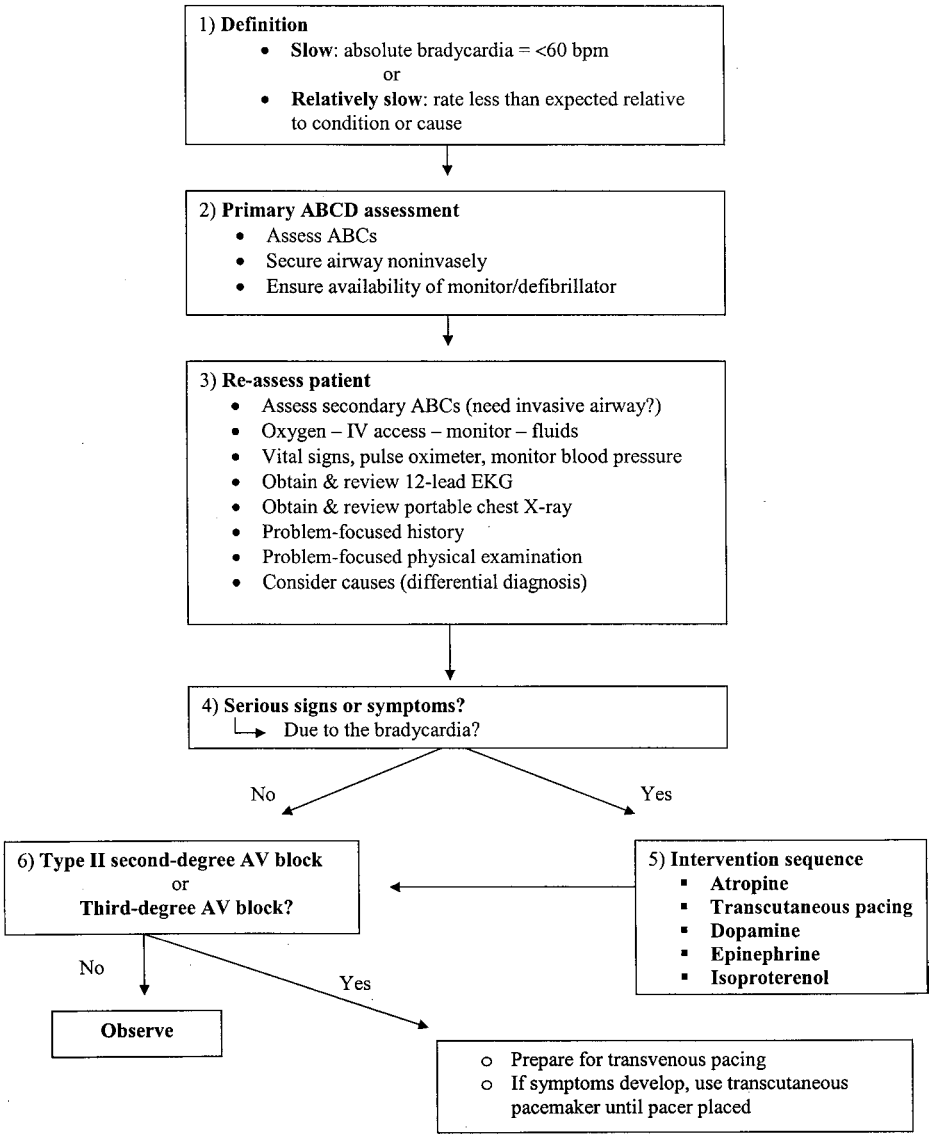

FIGURE 15-3 ACLS algorithm for bradycardia. *(Modified from American Heart Association ACLS Manual.)*

The patient should be evaluated for other causes of PEA. These include cardiac tamponade, for which pericardiocentesis with a long spinal needle can be lifesaving; hyperkalemia, requiring treatment with intravenous calcium, insulin, and glucose; and drug toxicity, which requires specific therapies depending on the drug in question.

Bradycardia

In some cases, a pulseless state can occur if the heart rate slows dramatically, e.g., to less than 30 to 40 beats per minute. This can occur in cases of complete heart block, hypoxemia, hypothermia, and toxic states from certain medications, especially β blockers and calcium channel blockers. In a sense, pulseless bradycardia is a subset of PEA arrest in which additional specific treatments may be attempted beyond that for PEA itself.

After standard ACLS maneuvers including CPR, intubation, and ventilation with 100% O_2 and administration of epinephrine (see preceding sections), treatment should be directed toward increasing the rate of electrical activity, which may be sufficient to generate a blood pressure (and therefore a pulse). If this increased rate does not generate a pulse, the patient truly can be considered to be in PEA arrest.

Methods to increase the heart rate include administration of atropine 1.0 mg IV, which may be repeated up to a total of 0.04 mg/kg, and a trial of electrical pacing (see Fig. 15-3 for a bradycardia algorithm). Transcutaneous electrical pacing, a standard capability of most hospital defibrillators, can be attempted as well, although no evidence-based recommendations exist regarding rate and current to be applied. We recommend starting at a rate of 80 impulses per minute and 50 mA current, ramping up the current as necessary to obtain capture, if possible at all.[46]

Asystole

All patients in cardiac arrest eventually converge into the rhythm of *asystole,* which is defined as no discernible electrical activity on cardiac monitoring (see Fig. 15-4 for an asystole algorithm). An occasional wide complex can be seen in asystole, which is known as an *agonal rhythm*—this carries the

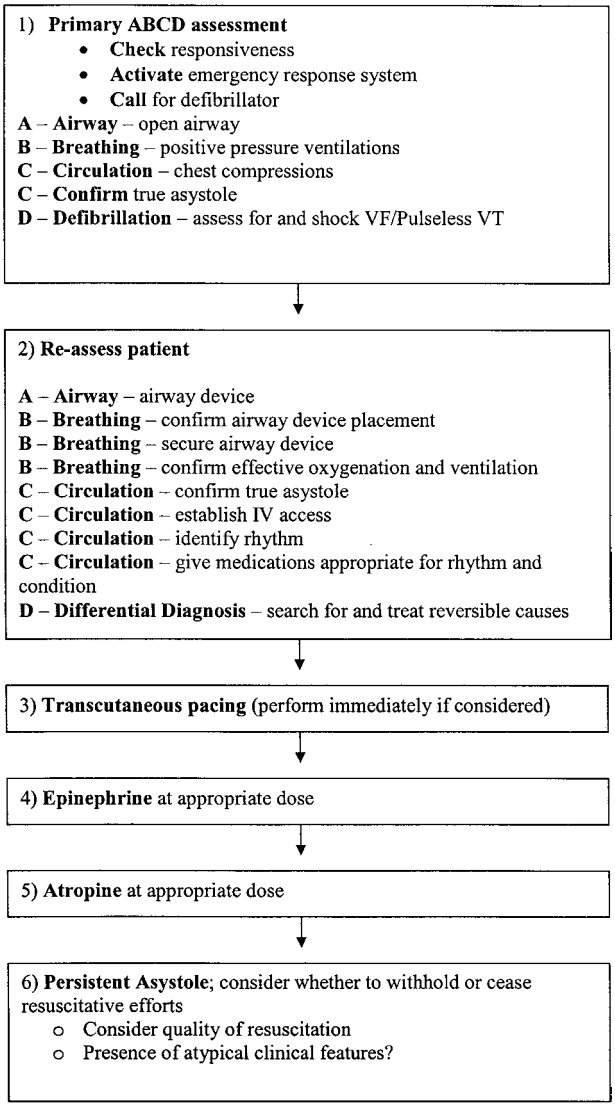

FIGURE 15-4 ACLS algorithm for asystole. ***(Modified from American Heart Association ACLS Manual.)***

same grave prognosis as asystole itself. Unwitnessed cardiac arrest with the presenting rhythm of asystole has a dismal rate of survival, usually considered to be less than 1%.[47] There are very few treatment options for rescuers confronted with asystolic patients, and therefore, a rapid search for reversible causes combined with standard ACLS measures in most cases should not lead to lengthy resuscitation efforts.

Besides standard resuscitation techniques (described earlier), including chest compressions, intubation, ventilation with 100% O_2, and administration of epinephrine, atropine infusion and a trial of electrical pacing may be used. Atropine should be dosed intravenously in 1-mg increments every 3 to 5 minutes during arrest, up to 0.04 mg/kg. Transcutaneous electrical pacing may be attempted as well, following the same recommendations as those for bradycardia (see discussion on bradycardia above).

After three rounds of epinephrine and atropine administration, 10 to 15 minutes of chest compressions, and possibly transcutaneous pacing, the clinical situation should be reassessed. If the rhythm remains in asystole, efforts should be terminated, because survival after 10 to 15 minutes of confirmed asystole despite pharmacologic intervention and intubation is essentially zero.[48,49] An important caveat in the assessment of asystole is that at least two cardiac monitoring leads should be examined for a rhythm—often what appears to be asystole in one lead actually represents a loose electrical connection, and one might find a treatable rhythm in another lead.

Ending Resuscitation Efforts

The subject of resuscitation team function and performance remains poorly studied, and usually ACLS training gives short shrift to team cooperation and leadership skills. The decision to terminate efforts represents a difficult moment for the resuscitation team and the team leader.[50] One simple recommendation to ease the tension of this moment and ensure that all reasonable effort has been given to save the life of the patient is to involve the entire team in the termination process. We recommend that the team leader, sensing that effort has become futile, should verbally summarize to the team all the treatment rendered so far, e.g., how long CPR has been performed, what drugs and shocks were given, and what underlying arrest etiologies were considered. The team leader then can ask if any team member has final recommendations or suggestions before efforts are halted. In this fashion, the decision to stop resuscitation procedures is made by the group, and staff will feel satisfied that resuscitation was not terminated prematurely. After termination, it is often useful to conduct a debriefing session among key team personnel before disbanding, especially to troubleshoot any technical or team function problems. Hospitals should establish CPR review committees to monitor the quality of resuscitations on a periodic basis and implement system changes as necessary to improve outcomes.

Aspects of Defibrillation

Modern electrical defibrillation, or the use of electric current applied directly to a patient's chest to restore a viable heart rhythm, grew out of research into electrocution deaths among maintenance workers at Consolidated Edison of New York. The first human defibrillation was performed intraoperatively by Claude Beck in 1947; the first external defibrillation was undertaken by Paul Zoll in 1955.[51] Since that time, defibrillation has become a cornerstone of cardiac resuscitation and has been used successfully by physicians, nurses, paramedics, police, and even the public at large.

The exact mechanism of defibrillation remains uncertain. Whether a critical number of myocardial cells require membrane depolarization to overcome ventricular fibrillation or whether certain regions of the heart must achieve a critical current density remains a subject of active study. Several mechanistic aspects are clear, however. The energy discharged (measured in joules, or watt-seconds) appears to have both dose-response and therapeutic window characteristics. That is, the chance of successful defibrillation rises with increasing energies delivered; however, as energy is increased further, functional myocardial injury predominates over useful resuscitative properties. With standard defibrillators, 200 J is the recommended energy for initial shock; 300 and 360 J are accepted levels for subsequent attempts to defibrillate. For children, the

recommended initial dose is 2 J/kg, with a second shock at 4 J/kg if the first shock fails.

Technique of defibrillation is also important. Firm pressure must be applied with defibrillation paddles to ensure proper delivery of energy without electrical arc or skin burn. Similarly, defibrillation pads must be well applied to the chest. Positioning of paddles or pads must ensure that the imaginary line connecting the two electrodes runs through the heart. That is, in one standard approach, an electrode should be placed at the right upper sternal border and the other at the left midaxillary line near the apex of the heart.

Perhaps the most important observation regarding electrical defibrillation is that the longer the delay before a shock is delivered, the less chance there is for a successful resuscitation. Ventricular fibrillation or tachycardia should be defibrillated immediately; this is the fundamental principle underlying implantable cardioverter defibrillators (ICDs), a commonly placed device for patients with recurrent ventricular tachycardia or history of cardiac arrest.[18] If VF/VT persists for even 5 minutes without CPR or defibrillation, the chance for a successful outcome falls dramatically.

Given the need for early defibrillation, automatic external defibrillators (AEDs) have become an important tool for paramedics and the lay public. These devices, commonly found in airports and other heavily trafficked public locales, perform rhythm analysis and provide defibrillatory shocks if needed. In theory, no prior experience should be required to operate such a device. AEDs are discussed in more detail below.

Most defibrillators in use today generate monophasic waveform shocks. Over the past few years, biphasic defibrillators have become available commercially and likely will become the standard of care over the next decade. These defibrillators have been shown to be equally effective as monophasic devices at lower energies, which may optimize the benefits of the shock while minimizing myocardial injury.[4]

A New Three-Phase Time-Sensitive Model of Cardiac Arrest Therapy

There is hope that in the coming years resuscitation science will offer substantially improved survival for victims of cardiac arrest. With the success of early defibrillation programs in airports, casinos, and other public places, survival rates in these special locales have soared to greater than 50%.[52] However, a new paradigm has emerged in our understanding of sudden death. The three-phase time-sensitive model of cardiac arrest, based on data from the past several years, offers the hope of better survival with therapy tailored to the time after initial arrest.[32]

This model proposes that time in cardiac arrest can be divided into different phases: the electrical phase (the first 4 minutes after arrest), the circulatory phase (minutes 4 through 10), and the metabolic phase (after 10 minutes), with each requiring different therapeutic approaches (Fig. 15-5). The electrical phase calls for defibrillation as the first therapy for VF/VT and is currently our standard of care regardless of time spent in cardiac arrest. This fits well with national efforts to get more rapid defibrillation with AEDs—because the evidence suggests that defibrillation within the first few minutes is associated with a better than 50% chance of initial survival. However, a challenge during this electrical phase is the need to get defibrillators rapidly to victims at home, where over 70% of cardiac arrests take place. The circulatory phase appears to be best treated initially with chest compressions and ventilations and then followed by defibrillation after several minutes of CPR. Note that this is not the current standard of care according to the American Heart Association at the time of this writing. Using this "CPR first" algorithm, paramedic services in Norway have improved survival rates from 4% to 20% over standard advanced cardiac life support during this circulatory phase.[30] However, another challenge becomes apparent during this phase: our current quality of CPR remains unmeasured and poorly controlled. Recent studies would suggest that CPR quality in real resuscitation falls far short of the high quality required for survival—and new technology offers us the ability to markedly improve on this in the next few years.[29] This circulatory phase may be difficult to identify because we usually do not have accurate information on time of collapse and thus may not know in which phase a patient resides. The circulatory phase depends on very good CPR, so prioritizing good compression rate, compression depth, minimal pauses in compression, and proper ventilatory management all become critical priorities.

The third so-called metabolic phase is the most lethal and challenges our basic scientific understanding of ischemia and

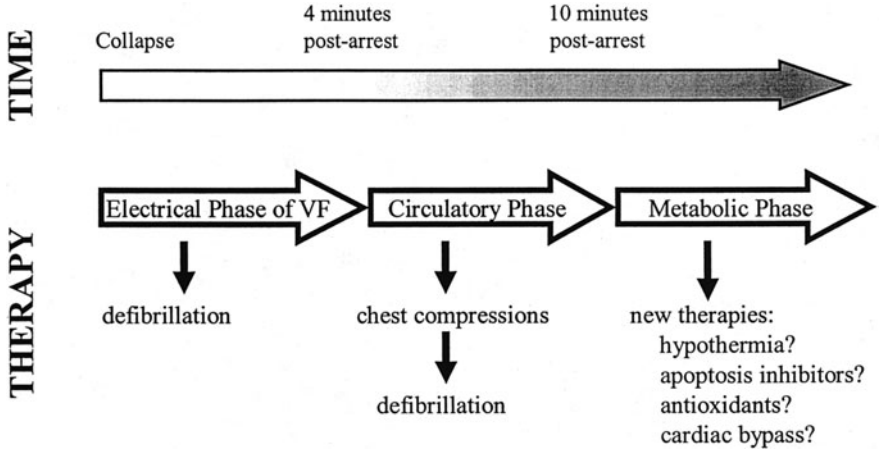

FIGURE 15-5 This three-phase model serves as a paradigm shift in the categorization and treatment of cardiac arrest. While some data have been published recently to support the model, it is still considered theoretical but likely will serve as a tool to think about future therapies.

reperfusion injury. Novel therapies, such as advanced cardioprotective pharmacologic agents, cardiopulmonary bypass, induced hypothermia (see Chap. 16), preconditioning pathways, inflammatory mediators, apoptosis signaling, and hibernation may offer promise in the understanding and treatment for this phase—but the need for new translational research in this area is vital. The tools of molecular biology, proteomics, and cellular physiology are likely to provide important insights and to create new biosensors that can guide clinical therapies. It is not unrealistic to believe that major improvements in survival rates will result as we change our current practices in the near future.[53]

Automatic External Defibrillators

Given the assumption that early defibrillation remains the best treatment for VF/VT cardiac arrest, a number of devices have been developed to allow inexperienced users to defibrillate victims before the arrival of medical personnel (reviewed in ref. 54). These devices, known as *automatic external defibrillators* (AEDs), have become ubiquitous in airports and other public locations. These simple-to-use defibrillators contain waveform analysis software that determines whether a shock is warranted when a layperson attaches sensing pads to the chest of a comatose individual. Appropriate shocks are then delivered. Audio prompts guide the user through the process.

The placement of AEDs in public places has been shown to affect survival from cardiac arrest, supporting the concept that earlier defibrillation correlates with improved outcomes.[52] However, the majority of cardiac arrests occur in the home, not in public. Data from Seattle suggest that as many as 70% of out-of-hospital cardiac arrests take place in residences, and only 21% occur in public locales.[1] Whether AEDs should be available for home installation, much like fire extinguishers, remains an active question. As AEDs become smaller, smarter, and cheaper, this debate may tip toward home availability.[55]

Whether AEDs should be placed in hospital wards remains another topic under current discussion.[56] Although hospital resuscitation teams include ACLS-trained personnel, most "first responders" in the hospital setting are nurses or other health care staff who may not be ACLS proficient and therefore unlikely to perform defibrillation. It has been argued that the availability of AEDs in the hospital would allow for rapid defibrillation attempts before the arrival of resuscitation teams. However, the presence of AEDs would not be sufficient—nurses and other health care workers would have to accept defibrillation as a possible primary responsibility. There are some data to suggest nurses would support such a role.[57]

Induced Hypothermia in Cardiac Arrest

In the search for novel cardiac arrest therapies, induced hypothermia has generated a great deal of recent interest, spurred by two well-conducted studies showing improved survival when patients were cooled to 32 to 34°C after resuscitation from cardiac arrest.[58,59] An international recommendation has been issued based on this evidence that patients should be cooled after out-of-hospital cardiac arrest; data on in-hospital cardiac arrest are still under discussion.[60] Much work remains to further define this treatment, regarding both depth and duration of hypothermia. Novel techniques for cooling patients are under development as well, including multiphase coolant fluids and cooling catheters. Chapter 16 of this book is devoted to this exciting field of induced hypothermia.

Pharmacologic Therapy of Cardiac Arrest

CPR and electrical defibrillation are the central treatment modalities for cardiac arrest in current practice. While medications such as epinephrine, atropine, lidocaine, and amiodarone have been incorporated into treatment algorithms for cardiac arrest, to this day they do not have any proven survival benefit.[61] A surge of interest in "high dose" epinephrine in recent years was quelled when a number of studies demonstrated no benefit from this approach.[42,62] Current interest in amiodarone as a treatment for VF/VT is based largely on one study that showed an improvement in initial resuscitation but did not demonstrate an improved survival to hospital discharge.[43] There are no definitive data to demonstrate a survival benefit from atropine or lidocaine. Similarly, bicarbonate, while widely administered during cardiac arrest, has not been proven to aid resuscitation. In fact, ACLS guidelines only recommend bicarbonate infusion in a small subset of cardiac arrest patients, namely, those known to be hyperkalemic.[15] Doses of standard ACLS medications are given in Table 15-4.

Thrombolytic therapy in cardiac arrest has received recent interest because a number of uncontrolled studies and cohort series have suggested a benefit from the use of urokinase or tPA.[63–65] A small but well-executed controlled study recently demonstrated no improvement in return of spontaneous circulation or survival with tPA in the treatment of PEA arrest.[66] A larger European study is currently ongoing and may help to resolve this controversy, and certain subsets of cardiac arrest patients may be found to benefit from this treatment modality. At this point, it is fair to say that thrombolytic therapy may be attempted if there is strong evidence to suspect pulmonary embolism as the cause of arrest.[61,67]

TABLE 15-4 Standard ACLS Medications and Doses

Medication	ACLS Dosing
Amiodarone	300 mg IV bolus, then 1 mg/min IV drip for up to 6 hours
Atropine (asystole)	1 mg IV bolus
Atropine (bradycardia)	0.5 mg IV bolus
Epinephrine	1 mg IV bolus (10 mL of a 1:10,000 solution)
Lidocaine	1.5 mg/kg IV bolus, then 1–4 mg/min (30–50 μg/kg/min) IV drip
Magnesium sulfate	1–2 g IV bolus
Sodium bicarbonate	1–2 mEq/kg IV bolus
Vasopressin	40 U IV bolus

NOTE: A more comprehensive list of ACLS medications and their dosing regimens can be found in the ACLS manual published by the American Heart Association. It is important to stress that very little data suggest that any of these medications actually improve survival to hospital discharge.

Limitations on Cardiac Arrest Efforts

The idea of a *chemical code,* i.e., performing resuscitation with pharmacologic agents only and not with chest compressions or defibrillation, is not controversial insofar as there is no disagreement among expert providers. Studies have demonstrated clearly that the concept lies much more in the realm of mythology or wishful thinking than in science. The only controversy is that the concept has persisted in hospitals and among health care workers across the world to this day.[68] It is important to stress the following point because the chemical code is often presented to family members as an option for care of their loved one: cardiac arrest is not a medical problem treatable by medications only.

In a similar vein, the *slow code,* in which efforts to resuscitate are intentionally delayed or limited by rescuers, is ethically unacceptable.[69] Patients who are *full code* should have every appropriate effort made to resuscitate them; decisions regarding appropriateness of resuscitation efforts should be made by patients and their primary physicians, not by a resuscitation team at the time of arrest.

Ethical Issues

The ethical dimensions of cardiac arrest treatment are complex and important for physicians to consider.[70,71] Decisions regarding termination of efforts and even the decision not to initiate efforts in the first place should be calibrated carefully depending on the individual case in question. The growing establishment of *do not resuscitate* (DNR) protocols has allowed patients and their families to avoid the traumatic and often futile efforts of resuscitation.

It cannot be stressed enough that physicians should initiate frank and truthful end-of-life discussions with patients early in their care, before hospitalization or cardiac arrest appear on the horizon. In this fashion, the use of cardiac arrest treatment can be judiciously tailored to the appropriate patients.[72] Physicians must emphasize the distinction to patients between DNR and *comfort care.* That is, a DNR order means that all curative measures could be employed except chest compressions and defibrillation. This distinction is also important for hospital personnel and physicians to understand, lest a DNR order influence other care decisions in the critically ill. In short, *do not resuscitate* should never mean *do not treat*.[73]

Chapter 16

THERAPEUTIC HYPOTHERMIA

BENJAMIN S. ABELLA
TERRY L. VANDEN HOEK
LANCE B. BECKER

KEY POINTS

- *Induced hypothermia has been shown to reduce mortality when applied after resuscitation from cardiac arrest.*
- *While the ideal temperature for hypothermia is not known, most experts believe that cooling to 32 to 34°C is optimal.*
- *Induced hypothermia may have benefit for other disease processes such as myocardial infarction and stroke.*
- *The mechanisms by which hypothermia acts are multifaceted and a focus of much current investigation.*

The notion of cooling patients for medical benefit is quite old. In 1814, Baron Larrey, a French surgeon in the service of Napoleon's army, reflected on soldiers who suffered major injuries on the frozen battlefields in Russia by commenting that "cold acts on the living parts . . . the parts may remain . . . in a state of asphyxia without losing their life."[1] A belated resurgence of interest in hypothermia has taken place in the past decade, expanding the possible medical indications for its use. Induced hypothermia, the intentional lowering of body temperature, has been explored in a number of acute critical care settings, including myocardial infarction, stroke, head trauma, and after cardiac arrest. While the optimal depth and timing of hypothermia are not yet established for these uses, most experts advocate a temperature goal of 32 to 34°C because it seems to provide significant benefit while avoiding most of the adverse effects associated with the intervention. Timing of hypothermia, with respect to both time of induction and duration of therapy, is even more uncertain, although general consensus holds that cooling should be initiated as soon as possible after the morbid event and should be maintained for at least 12 to 24 hours. Regarding specific uses, there is particularly good evidence that hypothermia is protective for the resuscitated cardiac arrest patient after return of spontaneous circulation.[2,3] The use of hypothermia in other clinical scenarios remains promising but less clear at present.

This chapter addresses elements of the history of hypothermia, the laboratory and clinical data that have developed our understanding of its use, some of the various techniques used to cool patients, and the clinical syndromes for which hypothermia appears to offer the greatest advantage.

History of Induced Hypothermia

The protective effects of hypothermia induction have been suggested since the time of Hippocrates, who advocated packing bleeding patients in snow.[4] Hypothermic protection also was noted by Napoleon's battlefield surgeon, Baron Larrey, during the French invasion of Russia. He observed improved survival of injured soldiers left in the snow compared with those treated with warm blankets and heated drinks.[1] Induced hypothermia has been studied in a wide variety of illnesses, both ischemic and nonischemic in nature (reviewed in refs. 5 through 7). These include traumatic brain injury,[8–10] status epilepticus,[11] arrhythmia, sepsis, and the ischemic illnesses of myocardial infarction, stroke, and cardiac arrest.[7,12] Interestingly, the first reported use of induced hypothermia was in the setting of malignancy. In 1939, Fay and colleagues treated patients with metastatic carcinoma, with the goal of both pain reduction and retardation of tumor growth.[13] While hypothermia to 32°C for 24 hours did not prove effective for the stated goals, it was considered well tolerated.[13]

A decade later, Bigelow studied the induction of hypothermia in the setting of cardiac surgery, with the goal of cerebral protection.[14] Two other studies using hypothermia as therapy for cardiac arrest also were published. Both these early cardiac arrest studies used moderate hypothermia of 30 to 34°C in patients after resuscitation from cardiac arrest. One of these pioneering papers presented a series of four patients, all of whom were cooled and survived arrest.[15] In the other study, 12 patients were cooled with a survival rate of 50% compared with 14% survival in 7 normothermic control patients.[16]

During the 1960s and 1970s, the field of induced hypothermia lay relatively dormant for reasons that remain unclear. Some have suggested that more dramatic therapies were developed that overshadowed cooling as a possible therapy, such as controlled ventilation, monitored ICU management, and cardiopulmonary resuscitation (CPR).[5] Additionally, several adverse effects of hypothermia were described, which may have dampened enthusiasm.[17,18]

Interest in "resuscitative hypothermia" was rekindled by Safar and others at the University of Pittsburgh, who demonstrated in a ventricular fibrillation dog model of cardiac arrest that mild to moderate hypothermia could be induced to improve outcomes.[19,20] Trauma research also provided a motivation for the development of induced hypothermia. It was understood from military combat experience that definitive therapy for penetrating trauma was often delayed for practical reasons (e.g., transportation and access to surgical care) and that measures were needed to preserve exsanguinating soldiers until appropriate care could be delivered.[21] Given the animal data on exsanguination and cooling, it appeared that hypothermia might be a suitable approach.[22]

Safar went on further to describe "suspended animation," a process that allows "rapid preservation of viability of the organisms in temporarily unresuscitable cardiac arrest, which allows time for transport and repair during clinical death and is followed by delayed resuscitation, hopefully to survival without brain damage."[12] Hypothermia has been a primary component of this concept of *stasis.* In this paradigm, victims of cardiac arrest may be cooled to some target temperature and maintained at that temperature for a specific period of time. With advanced medical interventions, which may include cardiopulmonary bypass, metabolic correction, and controlled reperfusion, the patient is stabilized and rewarmed, and "reanimation" is initiated. While many methodologies have been studied under the rubric of suspended animation, including cardiopulmonary bypass and pharmacologic interventions,[23] these are used most often as adjuncts to the use of hypothermia.

Since these initial observations in the 1980s and early 1990s, much of the work pertaining to hypothermia and ischemic disease has focused on focal ischemia and reperfusion, e.g., animal stroke and myocardial infarction models. A number of ischemia-reperfusion (IR) model systems have been developed over the last two decades, including cellular,[24] isolated organ,[25] and whole-animal models in which arterial supply to the organ under study is temporarily occluded.[26,27] In this latter category are included experiences with human IR, for example, during coronary vascular procedures.[28] Recently, two seminal papers were published describing the use of hypothermia to successfully treat resuscitated cardiac arrest patients.[2,3] With these studies, hypothermia has moved from the laboratory to active clinical use.

Mechanisms of Hypothermic Protection

The mechanisms by which induced hypothermia protects against cellular and tissue injury are poorly understood. Given the importance of temperature in a wide range of physiologic processes, it is reasonable to conclude that multiple mechanisms may be involved in any given tissue (reviewed in refs. 5 and 6). Some mechanisms implicated in hypothermic protection include modulation of transcription and/or translation, suppression of reactive oxygen species (ROS) production, and inhibition of programmed cell death, or apoptosis. The mechanisms by which cooling protects tissues may overlap as well. For example, the effect of hypothermia on cellular metabolism may lead indirectly to modulation of programmed cell death, and cooling may have a direct effect on cell death machinery itself. Most of the data pertaining to mechanism of hypothermic protection comes from studies of IR injury in models of stroke and myocardial infarction.

A number of gross physiologic changes have been observed in the setting of hypothermia that may contribute to decreased injury. As early as 1954 it was noted that hypothermia induced by ice water immersion could lower cerebral oxygen consumption in dogs by approximately 7% per 1°C drop in temperature.[29] Other studies have demonstrated that mild hypothermia in rats improves postischemic cerebral blood flow disturbances.[30] Another marker of general physiologic injury after reperfusion, brain edema, also was found to be reduced by hypothermia in a rat model of global ischemia.[30,31] Finally, hypothermia has been shown to minimize damage to the blood-brain barrier, which in turn may protect against blood-borne toxic metabolites reaching brain tissues through the compromised barrier.[30,32]

Intracellular signaling can alter the array of gene transcription activity of a cell quickly and dramatically, and this, in turn, can trigger a variety of injury processes. In a cardiac arrest mouse model, a group of signaling pathway genes known as the *immediate early genes* was activated after resuscitation.[33] A study of liver IR demonstrated a drop in c-jun terminal kinase activity at 25°C when compared with normothermic controls.[34] An extracellular signaling molecule thought to protect against injury, BDNF, was increased in a rat model of cardiac arrest when animals were cooled to 33°C.[35]

A number of biochemical changes during IR can be modified by the induction of hypothermia. In a gerbil stroke model, animals subjected to mild hypothermia were found to have decreased arachidonic acid metabolism compared with normothermic controls.[36] In a rat brain ischemia model, hypothermia to 32°C reduced nitric oxide production, as measured in jugular blood.[37] Whether these attenuations are simply markers of hypothermic effects or actually relevant factors in reperfusion injury remains to be clearly established. Other biochemical phenomena seem more likely to be linked directly to damage processes, such as the observation that hypothermia slows ATP depletion during IR.[38] ROS production also appears to be attenuated by hypothermic conditions in a rat cerebral ischemia model.[39]

Programmed cell death is a complex yet ubiquitous process by which cells actively chose or are chosen to die. This cellular program can be activated as part of normal physiology, such as during embryonic development, or as an abnormal response in a wide variety of disease states.[40,41] Much evidence implicates the induction of apoptosis as a component of reperfusion injury.[42,43] A recent report showed that the apoptotic pathway enzyme caspase 3 was upregulated in brain tissue after resuscitation from cardiac arrest, as measured at autopsy in patients who died within days of undergoing resuscitative measures.[44] Widespread evidence from animals also supports the notion that apoptosis is activated after reperfusion.[25,45] Hypothermia may inhibit this process. Proteolysis of the cytoskeletal protein fodrin, a characteristic step in the apoptotic pathway, is inhibited by hypothermia to 32°C in a rat brain IR model.[46] The process of apoptosis is an active one, requiring protein synthesis and enzymatic activity, both of which may be inhibited by lower temperatures. While some data suggest that the degree of apoptosis can be reduced by hypothermia, the topic certainly deserves more investigation in animal models.

Hypothermia in Cardiac Arrest

Cardiac arrest is a highly mortal condition that leads to at least 300,000 deaths each year in the United States alone.[47] Survival from cardiac arrest remains dismal some 50 years after introduction of chest compressions and electrical defibrillation, with only 1% to 11% of patients surviving until hospital discharge after out-of-hospital cardiac arrest.[48–50] While initial survival from in-hospital cardiac arrest ranges from 25% to over 50%, subsequent survival until hospital discharge is much lower, from 5% to 22%, suggesting that a high mortality rate is seen shortly after initial return of spontaneous circulation. Some of this mortality after return of normal circulation may be due to events related to reperfusion injury. For further discussion of cardiac arrest and resuscitation therapies, see Chap. 15.

Cardiac arrest remains a major medical challenge despite research efforts over the past few decades. There is little time after arrest to defibrillate the heart and thereby stop ongoing ischemic injury to key organs such as the heart and brain, and few therapies are proven to be useful during the postresuscitation phase of cardiac arrest—when up to 90% of patients go on to die despite successful defibrillation. New approaches are desperately needed to improve cardiac arrest survival, and induced hypothermia may be one of the most promising new approaches.[51]

Hypothermia may be helpful during three periods of time in a cardiac arrest (Fig. 16-1): (1) prearrest, (2) intraarrest, and (3) postarrest. Prearrest cooling can only be used practically

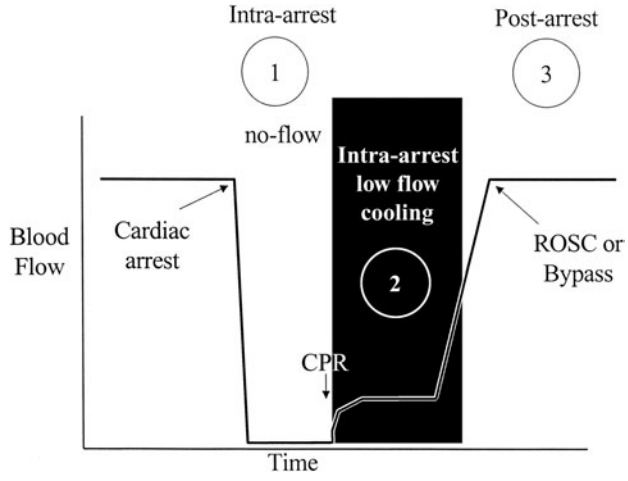

FIGURE 16-1 Time periods during which hypothermia may be used during an ischemia-reperfusion injury such as cardiac arrest or myocardial infaction.

as a preoperative intervention when the heart is stopped in a controlled fashion during cardiac surgery. Postarrest cooling to 32 to 34°C was found to be protective in recent human cardiac arrest trials, induced by applying cooling blankets or ice packing in the subset of cardiac arrest patients having return of spontaneous circulation (ROSC) who remained unresponsive.[2,3] The goal of this level of hypothermia was to prevent neurologic injury and decrease mortality while maintaining a temperature warm enough to prevent the other adverse effects of more profound cooling (e.g., cardiac arrhythmia, coagulopathy, and infection—see discussion of adverse effects later in this chapter). This cooling was protective despite taking 4 to 8 hours to reach target temperature after ROSC (Fig. 16-2). Intraarrest cooling, when cooling is induced after failed initial CPR, has the potential to induce a protective state long enough for more definitive circulation (e.g., cardiac bypass) to be established and life restored. Little is known about the optimal depth or clinical potential of such hypothermia owing in large part to the technical difficulties involved in inducing hypothermia during the low-flow states of sudden cardiac arrest.

Given the current data on hypothermia in cardiac arrest, guidelines for resuscitation likely will include hypothermia as a recommended intervention in the not too distant future. Recent large clinical trials support the use of hypothermia to 32 to 34°C in the successfully resuscitated patient with postarrest global neurologic dysfunction.

Cooling in these patients should be achieved as rapidly as possible using cooling blankets or ice. When ice is used, cloth or other material should be placed between the skin and the ice to avoid frostbite. Temperature should be measured via bladder probe, pulmonary artery catheter, or tympanic probe if invasive temperature monitoring is not available. Temperature should be taken every 15 to 30 minutes during the cooling protocol and until a stable cooled temperature state is achieved. Avoidance of temperatures below 32°C is important, and further temperature drops need to be addressed.

Cooling almost always will induce shivering and could result in discomfort. In the published studies of hypothermia after cardiac arrest, patients uniformly received neuromuscular blockade and sedation, and it is likely most patients will require such pharmacologic treatment. The disadvantages of this management strategy is that neurologic examination is not interpretable, and paralytic agents carry the risk of long-term neuromyopathy.

Rewarming often requires active intervention, which can include warmed intravenous fluids and warming blankets.

Although induced hypothermia has not been formally included in Advanced Cardiac Life Support (ACLS) guidelines at the time of this writing, it is recommended that ICU physicians and staff develop protocols for cooling after cardiac arrest because this recommendation likely will be forthcoming soon. Development of cooling protocols will require some time because a number of hospital-specific technical issues (e.g., how to cool, who will do the cooling, how to monitor temperature) will need to be established.

Induced Hypothermia in Myocardial Infarction

Induced hypothermia to 32 to 34°C has been shown in a variety of model systems to limit the size of a myocardial infarction in ischemia without reperfusion and to limit myocardial

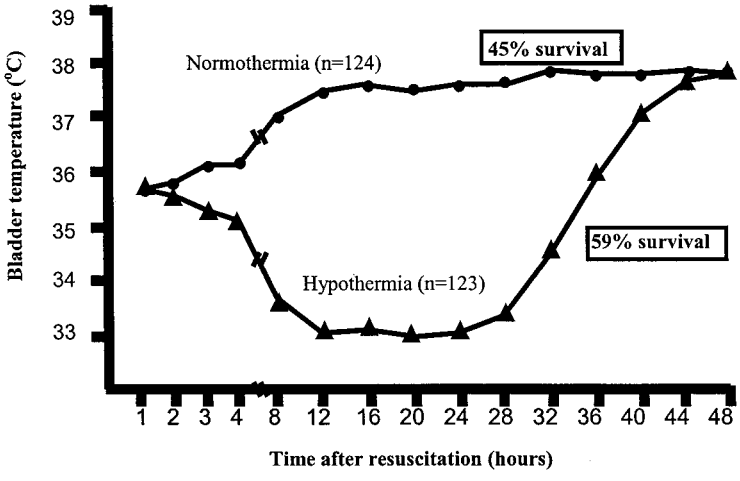

FIGURE 16-2 Data from the Hypothermia After Cardiac Arrest (HACA) study, in which hypothermia was induced via circulated-air cooling blankets. Temperatures shown are taken via bladder monitoring. Mortality differences between the hypothermia patient group and normothermic groups are shown at right. (*Adapted from the HACA study data.*[2])

injury when reperfusion is established. Given that current clinical practice is directed toward early reperfusion of myocardial tissue via thrombolytic therapy or percutaneous coronary intervention (PCI), it is the IR model that has received the most current attention. A recent trial in pigs used an endovascular cooling catheter to induce hypothermia during ischemia and after reperfusion of 60-minute coronary occlusions. Hypothermia to 34°C had a substantial protective effect, with smaller infarct size, better cardiac output, and improved microvascular flow.[52]

Endovascular cooling also has been studied to induce hypothermia during PCI in humans. In a pilot study, patients were randomized to cooled (34 to 35°C) or normothermic PCI. Cooling was maintained for 3 hours after intervention. No patients suffered adverse effects from cooling, and there was a trend toward smaller infarct size in the cooled patients.[53] Larger studies will be required to both confirm this finding and test the induction of hypothermia in the setting of thrombolytic therapy as well. Given that no major randomized studies have shown benefit from induced hypothermia in myocardial infarction, there is currently no clinical recommendation for its use. However, it is likely that hypothermia will become a standard technique to reduce infarct damage in the next decade.

Induced Hypothermia in Stroke

The rationale for the consideration of induced hypothermia in acute ischemic stroke is similar to that for cardiac arrest and myocardial infarction. Stroke is a difficult clinical problem with severe outcomes; not only is stroke the second most common cause of death in the world, but it is also the leading cause of disability in patients over 65 years of age.[54] Moreover, few improvements in acute stroke care have improved the general outcome of the disease.[55,56] Treatment with thrombolytic agents such as tissue plasminogen activator, while a powerful option when a patient presents within 3 hours of ischemic stroke onset, carries significant risks and has only demonstrated improvement in a subset of stroke patients.[57,58] In part, this is so because irreversible damage to brain tissue may have occurred already before restoration of blood flow. However, reperfusion of ischemic neuronal tissues also may produce additional damage via free radical production and induction of programmed cell death and the other so-called IR injury mechanisms described earlier[59] (reviewed in ref. 42).

The use of induced hypothermia in the setting of stroke remains experimental, although promising data exist to support its use (reviewed in refs. 60 and 61). In a variety of model systems, hypothermia reduces injury, as measured by biochemical and histologic markers. Cooling also appears to extend the time in which brain tissue can suffer ischemia without irreversible damage.[62,63] In several animal models, cooling to 32 to 34°C for greater than 24 hours provided significant benefit, whereas shorter periods of hypothermia provided more inconsistent results.[64,65] Several pilot studies have evaluated the feasibility and safety of cooling after ischemic stroke in humans. In one study, cooling to 33 to 34°C appeared to reduce intracranial pressure in patients with severe middle cerebral artery strokes.[66] In a trial of induced hypothermia after thrombolysis, cooling stroke patients to 32°C for at least 12 hours demonstrated a nonsignificant trend toward improved functional outcomes compared with normothermic controls.[56] These pilot studies were limited by small sample size. Larger randomized trials of induced hypothermia in stroke are currently underway in Europe.

While the induction of hypothermia after ischemic stroke requires additional refinement before becoming the established standard of care, aggressive prevention of hyperthermia is clearly indicated. A number of epidemiologic and clinical studies have shown that even modest elevations in temperature increase stroke severity and patient mortality.[67,68] Antipyretic medications in combination with either forced-air cooling or cooling blankets are sufficient to maintain core temperatures below 37°C. A clinical investigation using such modest measures demonstrated significant mortality risk reduction.[69]

Additional Clinical Applications

The induction of hypothermia has been used experimentally in a number of other clinical scenarios from surgical to critical care applications. One such indication is traumatic brain injury, in which an extensive body of laboratory work suggests that hypothermia may improve outcomes for severe trauma.[70] In one clinical study of 87 patients, hypothermia to 33 to 35°C for at least 72 hours provided a significant functional benefit at 1 year after injury.[71] However, a larger randomized trial of 392 patients failed to find a significant benefit at 6 months after cooling to 33°C for 48 hours.[10] While this has been widely interpreted as a "negative study," the authors have pointed out that the likely reason for finding no benefit was that owing to technical challenges (including taking 4 hours to get informed consent), the average time to cooling was nearly 8 hours after injury. There are no animal studies that suggest any improvement in neurologic results at this late time—the longest delay in cooling that shows any positive effect is about 1 hour following injury. Another clue to these conflicting results was provided by a clinical trial in which hypothermia was found to have no benefit in patients who did not exhibit elevated intracranial pressure.[72] Thus hypothermia may be useful in only a subset of brain injury patients. Taken together with studies demonstrating worrisome electrolyte abnormalities and pneumonia in cooled head injury patients,[73,74] no definitive recommendations exist currently for treatment of traumatic brain injury with induced hypothermia, although it is likely that future work will establish a role for cooling in this disease entity.

Induced hypothermia also has been studied in the setting of acute liver failure, such as from acetaminophen toxicity.[75] As many as 50% of patients with acute liver failure succumb from complications of increased intracranial pressure,[76] and induced hypothermia to 32 to 33°C has been shown to reduce intracranial pressure as much as 20 to 30 mm Hg in patients awaiting orthotopic liver transplantation.[77] Cooling also lowers arterial ammonia concentration and ammonia delivery to the brain, which may be one of the mechanisms by which hypothermia acts, because ammonia delivery to the brain contributes to increased brain edema and intracranial pressure.[78] It remains an open question whether hypothermia could be used to treat the hepatic encephalopathy of cirrhosis, also felt to be mediated by ammonia or at least compounds for which ammonia acts as a surrogate marker.

Neonatologists have studied induced hypothermia in the setting of hypoxic-ischemic encephalopathy after perinatal

asphyxia, an important cause of acute neurologic injury at the time of birth.[79] In a piglet model of brain ischemia, early cooling to 33 to 35°C improved neurologic outcomes by both functional and histologic criteria, whereas a delay in cooling by even 30 minutes negated this benefit.[80,81] Initial clinical trials have demonstrated the feasibility of selective head cooling in infants, with minimal differences in complications between cooled patients and normothermic controls.[82] Larger randomized clinical trials are in progress at the time of this writing.

A number of surgical applications of induced hypothermia have been evaluated, including aortic arch repair[83] and cardiac bypass surgery.[84] In these settings, hypothermia induction and rewarming can be controlled precisely and used for presumed important portions of the procedure in question. Unlike the clinical scenarios described earlier, surgical hypothermia does not attempt to treat a pathophysiologic problem but rather to prevent one from occurring. On a cautionary note, however, an extensive meta-analysis showed only a modest trend toward morbidity benefit in the setting of cardiac bypass surgery, with a trend toward decreased stroke rate offset by increased perioperative complications and myocardial injury.[84]

Risks of Hypothermia

Hypothermia is not without risk of adverse effects. As the body cools, a series of physiologic changes take place, including shivering, alterations in the clotting cascade, immunologic suppression, and cardiac membrane changes that increase the risk of arrhythmia (see Chap. 110). These effects are poorly characterized and depend on the extent and duration of cooling. Therefore, the optimal therapeutic window of hypothermia needs to be established.

Shivering, a common occurrence during the induction of hypothermia, can serve to counteract the mechanisms thought to be beneficial from the cooling itself, raising metabolic rates and myocardial oxygen demands. Pharmacologic options to control shivering include opioid and neuroleptic medications. Simply covering the arms and legs during central cooling has demonstrated some reduction in shivering as well, supporting the notion that an increase in peripheral to central temperature gradient may be responsible for triggering a shivering response.[85] A recent study demonstrated that meperidine and buspirone acted synergistically to reduce shivering,[86] and this technique has been used successfully with endovascular cooling in myocardial infarction.[53]

Hypothermia induces a poorly characterized diuresis in which patients may develop significant hypokalemia, hypomagnesemia, and/or hypophosphatemia.[74] Careful attention to electrolytes during the period of cooling and rewarming is required, and aggressive supplementation should be given when indicated.

A study of stroke patients demonstrated a risk of pneumonia with hypothermia, consistent with the cardiac arrest study results.[66] It is unclear whether the immune system is globally suppressed by hypothermia or whether some pulmonary-specific mechanism is the culprit for this increased pneumonia risk. Induced hypothermia does not seem to lead to a significantly increased risk of bacteremia, urinary tract infection, or other infectious complications. Whether patients undergoing induced hypothermia should be treated prophylactically with antibiotics remains to be determined.

While cardiac arrythmias are a theoretical risk of induced hypothermia, human studies in which target temperatures were above 32°C did not exhibit significant arrhythmia. It is possible that deeper cooling may provoke such electrical dysfunction. Therefore, no additional clinical precautions need be taken when hypothermia to 32 to 34°C is performed.

Unresolved Questions

There are a number of unresolved questions regarding the use of induced hypothermia. First, the optimal degree of cooling has yet to be established. As described earlier, hypothermia can have adverse effects such as shivering, reduced immune system function, and other possible complications.[87–89] Therefore, the therapeutic window of hypothermia must be defined to provide maximum benefit. Most clinical research has concentrated on the use of mild (34 to 36°C) or moderate (30 to 34°C) hypothermia. Evaluation of deep hypothermia has been confined largely to specific applications such as brain cooling during surgery and reduced cerebral perfusion.[90] Some animal investigations have compared different depths of cooling directly.[91] It is possible that different disease states may require different depths of cooling to provide optimal protection.

The timing of hypothermia is another crucial question. There are three general time periods in which hypothermia may be considered, although only two are realistic for clinicians. Preinsult hypothermia, or cooling some time before the onset of an ischemic process, is only possible in the setting of surgical intervention, in which ischemia is iatrogenic and controlled.[92,93] Induced hypothermia initiated immediately during an ischemic process, such as during stroke or myocardial infarction but before reperfusion has been initiated, is feasible but poorly studied in the clinical setting. A more dramatic example of this, the induction of hypothermia during CPR, is theoretically attractive and a promising area of current research but has not been attempted clinically. Postreperfusion hypothermia, or cooling after definitive treatment such as thrombolytic therapy or resuscitation, has been the most commonly attempted timing strategy and is certainly the most clinically convenient. Recent large-scale clinical trials have demonstrated significant benefit from induced hypothermia after resuscitation from cardiac arrest.[2,3] These studies raise a secondary timing question related to postreperfusion hypothermia: Is the delay in hypothermia initiation clinically important? Cooling to target core body temperatures may take several hours in clinical settings.[94,95] A variety of laboratory data suggests that earlier induction of hypothermia confers a greater benefit.[27,96]

The duration of the hypothermic state required for protection also remains to be clearly established. Clinical studies to date have all maintained mild hypothermic conditions for at least 12 hours.[2,3,87] However, animal studies have shown benefit from hypothermia lasting only 2 to 6 hours.[26,27] Certainly, a shorter duration of cooling would have a number of clinical advantages, including minimizing the logistical difficulties of maintaining a constant cooled state and also minimizing the potential adverse effects from hypothermia. This question has not been addressed directly in clinical studies at this time.

Finally, a number of other aspects of induced hypothermia remain to be examined. How quickly should patients be rewarmed at the end of a period of hypothermia? Would certain

drugs serve as useful adjuncts to hypothermia, either to provide additional benefit or to protect against certain adverse effects of a cooled state? A number of pharmacologic strategies have been employed to protect against IR injury, including barbiturates, benzodiazepines, and gas anesthetic agents. These and other issues surrounding induced hypothermia await randomized clinical trials.

Future of Induced Hypothermia

Before induced hypothermia becomes a standard therapy for such critical illnesses as myocardial infarction, stroke, and cardiac arrest, many of the questions just posed will require resolution. It is also important to note that the optimal combination of these factors may be different for each disease state, and therefore, such principles may not be generalized easily. It is possible, for example, that adverse effects such as electrolyte abnormalities may limit the depth of cooling in the more critically ill state of resuscitated cardiac arrest compared with myocardial infarction or that cardiac arrest patients require a slower rewarming period.

One such parameter, the time between injury and the initiation of cooling, may be the most consistent between different disease states. That is, the sooner a patient is cooled after a given insult, the more likely it is to prevent tissue injury from that disease process. This has been shown in a large variety of IR models at the cellular, organ, and whole-animal levels.[20,52] Therefore, techniques to allow for early and rapid cooling will need to be developed. Current external cooling methods such as ice packing and cooling blankets take several hours to lower core body temperatures adequately in humans. Endovascular cooling catheters appear promising, especially for localized cooling in stroke or myocardial infarction. Additional techniques involving multiphase coolants are currently under development. One goal for induced hypothermia research in cardiac arrest would be to develop a cooling method that could be initiated in the prehospital setting by paramedics.

Hypothermia induction in cardiac arrest fits squarely within the metabolic phase of cardiac arrest, as part of the three-phase time-sensitive model of CPR (see further discussion of the three-phase model in Chap. 15).[97] With the failure of defibrillation and medications to restore viable hemodynamics, patients could be cooled rapidly to protect organs from ongoing ischemia and as a bridge to additional therapies such as establishment of cardiopulmonary bypass with controlled reperfusion.[98–103] Under such intensive control, further attention could be given to reversal of metabolic injury caused by reactive oxygen species, mediators of apoptosis, compromise of cell membrane integrity, and so forth. The limits for reversal of ischemic injury when treated under such a "suspended animation" paradigm remain to be determined.

Chapter 17

WITHHOLDING OR WITHDRAWING OF LIFE-SUSTAINING THERAPY AND ADMINISTERING OF PALLIATIVE CARE

JOHN M. LUCE

KEY POINTS

- *Many, if not most, patients who die in intensive care units do so during the withholding or withdrawing of life-sustaining therapy and the administering of palliative care.*
- *Life-sustaining therapy usually is withheld or withdrawn and palliative care is administered because physicians and patients or their surrogates agree that further restorative care would not be beneficial.*
- *Cardiopulmonary resuscitation, mechanical ventilation, and vasoactive drugs are the therapies most commonly withheld or withdrawn.*
- *Palliative care involves attention to the physical, emotional, and spiritual needs of patients and their families.*
- *Withholding or withdrawing of life-sustaining therapy and administering of palliative care are well supported by ethical pronouncements and case law.*

Defining Withholding or Withdrawing of Life-Sustaining Therapy and Palliative Care

Withholding or withdrawing of life-sustaining therapy or life support is a process by which various medical interventions either are not given to or are taken away from patients with the expectation that they will die from their underlying illnesses. This process is carried out in many medical settings but is especially common in the ICU, which offers an array of therapies capable of sustaining life. An example of withholding life-sustaining therapy is to not provide mechanical ventilation to a patient with chronic obstructive pulmonary disease (COPD) and acute respiratory failure who probably will die without the ventilator but is thought to be unweanable once mechanical ventilation is begun. An example of withdrawing life-sustaining therapy is the removal of mechanical ventilation from a patient with COPD with the provision that he or she will neither be ventilated again if acute respiratory failure recurs nor receive cardiopulmonary resuscitation (CPR) in the event of cardiopulmonary arrest. This second patient is different from a patient with COPD who is being weaned from mechanical ventilation and will be ventilated again or resuscitated if he or she deteriorates during the weaning process.

Strictly speaking, all patients who die while receiving close medical attention in an ICU or elsewhere do so as a direct result of the withholding or withdrawal of life-sustaining therapy. This is either because a decision has been made not to resuscitate the patient in advance of decompensation or because even vigorous resuscitation will not be provided indefinitely. For example, the second patient described earlier would receive CPR if he or she were to suffer an unexpected cardiopulmonary arrest during weaning, but CPR would be discontinued if it were not of benefit in restoring a viable cardiac rhythm in, say, an hour. The withdrawal of life support in this second patient would be comparable to the withholding of CPR in the first patient but for the fact that deliberate planning was more possible for the first patient before cardiopulmonary arrest. It is this more deliberate form of withholding and withdrawing of life-sustaining therapy from critically ill adults that is focused on in this chapter, in which the ethical, legal, clinical, and practical aspects of limiting care are discussed.

Note that the only patients who die in the ICU during the withholding or withdrawing of life-sustaining therapy who are not expected to die are those who are dead already owing to complete and irreversible loss of function of the cerebral hemisphere and brain stem. These patients frequently receive mechanical ventilation and other forms of life support either because the diagnosis of brain death has not been confirmed by apnea testing (after which the ventilator will be removed) or because vital organs (excluding the central nervous system) are being preserved prior to transplantation. Indeed, if transplantation is accomplished, the withholding or withdrawing of mechanical ventilation and other therapies usually takes place in the operating room, where the patient's organs are harvested. Because in brain-dead patients interventions such as mechanical ventilation are removed after death, these interventions are better thought of as organ support than as life support. Nevertheless, because patients and surrogates may not appreciate this distinction, and because the decisions and practical steps preceding the removal of interventions are similar in brain-dead and non-brain-dead patients, mention is made of brain-dead patients in this chapter.

Palliative care may be described as the prevention or treatment of pain, dyspnea, anxiety, and other kinds of suffering in dying patients. Palliative care represents an attitude in addition to a series of actions that ideally bring symptomatic relief and comfort as patients die. This attitude includes an emphasis on the family as well as the patient as the focus of treatment, a commitment to clear and continuous communication between the critical care team and these parties, and a concern for the emotional and spiritual, as well as the physical, well-being of patients and families. As in the withholding or withdrawing of life-sustaining treatment, the administering of palliative care is prompted by the appreciation that further restorative treatment would no longer be beneficial to patients who are dying.

Ethical Aspects of Withholding or Withdrawing of Life-Sustaining Therapy and Administering of Palliative Care

Physicians who care for critically ill adults and are considering withholding or withdrawing life-sustaining therapy care

can draw from several summaries of the ethical propriety of limiting care.[1–5] One of the most succinct group statements is the "Consensus Report on the Ethics of Foregoing Life-Sustaining Treatments in the Critically Ill," which was published by the Task Force on Ethics of the Society of Critical Care Medicine in 1990.[6] This report noted that it is ethically appropriate to withhold or withdraw therapy either because a patient or surrogate decides to forego treatment or because a physician judges that further treatment is not likely to be beneficial. A decision to withdraw a treatment should not be more problematic than a decision not to initiate a treatment, particularly because starting a therapy may be necessary to adequately evaluate a patient's condition. Any treatment derives its medical justification from the benefits that a patient and physician hope to achieve by employing it. When the treatment has achieved those benefits or can no longer be expected to do so, it loses its justification and may be withdrawn.

The Society of Critical Care Medicine Task Force consensus statement also noted that there are no intrinsic moral differences between categories of treatment, such as CPR, ventilatory support, medications such as vasopressors and antibiotics, and the provision of hydration and nutrition by artificial means. Each treatment should be considered from the patient's perspective in light of the overall benefit that it may offer and the burdens it may entail, as well as the professional duties that are involved. Treatments that serve only to prolong the dying process should not be employed, and the indefinite maintenance of patients in a persistent vegetative state raises ethical concerns both for the dignity of the patient and for the appropriate use of health care resources.

A basic provision of the consensus statement was that the wishes of an informed adult patient with decision-making capacity should be the primary consideration in almost all decisions regarding treatment. When the patient (or surrogate in the case of a patient who is incapable of making decisions) and the physician (and other members of the critical care team) agree that therapy should be limited, it usually should be. When the patient or surrogate requests therapy that the physician considers nonbeneficial, the physician should clarify the goals of treatment with the patient or surrogate and may accede to their wishes. However, the physician is not ethically obligated to provide therapy and may elect to transfer the patient's care.

In 2001, the Ethics Committee of the Society of Critical Care Medicine published a statement entitled "Recommendations for End-of-Life Care in the Intensive Care Unit" that explored the ethical aspects of administering palliative care.[7] The recommendations were based on recognition of the needs of patients, families, and providers during the dying process. The patients' needs are to receive adequate pain management, to avoid inappropriate prolongation of dying, to achieve a sense of control, to relieve themselves of burdens, and to strengthen their relationships with loved ones. The families' needs are to be with dying persons, to be helpful to them, to be informed of their changing condition, to understand what is being done to them and why, to be assured of the patients' comfort, to be comforted themselves, to express their own emotions, to be assured that their decisions regarding the patients were correct, to find meaning in the dying of their loved ones, and to be fed and rested. The needs of the critical care team are to establish consensus regarding the goals and strategies for providing palliative care, to gain knowledge and skills in palliation, to be supported in their tasks by their institutions, and to have opportunities for grieving and bereavement after patients die. In addition to articulating these needs, the recent statement by the Society of Critical Care Medicine offers a number of helpful recommendations in delivering end-of-life care.

Legal Aspects of Withholding or Withdrawing of Life-Sustaining Therapy and Administering of Palliative Care

In the United States, withholding and withdrawing life support are legally justified primarily by the principles of informed consent and informed refusal. Both principles have strong roots in the common law and reflect the American regard for self-determination. The principles hold that treatment may not be initiated without the approval of patients or their surrogates, except in emergency situations, and that patients or surrogates may refuse any and all therapies.[8]

The right of competent patients to refuse therapy was established directly in *Bartling v. Superior Court,*[9] in which a California Court of Appeal held that a patient could be removed from a ventilator at his request over the objections of his physicians and the hospital where he was cared for. In *Bouvia v. Superior Court,*[10] the California Court of Appeal held that a conscious and competent hospitalized patient with severe pain could refuse nutrition and hydration even if by doing so she believed she would die. Currently, all American courts recognize a competent adult's right to refuse life-sustaining treatment, although the constitutional, statutory, and common-law bases of the right may vary by jurisdiction. Most of the cases concerning that right have arisen, however, from situations involving patients who cannot make medical decisions for themselves.

The application of the principles of informed consent and informed refusal to the care of decisionally impaired critically ill patients began with *In re Quinlan.*[11] In this case, the Supreme Court of New Jersey held that a patient had the right to refuse mechanical ventilation and that, because she was vegetative and could not exercise that right directly, her parents could act as surrogates and make a "substituted judgment" for her. The California Court of Appeal took a similar approach in *Barber v. Superior Court,*[12] in which it held that physicians charged with murder had not committed an unlawful act when, with permission from a patient's family, they removed nutrition and hydration from a comatose patient. In *Barber*, the court noted that medical interventions ranging from mechanical ventilation to nutrition and hydration should not be distinguished by terms such as *extraordinary* and *ordinary* that had been used previously. Rather, the court stated, medical interventions should be evaluated by the benefits and burdens they offer patients; if the burdens of a particular treatment outweigh the benefits it confers, the treatment can be foregone.

Although the principles of informed consent and refusal articulated in *Quinlan*, *Barber*, and other cases are well established, states vary in their processes and rules for vindicating these principles for decisionally impaired patients. In general, these variations fall into two categories: rules for selecting

surrogate decision makers and rules determining what surrogates can decide. As for the latter rules, all states agree that medical decisions should be guided by the wishes of the patient whenever possible. Some states require a high level of certainty before a surrogate may refuse life-sustaining treatment. For example, in the *O'Conner* case,[13] a New York court ruled that treatment is obligatory unless evidence shows that it is almost certain that the patient would have refused treatment. Missouri also requires "clear and convincing evidence" of a decisionally impaired patient's wishes, a position that was contested in *Cruzan v. Director, Missouri Department of Health,*[14] as will be discussed.

In most other states, however, surrogates may consider other factors, such as the patient's "best interests," when a patient has not expressed a prior unequivocal preference. The most influential case to describe the best interests standard is the New Jersey Supreme Court's decision in *In re Conroy,*[15] which was made 9 years after that court decided *Quinlan*. The *Conroy* court would apply the best interests standard only when there was no reliable evidence of the patient's wishes. The test of this standard has two elements. First, the burdens of the patient's life with treatment must outweigh the benefits to the patient of continued life. Second, the recurring, unavoidable pain of the patient's life with treatment must be such that administering the treatment is inhumane.

The issue of withholding or withdrawing life-sustaining treatment was first addressed by the U. S. Supreme Court in the aforementioned *Cruzan* case,[14] which involved a request by parents to have a feeding tube removed from their daughter in a Missouri nursing home. In its decision, the Court allowed Missouri and other states to require "clear and convincing evidence" of patients' wishes and thereby potentially limited the role of surrogates in making decisions for decisionally impaired patients without advance directives. Nevertheless, the Court accepted the principle that a competent person's right to forego treatment, including nutrition and hydration, is a liberty interest protected under the Fourteenth Amendment to the Constitution. Thus, although *Cruzan* did not set a single standard for surrogate decision making for patients who cannot make decisions for themselves, it did affirm the legal principles of informed consent and refusal that are used in all the United States.

After *Cruzan*, the Supreme Court confirmed its approval of the foregoing of life-sustaining treatment in *Washington v. Glucksberg*[16] and *Vacco v. Quill*[17] and also furnished guidelines for administering palliative care. These last two cases dealt with the constitutionality of laws prohibiting physician-assisted suicide in Washington and New York. In *Glucksberg*, the court decided that terminally ill patients did not have a liberty interest in committing suicide or in receiving physician assistance in suicide because of both the long tradition of prohibiting suicide in the United States and the states' legitimate reasons for continuing to make suicide illegal. In *Vacco*, the court drew further distinctions between assisted suicide and withholding or withdrawing life-sustaining therapy. "Everyone, regardless of physical condition, is entitled, if competent, to refuse lifesaving medical treatment; no one is permitted to assist a suicide," the court wrote. "When a patient refuses life-sustaining medical treatment, he dies from an underlying fatal disease or pathology; but if a patient ingests lethal medication prescribed by a physician, he is killed by that medication."

In *Glucksberg* and *Vacco*, five justices of the Supreme Court reasoned in concurring opinions that Washington and New York could prohibit assisted suicide because these states had no legal barriers that prevented patients from obtaining medications to relieve pain and suffering and therefore had no need for assisted suicide. However, as Justice Breyer wrote in his opinion concurring in the judgment in the two cases, "Were state law to prevent the provision of palliative care, including the administration of drugs as needed to avoid pain at the end of life, an action against such law might be called for by the Supreme Court." Through this and other statements, a majority of Supreme Court justices suggested that the Constitution's guarantee of individual liberty included the liberty to be free of unnecessary pain during the dying process.[18] Indeed, the justices' opinions have been interpreted as indicating a willingness on the part of the Supreme Court to mandate patient access to palliative care.[19]

The Supreme Court distinguished assisted suicide from palliative care in *Glucksberg* and *Vacco* by accepting the principle of double effect. Under this principle, acts such as giving sedatives and analgesics that lead to morally good effects, such as the relief of pain, are permissible even if they produce morally bad effects, such as the hastening of death, provided that only the good effect is intended.[20] The Supreme Court's approval of palliative care included sanctioning the practice of terminal sedation, in which patients are rendered comatose and then may have nutrition and hydration withdrawn. The term *terminal sedation* appears only in a footnote concerning sedation while withdrawing ventilatory support or other treatment in the *Vacco* majority opinion. Nevertheless, under *Vacco*, a state may allow terminal sedation if it is "based on informed consent and the double effect. Just as a state may prohibit assisting suicide while permitting patients to refuse unwanted lifesaving treatment, it may permit palliative care related to that refusal, which may have the foreseen but unintended 'double effect' of hastening the patient's death."

Clinical Aspects of Withholding or Withdrawing Life-Sustaining Therapy

Information about the clinical aspects of withholding or withdrawing life support has come primarily from surveys of physicians and other health professionals and from observational studies of the limiting of life-sustaining care. For example, several surveys[21–23] have suggested that the great majority of critical care physicians have withheld or withdrawn life support at one time or another and that many have done so frequently. Similarly, retrospective studies[24–26] have revealed that approximately one-half of the patients who die in ICUs do so during the withholding or withdrawal of life-sustaining therapy. Prospective studies[27,28] conducted in two ICUs in hospitals affiliated with the University of California, San Francisco, revealed that withholding or withdrawal of life support preceded 90% of deaths in 1992 and 1993 compared with 51% of deaths in 1988 and 1989. To determine whether limiting care is as commonplace as suggested by the aforementioned studies, a prospective survey[29] was conducted in 1994 and 1995 of 107 ICUs associated with all U.S. training programs in critical care medicine or pulmonary and critical

care medicine. It revealed that only 25% of deaths followed full ICU care and failed CPR.

Similar observations have been reported recently concerning the practice of critical care medicine in Europe.[29a] In a prospective observational study in 37 ICUs in 17 European countries from 1999–2000, of the patients who died, 72.6% had a limitation of therapy, although substantial intercountry variability in practice was noted. Limitation of therapy versus continuation of life-sustaining therapy was associated with patient age, acute and chronic diagnoses, number of days in the ICU, region, and religion.

Most surveys[21–23,30] and studies[24–28,30,31] have indicated that physicians recommend that life support be withheld or withdrawn either because patients or surrogates request this action or because physicians believe that further care is not beneficial. This belief stems from prognostication on the physicians' part. They generally arrive at estimates of prognosis through their personal experience and knowledge of the medical literature and not with the help of prognostic scoring systems such as the Acute Physiology and Chronic Health Evaluation (APACHE) system, although use of such systems is increasing in some ICUs. If present, brain death, persistent coma, other unacceptable neurologic prognoses, and multiple-organ-system failure are important rationales for care withdrawal. The need for ICU beds, patients' social worth, and financial cost-benefit analyses are not important rationales.

Most patients have not prepared medical directives in advance of suffering a critical illness, and most patients are too neurologically depressed by their disease or by therapeutic drugs to make medical decisions when they become critically ill. Surrogates usually were available and willing to take part in the decision-making process in the prospective studies[27,28] of withholding or withdrawing life support. When surrogates were not available, physicians were willing to make decisions for the patients. Although consultation from other physicians often was sought before deciding to limit care, hospital ethics committees were involved infrequently. Furthermore, probate courts or judicial hearings were never used.

The surrogates who were available in these studies[27,28] either recommended by themselves that support be withheld or withdrawn when patients were not improving or accepted physician recommendations to that effect. These recommendations were not always accepted immediately, but in most cases the surrogates agreed within a few days. Only rarely did surrogates insist on continued care against the advice of physicians, and in all cases care was continued. In certain instances, however, the physicians stopped short of providing CPR in patients who were otherwise supported.

Although differences between physicians and surrogates do occur over the issue of limiting care, their incidence is uncertain. In one survey[22] of self-identified members of the critical care section of the American Thoracic Society, 34% of respondents reported that they had refused surrogate requests to withdraw care either because they believed that the patient still had a reasonable chance of recovery or because they believed that the surrogates might not be acting in the best interest of the patient. At the same time, 83% of physicians reported that they had unilaterally withheld life-sustaining treatment on the basis of futility, often without patient or surrogate knowledge or consent, and 82% had withdrawn treatment on the same basis.

CPR probably is the therapy most often withheld from ICU patients, as suggested by the finding that do-not-resuscitate (DNR) orders preceded 60% of all in-unit deaths in a large observational study[32] in 40 U.S. hospitals. Antibiotics, vasoactive drugs, renal dialysis, and mechanical ventilation were withheld commonly in the two studies[27,28] from ICUs in hospitals affiliated with the University of California, San Francisco. Mechanical ventilation was the therapy most commonly withdrawn in these studies, followed by vasoactive drugs. In the survey[22] of American Thoracic Society members, 89% of the respondents had withdrawn mechanical ventilation, 88% had withdrawn vasoactive drugs, and 80% had withdrawn blood or blood products.

In a study[33] conducted in the two ICUs at hospitals affiliated with the University of California, San Francisco, analgesics and sedatives were given to 75% of non–brain-dead patients during the withholding or withdrawal of life support. Patients who did not receive medication were comatose and considered incapable of benefiting from the drugs. Physicians ordered analgesics and sedatives to decrease pain in 88% of patients, to decrease anxiety in 85%, to comfort families in 82%, to decrease air hunger in 76%, and to hasten death in 39%; in no instance was hastening death the only reason cited. The amounts of opiates and benzodiazepines averaged 3.3 mg/h of morphine and 2.2 mg/h of diazepam in the 24 hours before withholding or withdrawing of life support and 11.2 and 9.8 mg/h, respectively, in the 24 hours thereafter. The median time until death following the initiation of withholding or withdrawal of life support was 3.5 hours in the patients who received drugs and 1.3 hours in patients who did not. Thus the administration of sedatives and analgesics did not appear to hasten death in this study.

It would appear from these surveys and studies that withholding or withdrawal of life-sustaining therapy from adults occurs frequently in most U.S. ICUs and that these processes commonly follow a similar course. Furthermore, professional attitudes and behaviors on the part of physicians are consistent with ethical pronouncements and judicial decisions regarding the withholding or withdrawal of life support. The only major area in which consistency may be lacking concerns physician refusal to follow surrogate demands either to limit care in certain circumstances or to provide care that the physicians consider nonbeneficial. This finding is not surprising given the lack of ethical and legal clarification of the issue; hopefully, such clarification will occur over time.

Practical Aspects of Withholding or Withdrawing of Life-Sustaining Therapy

The surveys and studies discussed in the preceding section suggest that physicians, patients, and surrogates generally reach consensus regarding when and how withholding or withdrawal of life support should take place. Consensus is not reached in all cases, at least not initially, and the process of foregoing life-sustaining treatment can be quite strained. Most of the differences that exist between the parties involved in this process result from difficulties in communication and can be breached if communication is improved. There is much interest in the critical care community for enhancing the process of withholding or withdrawing care and providing palliative care, as well as enhancing communication generally

in the ICU. Models for improved communication have been proposed and at least preliminarily tested.[34]

The following 12 suggestions are designed to facilitate communication inside and outside the ICU[34a]:

1. Regular meetings should be held with physicians and patients or their surrogates from the time of ICU admission to discuss all medical matters, including prognosis. The meetings should be held in a quiet, comfortable, and private place conducive to conversation. The timing of the meetings should allow the participation of the attending physician, the primary physician (if different from the attending), consultants, bedside nurses, and facilitators such as family counselors or clergy. House staff may be included, but a physician in training should not serve as a substitute for an experienced attending in directing the course of the meetings.
2. Consensus should be reached by the physicians regarding prognosis and other medical matters before they communicate with the patients or their surrogates. Although physicians may disagree privately among themselves, they should be prepared to present an opinion to the family that they can publicly agree on. This includes neurologists or neurosurgeons who may be asked to consult regarding functional outcome. Ideally, the viewpoints of all physicians can be summed up and communicated by the attending physician to patients or surrogates. Nurses and other caregivers should be included in the consensus-building process.
3. The role of surrogates in decision making should be clarified from the outset of ICU admission.[35] Surrogates should be informed that they can help the patient best by articulating his or her wishes and determining what he or she would want done in a given situation instead of expressing the surrogates' wishes and what the surrogates themselves would want done. If a certain family member carries a durable power of attorney for the patient or only one family member is available, this individual will act for the family as a whole. Otherwise, and especially if the family is divided in opinion, it should be asked to designate a spokesperson.
4. Discussions with surrogates should be frank, informative, and as consistent as possible. The major purpose should be a regular updating of the family about the patient's condition, including his or her chances of recovery. Physicians should be aware that the ICU is a foreign and often frightening place for most family members. Bedside explanations, drawings, radiographs, CT scans, and other visual aids may help families understand the patient's status and appreciate the full extent of supportive therapy.
5. Withholding or withdrawal of life support should be recommended, not merely listed as a therapeutic option, once physicians and nurses agree that life support should be withheld or withdrawn. This agreement should be based on disease-specific data, prognostic indices, and clinical experience, all of which should be explained to the family in detail. The family then should be asked to respond to the recommendation as the patient would if he or she were able to do so.
6. CPR should not be the focus of discussions regarding the withholding or withdrawing of life support. Some physicians who intend to recommend the forgoing of further life-sustaining therapy instead advise that the patient not be resuscitated in the event of cardiopulmonary arrest. Yet such events are uncommon in the ICU unless another form of life support such as mechanical ventilation is withheld or withdrawn. Furthermore, by focusing on CPR, the physician implies that the patient actually may benefit from the procedure despite medical evidence to the contrary[36] and puts surrogates in the uncomfortable position of having to refuse what is presented as a potentially beneficial therapy. A better approach is to recommend that all therapies considered incapable of benefiting the patient, including CPR, will be withheld or withdrawn.
7. Surrogates should be allowed to accept the recommendation to forgo life-sustaining therapy. Some families actually precede physicians in their realization that further care would be futile for and unwanted by a given patient. Others are willing to accept the recommendation to withhold or withdraw life support once they have accepted the prognosis offered them. Even if the patient is brain dead, surrogates may have difficulty realizing that the patient is not alive despite the presence of a heart beat and respiratory excursions caused by a mechanical ventilator. Such acceptance may take time, particularly if the patient was entirely well prior to a critical illness. Only a few surrogates are unwilling to accept the prognosis or demand that the patient be supported indefinitely because he or she would prefer life under any circumstances.
8. Physicians should inform surrogates that physicians are not obligated to provide nonbeneficial care if the issue arises. In general, a physician who cannot in good conscience continue therapy he or she considers nonbeneficial should transfer responsibility for the patient's care to another physician in the same or another institution. If transfer is not possible, life support may be withdrawn in accordance with institutional policies. However, such policies are uncommon, and the courts may require that life support be continued when a family insists that a patient would so desire.
9. Surrogates should be told that life support will be withheld or withdrawn as humanely and expeditiously as possible once they have accepted the recommendation to forgo further life-sustaining therapy. They should be given time to spend with the patient and may, if they wish, be present at the patient's death. For many ICU patients, death will come only after removal of supplemental oxygen, positive end-expiratory pressure (PEEP), and the mechanical ventilator. Terminal weaning of this sort should be long enough to allow the family to visit with the patient but should not be prolonged beyond several hours or, in rare cases, a few days. However, early extubation may produce signs of upper airway restriction that are uncomfortable to surrogates and caregivers alike and therefore should be avoided unless sedatives are provided.
10. Whatever process of withholding or withdrawing of life support is followed, surrogates should be assured that the patient will receive sedatives and analgesics to relieve pain and suffering but that death will not be hastened intentionally, in keeping with the principle of double effect. Drugs are best given unobtrusively by constant infusion

at doses sufficient to suppress grimacing and signs of air hunger. Formal protocols that dictate how sedatives and analgesics are to be given may help nurses who give the drugs feel that they are doing so properly and to avoid the impression of hastening death. Muscle relaxants should be avoided if at all possible because they provide no therapeutic benefit in the dying patient. The same is true for agents such as potassium chloride that do not relieve pain and suffering but merely hasten death.

11. Physicians, nurses, and other caregivers should meet after the patient dies to discuss how his or her death was managed. Discussions are particularly helpful to the ICU team when conflicts have existed with the patient and his or her surrogates. These discussions provide emotional support for the team and can generate ideas about how to improve the dying process for future patients. They may even inspire the development of guidelines and standing orders used during the dying process.

12. Physicians should be as available to surrogates after the patient dies as they were beforehand. In particular, the attending or primary physician should be accessible by telephone or in person to answer medical questions and report the results of an autopsy or other postmortem procedure. The bedside nurse or family counselor may have been helpful to the family in the ICU and may continue to be a source of emotional support. Through such actions, the caregivers communicate their ongoing concern for the patient and his or her family.

Chapter 18

CHRONIC CRITICAL ILLNESS

SHANNON S. CARSON

KEY POINTS

- *Chronically critically ill patients account for 5% to 10% of patients admitted to an adult ICU. They account for as many as 88,000 hospital discharges per year in the United States. Most chronically critically ill patients are over age 65. The burden of chronic critical illness is anticipated to increase dramatically in the next decade.*
- *Chronically critically ill patients have distinct physiology compared with more acutely ill patients, including suppressed levels of anterior pituitary hormones and severe depletion of protein stores with muscle wasting.*
- *Important principles of patient management include prevention of infection, protein repletion, aggressive physical therapy, and careful attention to treating symptoms.*
- *Liberation from mechanical ventilation usually is achieved with work-rest cycles that are guided by frequent assessments of readiness for weaning and careful monitoring to avoid fatigue.*
- *One-year survival for chronically critically ill patients is between 23% and 38% in most cohorts, but younger patients with few comorbidities have distinctly better chances of survival. Quality of life for survivors is similar to that of patients with shorter periods of critical illness.*
- *Costs of care for chronically critically ill patients are extreme during hospitalization and after discharge. Cost savings can be achieved by managing patients in dedicated wards or facilities outside of the acute ICU setting.*

Advances in medical management and technology have greatly enhanced patients' ability to survive critical illness and injury. For most critically ill patients, the clinical course is typified by liberation from organ support systems such as vasoactive drugs and mechanical ventilation after reversal of the acute process, followed by a short period of observation before transfer from the ICU to a medical/surgical ward or an intermediate care unit. For a significant number of patients however, this timely transition to a more stable condition does not occur, and they remain dependent on life support systems or other ICU services for prolonged periods. These patients often are referred to as the *chronically critically ill* (CCI). As larger proportions of patients are surviving episodes of severe sepsis, acute respiratory distress syndrome (ARDS), multiple trauma, or acute or chronic respiratory failure, CCI patients are becoming a significant component of the practice of critical care medicine.

CCI patients are recognized more easily than defined. Every clinician in the ICU is familiar with the patient who has been supported through the initial period of hemodynamic, neurologic, or respiratory instability that characterized their first few days in the ICU but whose continued recovery has been arrested by the persistence of the acute insult, new complications, or decompensation of severe underlying comorbidities. The patient is weak and frequently dependent on mechanical ventilation. A tracheostomy is present or being contemplated. Such patients are often delirious, if not minimally responsive, and the more alert among them are troubled by significant discomfort. Their physical appearance is altered by muscle atrophy and diffuse edema. They are often cycling through recurring infections, multiple antibiotics, and evolving resistant organisms. Their families are distressed, frustrated, and exhausted. Finally, their physicians and nurses are equally frustrated and often are challenged to maintain enthusiasm for their care.

A specific definition for chronic critical illness is more elusive. For the purposes of epidemiologic studies and clinical trials, patients usually are identified by the requirement for prolonged mechanical ventilation, by number of days in the ICU, by presence of a tracheostomy for prolonged mechanical ventilation, or by transfer to a ventilator rehabilitation unit. The actual number of days of ventilation or ICU stay that is considered to meet a threshold of *prolonged* has varied from 5 to 28 days depending on restrictions of administrative databases used in studies or an investigator's intuitive sense of what is exceptional. Care must be taken to consider the actual population enrolled in any study describing CCI patients. For example, there may be significant differences between populations of patients who have been ventilated for 28 days compared with those ventilated for 5 days. Diagnosis, comorbidities, and severity of acute processes can vary considerably between CCI patients at different types of institutions or even within a single ICU. Despite this heterogeneity, a number of important clinical factors are common to CCI patients and require a different approach to management than for a typical patient in the ICU. These unique factors will be discussed in this chapter.

Incidence

Depending on the definition, between 5% and 10% of patients admitted to adult ICUs become chronically critically ill.[1,2] Using DRG 483 (tracheostomy for conditions other than face, neck, and mouth diagnoses) to identify patients requiring prolonged mechanical ventilation in the Nationwide Inpatient Sample, it was estimated that there were 88,000 such discharges in the United States in 1997[3] (Table 18-1). These represent 0.25% of the 35 million annual hospital discharges in the United States. Although this is a small fraction of all hospital admissions, these patients have a substantial impact on hospital resources owing to prolonged stays and high-intensity care. Importantly, 52% of patients in that sample were over age 65. This reflects an overall higher incidence of acute respiratory failure in elderly patients. As the baby boom generation approaches this age group in the next 10 years, the number of CCI patients in ICUs is expected to increase substantially. A trend toward increasing numbers of discharges under DRG 483 is already evident in the state of New York according to an analysis from 1992 to 1996.[4]

Risk Factors

Patients who are susceptible to chronic critical illness are as heterogeneous as the general ICU population (Table 18-2). Pa-

tients with postoperative complications from cardiac or abdominal surgery are at risk, and trauma patients are common as well. Medical patients with acute lung disease with or without multiorgan failure and patients with chronic lung disease (especially COPD) or neurologic diseases as their primary diagnoses are also susceptible. Critically ill patients admitted to the ICU with significant comorbidities are at higher risk, especially those with underlying heart disease, chronic obstructive pulmonary disease (COPD), and kidney disease. For surgical patients, preoperative instability, COPD, prolonged operation, and in the case of cardiac surgery patients, increased bypass time are important risk factors for prolonged mechanical ventilation.[5] Development of nosocomial pneumonia, aspiration events, and failed extubations are additional proven risk factors for prolonged mechanical ventilation.[6] In one predictive model, primary disease, Acute Physiology and Chronic Health Evaluation survey (APACHE III) score, age, COPD, prior functional limitations, and length of hospital stay prior to ICU admission were significant risk factors for mechanical ventilation for greater than 7 days.[1] The acute physiology score and primary reason for ICU admission accounted for 0.66 of the explanatory power for the model. Of the variables in the acute physiology score, pH, Pa_{CO_2}, Pa_{O_2}/FI_{O_2} ratio, albumin level, and respiratory rate were significant. Further development of clinically useful prediction models for prolonged mechanical ventilation would be of great benefit for resource planning in the ICU.

TABLE 18-2 Risk Factors and Predictors for Chronic Critical Illness

- Preexisting factors:
  - Advanced age
  - Prior functional limitations
  - Length of hospital stay prior to ICU
  - Poor nutrition
  - Comorbidities
    - COPD
    - Renal failure
    - Congestive heart failure
    - Morbid obesity
- Surgical issues:
  - Preoperative instability
  - Prolonged operation
  - Prolonged cardiopulmonary bypass time
  - Hemidiaphragm paralysis
- Complications of critical illness:
  - Nosocomial pneumonia
  - Aspiration
  - Failed extubation
  - Critical illness polyneuropathy
- Acute factors:
  - Primary disease
    - Pneumonia
    - ARDS
    - Neuromuscular disease
    - Postoperative head trauma
    - Postoperative intracerebral hemorrhage
  - Abnormal acute physiology
    - pH
    - Pa_{CO_2}
    - Pa_{O_2}/FI_{O_2} ratio
    - Serum albumin
    - Respiratory rate

Perhaps one of the most important risk factors for chronic critical illness is neuromuscular abnormalities associated with acute critical illness. Critical illness polyneuropathy (CIP) is evident in up to 47% of patients who are ventilated for greater than 7 days[7] and in 95% of patients who are ventilated for more than 28 days.[8] The presence of the systemic inflammatory response syndrome (SIRS) or sepsis is the greatest risk factor. The use of aminoglycosides, neuromuscular blockers, and steroids also may contribute to the development of CIP in some patients. Abnormalities on neurophysiologic testing persist for up to 5 years, but functional deficits after that much time are unusual.[8] There is no specific therapy for this condition other than aggressive rehabilitation. In most cases, recovery is very slow.

Diaphragm paralysis from phrenic nerve injury is another neuromuscular condition that contributes to prolonged mechanical ventilation. It is difficult to diagnose, but it should be suspected in any patient who has had cardiothoracic or neck surgery and has difficulty with spontaneous breathing, especially in the supine position. An elevated hemidiaphragm on chest radiograph is suggestive, but it is often not present.

Pathophysiology of Chronic Critical Illness: The Neuroendocrine Model

Despite the varied definitions and nonspecific clinical findings that have been used to describe CCI patients, they appear to be a physiologically distinct subset of the overall ICU population. This has been best demonstrated by the work of Grete Van den Berghe and others who have examined neuroendocrine responses to critical illness. During the acute phase of critical illness, adrenocorticotropic hormone (ACTH), cortisol, and prolactin levels are elevated, whereas thyrotropic and gonadotropic hormone levels are reduced.[9] During the chronic phase of critical illness, hormonal responses are significantly different (Fig. 18-1). ACTH and other anterior pituitary hormone levels decrease, but hypercortisolism persists, suggesting an alternative pathway for cortisol release.[10] CCI patients lose thyroid-stimulating hormone (TSH) pulse amplitude, which results in typically low or low-normal TSH

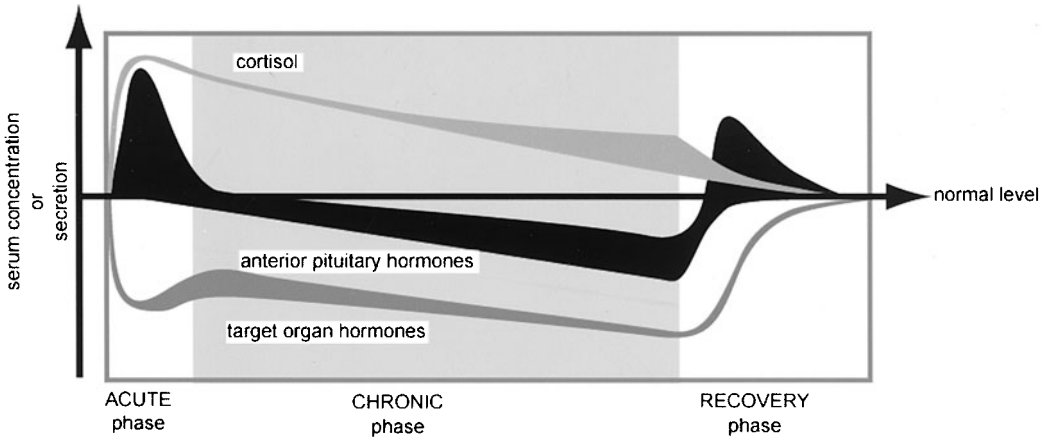

FIGURE 18-1 Simplified concept of the pituitary-dependent changes during the course of critical illness. In the acute phase of illness (first hours to a few days after onset), the secretory activity of the anterior pituitary is essentially maintained or amplified, whereas anabolic target-organ hormones are inactivated. Cortisol levels are elevated in concert with ACTH. In the chronic phase of protracted critical illness (intensive care–dependent for weeks), the secretory activity of the anterior pituitary appears uniformly suppressed in relation to reduced circulating levels of target-organ hormones. Impaired anterior pituitary hormone secretion allows the respective target-organ hormones to decrease proportionately over time, with cortisol being a notable exception, the circulating levels of which remain elevated through a peripheral drive, a mechanism that ultimately also may fail. The onset of recovery is characterized by restored sensitivity of the anterior pituitary to reduced feedback control. ***(Used with permission from Van den Berghe G, de Zegher F, Bouillon R: Acute and prolonged critical illness as different neuroendocrine paradigms.*** **J Clin Endocrinol Metab** ***83:1827, 1998.)***

levels and low triiodothyroxine (T_4) and triiodothyronine (T_3) concentrations compared to acutely stressed patients.[11] This may be related to reduced expression of the thyrotropin-releasing hormone (TRH) gene in the hypothalamic paraventricular nuclei.[12]

The somatotropic axis also demonstrates important differences between acute and chronic critical illness. For patients who are in the acute phase of critical illness, the pituitary gland actively secretes growth hormone (GH) into the circulation in a pulsatile fashion that is regulated by hypothalamic growth hormone–releasing hormone (GHRH). GH levels and GH pulse frequency are increased compared with normal function. In contrast, for patients who have received mechanical ventilation for greater than 21 days, the pattern of GH secretion is less regular, and the amount that is released in pulses is greatly reduced.[9] Nocturnal secretion of GH is reduced relative to the acute stressed condition.

The hormonal changes that occur in acute illness may be positive adaptations that help divert energy away from anabolism and toward maintenance of vital tissues and immune function, for example. However, the hormonal responses to chronic critical illness may be maladaptive. CCI patients suffer from significant protein deficiencies owing to ongoing degradation and suppressed production. This hypercatabolic state likely contributes to the severe and prolonged muscle weakness that is characteristic of these patients. While protein is lost despite feeding, reesterification of free fatty acids allows fat stores to build up.[9] Hyperglycemia, insulin resistance, and hypertriglyceridemia are common. Prolonged hypercortisolism and low levels of GH and thyroid hormone may contribute significantly to these processes. In addition to prolonged wasting, immune function is also likely to be affected as well. As a clinical correlate, prolonged weakness associated with ventilator dependence and recurrent infectious complications are hallmarks of the CCI condition.

Management of the CCI Patient

INFECTION CONTROL

CCI patients are at very high risk for nosocomial infection. Perhaps their greatest risk factor is disruption of multiple infection barriers. Most patients have tracheostomies or endotracheal tubes that promote aspiration, inhibit cough, and greatly increase their risk of airway colonization with nosocomial organisms. Central venous catheters are common and remain in place for long periods, significantly increasing the risk of bloodstream infections. The presence of bladder catheters promotes urinary tract infections, and nasogastric tubes increase the risk of sinusitis. Weeks of immobility and edema predispose patients to skin breakdown, which provides another infection source.

The underlying comorbidities that make patients susceptible to chronic critical illness also make them susceptible to infections. COPD is often accompanied by bacterial colonization of lower airways and compromised airway clearance. Neurologic impairment increases aspiration risk and weakens cough response. Diabetes mellitus, renal failure, congestive heart failure, and hepatic dysfunction are all associated with compromised immune function and are important risk factors for pneumonia. Diabetes mellitus and hepatic dysfunction also increase the risk for fungemia. Immune function is further compromised by nutritional deficiencies, protein depletion, and ongoing catabolic processes.

Because CCI patients spend weeks in ICUs where multidrug-resistant bacteria are common, the incidence of infection or colonization with these organisms is quite high. This problem is compounded by multiple rounds of broad-spectrum antibiotics over the course of their hospitalization. This is a particularly important issue for ventilator rehabilitation hospitals, where patients are admitted from numerous different referring hospitals. Nearly every new admission brings

unique strains of resistant organisms. Containing the spread of these organisms is a constant challenge.

Infectious complications were documented in a series of 100 patients admitted to a hospital unit dedicated to the care of patients with chronic critical illness.[13] All patients were receiving mechanical ventilation through a tracheostomy after at least 2 weeks of critical illness. During hospitalization on this unit, 61% of patients developed evidence of SIRS, and 11% developed septic shock. Line sepsis (11%), primary bacteremia (6%), tracheostomy-associated pneumonia (10%), and *Clostridium difficile* colitis (10%) were the most common infections. Urosepsis was less common in this series, but the authors were appropriately conservative in the diagnosis of urosepsis. This diagnosis required the presence of SIRS and pyuria or a positive urine culture without any other obvious source of infection.

The management of nosocomial infections in CCI patients begins with prevention. Elimination of all unnecessary compromise of barriers to infection is paramount. Venous catheters should be well maintained and removed as soon as possible. A patient who is hemodynamically stable with a functioning gastrointestinal tract may be able to receive all medications enterally. Continued maintenance of a venous catheter out of habit or ICU policy in a hemodynamically stable patient is inappropriate. When central venous catheters are necessary for long periods, tunneled catheters or chlorhexadine-, silver-, or antimicrobial-impregnated catheters should be considered. Bladder catheters should be removed as soon as possible. Strategies to prevent ventilator-associated pneumonia include semirecumbent positioning, removal of the nasogastric tube when possible, avoidance of gastric overdistention, and scheduled drainage of condensate from ventilator circuits.[14] As always, effective hand washing is essential. Judicious use of broad-spectrum antibiotics and effective isolation will decrease the incidence of *C. difficile* colitis and infections with multiresistant organisms. Routine surveillance for these organisms may be beneficial.

NUTRITION

Some of the hallmarks of chronic critical illness include low protein stores owing to impaired synthesis and persistent losses, muscle wasting and atrophy, and weight loss (unless volume overload persists). Adequate nutrition is essential if a patient is going to improve respiratory and skeletal muscle function and avoid life-threatening infectious complications. Clinical studies specifically addressing nutrition management for CCI patients are lacking. However, some systematic approaches have been developed based on principles derived from the literature for acutely critically ill patients and nonventilated long-term care patients. One approach attempts to replace protein stores in the hypoalbuminemic patient while trying to avoid the common complication of overfeeding.[15] Caloric overfeeding results in volume expansion, hyperglycemia, steatocholestasis, and possibly hypercapnea with increased ventilatory load. In a study of 213 CCI patients from 32 hospitals,[16] 58.2% of patients were receiving more than 110% of required calories according to indirect calorimetry, whereas only 12.2% were being underfed. To avoid this syndrome, one initially can provide lower total calories (20 to 25 kcal/kg per day) than is usually recommended for ICU patients with greater protein content (1.2 to 1.5 g/kg per day). Adjustments to this balance can be made by following clinical parameters and biochemical measurements such as serum albumin and prealbumin levels, blood urea nitrogen levels, and urine urea nitrogen levels. Indirect calorimetry can be used if overfeeding remains a concern. For enteral formulas, a semielemental feed may be most appropriate for CCI patients with serum albumin concentrations of less than 2.5 g/dL to achieve better amino acid absorption and insulin response.[15]

Enteral feeding through a nasogastric tube or a gastrostomy tube is the most common route of nutrition for the CCI patient. Enteral feeding should be accompanied by careful attention to common complications. Aspiration may be reduced by head elevation, postpyloric tube placement, promotility agents, and avoidance of persistently increasing gastric residuals. Sinus infections and nasal complications can be reduced by using gastrostomy tubes placed with the help of interventional radiologists, endoscopists, or surgeons when enteral nutrition is expected to be prolonged. Frequent assessments should be made of a patient's swallowing capabilities to allow for as much oral feeding as possible. Oral feeding provides significant comfort to the patient and provides an important source of enjoyment and empowerment. Oral feeding may have to be supplemented, however, if it is limited by reduced stamina, nausea, or depression. Parenteral nutrition usually is reserved for situations where enteral feeding is not possible owing to issues with enteral access or function.

LIBERATION FROM MECHANICAL VENTILATION

Although prolonged mechanical ventilation is one of the defining characteristics of CCI patients, little data exist regarding optimal approaches to liberation from mechanical ventilation. Patients' generally weakened states usually dictate a slower pace of weaning than is recommended in the acutely critically ill patient. However, patients also can have an unnecessarily prolonged course when clinicians and therapists are not aggressive enough. By definition, most of these patients have failed early attempts at liberation. Subsequent efforts depend on continued maintenance of hemodynamic stability, avoidance of preventable complications, optimal nutrition, frequent assessments of readiness for weaning, and careful exercise of respiratory muscles to improve strength and function.

A standard approach to weaning usually involves work-rest cycles that include periods of "exercise" alternating with periods of "rest." What constitutes appropriate exercise and actual rest is debatable. Patients typically are maintained on mandatory ventilation with assist control or synchronized intermittent mandatory ventilation during the night. In the morning, the patient is placed on a setting requiring more patient effort using some degree of pressure-support ventilation. Alternatively, spontaneous breathing trials are performed using humidified oxygen via a tracheostomy collar. The degree of ventilatory support and length of exercise efforts depend on patient strength and endurance. Patients are monitored for early evidence of fatigue, as suggested by increased heart rate or blood pressure, increased respiratory rate, anxiety or diaphoresis, or oxygen desaturation. Frequent blood gas monitoring in slowly weaning CCI patients is not useful. While work-rest cycles is a common approach, there are no data to suggest that this is a more effective weaning method in

CCI patients compared with gradual decreases in continuous pressure-support ventilation, for example.

The advantage of exercising with spontaneous breathing trials is that rapid improvements in strength are recognized more easily, and earlier weaning may be accomplished. The disadvantage is that these patients are very weak and have limited ability to signal for help if they become acutely distressed. Acute respiratory distress is frequent in these patients owing to rapid fatigue, myocardial ischemia, and especially airway occlusion from mucous plugging or tracheostomy dysfunction. Therefore, spontaneous breathing trials require careful supervision and monitoring because ventilator alarms are not available.

As with liberating more acutely ill patients from the ventilator, some data support the use of formal weaning protocols in CCI patients. In one prospective cohort study using historical controls, a respiratory therapist–implemented weaning protocol decreased median time to wean from 29 days in historical control subjects to 17 days in the protocol group.[17] In the historical control group, weaning orders had been written by physicians on a daily or as-needed basis. Important components of this work-rest cycle–based therapist-driven protocol include (1) daily objective screens for readiness to wean, (2) regular assessments of how the patient tolerates decreases in respiratory support, and (3) acceleration steps for patients showing rapid progress to allow them to progress as fast as possible. This protocol was applied in a long-term acute care hospital where the respiratory therapist-to-patient ratio was 1:7. A therapist-implemented protocol such as this may be even more effective for CCI patients who are being managed in acute ICU settings where physician attention is often drawn to more severely ill patients. Success would be contingent on availability of enough experienced respiratory therapy staff.

AIRWAY MANAGEMENT

Most CCI patients who require prolonged mechanical ventilation are managed with a tracheostomy. Tracheostomies have many advantages, including improved comfort and communication, less sedation requirement, lower dead space, and better pulmonary toilet, and they allow for oral feeding in some patients. They require lower levels of monitoring than endotracheal tubes, and they facilitate transfer of the patient to lower levels of care. Despite their advantages, they are not without acute and long-term complications. Acute obstruction by mucous plugging or malfunction happens uncommonly, but consequences are devastating. Therefore, caregivers should not become complacent with regard to pulmonary toilet and monitoring, especially when patients are weak and unable to signal for assistance. Long-term complications and controversies regarding the timing of tracheostomies are discussed elsewhere.

An important question for CCI patients is timing of decannulation after liberation from the ventilator. Clinicians often are tempted to remove the tracheostomy tube quickly in order to simplify discharge planning and improve patient comfort. This can be hazardous, however, because patients remain diffusely weak after weaning and are at risk for recurrence of respiratory failure for at least several weeks. They are also at great risk for aspiration. Swallowing function remains compromised in many of these patients owing to muscle atrophy, pharyngeal edema, neurologic dysfunction, and effects of the tracheostomy itself on swallowing mechanics. Upper airway obstruction is also common due to granulation tissue associated with the tracheostomy, vocal cord dysfunction, and upper airway edema. Therefore, decannulation should take place in a stepwise fashion with careful assessments of swallowing function and airway patency. Some clinicians advocate waiting at least 2 weeks before decannulation to help avoid common complications. For patients who demonstrate adequate ability to protect their airway but remain at high risk of respiratory failure for other reasons, the tracheostomy tract can be kept patent after the tracheostomy tube has been removed using a stoma stent.[18]

PHYSICAL THERAPY

Owing to their immobility, generalized edema, and poor nutrition, CCI patients are prone to skin breakdown, particularly in the regions of the sacrum, coccyx, and heels. Pressure ulcers become an important site of infection, protein loss, and discomfort. Courses of antibiotics, débridements, and diverting colostomies that are required for treatment of the ulcers further complicate a complex medical course. Frequent turning is essential for prevention, but care should be taken to avoid skin breakdown related to other positions, such as the ears, the greater trochanter, and the lateral malleoli. Specialty beds offer benefit and should be considered as soon as a persistent immobilized state becomes likely. Specialty beds should not, however, lead to relaxed vigilance toward skin condition in vulnerable sites.

Routine interventions typical of care on a general medical or surgical ward such as physical or occupational therapy often are overlooked for patients in an ICU setting, but critically ill patients are in great need of these services. Prolonged immobility can predispose patients to a range of organ dysfunctions, some of which can be prevented[19] (Table 18-3). While critical illness polyneuropathy is difficult

TABLE 18-3 Adverse Effects of Immobilization on Different Organ Systems

Organ Systems	Conditions
Muscles	Reduced strength, endurance, flexibility, and bulk
Joints	Reduced flexibility, joint contractures
Bones	Osteopenia and osteoporosis
Heart	Reduced stroke volume, cardiac output, and exercise capacity
Peripheral circulation	Reduced orthostatic tolerance and venous return, deep vein thrombosis
Lungs	Atelectasis and pneumonia, pulmonary embolism
Gastrointestinal tract	Reduced appetite and bowel motility, constipation
Urinary tract	Urolithiasis, infection
Skin	Pressure ulcers
Endocrine	Reduced endorphin production and insulin sensitivity, reduced lean body mass, obesity
Psychological	Reduced self-image and stress tolerance, anxiety and depression

SOURCE: From Thomas DC, Kreizman IJ, Melchiorre P, Ragnarsson KT: Rehabilitation of the patients with chronic critical illness. *Crit Care Clin* 18:695, 2002. Reproduced by permission of W. B. Saunders Company.

to prevent, disuse atrophy can be lessened in some patients, and joint contractures can be avoided in most. Range-of-motion exercises should begin as soon as a period of immobility exceeding 3 or 4 days is expected. While full range-of-motion exercises involving multiple joints can tax a busy ICU nurse, nursing aides and even family members can contribute to the effort with instruction from physical therapists. Once the patient is hemodynamically stable and alert, a mechanical ventilator should not prevent strengthening exercises against resistance, sitting in bed with legs dangling, or transfers to a bedside chair. These activities help patients to regain balance and overcome orthostatic hypotension, which can develop after only 4 to 7 days of bed rest.[20]

If a patient continues to require mechanical ventilation because of persistent respiratory muscle weakness or increased ventilatory load but is otherwise stable and free of multiple IV lines, many centers encourage CCI patients to ambulate while ventilation is provided via a bag-valve connection to their tracheostomy. This effort requires the help of at least two caregivers, and they must be careful to maintain the airway and IV lines and protect against falls. While this therapy is personnel-intensive, it can be managed if it is organized into the daily care plan and anticipated by the unit. It is also another opportunity to involve able family members. While there is little evidence that this type of advanced physical therapy decreases time on the ventilator or in the ICU, it may decrease overall length of stay in the hospital. It has other benefits, such as prevention of deep venous thrombosis (DVT), pressure ulcers, bone demineralization, and atelectasis. It also provides an important psychological benefit to the patient. Care must be taken not to push the patient beyond his or her physical capabilities. Muscle fatigue and injury should be carefully avoided.

PSYCHOLOGICAL SUPPORT

Common barriers to ventilator weaning and physical therapy include oversedation and delirium. While some patients with acute respiratory failure initially may require high doses of sedatives to decrease anxiety and facilitate mandatory ventilation, the clinician should decrease sedative usage as much as possible as soon as the patient achieves a more stable condition. Less sedative medication improves delirium, thus further decreasing the amount of sedating medications that are given. Alert patients are better able to participate in weaning efforts and physical therapy. Importantly, they are also able to communicate their symptoms, which can allow the clinician to formulate a more rational approach to anxiolysis, pain control, and diagnosis and management of depression.

Symptoms of depression are common in CCI patients.[21] Depression should be considered in patients who appear unmotivated despite gradual improvement in their condition or in patients with persistent symptoms of delirium despite simplification of their medical regimen. This should not be considered a "reactive depression" related to their difficult circumstances because there are usually other important contributors. Many patients, particularly the elderly, have preexisting depression that was either being treated or was undiagnosed. Changes in the neurohumoral axis described earlier may play a role, and other metabolic disturbances could contribute as well. After correcting medical factors, including control of pain and delirium, medical therapy with antidepressants can be started, especially when the depressive symptoms are interfering with the patient's participation in care. It should be remembered that clinical benefit from such medical therapies is slow to develop, and rapid escalation of doses should be avoided. Low doses of psychostimulants such as methylphenidate can be considered when a more immediate impact is desired.[22] Taking time to communicate with the patient, promoting family interactions, and general supportive care can be very effective and also will have an immediate impact.

Other common symptoms in CCI patients include dyspnea, pain, anxiety, and sleep disturbance.[21] These symptoms can elicit physiologic responses that will worsen the course of critical illness, such as increased oxygen consumption, immune dysfunction, protein catabolism, and electrolyte disturbance. Addressing these symptoms through appropriate medical and environmental interventions may improve patient outcome while providing humane care for a desperately ill patient. Frustration from inability to communicate is a particularly common problem that exacerbates other symptoms. Letter boards and writing pads should be easily accessible to patients. One-way valves on tracheostomies that allow for air passage through the vocal cords with cuff deflation should be used as soon as the patient is able to protect his or her airway. Regaining vocalization is a tremendous relief to the patient. Most of all, time should be taken to inform the patient of his or her condition and elicit responses and concerns.

ALTERNATIVE SITES OF CARE

In the 1980s, clinicians in the ICU began to understand the unique medical requirements of CCI patients, and they recognized that these needs often could be better accommodated in settings that are removed from the acute ICU. Otherwise stable CCI patients requiring prolonged mechanical ventilation can be managed safely outside the ICU setting. Patients should be off vasopressors, have simple fluid requirements, and have stable airways. Managing such patients outside the ICU allows for lower nurse-to-patient ratios, which results in substantial cost savings. At the same time, other essential services such as physical therapy, speech therapy, or occupational therapy can be provided more consistently, especially if they are managed in a dedicated unit whose focus is on the CCI patient. These dedicated units have taken a number of forms, including separate units in acute care hospitals, specialized units in acute rehabilitation hospitals or subacute care facilities, or free-standing long-term acute care hospitals designed specifically for the care of CCI patients. Units dedicated to CCI patients vary in the type and acuity of the patients they manage. This variation usually is driven by resource needs and goals of care. Some units exist primarily to offload the acute ICU of patients with prolonged courses and poor prospects of recovery. Other units restrict admissions to patients who have good rehabilitation potential and can benefit most from a multidisciplinary approach to weaning and comprehensive rehabilitation.

ICU physicians should familiarize themselves with the units and facilities that are available in their region. They should be aware of the resources that are available and general approaches to care in each facility so that they can make referrals according to patient needs and best possible outcome. Referrals to facilities outside the acute hospital setting

should be made only when it is clear that complex diagnostic services are no longer required for the patient and that the receiving center can manage any active medical or surgical issues adequately. It also should be remembered that a seemingly stable patient in an acute ICU setting may become somewhat unstable with the stress of transportation. Studies have documented trends toward earlier discharge of CCI patients to post-ICU care settings. These earlier discharges have resulted in a high rate of urgent transfers back to the acute ICU.[23]

Only a minority of CCI patients will have access to specialized acute hospital units or long-term acute care hospitals. The rest will continue to receive care in the acute ICU setting until they are free of life-sustaining therapies. This should not be an impediment to excellent care. Physicians and nurses should adapt their approach to care of the patient according to the principles discussed earlier, and they should involve the essential ancillary services as soon as indicated. For hospitals that do not have access to specialized facilities, multidisciplinary care teams consisting of physicians, respiratory therapists, nutritionists, physical therapists, and social workers who have expertise in managing chronic critical illness can be helpful.[24]

Outcomes

SURVIVAL

The study of outcomes for CCI patients has generated a great deal of interest in recent years. Intuitively, many clinicians assume that their long-term outcomes are poor based on the many physical challenges that were discussed earlier. The clinicians witness a relatively high hospital mortality and a high degree of suffering on the part of patients and families. These observations raise the question, "Is this prolonged invasive care worth what the patient is going through?" A number of studies have been designed to try to address this type of question. Results of these studies have been informative, but much more remains to be learned. The greatest challenge in interpreting outcomes data in this population is the heterogeneity of patients and patient settings. There is tremendous variation in age, primary ICU diagnosis, comorbidities, complications, disease states prior to the acute illness, and care before and after hospital discharge. All these factors likely have some impact on long-term outcomes. The same holds true for more acute critically ill patients, but for that population there exist validated measures of illness severity such as APACHE II that can be used to standardize comparisons among different groups of ICU patients. No such measure exists for CCI patients. As discussed at the beginning of this chapter, there is not even a commonly accepted definition of chronic critical illness. For these reasons, any conclusions that are to be gained from outcomes studies in the CCI population need to be interpreted carefully based on the setting and methodology of the study and the predominant type of patient that is represented.

Population-based studies can overcome some of these problems by being inclusive of many types of hospitals, with all types of patients being represented. The Nationwide Inpatient Sample, described earlier, includes discharge data from a large probability sample of patients from general hospitals in the United States. Using DRG 483 (tracheostomy for conditions other than face, mouth, and neck diagnoses) to identify patients requiring prolonged mechanical ventilation, it was estimated that at least 88,000 patients in the United States suffered some degree of chronic critical illness in 1997.[3] Patients in all age groups are susceptible, but prevalence increases with age. Hospital mortality increases with age also. Average hospital mortality for the whole population is 27%, which does not differ substantially from hospital mortality for the general population of mechanically ventilated ICU patients. These mortality figures do not account for patients who were transferred alive on a ventilator to a long-term acute care hospital but died before final discharge.

Considering that CCI patients who survive hospitalization are discharged with a high degree of unresolved acute and chronic medical problems, 1-year outcomes are better indicators of overall outcome. Currently, long-term outcomes studies in this population are limited to single-institution cohort studies. Most of those studies represent patients who had been transferred to long-term acute care institutions. One-year survival in these studies ranges from 23% to 38% in relatively nonselective institutions, although survival can be as high as 76% for patients managed in institutions that select for likelihood of better outcomes. While these 1-year outcomes are not encouraging, it should be noted that long-term acute care hospitals generally select for older patients who have poorer long-term prognoses than younger patients. However, cohort studies following CCI patients from more general acute care hospitals before 1990 report 1-year survival to be in a similar range. It is possible that outcomes for the general population of CCI patients in acute care hospitals have improved since 1990 as clinicians have become more familiar with their unique problems and postdischarge care has improved, but this remains to be seen. Results of more recent studies are pending.

While long-term survival for the overall population of CCI patients is poor, a significant number of patients do survive. Investigators have been attempting recently to identify patients with better long-term prognoses. One study in a single long-term acute care population indicated that patients who were younger than age 65 or between the ages of 65 and 75 with good prior functional status had a 1-year survival rate of 56%.[25] In contrast, patients over age 75 or over age 65 with poor prior functional status had a 1-year survival rate of only 5% (Fig. 18-2). Another important risk factor for poor outcome is the requirement for hemodialysis in addition to prolonged mechanical ventilation. Underlying cardiac dysfunction or chronic pulmonary disease are significant risk factors as well. Further studies are underway in more general CCI populations to gain more specific information regarding long-term prognoses.

QUALITY OF LIFE

CCI patients experience considerable functional limitations in long-term follow-up. Cohort studies of patients discharged to long-term acute care hospitals or other post–acute care institutions indicate that only 40% to 50% of survivors, or 10% of total patients, are completely independent in activities of daily living after 1 year. Clearly, chronic critical illness combined with the patients' underlying comorbidities takes a heavy toll on physical functioning. However, overall quality of life is not as closely linked to functional limitations as

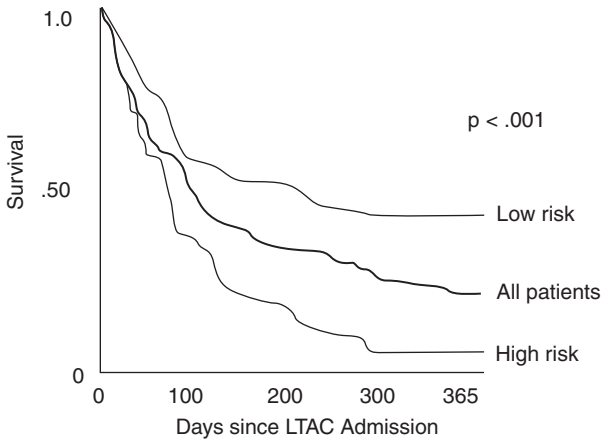

FIGURE 18-2 One-year mortality risk for 133 mechanically ventilated patients admitted to a long-term acute care hospital from 37 acute hospital ICUs. High risk: Age $\geq$ 75 or age $\geq$ 65 and poor functional status prior to illness. Low risk: Age $<$ 65 or age $<$ 75 with good functional status prior to illness.
SOURCE: **From Carson SS, Bach PB: The epidemiology and costs of chronic critical illness. *Crit Care Clin* 18:461, 2002. Reproduced with permission of W.B. Saunders Company.**

many people would believe. Patients who have experienced near-death events can be satisfied with living with physical limitations when death is the obvious alternative. This is especially true in the elderly, for whom physical limitations often were present before their critical illness. Recent assessments of quality of life in long-term survivors of chronic critical illness support these statements. Depending on the setting, between 50% and 80% of survivors report their quality of life to be fair, good, or excellent. In fact, quality-of-life outcomes do not differ significantly from those of other ICU patients.[3] It should be remembered, however, that the majority of patients in these studies do not survive to 1 year. Additionally, a significant proportion of those who do survive are not able to respond to quality-of-life surveys owing to cognitive deficits or severe physical limitations. For the majority of patients who die within the year, their terminal courses are characterized by long periods of invasive and institutionalized care, with accompanying symptoms of discomfort and emotional distress.

COSTS

The growing burden of chronic critical illness has significant cost implications for health care systems. Annual ICU costs for CCI patients in the United States have been estimated to be as high as $24 billion. Patients who require more than 7 days of mechanical ventilation consume as much as 37% of ICU resources, and 21% of ICU resources are consumed after their seventh day of mechanical ventilation.[2] Median hospital charges per patient with DRG 483 in the Nationwide Inpatient Sample range from $120,000 to $135,000 depending on age group (see Table 18-1). Actual hospital costs are lower than these figures, but the costs are still quite substantial. Since few of these patients are discharged home, additional costs are accrued from rehabilitation or long-term care charges. In a cohort of patients from three hospitals who received mechanical ventilation for more than 96 hours, the mean total charges for health care for the year after hospital discharge was $131,190 for all patients and $178,516 per 1-year survivor.[26]

These high costs attract the attention of hospital administrators and third-party payers, and given the overall poor outcomes for many of these patients, clinicians often wonder about the appropriateness of some of these expenditures. Only one study has addressed the subject of cost-effectiveness of care for CCI patients. Heyland and colleagues[27] compared costs for patients who required ICU care for more than 14 days (mean ICU length of stay 24.5 $\pm$ 11.7 days) with costs for patients in the ICU who had life support withdrawn. In their analysis, the incremental cost-effectiveness ratio was Can$65,219 per life saved or Can$4350 per life-year saved. They concluded that continuing treatment for patients with prolonged ICU stays may be an efficient use of hospital resources. It should be noted, however, that their study did not account for costs associated with care after the acute hospitalization. While similar studies involving a broader range of patients will be helpful in the future, for now it appears that the high costs of care for CCI patients may not be out of line with that of other medical interventions. Clinicians should use good judgment, however, recognizing that continued aggressive care in individual patients who are unlikely to survive or have an acceptable quality of life is not an appropriate use of resources, nor is it in the patient's best interests. Clinicians also should remain cognizant of ways to decrease costs in this patient population.

Alternative sites of care are the most effective means of reducing costs for the care of CCI patients. These cost savings are largely related to lower-intensity nursing. In one study, CCI patients were randomized to receive continued care in the acute ICU versus further management in a specialized multidisciplinary unit in the same hospital.[28] Hospital mortality did not differ between the two groups, but mean hospital costs per survivor in the specialized unit were $109,220 compared with $138,434 in the ICU ($p = 0.0005$). There have been no direct cost comparisons between acute ICU care and offsite facilities, but costs likely decrease continuously as intensity of services decreases from acute hospital ICUs to long-term acute care hospitals to subacute care.[23] Limitations in acute hospital reimbursement, combined with potential for cost savings, have been a major factor driving the proliferation of post-ICU care facilities in the United States over the last decade.

Chapter 19

LONG-TERM OUTCOMES OF CRITICAL ILLNESS

MARGARET S. HERRIDGE
RAMONA O. HOPKINS

KEY POINTS

- *Survivors of critical illness experience decreased health-related quality of life due to physical limitations, depression and anxiety, and cognitive impairments.*
- *There may be irreversible long-term neuromuscular dysfunction (e.g., muscle weakness, critical illness polyneuropathy, and myopathy).*
- *Other organ dysfunction (e.g., pulmonary) is present following critical illness but does not appear to have the same impact on patients' self-reported quality-of-life outcomes as other morbidities.*
- *Hypoxia and delirium are risk factors for poor long-term outcome resulting from cognitive impairments.*
- *Approximately one-third to one-half of survivors of critical illness will develop long-term cognitive impairments.*
- *Recent reports suggest that exercise capacity and cognitive function plateau at a lower than normal level at 1 year with limited improvement 2 years following ICU discharge.*
- *Long-term physical and neuropsychological dysfunction may be remediable through the implementation of a multidisciplinary and family-centered rehabilitation program. This is currently being evaluated.*

Background

In the United States, 55,000 patients are hospitalized in the ICU on any given day,[1] and approximately one-half million Americans undergo protracted (>96 hours) mechanical ventilation in an ICU each year. Historically, outcome studies in adult critically ill patients have focused on mortality. Recently, survival in some of our highest-acuity patients (e.g., acute respiratory distress syndrome, sepsis) has improved significantly[2] through novel ventilation strategies,[3] early interventions for sepsis,[4,5] daily administration of renal replacement therapy,[6] tight glycemic control,[7] and other emerging therapeutic modalities. These dramatic improvements in ICU survival have reinvigorated interest in understanding the nature, determinants, and modifiers of long-term morbidity in ICU survivors.

Patients who survive critical illness are at risk for permanent physical, functional, emotional, and neurocognitive deficits, of which some or all may contribute to decreased health-related quality of life (HRQL). The reasons for this late morbidity after ICU care are multifactorial and include but are not limited to the following: (1) nature of and treatment for the inciting critical illness; (2) multiple-organ-dysfunction syndrome and hypoxemia; (3) physiologic and emotional stress in the ICU related to the illness itself, sleep fragmentation, psychoactive medications, and impaired drug metabolism owing to simultaneous administration of multiple medications; and (4) prolonged immobility and long ICU stay.

Patients with the acute respiratory distress syndrome (ARDS) represent some of the most complex, highest-acuity, and long-stay ICU patients (see Chap. 38). ARDS affects an estimated 150,000 people per year in the United States and is manifested by acute lung injury and severe hypoxemic respiratory failure.[8] ARDS is associated with a variety of insults, including, pneumonia, sepsis, trauma, massive transfusion, and other medical/surgical conditions.[9] It is a systemic illness involving inflammatory and coagulopathic disturbances that may induce dysfunction of multiple organ systems, including skeletal muscle and the peripheral and central nervous systems.[10,11] Because of the significant potential for morbidity, ARDS patients have been the focus in long-term outcome studies in survivors of critical illness. We are in the early stages of understanding the long-term impact of ARDS on physical, emotional, and cognitive functioning and how each contributes to the patients' HRQL. Most studies in ARDS survivors have focused on 6- to 12-month outcomes, and there is limited information on morbidity beyond this time point. Comprehensive 5- and 10-year follow-up data are not available for ARDS patients, and it is unclear whether all survivors of critical illness—even with a severe episode—will suffer from the same morbidity as observed in ARDS survivors. Despite these limitations, the ARDS survivor data are some of the most complete long-term outcome data available and represent the current state of the art in the critical care outcomes literature. As such, they will form the primary basis for this review.

Evolution of Outcomes Research in Survivors of Critical Illness

Historically, the assessment of outcome in critical care has focused largely on mortality and to a lesser extent on short-term physiologic and radiologic measures of impairment. As the focus has shifted to include the evaluation of longer-term outcomes, more investigators have moved toward patient-centered measures of functional status and HRQL. One advantage of these measures is that many are self-administered, and valuable information pertaining to physical, emotional, and cognitive well-being can be obtained without an in-person visit. This strength is also a limitation because these data will not facilitate understanding of the many and varied determinants of reported impairments in HRQL. This limitation is further compounded by heterogeneity across studies related to study sample, case mix, follow-up time for the population of interest, and difficulties comparing studies owing to the different HRQL measures administered. One potential solution to this dilemma is to focus on relatively homogeneous populations of patients, characterize their HRQL, and then proceed with in-person natural history cohort studies to identify and describe the specific determinants of reported morbidity. One example of data on a relatively homogeneous group is the ARDS long-term outcomes literature. Many recent publications describe decreased quality of life in ARDS survivors. Most studies suggest that physical and/or

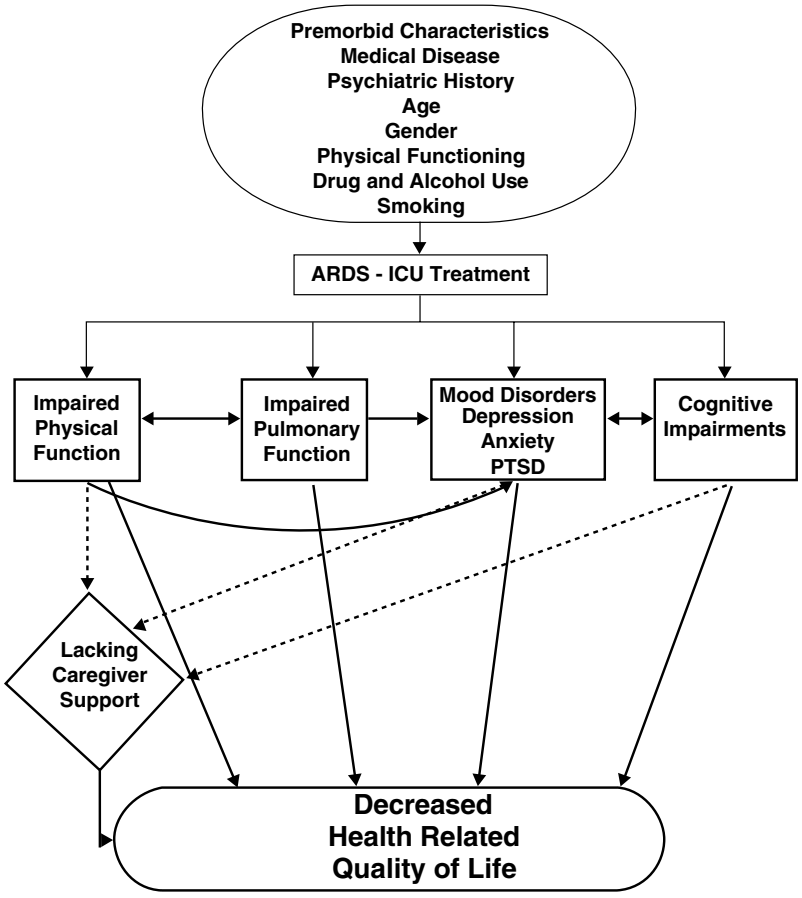

FIGURE 19-1 Determinants of health-related quality of life in ARDS survivors.

cognitive impairments are the main determinants of long-term disability. Through natural history cohort data in ARDS survivors, we have gained important insights into the heterogeneity of pulmonary, neuromuscular, and neuropsychological sequelae that contribute—to a greater or lesser extent in individual patients—to decreased HRQL. Ultimately, a detailed understanding of the spectrum of contributors to morbidity and their determinants will allow development, testing, and implementation of interventions that will lead to improved functional status and HRQL (Fig. 19-1).

Long-Term Outcome Measures in Critical Illness

HEALTH-RELATED QUALITY OF LIFE (HRQL)

HRQL can be defined as a set of causally linked dimensions of health, including biologic/physiologic, mental, physical, social function, cognitive, and health perception.[12] Measures of HRQL assess how disease and its treatment are related to physical, social, emotional, or cognitive functioning. HRQL has emerged as an important measure of recovery from a variety of disease states, including critical illness, and has been used to evaluate patient-centered outcomes.

Most studies indicate that a significant proportion of ICU survivors experience some impairment in HRQL; however, this can be quite variable.[13,14] Case mix may represent one important reason for these differences in reported HRQL. Critically ill patient populations are very diverse. The premorbid functional status of the patient and the etiology of the critical illness and its outcome represent important determinants of reported HRQL. Trauma patients with brain injury but normal cognitive function and intact social and work functioning reported a higher quality of life than trauma patients who were unemployed and had cognitive impairment.[15] Critically ill multiple-trauma survivors experience decreased quality of life associated with cognitive impairments and decreased income.[16] Elderly patients (>70 years) hospitalized in the ICU more than 30 days reported decreased physical functioning and poorer health and memory, but most were still functionally independent.[17] Survivors of sepsis[18] and prolonged mechanical ventilatory support (mean of 45 days) had compromised physical function, and the degree of dysfunction was related to premorbid functional status and the underlying disease.[19]

Although there is clearly some heterogeneity across different populations of ARDS patients, there appears to be less variability in reported HRQL compared with general populations of critically ill patients. In 1994, McHugh and her colleagues,[20] using a prospective cohort study, serially evaluated pulmonary function and quality of life to assess the relationship between pulmonary dysfunction and functional disability. These authors found that the Sickness Impact Profile (generic quality-of-life measure of the subject's self-perceived physical and psychological condition) scores were very low at extubation, rose substantially in the first 3 months, and then exhibited only slight improvement to 1 year. When quality of

life was assessed using a lung-related Sickness Impact Profile score, only a modest proportion of the patients' overall dysfunction was attributed to residual pulmonary problems. Weinert and coworkers[21] identified functional impairment in a cohort of acute lung injury survivors. They administered the Medical Outcomes Study 36-item short-form health survey (SF-36), which yields scores in eight domains including physical and social functioning, role limitations because of emotional or physical problems, mental health, vitality, bodily pain, and general health perceptions.[22] While all domains of the SF-36 were reduced, the largest decrements were in physical ability to maintain their roles (role-physical) and physical functioning. While some decreased quality of life was attributed to pulmonary dysfunction, many more patients attributed this to global and generalized disability. Schelling and colleagues[23] made similar observations about impaired physical functioning and inferred that disability was due to pulmonary dysfunction; however, they did not assess this in their study. Davidson and colleagues[24] designed a study to determine if there were differences in health-related quality of life in ARDS survivors and comparably ill controls. They used the SF-36 and a pulmonary disease–specific measure (St. George's Respiratory Questionnaire [SGRQ]) to determine the degree to which perceived physical disability in ARDS survivors was related to pulmonary dysfunction. Similar to previous reports, all domains of the SF-36 were reduced, and the largest decrement was in the role-physical domain. ARDS survivors had significantly worse scores on the SGRQ compared with critically ill controls. There appeared to be an ARDS-specific degree of physical disability, but it was not clear whether this was solely related to pulmonary dysfunction or there were other important extrapulmonary contributors.

Angus and colleagues[25] used the quality-of-well-being (QWB) score in a prospective cohort of ARDS survivors to measure quality-adjusted survival in the first year after hospital discharge. The mean QWB scores for the ARDS cohort at 6 and 12 months were significantly lower than the scores of a control population of patients with cystic fibrosis. When QWB was disaggregated into its component subscores, post hoc analyses showed that the symptom-component scores of the QWB accounted for 70 percent of the decrement in perfect health at 6 and 12 months. Although respiratory symptoms were reported in almost half the patients, the most common complaints were musculoskeletal and constitutional.

In a prospective cohort study of 78 survivors of ARDS, Orme and coworkers[26] evaluated HRQL and pulmonary function outcomes in patients treated with higher tidal volume versus lower tidal volume ventilation strategies. Both groups (higher and lower tidal volumes) reported decreased HRQL in physical functioning, role-physical, bodily pain, general health, and vitality (energy) on the SF-36. The pulmonary function abnormalities correlated with decreased HRQL for domains reflecting physical function.

Not only is the observation of impaired physical functioning robust across studies and investigators, but it also appears to persist for long periods of time following ICU or hospital discharge. The paper by Davidson and coworkers[24] discussed earlier reported outcomes at 23 months after discharge, and Herridge and colleagues[27] also have reported persistent physical dysfunction at 2 years after ICU discharge.

Hopkins and colleagues[28] were the first to rigorously evaluate cognitive dysfunction in ARDS survivors and toreport the significant impact this had on reported HRQL outcomes. Fifty-five consecutive ARDS survivors completed detailed neuropsychological testing and questionnaires relating to health status and cognitive and psychological function at hospital discharge and 1 year after ARDS onset. These authors reported that decreased HRQL was related to cognitive dysfunction. Impaired cognitive function following ARDS also has been reported by others.[29]

Decreased HRQL has been associated with posttraumatic stress disorder (PTSD) and is manifest in the emotional domains of the SF-36 (e.g., role-emotional, mental health, and vitality). PTSD may represent yet another important contributor to subsequent disability and loss of employment.[30]

HRQL in ARDS survivors is affected by physical limitation, cognitive impairment, and emotional dysfunction. The HRQL data have had an enormous impact on the critical care community and have helped to focus attention on long-term morbidity after critical illness. However, these data provide limited insights into the specific determinants of morbidity. Natural history cohort data—evaluating both functional and cognitive long-term outcomes—have helped us to begin to understand the heterogeneous nature of reported morbidity and the complexity of interaction among physical, emotional, and cognitive domains in individual patients (see Fig. 19-1).

PHYSIOLOGIC AND FUNCTIONAL OUTCOMES IN ARDS SURVIVORS

Many authors have focused on residual pulmonary function abnormalities as a probable explanation for long-term functional impairment in ARDS patients. While most ARDS follow-up studies report pulmonary dysfunction, the pulmonary function abnormalities tend to be modest and may not fully explain functional limitation. More recently, neuromuscular dysfunction sustained as a result of the inciting critical illness and its attendant ICU care has been associated with ongoing physical impairment in ARDS survivors. These data have been gleaned from in-person prospective natural history cohort data.

PULMONARY FUNCTION ABNORMALITIES

The lung was the obvious focus of outcome studies early after the first description of ARDS in 1967. The studies of pulmonary function have suffered from several limitations, including a lack of consecutive patient recruitment and loss to follow-up, limited sample size, limited follow-up times, and studies of pulmonary function in isolation without any concurrent functional evaluation. Evaluation of pulmonary function on its own or coupled with HRQL measures has remained a dominant theme until recently.

Many ARDS survivors have persistent pulmonary function impairments that typically are mild to moderate, with restrictive changes and a reduction in diffusion capacity.[31–33] Orme and colleagues[26] reported that ARDS survivors had abnormal pulmonary function associated with decreased health-related quality of life 1 year following hospital discharge, and Schelling and colleagues[34] recently reported no additional improvement in pulmonary function after the first year following ARDS. In a recent publication, Neff and

colleagues[35] reviewed 30 studies that evaluated pulmonary function in ARDS survivors. They reported significant variability in obstructive (0% to 33%) and restrictive (0% to 50%) defects, as well as compromised diffusion capacity (33% to 82%). This spectrum of pulmonary dysfunction may relate to population heterogeneity with respect to evolving definitions or severity of ARDS, severity of lung injury, ICU ventilatory strategy, prior history of lung disease or smoking, and the presence of other pulmonary processes that fulfill the ARDS definition but have a very different natural history (e.g., bronchiolitis obliterans organizing pneumonia).

Most outcome studies found that ARDS survivors frequently are unable to resume their prior lifestyle, but the degree of pulmonary dysfunction does not fully explain their functional limitation. This observation has led investigators to explore other possible contributors to physical disability.

LIMITATION IN PHYSICAL FUNCTIONING

One of the limitations in the ARDS morbidity literature has been an absence of data that objectively quantify functional disability. These data would be most useful in the context of in-person assessment in addition to concurrent physiologic and HRQL outcome measures. Multiple outcome measures may result in a better understanding of the determinants of functional morbidity and how this might be ameliorated. The Toronto ARDS Outcomes group evaluated exercise capacity (distance walked in 6 minutes with continuous oximetry) and pulmonary function and conducted an interview, physical examination, and HRQL measure in 109 ARDS survivors at 3, 6, and 12 months after ICU discharge.[36,37] Similar to other pulmonary function studies, the ARDS patients had mild restrictive disease and reduced diffusion capacity at 3 months following ICU discharge. By 6 and 12 months, they had normal to near-normal lung volumes and spirometric measures with a persistent mild reduction in carbon dioxide diffusion capacity—lung impairment similar to that noted by others. The ARDS survivors had profound muscle weakness and wasting and were only able to achieve 66% of their predicted exercise capacity 1 year after ICU discharge. This functional disability was reflected in the HRQL assessment, in which patients reported profound reduction in the physical functioning and role-physical domains of the SF-36. Impaired exercise capacity was related to burden of comorbid disease, exposure to systemic corticosteroid treatment during the ICU period and the rate of resolution of lung injury, and multiple-organ dysfunction during the ICU stay. The precise determinant(s) of the observed muscle wasting and weakness were not clear, but possibilities included critical illness polyneuropathy, ICU-acquired myopathy, and entrapment neuropathies.

Critical Illness Polyneuropathy

An acute polyneuropathy was described in the 1980s in association with multiple-organ dysfunction and sepsis. This was called *critical illness polyneuropathy* and has been characterized electrically and morphologically by a primary axonal degeneration of motor and sensory fibers.[38,39] The prevalence of critical illness polyneuropathy is 70 percent and has been documented in populations with sepsis, multiple-organ dysfunction, and ARDS.[40] The precise etiology is unknown, but it may represent ischemic nerve injury secondary to a disturbance in the microcirculation. There has been a recent report that critical illness polyneuropathy may persist for years following ICU discharge and contribute to long-term physical limitation.[41]

ICU-Acquired Myopathy

The incidence of an ICU-acquired myopathy and its impact on disability and prolonged rehabilitation in the post-ICU period are uncertain. A recent report described a 25% incidence of ICU-acquired paresis in patients remaining on the mechanical ventilator for 7 or more days.[42] Myopathic changes have been documented both in the presence[43] and the absence[44] of corticosteroid and neuromuscular blockade use. Several patients from the Toronto ARDS Outcomes study underwent open muscle biopsy[45] in an attempt to better understand the nature of the observed muscle wasting and weakness. The median time to biopsy was almost 1 year after ICU discharge, and all patients had histopathologic evidence of a chronic myopathic process. Muscle injury is likely multifactorial, and it may represent an important determinant of long-term functional impairment.

Entrapment Neuropathy

The Toronto ARDS Outcomes study observed a 6% prevalence of peroneal and ulnar nerve palsies.[37] Although this represents only a small proportion of patients, these nerve palsies complicated rehabilitation therapy and precluded return to original work in some cases. Other studies also have found detrimental long-term consequences resulting from compression neuropathies.[46]

Heterotopic Ossification

Heterotopic ossification is the deposition of para-articular ectopic bone and has been associated previously with polytrauma, burns, pancreatitis, and ARDS.[47,48] It has been linked with paralysis and prolonged immobilization. There was a 5% prevalence of heterotopic ossification in the Toronto ARDS Outcomes study, with all patients having large joint immobilization, leading to important functional limitation (Fig. 19-2). Natural history cohort studies facilitate unexpected observations—such as heterotopic ossification—and

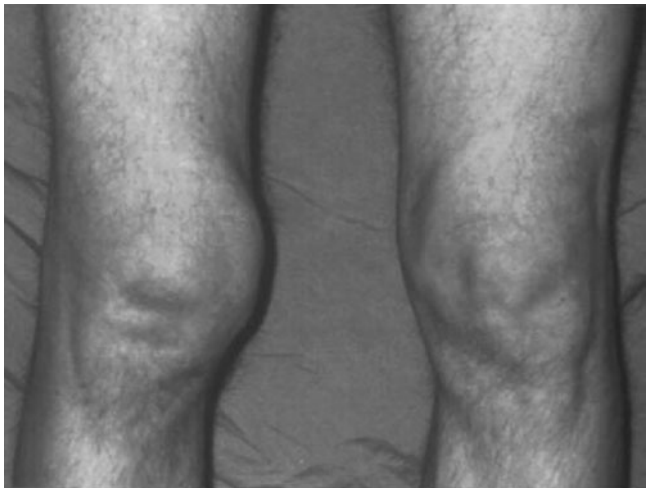

FIGURE 19-2 Heterotopic ossification involving the right knee of an ARDS survivor.

link them to functional disability. Heterotopic ossification is remediable with appropriate surgical intervention, and screening for this might be an important part of a multidisciplinary intervention to improve functional outcomes.

EMOTIONAL OUTCOMES

Emotional Function after ARDS

The relationship between critical illness and emotional (mood) disorders is being recognized increasingly. Mood disorders represent important contributors to long-term HRQL impairments in survivors of critical illness. However, it is unclear whether these disorders are a psychological reaction to extraordinary emotional and physiologic stress, sequelae of brain injury sustained due to a critical illness and its treatment, or both.

Individuals with critical illness have to cope with a disease or injury that is life threatening as well as very burdensome interventions. The combination of medications, physiologic changes, pain, altered sensory inputs, and an unfamiliar environment may contribute to emotional changes following critical illness.[49–51] Recent evidence suggests that mood disorders that occur secondary to medical illness may constitute discrete entities in which symptoms are similar to primary mood disorders, but there is a male predominance and earlier onset.[52]

The reported prevalence and severity of mood disorders including symptoms of depression, anxiety, and PTSD in survivors of critical illness are quite variable among patients following ICU hospitalization.[49,50,53–54] Rincon and colleagues[55] noted symptoms of depression and anxiety in 14% and 24%, respectively, of patients following critical illness. Similar prevalence rates of anxiety and depression have been reported by Scragg[56] and Orme and coworkers.[26] In contrast, Weinert and colleagues[21] found that 43% of patients with acute lung injury reported symptoms of depression, and Angus and coworkers[25] reported a 50% prevalence of depression and anxiety at 1 year in ARDS patients. The Toronto ARDS Outcomes study found that 58% of ARDS survivors reported depressive symptoms almost 2 years after ICU discharge.[57] By contrast, Hopkins and coworkers[28] found that ARDS patients reported minimal symptoms of depression or anxiety that were within the normal range in their natural history ARDS cohort study. The observed depression and anxiety after ICU treatment are likely multifactorial, and further study will be needed to better understand patient predisposition, illness, and treatment-specific determinants of affective morbidity.

PTSD is the development of characteristic symptoms that occur following a traumatic event(s) where triggers include a serious personal threat experienced with helplessness and intense fear.[58,59] The diagnostic criteria include a history of traumatic event(s) accompanied by symptoms from each of three symptom clusters: hyperarousal symptoms, intrusive recollections, and avoidant/numbing symptoms.[60] Schelling and colleagues[30] were the first to introduce the concept of PTSD resulting from critical illness and ICU treatment to the critical care community. These authors evaluated HRQL and PTSD in a cohort of 80 ARDS survivors 4 years following discharge from the ICU. Almost a third of the ARDS survivors reported impaired memory, bad dreams, anxiety, and sleeping difficulties after ICU discharge, with a prevalence rate of PTSD of 28%. PTSD was related to the number of adverse ICU-related memories recalled by patients. Other authors[61,62] also have noted this relationship. Memory for nightmares or delusions while in the ICU, as well as a complete absence of any ICU memories, also has been perceived as a traumatic event.[63] The prevalence of PTSD has been reported to be as high as 38%[61] and is a persistent complaint for years after ICU discharge.[29,61,63a] We are just beginning to fully appreciate how long-standing and debilitating mood disorders are following critical illness and the important contribution they have to decreased HRQL.

COGNITIVE OUTCOMES

Cognitive Impairment in ARDS Survivors

Cognitive impairment represents the major threat to both recovery and quality of life following an acute illness.[29] Quality of life is largely determined by the ability to return to baseline level of cognitive performance.[24,28,56] Long-term cognitive dysfunction—even when modest—results in vastly increased medical and disability costs. For example, a 3-point decrease on the Mini Mental State Exam was associated with increased overall health care expenditures of $6000 per year.[29] The per-patient societal cost burden for even mild cognitive impairments is over $15,000 per year, and it is considerably higher ($34,515) for individuals with moderate to severe cognitive dysfunction.[64]

Cognitive impairments have been observed in a variety of patient populations with hypoxia.[65–73] Hypoxia-related cognitive impairments include memory deficits,[74] executive dysfunction,[74,75] visual-spatial deficits,[77] and intellectual decline.[73,77] Critical illness, including ARDS, is associated with significant cognitive dysfunction.[28,29,78,79] Approximately 33% of ICU survivors develop cognitive impairments that are similar to the cognitive dysfunction observed in mild dementia.[66] Cognitive impairments are a major determinant of the ability to return to work, work productivity, and life satisfaction following cardiac surgery,[80,81] traumatic brain injury,[82] and ARDS.[29] Even mild cognitive dysfunction results in clinically significant difficulties in driving, money management, and activities of daily living.[83–87] Data obtained from interviews with seriously ill patients indicate that 90 percent of these patients would rather die than survive with cognitive disability.[88]

Hopkins and colleagues[28] published the seminal long-term cognitive outcome study in ARDS survivors in 1999. In this natural history cohort, they found that 100% of ARDS survivors had cognitive impairments, including memory, attention, concentration, and decreased intellectual function, at the time of hospital discharge. At 1-year follow-up, 30% of the survivors had decreased intellectual function, and 78% had impaired memory, attention, concentration, and/or mental processing speed. ARDS survivors had significantly lower IQ than their estimated premorbid IQ ($p \leq 0.05$) and the measured IQ 1 year later.

Hopkins and colleagues[28] hypothesized that hypoxia may be an important contributor to cognitive dysfunction in ARDS survivors, and they undertook a detailed assessment of oximetry during the period of critical illness. The ARDS survivors' oximetry was measured for a total of 31,665 hours, with a mean of 609 ± 423 hours. The patients' mean oxygen saturations and their duration were outlined as follows: <90% = 122 ± 144 hours, <85% = 13 ± 18 hours, and <80% = 1 ± 3 hours. On average, these patients had 25 episodes

of oxygen desaturation of less than 90% and 1 episode of desaturation of less than 85% for a duration of more than 2 hours. In this cohort, the degree of hypoxia was significantly correlated with neurocognitive sequelae ($r^2 = 0.25–0.45$, all $p < 0.01$).[28]

Since the Hopkins and colleagues report of cognitive impairments in ARDS survivors, other groups have confirmed their findings.[29,57,78] In a retrospective study of 33 ARDS survivors, Marquis and coworkers[78] reported impaired attention, visual processing, psychomotor speed, and cognitive flexibility compared with critically ill control subjects. Rothenhäusler and colleagues[29] retrospectively evaluated 46 ARDS survivors and found that 24% had cognitive impairments and 41% were disabled and could not return to work. Limitations of this study were low follow-up rate and the administration of one brief cognitive test that assessed only memory and attention. A study of self-reported memory problems in the Toronto ARDS Outcomes cohort found that 20% of ARDS survivors rated their memory as poor 18 months following their ICU discharge.[57]

Cognitive impairments occur in a significant number of ARDS survivors at 1 year, with little improvement at 2 years after hospital discharge.[89] In their recent prospective 2-year follow-up study, Hopkins and colleagues[28] assessed cognitive outcome in 71 consecutive ARDS survivors treated with higher and lower tidal volume strategies. The result was that 59% and 43% of patients had evidence of cognitive dysfunction (>1.5 SD below the mean) in at least two cognitive domains at 1- and 2-year follow-up, respectively. Cognitive performance at hospital discharge was significantly lower than at 1- and 2-year follow-up ($p < 0.001$). There were no significant differences between 1- and 2-year cognitive outcomes except improvement in performance IQ. Cognitive impairments at 1 and 2 years correlated with duration of hypoxemia, but they were not associated with gender, type of ventilator treatment, mean blood pressure, or time on sedative medications.

The recent report entitled, "Surviving Intensive Care: A Report from the 2002 Brussels Roundtable," indicated that future investigations should prioritize studies of cognitive impairments in survivors of critical illness.[90] Cognitive dysfunction in ARDS survivors is prevalent, with impairments reported in up to 78% of patients in some studies.[28] It represents significant morbidity and is a major obstacle to recovery in severely ill patients. The etiology of the cognitive impairments is likely multifactorial and the subject of ongoing debate, but the paper by Hopkins and colleagues[28] already has demonstrated a relationship to hypoxia, and several recent studies have demonstrated an association between delirium and cognitive impairments in critically ill patients.[91,92] For a detailed review of delirium in this book, see Chap. 62. Future investigations are required to further delineate etiology and to identify interventions that may improve or prevent cognitive impairment in ARDS survivors.

BRAIN TISSUE LOSS AFTER ARDS

Hypoxia and/or ischemia damage the hippocampus in humans,[74,93–95] rats,[96] and monkeys.[97] Research in humans using quantitative magnetic resonance imaging (MRI) analysis of neural structures shows significant reductions in hippocampus volume associated with hypoxia but not in the nearby areas of the parahippocampal gyrus or the temporal lobe.[75,94,95,98] Using quantitative MRI, brain morphologic changes, including ventricular enlargement, cerebral atrophy, and hippocampal atrophy, have been found in patients with pulmonary disorders following anoxia,[98] asthma,[99] carbon monoxide poisoning,[73,100] and obstructive sleep apnea.[68,69,101] Carbon monoxide poisoning and its concomitant hypoxia result in acute demyelination, generalized cortical atrophy,[73] and discrete lesions in the basal ganglia,[102] thalamus,[103] substantia nigra,[104] and white matter.[72] Hopkins and colleagues reported recently generalized atrophy[68] and atrophy of both gray and white matter structures, including the corpus callosum,[105] fornix,[106] and hippocampus,[74,94,95] following carbon monoxide poisoning.

In light of their prior work linking hypoxia to morphologic changes in the brain and cognitive dysfunction, Hopkins and colleagues sought to evaluate whether there was a structural correlate for hypoxia and impaired cognition in ARDS survivors. They compared computed tomographic (CT) brain scans of 15 ARDS patients with those of normal age- and gender-matched controls (with normal scans) using quantitative image analysis.[107] ARDS survivors exhibited brain atrophy, significantly enlarged ventricles, and an increased ventricle-to-brain ratio (another measure of generalized atrophy and an indirect index of white matter integrity) compared with the matched controls. The generalized brain atrophy, which was similar morphologically to that found in carbon monoxide poisoning, was associated with cognitive dysfunction.

Caregiver and Family Burden in Critical Illness

As more patients are surviving critical illness and are being discharged from hospital more quickly, the burden of caregiving has shifted to family members. It is important to note that in most cases the caregivers are the same individuals who have just completed a protracted bedside vigil in the ICU. They may be physically and emotionally spent and experiencing financial stress due to the cost of medical care and time spent at the hospital and away from their workplace. They are likely to have very little reserve and will now be responsible for all aspects of the patient's recovery.

It is surprising that there is such limited literature on caregiver and family burden in survivors of a severe episode of critical illness. Potential contributors to this paucity of information include the historic focus on mortality as the main outcome of interest in critical illness and exclusive focus on patient-centered care. Neonatologists and pediatric intensivists understand that critical illness disrupts families—not just the lives of their patients—and adult critical care physicians might do well to embrace the concept of family-centered care.

The following discussion has been excerpted from an excellent recent review on this subject by Levy.[108] In this review, Levy notes that Grad and Sainsbury first introduced the concept of family burden in 1966.[109] These authors defined *burden* as the cost or negative consequences sustained by the family or caregiver and whether these were of a subjective or objective nature. *Subjective* burden refers to the caregivers' attitude

toward or emotional reaction to the caregiving experience, and *objective* burden relates to the nature or degree of family disruption that can be observed directly or verified.

Chou and colleagues[110] introduced a conceptual model of caregiver burden. The model includes four components: critical attributes and predisposing factors that influence the occurrence of burden, moderating/mediating factors, and consequences or outcomes. *Critical attributes* refer to the primary determinants of burden, including (1) the subjective burden as outlined earlier, (2) the multidimensional nature of demands that arise from caregiving, (3) the concept that illness is dynamic and therefore that the demands of caregiving also will be dynamic, and (4) the concept of overload, where the demands of caregiving exceed available resources. Predisposing factors relate to caregiver characteristics, including economic resources, race, and ethnicity. *Mediating* or *moderating factors* refer to elements that may alter the impact of burden, such as social or spiritual support. Consequences and outcome include the impact of the caregiving responsibilities on the caregiver and family.

Two recent papers highlight the burden of caregivers of ICU survivors. In a comprehensive review, Johnson and colleagues[111] indicated that a very high degree of caregiver burden is related to patient neuropsychological dysfunction as compared with severe physical disability. Caregiver stress is also related to lack of education about the demands of the caregiver role and the responsibility of managing complex medical treatments and technology in the home.

Pouchard and coworkers[112] conducted a prospective evaluation of anxiety and depression in 836 family members of critically ill patients. The prevalence of symptoms of anxiety and depression was almost 70% and 35%, respectively. It is still unclear whether or how long these symptoms persist and how they affect the care of the patient and the ability of the family to function normally.

CASE HISTORY FROM THE TORONTO ARDS OUTCOMES COHORT[37]

The following case history will help to emphasize the functional and neuropsychological morbidity in survivors of critical illness that has been the focus of this chapter.

- A 47-year-old previously healthy female teacher presented to the ICU with hypoxemic respiratory failure secondary to pneumococcal pneumonia complicated by ARDS.
- The patient was intubated and mechanically ventilated for 5 weeks in the ICU.
- Her ICU course was complicated by the development of multiple-organ dysfunction requiring pressor support and renal replacement therapy.
- Three chest tubes were inserted during the ICU stay for pneumothoraces resulting from her complicated ventilatory management.
- The patient underwent tracheostomy at 3 weeks into the ICU stay and had a protracted wean from the ventilator related to weakness and difficulty clearing secretions.
- The patient had received continuous sedation and analgesia during the first 3 ICU weeks to facilitate mechanical ventilation. She had been immobile and noncommunicative.
- At the time of ICU discharge, the patient had severe weakness and generalized muscle wasting. She was unable to sit up. She could not walk, bear weight, or even transfer on her own.
- Prior to transfer, she was confused and was only able to obey simple commands intermittently.
- On transfer to the medical ward, she complained of insomnia and disturbing and recurrent dreams that she had been physically and sexually assaulted during her ICU stay.
- After 2 weeks on the medical ward, she was able to stand and take a few steps and was transferred to a rehabilitation facility for ongoing physical therapy.
- At 4 weeks, she was decannulated and discharged to her friend's home.
- She did not return to her own home because she couldn't be left by herself, and her husband and children were at work/school for the entire day.
- At 3 months following ICU discharge, she continued to have significant proximal muscle weakness with inability to fully abduct her arms. She could not get in or out of cars nor climb stairs because of proximal leg weakness (Fig. 19-3).
- At 12 months following ICU discharge, she had regained her lost weight, had mild proximal muscle weakness, but now could abduct her arms and reported being quite functional (see Fig. 19-3). However, because of her need to stand most of the day as a teacher, she was unable to return to work because of residual weakness and fatigue.
- A more intensive physical rehabilitation program was organized for her, and she continued to experience slow and progressive improvement in her weakness.
- At 18 months following ICU discharge, she returned to her original job on a part-time basis. At that time, she found her tracheostomy scar stigmatizing and underwent scar revision by a plastic surgeon.
- She began to complain of very severe depression and inability to cope with the stressors in her workplace. She underwent formal neuropsychological and psychiatric assessments.
- At 20 months after ICU discharge, she was diagnosed with mild cognitive dysfunction and PTSD. She received psychiatric treatment.
- At 24 months—with modest residual weakness and mild cognitive dysfunction—she returned to full-time work as a teacher and is performing well in the workplace.
- Throughout her recovery period, her family has endured significant financial stress related to her inability to work, and her children have had significant behavioral and academic problems.

Multidisciplinary Intervention

The goal of this chapter was to review the current state of the art in the outcomes literature in survivors of critical illness. Another goal was to emphasize the importance of viewing critical illness as a continuum—from inciting illness through the ICU course and through recovery and rehabilitation. Understanding long-term outcome following critical illness is in

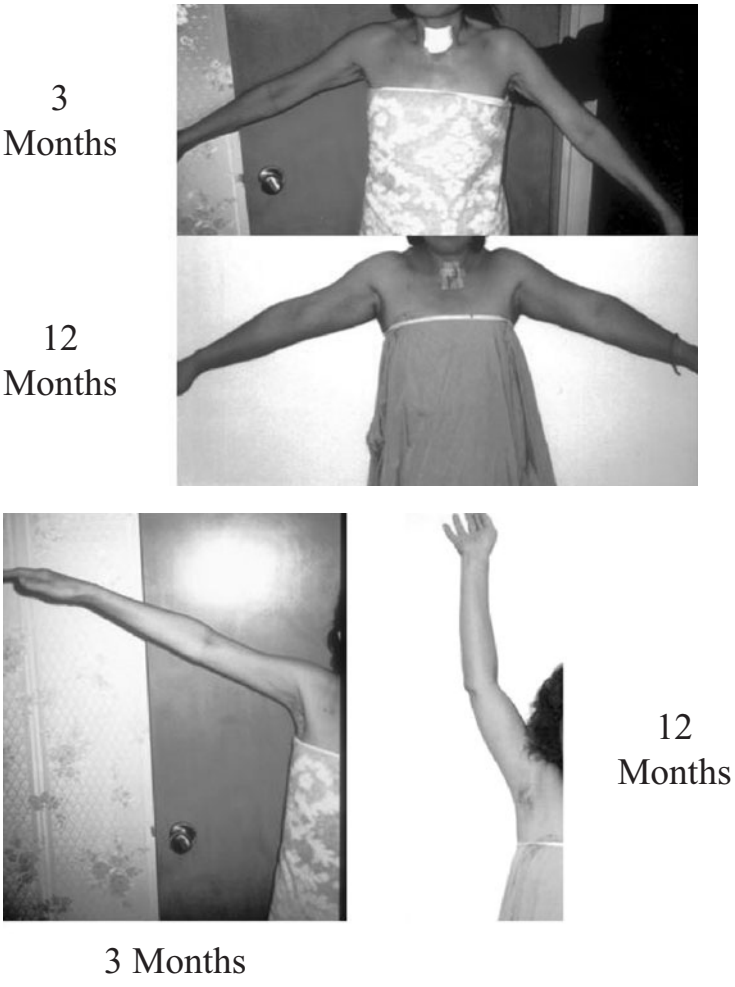

FIGURE 19-3 Resolution of muscle wasting and proximal muscle weakness from 3 to 12 months after ICU discharge in ARDS survivor.

its infancy. We are just beginning to understand the profound nature of functional and neuropsychological morbidity that may be sustained by the patients under our care every day in the ICU. In addition, we are only beginning to appreciate the caregiver and family burden experienced during and following the ICU stay.

A multidisciplinary model has been proposed[113] that identifies predictors and modifiers of morbidity outcomes in survivors of critical illness (Fig. 19-4). This model is centered on a longitudinal post–critical illness clinic in which the physician and his or her team provide a support network. The goal is to provide ongoing continuity of care as patients recover from the morbidity of critical illness and to facilitate patient access to appropriate diagnostic and treatment referrals.

The different components of this model reflect the different types of morbidity that we have described in this chapter. Given the burden of neuropsychological morbidity, one component of this intervention is to offer neuropsychological and psychiatric assessment and supportive counseling to survivors of critical illness *and* their family members. The determinants of muscle wasting and weakness would be further delineated through formal neurologic and physiatry assessments, and treatment programs would be organized through occupational and physical therapy. Social work supports also would facilitate return to work and management of other family or child-related concerns. Variations of this model are currently under study, and hopefully, we will soon be in a position to ameliorate the long-term morbidity of critical illness.

Summary

Survivors of critical illness experience decreased health-related quality of life due to physical limitations, depression and anxiety, and cognitive impairments. Neuromuscular dysfunction may represent an important—and potentially irreversible—determinant of long-term functional disability in these patients. Other organ impairment such as pulmonary dysfunction also has been documented following critical illness but does not appear to have the same impact on patients' health-related quality of life. We now understand that approximately one-third to one-half of survivors of critical illness will develop long-term cognitive impairments and that both this and functional capacity appear to plateau at a lower than normal level at 1 to 2 years following ICU discharge. Long-term physical and neuropsychological dysfunction may be remediable through the implementation of a multidisciplinary and family-centered rehabilitation program, and this hypothesis is currently being tested.

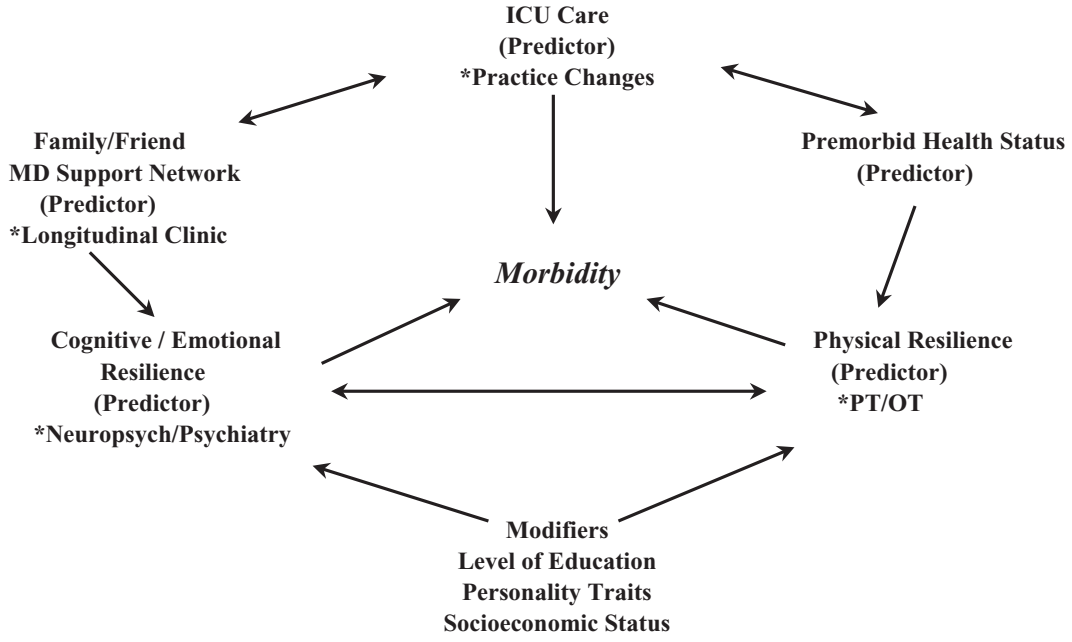

FIGURE 19-4 Model of predictors and modifiers of morbidity in survivors of critical illness. Asterisks mark components of Multidisciplinary Intervention.

Chapter 20

THE PATHOPHYSIOLOGY OF THE CIRCULATION IN CRITICAL ILLNESS

LAWRENCE D. H. WOOD

KEY POINTS

- *Left ventricular (LV) stroke volume (SV) creates arterial pulse pressure (PP) by distending conducting vessels during systole, and systemic vascular resistance (SVR) preserves diastolic pressure (DP) by preventing SV from flowing through arterioles during diastole.*
- *This coupling of ventricular and vascular elements allows rapid clinical separation of hypotensive patients into those with increased SV and cardiac output ($\dot{Q}_T$) demonstrating bounding pulses with large PP, low DP, and warm digits (low SVR, high $\dot{Q}_T$ hypotension, or septic shock) from those who demonstrate thready pulses with small PP and cool digits signaling low SV and $\dot{Q}_T$ with increased SVR, as in cardiogenic or hypovolemic shock.*
- *LV pumping function is described by relating LV end-DP as estimated by pulmonary wedge pressure (Ppw) to SV; LV dysfunction is signaled by increased Ppw and decreased SV and may be due to systolic or diastolic dysfunction.*
- *Systolic dysfunction, or decreased contractility, connotes increased LV end-systolic volume for a given LV end-systolic pressure that is approximately the mean blood pressure (BP); common causes of acute systolic dysfunction in critical illness are myocardial ischemia, hypoxia, acidosis, sepsis, intercurrent negative inotropic drugs (β or calcium blockers), and acute-on-chronic systolic dysfunction in cardiomyopathies.*
- *Diastolic dysfunction connotes decreased LV end-diastolic volume despite increased Ppw because the heart cannot fill normally; common causes of diastolic dysfunction in critical illness are pericardial tamponade or constriction, positive end-expiratory pressure (PEEP), or other causes of increased pleural pressure as in pneumothorax, pleural effusion, or abdominal distention, ventricular interdependence in acute right heart syndromes, and chronic LV stiffness as in LV hypertrophy.*
- *Early differentiation between diastolic and systolic dysfunctions in critical illness is aided by a questioning approach and dynamic imaging such as echocardiography; this avoids inappropriate and ineffective therapy for the wrong etiology of LV dysfunction.*
- *Venous return (VR) to the right atrium is controlled by mechanical characteristics of the systemic vessels (unstressed volume, vascular capacitance, vascular volume); together these determine the mean systemic pressure responsible for driving VR back to the right atrium (Pra) through the resistance to VR.*
- *For a given Pms, VR increases as Pra decreases to define the VR curve of the circulation, whereas SV and $\dot{Q}_T$ from the heart increase as Pra and preload increase to define the cardiac function curve that intersects the VR curve at a unique value of Pra where VR = $\dot{Q}_T$.*
- *When $\dot{Q}_T$ is insufficient, volume infusion, baroreceptors, or metabolic receptors can increase mean systemic pressure to increase VR and Pra; this effect is mimicked by venoconstricting drugs such as dopamine or epinephrine; alternatively, VR can be increased by positive inotropic (dobutamine) or afterload-reducing (sodium nitroprusside) drugs that decrease Pra by enhancing cardiac function.*
- *In hypovolemic shock, hemostasis and volume resuscitation are essential, whereas arteriolar constricting agents such as norepinephrine may be used briefly to provide a window of higher BP; in septic shock, considerable volume resuscitation is needed due to nitric oxide–mediated venodilation and decreased Pms, positive inotropic agents such as dobutamine treat the myocardial depression, and arterial vasoconstrictors such as norepinephrine may be needed to maintain BP despite high $\dot{Q}_T$ due to very low SVR.*
- *In cardiogenic shock, preload reduction (morphine, nitroglycerin, furosemide) is effected by venodilation and decreased Pms, but VR often increases because cardiac function improves to decrease Pra; arterial dilating drugs often increase $\dot{Q}_T$ from the injured LV, so BP may even increase despite impaired contractility and $\dot{Q}_T$ without increasing myocardial O_2 consumption when heart rate does not increase.*
- *Early airway control and continuous mechanical ventilation decrease oxygen consumption and prevent respiratory acidosis but may decrease VR further in hypovolemic patients by raising pleural pressure and Pra; in cardiogenic shock, continuous mechanical ventilation and PEEP have less effect on VR and may increase $\dot{Q}_T$ by decreasing LV afterload.*
- *Cardiogenic and low-pressure pulmonary edema are decreased by decreasing Ppw, and $\dot{Q}_T$ and oxygen delivery can be maintained at low Ppw with vasoactive drugs and blood transfusion; arterial oxygenation can be supported with PEEP without decreasing $\dot{Q}_T$ and oxygen delivery by affecting the least PEEP and tidal volumes that achieve 90% O_2 saturation of an adequate hematocrit on a nontoxic fraction of inspired O_2 without profound acidosis.*

This chapter reviews several essential concepts of normal cardiovascular function as a basis for approaching and correcting disturbed circulation in critical illness. It begins with a discussion of left ventricular (LV) pumping function and an approach to ventricular dysfunction. Then follows a review of the mechanisms by which the venous return (VR) to the heart is controlled by the systemic vessels as a basis for diagnosis and treatment of hypoperfusion states. The pulmonary circulation and factors governing lung liquid flux are described through measurements obtained by right heart catheterization to provide an approach to treating pulmonary edema without compromising adequate peripheral perfusion. Along this discussion pathway, common mechanical interactions between respiration and circulation are highlighted as a basis for understanding the cardiovascular diseases discussed in the following chapters in this section and in the next section on pulmonary disorders in critical illness.

A primary role of the cardiovascular system is to deliver energy sources from the gut and liver and oxygen from the lungs to all systemic organ systems for their aerobic metabolism; effluent from these tissues removes the waste products of

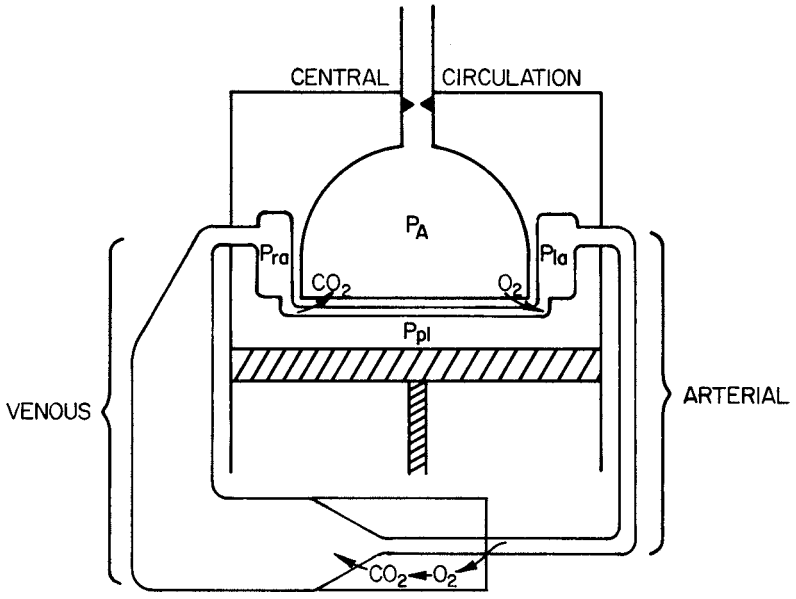

FIGURE 20-1 Schematic showing circulation proceeding from the left atrium (Pla, left atrial pressure) through a high-pressure arterial system (low volume, low compliance, high resistance) to peripheral tissues (where oxygen leaves the vessels to produce energy and CO_2, shown entering the vessels) and through the low-pressure venous system (high volume, high compliance, low resistance), which returns blood to the right atrium (Pra, right atrial pressure). The circuit is completed by perfusing the lung back to the left atrium; the pulmonary vessels are shown in close apposition with the alveoli (P_A, alveolar pressure), facilitating gas exchange. This central circulation is enclosed in the thorax, the floor of which is the diaphragm (indicated by the piston). Between the lungs and the thorax is the pleural space (Ppl, pleural pressure). Ppl approximates the pressure on the outside of all extraalveolar vessels within the central circulation, including the heart, whereas P_A is the pressure outside the alveolar vessels. The anatomic arrangement accounts for the many mechanical interactions between respiration and circulation in critical illness described throughout this chapter.

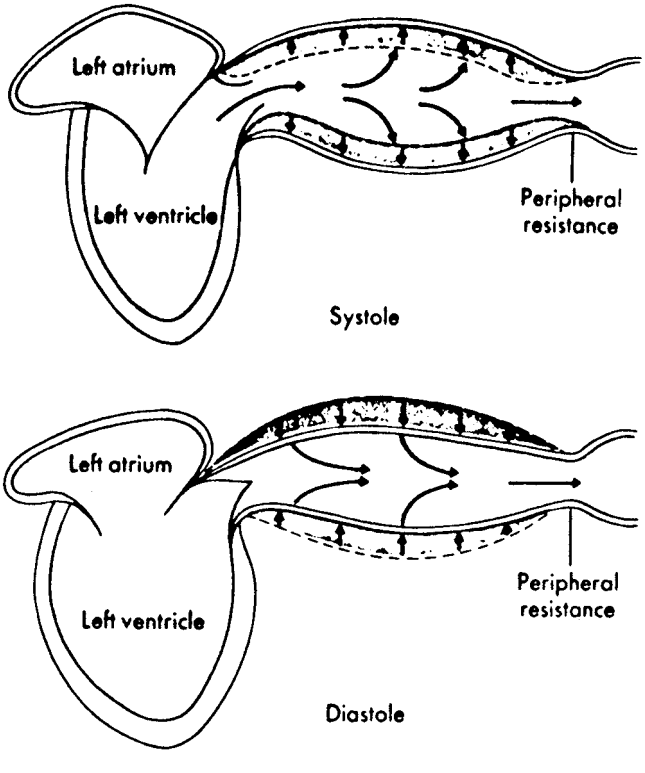

metabolism and delivers them to the lungs, kidney, and liver for excretion. This process is facilitated by return of the entire circulation through the lungs, where CO_2 is eliminated and O_2 is taken up to arterialize the blood. As depicted in Fig. 20-1, this central circulation is located within the thoracic cavity; movement of gas between the atmosphere and the alveolar space is done by the respiratory muscles, especially the diaphragm, depicted as a piston at the floor of the thoracic cavity. Beyond effecting ventilation to permit pulmonary gas exchange, spontaneous movement of the piston decreases the pleural pressure (Ppl), which approximates the pressure on the outside of extraalveolar vessels including the right and left heart (depicted as chambers labeled Pra [right atrial pressure] and Pla [left atrial pressure]); changes in alveolar pressure (P_A) affect pressures within alveolar vessels. Once the blood leaves the lung and enters the left heart, the ventricular pumping function ejects blood into the stiff, high-resistance arterial circulation to perfuse the systemic capillary beds, where O_2 is consumed and CO_2 is taken up before the venous blood returns to the right heart through the large-volume, very compliant, low-resistance venous circuit.[1,2]

Ventricular Dysfunction in Critical Illness

VENTRICULAR–VASCULAR COUPLING

Figure 20-2 illustrates the typical events in the two phases of ventricular activity: active contraction (systole) and relaxation (diastole). In diastole, the left ventricle fills through the open mitral valve from the left atrium while the aortic valve is closed. After electrical stimulation and contraction of the left ventricle in systole, a stroke volume (SV) is ejected into the proximal arterial chamber. Because more blood is being ejected than runs off through the peripheral resistance located in the distal arterioles, the arterial walls are distended outward, thus raising the pressure (P) in inverse proportion to the capacitance ($C = \Delta V / \Delta P$) of the walls of the larger arteries

FIGURE 20-2 During ventricular systole, the stroke volume ejected by the ventricle results in some forward capillary flow, but most of the ejected volume is stored in the elastic arteries. During ventricular diastole, the elastic recoil of the arterial walls maintains capillary flow through the remainder of the cardiac cycle. Accordingly, pulse pressure is proportional to stroke volume, and diastolic pressure increases with peripheral resistance, heart rate, and vascular capacitance, all of which reduce the diastolic runoff of the ejected volume. (*Reproduced with permission from Berne RM, Levy MN (eds): Physiology. St. Louis, Mosby, 1988, p 487.*)

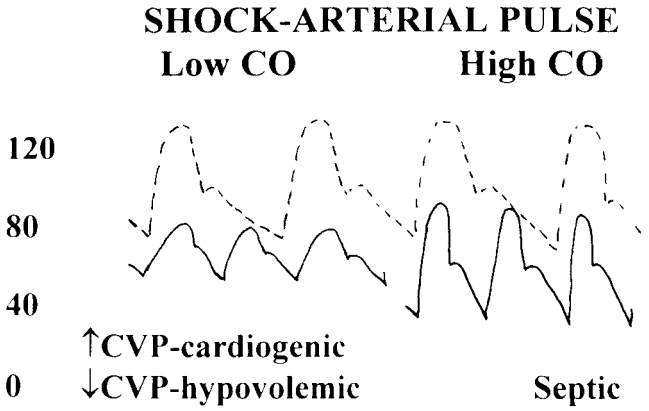

FIGURE 20-3 Schematic illustrations of the normal arterial pressure waveform (interrupted pulse pressure); the continuous pressure waves in low cardiac output ($\dot{Q}_T$) hypotension (*left*) and in high $\dot{Q}_T$ hypotension (*right*) illustrate key differences from the normal pulse. Ordinate, arterial pressure (mm Hg); abscissa, time (seconds). The lower left panel illustrates the difference between cardiogenic shock (increased central venous pressure = 20 mm Hg) and hypovolemic shock (central venous pressure = 0 mm Hg). For discussion, see text.

proximal to the resistance vessels. As the ventricle's volume (V) decreases, its ability to generate pressure decreases, as dictated by the length-dependent activation of actin and myosin cross-bridges in the cardiac myocytes,[3] until ventricular systolic pressure (SP) falls below the simultaneous arterial pressure. Then the aortic valve closes, as indicated by the dicrotic notch on the arterial pressure pulse (Fig. 20-3). As the ventricle relaxes, the mitral valve opens, and the ventricle fills along its diastolic volume-pressure (V-P) curve; this diastolic filling is aided by atrial contraction and by suction by the ventricle relaxing from its low end-contraction volume. During diastole, the part of the SV stored in the distended arterial bed continues to run off through the peripheral resistance, associated with a progressive decrease in arterial pressure until the next contraction.

This ventricular–vascular coupling acts as a hydraulic filter to convert the intermittent ejection of an SV into a continuous organ flow, the cardiac output ($\dot{Q}_T$). It also decreases the work of the heart by allowing some of the energy imparted by the systolic ventricle to the blood to be stored in distention of the arterial chamber and returned to the circulation by continued flow while the ventricle is resting in diastole. The systemic vascular resistance (SVR) is also essential to the control of blood pressure (BP = $\dot{Q}_T \times$ SVR) and to the distribution of blood flow among, or within, organs according to tissue needs. For example, in conditions of hypovolemic or cardiogenic shock, reflex sympathetic output constricts arterioles, especially in the mesenteric, renal, and skin vascular beds, to preserve flow to vital organs such as the heart and brain by maintaining aortic BP; alternatively, during pyrexia and tachypnea, the increased metabolic need demands a high $\dot{Q}_T$ associated with dilation of the coronary and respiratory muscle vessels induced by accumulation of anaerobic metabolites (e.g., adenosine, H^+, and K^+) to maintain adequate O_2 flow to these vital pumps.

Clinical evaluation of the cardiovascular system in patients with critical illness is much aided by interpretation of the diastolic pressure (DP), the pulse pressure (PP), and indices of SVR such as the rate of color return to the nail bed after releasing pressure on the fingernail and digital temperature. For example, a hypotensive patient with a heart rate (HR) of 110 beats/min, an SP/DP of 100/40 mm Hg, and warm extremities with good color return to the nail bed has a high $\dot{Q}_T$ and a low SVR (see Fig. 20-3). This is because the large PP (60 mm Hg) signals a large SV, which, when multiplied by the increased HR, produces increased $\dot{Q}_T$, and the low DP indicates rapid peripheral runoff through low SVR confirmed by digital examination and low mean BP (60 mm Hg) in the face of the high $\dot{Q}_T$. In contrast, a second hypotensive patient with the same HR and mean BP but an SP/DP of 80/65 mm Hg and cold extremities with very slow return of color to the nail bed has a low $\dot{Q}_T$ with increased SVR indicated by the small PP (hence, low SV and $\dot{Q}_T$), preserved DP, and constricted digital vessels. As indicated in the lower left panel of Fig. 20-3, this low $\dot{Q}_T$ hypotension is cardiogenic when the central venous pressure (CVP) is high and hypovolemic when the CVP is low. Of course, the relation between PP and SV is not quantitative, because it is proportioned by an unknown constant—the vascular capacitance. Nevertheless, in a given critically ill patient whose vascular capacitance changes minimally in a course of acute interventions, a change in PP is the earliest indicator of a change in SV.

THE STARLING CURVE OF THE HEART

Figure 20-4 presents Starling relations of the heart.[2,3] On the abscissa is plotted Pla, which approximates the filling pressure of the left ventricle. On the ordinate is plotted SV (in milliliters); this volume ejected per heartbeat is one measure of ventricular output. Another measure of output can be expressed by multiplying stroke volume by the pressure developed during each beat to obtain stroke work (SV $\times$ [BP − Pla]). As filling pressure of the heart increases, the ejected volume and the work done by the heart increase in a curvilinear manner; at higher filling pressures, there is less increase in SV per increase in Pla than at lower values of Pla. On the continuous Starling curve shown in Fig. 20-4B, the normal Pla (10 mm Hg) is associated with a normal SV (75 mL) calculated from $\dot{Q}_T$ (6.0 L/min) divided by HR (80 beats/min). When hypovolemia decreases the Pla to 5 mm Hg, SV decreases to 40 mL, thus decreasing $\dot{Q}_T$; if therapeutic expansion of the circulating volume increases Pla to 20 mm Hg, SV increases to 100 mL, thus increasing $\dot{Q}_T$ above normal. These relations comprise a common framework for understanding ventricular function in critical illness. A shift up and to the left of the Starling curve generally indicates enhanced ventricular function, with greater SV for a given filling pressure (see interrupted curve in Fig. 20-4). Conversely, a shift down and to the right with reduced SV at a given filling pressure (see dotted Starling curve through points *A* and *B*) indicates depressed ventricular function. The lower SV for a Pla of 10 mm Hg at point *A* could be due to reduced contractility, to increased BP allowing the same stroke work to eject a smaller SV at point *A*, or to a stiffer ventricle allowing a smaller LV end-diastolic volume (LVEDV) at a Pla of 10 mm Hg. This variety of mechanisms to explain the same data is a limitation of the analysis of hemodynamics by the Starling curve, so a more complete description of ventricular function is helpful.

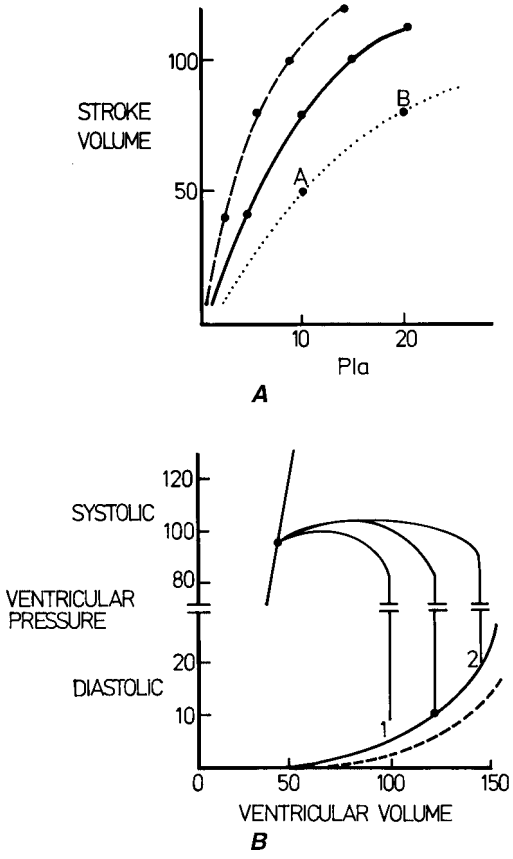

FIGURE 20-4 ***A.*** **Starling function curves. Stroke volume (SV, in milliliters;** ***ordinate*****) is plotted against left atrial pressure (Pla, in mm Hg;** ***abscissa*****). The middle continuous line depicts a normal Starling function curve for comparison with a depressed curve (*dotted line AB*) and with a curve depicting enhanced ventricular function (*interrupted curve*); all three curves may have the same systolic function (contractility) if diastolic volume-pressure (V-P) relations or afterload differs from each other.** ***B.*** **Corresponding left ventricular volume (milliliters;** ***abscissa*****) versus pressure (mm Hg;** ***ordinate*****) relations; the break in the ordinate scale emphasizes the normal diastolic V-P relation (*continuous line 1,2*) and the end-systolic V-P relation (*continuous line up and to the left*). For discussion of the three V-P loops originating from the diastolic curve, see text. The interrupted diastolic V-P curve depicts a more compliant chamber such as the right ventricle, where there is less diastolic pressure for each volume.**

The ventricular function shown by the Starling relation is based on the mechanical properties of the relaxed (diastolic) or contracting (systolic) V-P relations of the ventricle. This section reviews the factors that influence the diastolic and systolic mechanics in health and in critical illness and relates these mechanics to the corresponding Starling function curves of the heart. In Fig. 20-4B, LV end-diastolic pressure (LVEDP) and LV end-systolic pressure (LVESP) are plotted against the corresponding volumes (LVEDV and LV end-systolic volume [LVESV]). The continuous end-diastolic V-P curve is marked with a dot at an LVEDP of 10 mm Hg, where the normal LVEDV is 120 mL. When the ventricle contracts, pressure increases at the same volume until the aortic valve is opened, and blood is ejected until the valve closes at an LVESV of 45 mL. The SV (LVEDV − LVESV) is 75 mL, as plotted on the continuous Starling curve shown in Fig. 20-4A. When hypovolemia decreases the LVEDV (1 in Fig. 20-4B), LVEDP and SV decrease along the Starling curve above; if volume expansion increases the LVEDV to position 2, SV and LVEDP increase along the Starling curve. Intracardiac pressures such as Pla are measured with respect to atmospheric pressure, so they do not represent true transmural, or filling, pressures of the heart chamber when the pressure on the outside of the heart is not atmospheric.[4,5] Pericardial pressure is most often equal to Ppl, which is subatmospheric during spontaneous breathing (−3 to −10 mm Hg) and can become very negative in airflow obstruction or very positive with mechanical ventilation and positive end-expiratory pressure (PEEP). For convenience, the following discussion refers to the intravascular pressures as transmural, or filling, pressures, and any cause for altered pericardial or pleural pressure is noted.

THE DIASTOLIC V-P CURVE AND VENTRICULAR FILLING DISORDERS

Figure 20-4B plots LVEDV against LVEDP. As ventricular volume increases from zero, the transmural pressure of the ventricle does not exceed zero until about 50 mL (the unstressed volume) is added. Then LVEDP increases in a curvilinear manner with ventricular volume (the stressed volume) first as a large change in volume for a small change in pressure and then as a small change in volume for a large change in pressure. If the pericardium is removed, these V-P characteristics are more linear such that the large change in LVEDP at higher values of LVEDV is no longer evident. Thus the pericardium acts like a membrane with a large unstressed volume loosely surrounding the heart up to a given ventricular volume, but at greater LVEDV the pericardium becomes very stiff. At higher heart volumes, most of the pressure across the heart is across the pericardium, accounting for the very steep rise in the diastolic V-P relation. In the presence of pericardial effusion, the volume at which the pericardium becomes a limiting membrane is reduced by the volume of the effusion. When the effusion is large enough, reduced end-diastolic volumes are associated with quite large end-DPs (see Chap. 28). In turn, pericardial pressure decreased VR by increasing Pra, thus keeping end-diastolic volume and $\dot{Q}_T$ abnormally low. Tension pneumothorax, massive pleural effusions, high levels of PEEP, and greatly increased abdominal pressures can increase pressure outside the heart (Ppl) and thus reduce LVEDV and SV despite high values of LVEDP (Table 20-1). Intercurrent LV hypertrophy or infiltrative diseases (amyloidosis) occasionally stiffen the relaxed ventricle such that high filling pressures are needed to maintain an adequate SV, and inadequate filling time or poorly coordinated atrial contraction also impairs ventricular filling.[6]

A right-to-left shift of the interventricular septum also can restrict diastolic filling. Presumably, the distention of the right ventricle causes the interventricular septum to bulge from right to left, thereby reducing the unstressed volume and compliance of the left ventricle.[2,7] This effect of ventricular interdependence is much less marked when the pericardium is removed, perhaps because the limiting membrane of the pericardium restricts freedom of motion of the left ventricle, making it more vulnerable to displacements of the septum. Accordingly, conditions in which the right ventricle is abnormally loaded (e.g., acute pulmonary embolism or acute-on-chronic respiratory failure due to obstructive or restrictive

TABLE 20-1 Common Causes of Diastolic Dysfunction in Critically Ill Patients Signaled by High Left Atrial Pressure and Low Ventricular End-Diastolic Volume

External compression
Pericardial effusion or construction
Positive pressure ventilation with PEEP, auto-PEEP
Tension pneumothorax, massive pleural effusions
Greatly increased abdominal pressure
Myocardial stiffness
LV hypertrophy—aortic stenosis, systemic hypertension
Infiltrative diseases—amyloidosis
Ischemic heart disease
Ventricular interdependence and right-to-left septal shift
Pulmonary hypertension
RV infarction
High levels of PEEP
Intraventricular filling defects
Tumor
Clot
Rhythm or valvular impediments to filling
Tachycardia
Heart block
Artial fibrillation, flutter
Mitral stenosis

ABBREVIATIONS: V, left ventricular; PEEP, positive end-expiratory pressure; RV, right ventricular.

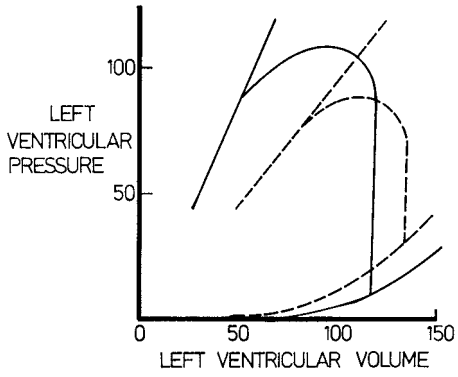

FIGURE 20-5 Schematic representation of left ventricular end-diastolic volume (LDEDV) and pressure (LVEDP) amd end-systolic (ES) volume and pressure relations before (*continuous curves*) and after (*interrupted curves*) acute myocardial infarction. The myocardial injury depresses the contractility to increase ES volume despite the decrease in pressure afterload; accordingly, LVEDV increases to accommodate venous return, whereas LVEDP increases even more due to the diastolic dysfunction of the myocardial injury. Accordingly, LV dysfunction is signaled by reduced stroke volume and cardiac output despite a large elevation in LVEDP; therapy aims to reduce preload, enhance contractility, and reduce afterload. For further discussion, see text.

lung disease) may impede the emptying of the right ventricle, causing it to work at a higher end-diastolic volume. Then LV filling pressures will be higher than expected for the end-diastolic volume. This provides one possible explanation for why PEEP is often associated with increased filling pressure to maintain a normal SV even when LVEDP is corrected to the true filling pressure by subtracting the increase in Ppl (ΔPpl) measured when PEEP is applied.[4,5,8,9] Acute myocardial ischemia also displaces the diastolic V-P curve of the left ventricle up and to the left (Fig. 20-5). Conceivably, myocardial injury alters the elastic properties of the relaxed ventricle.[6] Therefore, a higher ventricular filling pressure is required at each end-diastolic volume. This accounts in part for the often noted observation that patients with acute myocardial injury need values of LVEDP as high as 30 mm Hg to maintain adequate $\dot{Q}_T$, whereas normal patients need filling pressures below 10 mm Hg.

THE END-SYSTOLIC V-P CURVE AND CONTRACTILITY

The normal diastolic V-P relation is demonstrated by the continuous line in the lower right-hand portion of Fig. 20-5. Consider the effects when the ventricle contracts during systole without ejecting any blood, as if the aortic valve could not open. A very large pressure is generated during this isovolumic contraction from a normal LVEDV, but when the LVEDV is reduced, the pressure generated during a similar isovolumic contraction is much less, as a manifestation of the force–length characteristics of the myocardium.[2,3,10,11] That is, the less the muscle is stretched, the less force it can generate, a manifestation of the length-dependent activation of actin–myosin cross-bridges. The units of force in the hollow sphere of myocardium are the units of pressure, or force per unit area. A line connecting the end-systolic V-P points is linear and extrapolates toward the origin (see the continuous end-systolic V-P line in Fig. 20-5, upper left).

Of course, the aortic valve does open in early systole when the isovolumic pressure exceeds the aortic DP; then LV volume decreases as the SV is ejected (see Fig. 20-5). The contracting ventricle shortens against the aortic afterload pressure until its volume reaches the end-systolic volume; at that lower volume, the maximum pressure that can be generated is equal to the afterload pressure, so the aortic valve closes and ejection is over. If the afterload pressure were decreased, the ventricle could eject further to a lower end-systolic volume, where the maximum generated pressure equals the reduced afterload; hence, SV would increase.

The line connecting all end-systolic V-P points is an indicator of the pumping function or contractility of the heart because this line defines the volume to which the ventricle can shorten against each afterload for a given contractile state.[10–13] Agents that enhance contractility (e.g., epinephrine, calcium, dobutamine, and dopamine) shift the end-systolic V-P relation up and to the left; then the ventricle can shorten to a smaller end-systolic volume for each afterload, thereby increasing SV at a given LVEDV/LVEDP.[10,11] Conversely, negative inotropic agents such as propranolol, myocardial ischemia, hypoxia, and acidemia depress the end-systolic V-P relation down and to the right, as indicated by the interrupted end-systolic V-P line shown in Fig. 20-5.[12,13] Then end-systolic volume is increased for a given pressure afterload, thereby reducing the SV at a given filling pressure. Such a reduction in contractility is a common cause for the depressed Starling curve *AB* shown in in Fig. 20-4.

AN APPROACH TO ACUTE VENTRICULAR DYSFUNCTION

These concepts provide a framework for understanding the pathophysiology and therapy of acute myocardial infarction

(see Chap. 25). Figure 20-5 depicts normal diastolic and systolic V-P relations and indicates a normal systolic ejection (continuous lines). From an LVEDV of 120 mL and an LVEDP of 10 mm Hg, the ventricle contracts isovolumically until the aortic valve opens at a DP of 80 mm Hg. Blood is then ejected as SP increases to 110 mm Hg and decreased toward an LVESP of 90 mm Hg and an LVESV of 50 mL, when the aortic valve closes to generate the dicrotic notch on the arterial pressure trace. Accordingly, SV is 70 mL at a Pla of 10 mm Hg and $\dot{Q}_T$ is 5.6 L/min when HR is 80 beats/min. Acute myocardial infarction depresses the end-systolic V-P relation so that the end-systolic volume is increased to 90 mL at a reduced LVESP of 75 mm Hg (interrupted lines). At the same time, the end-diastolic volume is increased to 130 mL to accommodate the VR, and end-DP is increased even more than expected (LVEDP = 30 mm Hg) due to the shift up and to the left of the end-diastolic V-P relation (interrupted line). Thus SV (40 mL) and $\dot{Q}_T$ (4.4 L/min) are reduced despite reflex tachycardia (HR = 110 beats/min) at an increased LV filling pressure, and BP is decreased (SP/DP = 90/70 mm Hg) despite the reflex increase in SVR.

Conventional therapy consists of preload reduction, inotropic agents, and afterload reduction, in addition to measures to reestablish and maintain coronary blood flow (see Chap. 25). Interventions such as morphine, furosemide, nitrates, and rotating tourniquets decrease VR by dilating venous capacitance beds to increase the unstressed volume and decrease mean systemic pressure (Pms; see below). These actions in turn decrease LVEDV and LVEDP. The reduction in end-diastolic volume tends to decrease LVEDP along the steep diastolic V-P curve so that there is a large reduction in LVEDP for a small reduction in LVEDV and SV. Further, the potential adverse effect of reduced SV is often offset by increased contractility and reduced afterload when myocardial wall stress is decreased by the reduction in LVEDV and LVEDP (see Chaps. 22 and 25). Reduced afterload and reduced myocardial O_2 consumption improve ventricular pumping function by shifting the end-systolic V-P relation up and to the left, so LVESV decreases and SV increases. Further, the decreased end-DP reduces the complication of cardiogenic pulmonary edema.

Positive inotropic agents such as dopamine and dobutamine act directly on the myocardium to reduce end-systolic volume at a given end-SP, thereby increasing SV (see Chaps. 22 and 25). Dopamine also causes venoconstriction by increasing Pms and VR, so the increase in SV is often associated with increased LVEDV, whereas dobutamine tends to increase SV and decrease LVEDV.[14] Afterload-reducing agents such as nitroprusside dilate peripheral arteries to decrease end-SP and afterload; in turn, end-systolic volume decreases along the depressed end-systolic V-P relation to increase SV.[14] Nitroprusside and other arteriolar vasodilating agents also decrease end-DP without changing end-diastolic volume; this effect appears to enhance ventricular function viewed on the Starling relation, as discussed above.[15] The decrease in LVEDP decreases pulmonary edema and may decrease myocardial oxygen demands by decreasing ventricular wall stress. To the extent that it decreases ventricular wall stress, end-systolic V-P relations may shift to the left due to enhanced contractility. In some patients with cardiogenic shock, vasodilator therapy appears to increase SV and $\dot{Q}_T$ without decreasing or even increasing arterial BP, that is, arterial dilation appears to reduce end-systolic volume at a given end-SP as if contractility were enhanced.[14,15]

Noninvasive mechanical ventilation (or continuous positive airway pressure, CPAP) lowers both preload and afterload, in addition to beneficial effects on gas exchange and work of breathing.[16] $\dot{Q}_T$ is not reduced despite decreased transmural pressures, indicating improved pump function.

Other concomitant effects of critical illness cause ventricular dysfunction characterized by reduced SV at increased Pla (see Table 20-1). Arterial hypoxemia[12] and acidemia[13] depress the end-systolic V-P curve and increase diastolic stiffness, as shown by the interrupted curve in Fig. 20-5. Acute arterial hypertension raises the pressure afterload, so SV decreases as end-systolic volume increases along the continuous end-systolic V-P curve in Fig. 20-5. Then LVEDV increases to accommodate VR, so LVEDP increases, often more than expected, due to diastolic stiffness, in turn due to LV hypertrophy in the hypertensive patient. Accordingly, pulmonary edema is a common complication, and it responds to vasodilator therapy when BP is decreased. In some or all of these conditions, diastolic dysfunction merits special management.[6] When acute or acute-on-chronic congestive heart failure is present, decreasing LVEDP and LVEDV, maintaining atrial contraction, increasing the duration of diastole, and minimizing myocardial ischemia are helpful. Each of these therapeutic measures is also helpful in managing hypoperfusion states associated with diastolic dysfunction.[6]

Valvular dysfunction mimics systolic and diastolic dysfunctions such that LVEDV is much increased and the forward SV is reduced (see Chap. 29). With aortic regurgitation, after a vigorous systolic ejection, aortic blood runs off forward and backward in diastole such that LVEDP increases and arterial DP decreases toward equal values at 40 mm Hg. The large LVEDV then ejects a large SV to increase SP to 120 mm Hg, causing a bounding PP of 80 mm Hg, but the aortic regurgitation reduces forward SV and $\dot{Q}_T$ to a low value. Consider also mitral valve incompetence. During systole, a large fraction of the blood ejected from the ventricle regurgitates to the left atrium, thereby reducing forward SV and $\dot{Q}_T$ but increasing LVEDV and LVEDP when the left atrium fills the ventricle in diastole. In this circumstance, PP and BP are decreased. In both cases, the ventricular mechanics resemble the interrupted curves shown in Fig. 20-5 and improve toward the normal continuous curves when forward flow is increased by vasodilator therapy that lowers SVR to allow more peripheral runoff and less regurgitant flow (see Chap. 29).

Control of Cardiac Output by the Systemic Vessels

Ventricular pumping function generates the flow in the circulation but retains control of the VR, so $\dot{Q}_T$ resides in the systemic vessels.[1,2] The heart is best regarded as a mechanical pump having diastolic and systolic properties that determine how it accommodates the VR. This section reviews the mechanical characteristics of the systemic vessels as a basis for understanding control of $\dot{Q}_T$ in health and in critical illness.

MEAN SYSTEMIC PRESSURE

When the heart stops beating (see Fig. 20-1), pressure equalizes throughout the vascular system, and its new value is the Pms (10 to 15 mm Hg). This pressure is much lower than the arterial pressure and is closer to the Pra. When flow stops, blood drains from the high-pressure, low-volume arterial system into the high-volume, low-pressure venous system, which accommodates the displaced volume with little change in pressure. When the heart begins to beat again, the left heart pumps blood from the central circulation into the systemic circuit, thus increasing pressure there. At the same time, the right heart pumps blood into the lungs, thereby decreasing its pressure (Pra) with respect to Pms, so blood flows from the venous reservoir into the right atrium. Pressure on the venous side decreases slightly below Pms, whereas pressure on the arterial side increases considerably above Pms with succeeding heartbeats. This continues until a steady state is reached, when arterial pressure has increased enough to drive the whole SV of each succeeding heartbeat through the high arterial resistance into the venous reservoir. The Pms does not change between the state of no flow and the new state of steady flow because neither the vascular volume nor the compliance of the vessels has changed. What has changed is the distribution of the vascular volume from the compliant veins to the stiff arteries; this volume shift creates the pressure difference driving flow through the circuit.[1,2,17,18]

Pms is the driving pressure for VR to the right atrium when circulation resumes. It can be increased to increase VR by increasing the vascular volume or by decreasing the unstressed volume and compliance of the vessels.[17,18] The latter two mechanisms are mediated by baroreceptor reflexes responding to hypotension by increasing venous tone and usually occur together. The unstressed volume also may be reduced by raising the legs of a supine patient or applying military antishock trousers; both methods return a portion of the unstressed vascular volume from the large veins in the legs to the stressed volume, thereby increasing Pms and VR. When the heart has an improvement in inotropic state or a reduction in afterload, blood is shifted from the central compartment to the stressed volume of the systemic circuit, thereby increasing Pms and VR;[18] moreover, improved ventricular pumping function decreases Pra to increase VR further (see below).

VENOUS RETURN AND CARDIAC FUNCTION CURVES

Before the heart was started in the discussion above, Pra was equal to the pressure throughout the vascular system, Pms. With each succeeding heartbeat, Pra decreases below Pms and VR increases. This sequence is repeated in a more controlled, steady state by replacing the heart with a pump set to keep Pra at a given value while VR is measured.[17,18] Typical data are plotted in Fig. 20-6. As Pra is decreased from 12 to 0 mm Hg (indicated by the thin continuous line), VR is progressively increased with the driving pressure (Pms − Pra). The slope of the relation between VR and Pms − Pra is the resistance to VR (RVR = Δ[Pms − Pra]/ΔVR). When Pra falls below zero, VR does not increase further because flow becomes limited while entering the thorax. This occurs when the pressure in

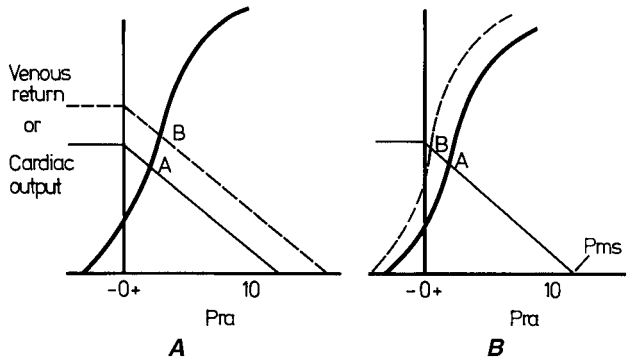

FIGURE 20-6 Control of cardiac output by systemic vessels. Venous return (VR) or cardiac output ($\dot{Q}_T$) is plotted on the ordinate against right atrial pressure (Pra) on the abscissa. *A*, *B*. The thin continuous VR curve shows that VR increases as Pra decreases below Pra equal to mean systemic pressure (Pms; where VR = 0), so the inverse of the slope of this VR curve ([Pms − Pra]/VR) is the resistance to VR (RVR). The thick continuous cardiac function curve shows that $\dot{Q}_T$ increases as Pra increases because ventricular end-diastolic volume increases. The intersection (shown in *A*) marks the unique value of Pra where VR equals $\dot{Q}_T$ in *A* and *B*. When this value of $\dot{Q}_T$ is insufficient, VR can be increased by increasing Pms without changing RVR, indicated by the interrupted VR curve intersecting the unchanged cardiac function curve at a higher $\dot{Q}_T$ and Pra (shown in *B*, *left panel*). In the *right panel*, VR is increased from point *A* to point *B* by increased cardiac function (see interrupted cardiac function curve intersecting the original VR curve at point *B*). Accordingly, inotropic agents that increase contractility (dobutamine) can produce modest increases in VR by lowering Pra, but further increases in VR are limited by compression of the great veins at lower values of Pra (*right panel*); such an enhanced cardiac function displaces central blood volume into the peripheral circulation, tending to increase Pms and thus promote further increases in VR (*left panel*). Often, other inotropic agents (dopamine, epinephrine) also raise Pms and VR by venoconstriction.

these collapsible great veins decreases below the atmospheric pressure outside the veins. Further decreases in Pra and CVP are associated with progressive collapse of the veins rather than with an increase in VR.

For a given stressed vascular volume and compliance, Pms is set and RVR is relatively constant. In the absence of pulmonary hypertension or right heart dysfunction, LV function will determine Pra and, hence, VR to the right heart, which must equal the $\dot{Q}_T$ from the left heart. $\dot{Q}_T$ is described by the cardiac function curve, drawn as a thick continuous line relating Pra (abscissa) to $\dot{Q}_T$ (ordinate), in Fig. 20-6. The heart is able to eject a larger SV and $\dot{Q}_T$ when the end-DP is greater because more distended ventricles eject to about the same end-systolic volume as less distended ventricles do. Accordingly, as Pra decreases, $\dot{Q}_T$ decreases along the cardiac function curve. However, VR increases as Pra decreases until VR equals $\dot{Q}_T$ at a unique value of Pra, indicated by the intersection of the cardiac function and VR curves in Fig. 20-6 (see point *A* in both panels).

When $\dot{Q}_T$ is insufficient, VR can be increased in several ways. A new steady state of increased VR is achieved by increasing Pms with no change in RVR, indicated by the interrupted VR curve in the left panel of Fig. 20-6. This new VR

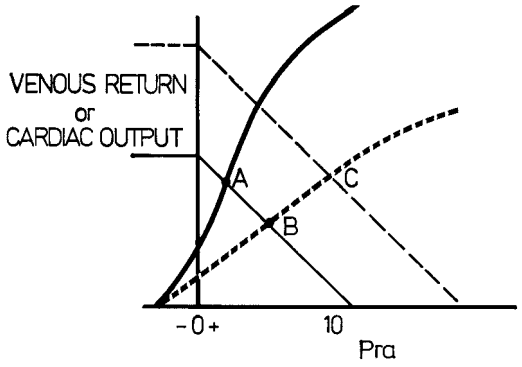

FIGURE 20-7 Reduced cardiac function (*interrupted curve BC*) decreases steady-state venous return from *A* to *B* because right atrial pressure (Pra) increases along the normal venous return curve (*continuous line AB*). In response, baroreceptor reflexes and/or vascular volume retention increase mean systemic pressure such that the new interrupted venous return curve intersects the depressed cardiac function curve at *C*, whereby caridac output has returned to normal at increased Pra. The new steady state can be produced by systolic or diastolic dysfunction of the left or right ventricle. For further discussion, see text.

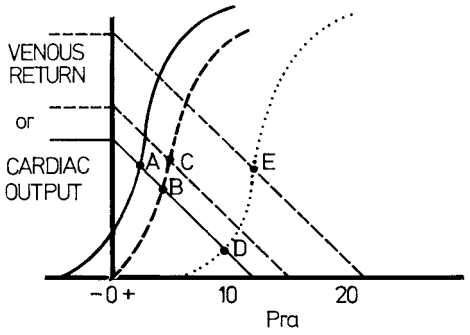

FIGURE 20-8 Schematic showing effects of increased pleural pressure (Ppl) on venous return (VR) and cardiac output ($\dot{Q}_T$). Compared with the normal steady state (*continuous VR and cardiac function curves*), increasing Ppl and right atrial pressure (Pra) by 4 mm Hg shifts the normal cardiac function curves to the right (*interrupted cardiac function curve BC*) so that venous return decreases from *A* to *B*. This accounts for the decrease in $\dot{Q}_T$ when thoracotomy exposes the right atrium to atmospheric pressure; similarly, the increase in Ppl and Pra when positive end-expiratory pressure (PEEP) is applied to a patient with an intact thorax decreases $\dot{Q}_T$. In both cases, baroreceptor reflexes or iatrogenic expansion of vascular volume increase Pms to allow the new interrupted VR curve to intersect the displaced cardiac function curve at *C*, thereby returning $\dot{Q}_T$ to normal. A much larger increase in PEEP increases Ppl and Pra even more so that the displaced normal cardiac function curve (*dotted curve DE*) intersects the normal VR curves at a very low value (*E*) required by a larger increase in mean systemic pressure to allow the new interrupted VR curve to intersect the dotted function curve at *E*. For further discussion, see text.

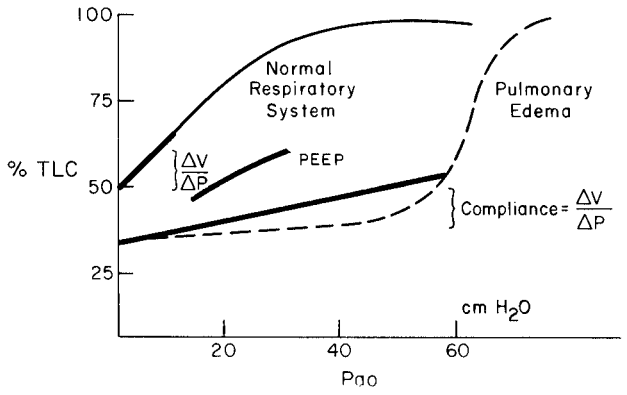

curve intersects the same cardiac function curve at a higher value of $\dot{Q}_T$ at point *B*. This method of increasing VR is associated with an increase in Pra. Due to the steep slope of the cardiac function curve in normal hearts, large increases in VR occur with only small increases in Pra. Alternatively, VR can be increased by enhanced cardiac function by increasing contractility or decreasing afterload of the heart. This is depicted as an upward shift of the cardiac function curve, as in the right panel of Fig. 20-6, such that greater $\dot{Q}_T$ occurs at each Pra. The increase on each VR curve by this mechanism is associated with a reduction in Pra. Further, in the normal heart, only a small change in VR is possible (from point *A* to point *B* in the right panel), and greater reductions in Pra do not increase $\dot{Q}_T$ further because VR becomes flow limited as Pra decreases to below zero. This explains why inotropic agents that enhance contractility are ineffective in hypovolemic shock.

When cardiac pumping function is depressed, as depicted by the interrupted line in Fig. 20-7, VR is decreased from point *A* to point *B* for the same value of Pms as Pra increases. The patient must then retain fluid or initiate cardiac reflexes to increase Pms toward the new value required to maintain adequate $\dot{Q}_T$, as in chronic congestive heart failure. This is associated with a large increase in Pra from point *B* to point *C*, which in turn causes jugular venous distention, hepatomegaly, and peripheral edema. Diuretic reduction of vascular volumes will correct these cosmetic abnormalities at the expense of decreasing Pms and VR. In contrast, inotropic and vasodilator drugs, which improve depressed cardiac function by shifting the interrupted cardiac function curve upward, increase $\dot{Q}_T$ and decrease Pra more effectively than in patients with normal cardiac function.

EFFECTS OF PRESSURE OUTSIDE THE HEART ON CARDIAC OUTPUT

In the figures cited and the preceding discussions, values of Pms and Pra were expressed relative to atmospheric pressure. However, the transmural pressure of the right atrium exceeds the Pra by the subatmospheric value (about −4 mm Hg) of the Ppl surrounding the heart. Consider the effect of opening the thorax, which raises Ppl from −4 to 0 mm Hg: VR decreases from point *A* to point *B* in Fig. 20-8 because Pra increases.[19] This is indicated by the interrupted cardiac function curve shifted to the right by the increase in pressure outside the heart but parallel to the normal cardiac function curve (continuous line through point *A*). Normal VR can be restored (point *B* to point *C*) by increasing Pms by an amount equal to the increase in Ppl and Pra induced by thoracotomy. Then transmural Pra will be the same as at point *A*, and Pra will have increased from point *A* to point *C* at the same $\dot{Q}_T$.

This mechanism for the decrease in $\dot{Q}_T$ with thoracotomy also partly explains the decrease in $\dot{Q}_T$ with PEEP. The Ppl within an intact thorax increases with passive positive-pressure ventilation, thereby increasing Pra and decreasing VR.[4,5,8,9,20] When 8 mm Hg of PEEP (10 cm H_2O) is added to the ventilator, the end-expiratory value of Ppl increases by about half that amount, e.g., from −4 to 0 mm Hg. Accordingly, VR decreases with PEEP from point *A* to point *B* in Fig. 20-8, with no change in cardiac function or Pms. $\dot{Q}_T$ is returned to normal by volume infusion or vascular reflexes that increase Pms by an amount equal to the increases in Ppl and Pra. Greater PEEP (20 cm H_2O, as in the dotted line shown in Fig. 20-8) decreases VR further (from point *A* to point *D*) and requires greater increases in Pms to return it to normal (from point *D* to point *E*). Alternatively, Pms increases as much as Pra when PEEP is added, so the decrease in VR must be due to an increase in RVR with PEEP.[20] In either event, VR can be restored on PEEP by increasing Pms.

	Before edema	After edema
ΔV(litres) with PEEP (20 cm H_2O)	1.42±0.38	1.39±0.22
ΔPpl (cm H_2O) with PEEP	10.1±2.2	9.7±0.7
Lung Compliance (ml/cm H_2O)	102±28	47±17

FIGURE 20-9 Relations between lung volume (percent total lung capacity, TLC; *ordinate*) and pressure across the respiratory system (pressure airway opening [cm H_2O], Pao; *abscissa*). The thin continuous line represents the inflation volume-pressure (V-P) relation of the normal respiratory system, showing an end-expired lung volume (Pao = 0) of 50% TLC and inflation compliance (V-P) during a tidal volume of about 10% TLC (*thick part of line*). In contrast, the interrupted line shows the inflation V-P curve after pulmonary edema floods many lung units, thereby decreasing end-expired lung volume to about 30% TLC; then a tidal inflation of the same volume causes a much larger increase in Pao because there are many fewer airspaces to accommodate the tidal volume. Adding 15 cm H_2O positive end-expiratory pressure (PEEP) might be expected to produce a much smaller increase in end-expired lung volume in edematous lungs than in a normal respiratory system; however, when PEEP is effective in reducing shunted fraction of total pulmonary blood flow by redistributing alveolar edema, the increase in end-expired lung volume (and, hence, pleural pressure) is as large after pulmonary edema as in the normal respiratory system (*table at right of graph*). (*Reproduced with permission from Prewitt and Wood[4] and Hall and Wood.[24]*)

$\dot{Q}_T$ is much less susceptible to the deleterious effects of PEEP when Pms is high. In patients with reduced circulatory volume, vascular reflexes are already operating to maintain VR and Pms by reducing unstressed volume or vascular compliance. Such patients have little vascular reflex reserve and poorly tolerate intubation and positive-pressure ventilation without considerable intravenous infusion to increase vascular stressed volume. In contrast, well-hydrated or overhydrated patients may tolerate even large amounts of PEEP with no reduction in $\dot{Q}_T$ because their previously inactive vascular reflexes can increase Pms in well-filled systemic vessels by the amount that Ppl increases with PEEP. These considerations allow the physician to anticipate and treat the hypotension induced by ventilator therapy; the concept should not be interpreted as an indication for maintaining high circulatory volume in critically ill patients on ventilators because this often increases lung edema and provides even more $\dot{Q}_T$ than was already deemed sufficient. Further, pressure outside the heart can be increased by a variety of other concomitant conditions and complications of critical illness; all these actions increase pressures measured in the heart chambers and decrease heart volume and, as a consequence, are often interpreted as diastolic dysfunction (see Table 20-1).

How much is the pressure outside the heart increased by PEEP, and is there a practical approach to relating the transmural wedge pressure to SV and $\dot{Q}_T$? When PEEP increases end-expired lung volume, the inflated lungs push the thorax to an increased volume through greater pleural pressure, and this change in Ppl (ΔPpl) with PEEP is approximately equal to the change in pressure outside the right and left ventricles.[8] During mechanical ventilation, the ratio of ΔPpl to the change in static elastic pressure across the lung and chest wall (ΔPel) for each breath is given by the ratio of respiratory system compliance (Crs) to the compliance of the chest wall (Cw); that is, $\Delta Ppl/\Delta Pel = Crs/Cw$ (assuming no alveolar recruitment). When lung compliance (C_L) is normal, $C_L = Cw$, so $\Delta Ppl/\Delta Pel = 0.5$. When the lungs lose compliance in acute hypoxemic respiratory failure (AHRF), ΔPel increases because Crs decreases, but ΔPpl changes little (at constant tidal volume) because Cw is unaffected by the lung disease, and ΔPpl becomes much less than half of ΔPel. To the extent that the increase in lung volume (ΔV_L) with PEEP is determined by Crs, $\Delta Ppl/PEEP = Crs/Cw$, and a decrease in Crs with AHRF would decrease Ppl for a given amount of PEEP well below the normal value of 0.5. However, ΔV_L with PEEP is much greater than that predicted by Crs in AHRF because PEEP recruits many previously flooded airspaces,[21,22] so ΔPpl/PEEP is as great after acute lung injury as before[4] (Fig. 20-9). Accordingly, the ΔPpl with PEEP is difficult to measure and hard to predict, so many approaches have been tested to estimate the transmural pressure of heart chambers on PEEP.[23] Because PEEP is used most often to decrease shunt in pulmonary edema and because accurate knowledge of transmural Pla shows that the value associated with an adequate $\dot{Q}_T$ can differ between patients by 20 mm Hg according to the extent of LV dysfunction, a better approach is to seek the lowest pulmonary wedge pressure (Ppw) that provides adequate output on each level of PEEP. In this way, therapy to decrease Ppw and edema and maintain $\dot{Q}_T$ is not confounded by erroneous estimates of transmural Ppw on PEEP.[24,25]

AN APPROACH TO HYPOPERFUSION STATES

A hypoperfusion state, or shock, is almost always signaled by systemic hypotension; commonly associated clinical features of multiple organ system hypoperfusion are tachycardia, tachypnea, prerenal oliguria (urine flow < 20 mL/h, urine $Na^+ > 20$ mEq/L, urine $K^+ > 20$ mEq/L, urine-specific

gravity > 1.020), abnormalities of mentation and consciousness, and metabolic acidosis. The mean BP is determined by the product of $\dot{Q}_T$ and SVR. A conceptual framework for the initial diagnosis and management of the hypotensive patient is outlined in Table 20-2. Utilization of this approach aims to categorize the patient's symptoms into one of the three common causes of shock (septic, cardiogenic, or hypovolemic) and to initiate early appropriate therapy of the presumed diagnosis (see Chap. 21). Response to the therapeutic intervention tests the accuracy of the initial diagnosis, so the hemodynamic response is reevaluated within 30 minutes. The diagnostic decision is aided by collating clinical data from the medical history, physical examination, and routine laboratory tests to answer three questions in sequence.

SEPTIC SHOCK

Is BP decreased because $\dot{Q}_T$ is decreased? If not, SVR must be reduced, a condition almost always related to sepsis or sterile endotoxemia associated with severe liver disease. As indicated in Table 20-2 (right column), a low BP is often characterized by a large PP because the SV is large and by a very low DP because each SV has a rapid peripheral runoff through dilated peripheral arterioles (see Fig. 20-3). This produces warm, pink skin with rapid return of color to the nail bed and crisp heart sounds. As in other types of shock, tachycardia is evident due in part to baroreceptor reflex response to hypotension, but the arterial vasoconstriction response to reflex sympathetic tone is blocked by relaxation of arteriolar smooth muscle induced by endothelium-derived relaxing factor (or nitric oxide). The combination of tachycardia and large PP indicates a large $\dot{Q}_T$ that is almost always present early unless concurrent hypovolemia or myocardial dysfunction precludes the hyperdynamic circulatory state of sepsis.

Initial therapy starts with appropriate broad-spectrum antibiotics (see Chap. 46) and expands the circulating volume by intravenous infusion of fluids to treat associated hypovolemia, which is due to venodilation decreasing Pms and VR lower than needed to maintain adequate perfusion pressure of vital organs. The end point of volume infusion is obscure because $\dot{Q}_T$ and oxygen delivery (D_{O_2}) are already increased, and although $\dot{Q}_T$ usually increases further with intravenous infusions, BP increases little with increased $\dot{Q}_T$. Further, the need for an even greater $\dot{Q}_T$ to increase D_{O_2} is questionable because the lactic acidosis of septic shock may not be due to anaerobic metabolism.[26–28] Accordingly, septic patients in whom $\dot{Q}_T$ is maximized do not have improved survival.[29,30] Conversely, pulmonary vascular pressures always increase with volume infusion, thus increasing pulmonary edema when the septic process increases the permeability of lung vessels.[25,31–33] This coincidence of the acute respiratory

TABLE 20-2 Initial Approach to the Diagnosis and Management of the Hypotensive Patient

Blood pressure (BP) = Cardiac output ($\dot{Q}_T$) × systematic vascular resistance (SVR)

	IS $\dot{Q}_T$ REDUCED?	
	Yes	No
BP	90/70 mm Hg	90/40 mm Hg
Skin	Cool, blue	Warm, pink
Nail bed return	Slow	Rapid
Heart sounds	Muffled	Crisp

	Cardiac tamponade Acute pulmonary hypertension Right ventricular infarction	Anaphylaxis Spinal shock Adrenal insufficiency
	Overlapping multiple etiologies	

ABBREVIATIONS: BUN, serum urea nitrogen; ECG, electrocardiogram; JVP, jugular venous pressure; WBC, white blood cell count.

distress syndrome (ARDS) and septic shock has created an apparent dilemma concerning fluid therapy and cardiovascular management of these conditions. My approach is to ensure resuscitation from septic shock as the first priority by ensuring a large $\dot{Q}_T$ with a Ppw that does not exceed 15 mmHg and add dobutamine to increase $\dot{Q}_T$ and BP as necessary.[25] When early ARDS is not associated with septic shock, I seek the lowest circulating volume to provide adequate $\dot{Q}_T$.[25]

The septic myocardium does not function normally,[34,35] but this dysfunction is often associated with SV values larger than 100 mL at normal values of LVEDP. Accordingly, it seems unlikely that systolic dysfunction contributes substantially to the shock, but infusion of dobutamine does increase $\dot{Q}_T$ for a given high-normal LVEDP without increasing O_2 uptake or correcting lactic acidosis in septic shock.[36] Even when $\dot{Q}_T$ and D_{O_2} are made adequate with fluid and dobutamine infusions, the perfusion pressure for vital organs such as the brain and heart may still be too low in some septic patients. In this case, norepinephrine infusion increases BP and splanchnic blood flow[37,38] without compromising renal function;[39] in contrast, dopamine and epinephrine infusions cause splanchnic hypoperfusion in septic shock.[37,38,40] Tachypnea and respiratory distress may be severe, so initial supportive therapy includes consideration of early intubation and mechanical ventilation and correction of hyperthermia with antipyretics, paralysis, and cooling (see Table 21-4). This prevents catastrophic respiratory muscle fatigue, respiratory acidosis, and the complications of emergent intubation and may improve tissue oxygenation by reducing O_2 requirements in patients with limited D_{O_2}.[41,42]

CARDIOGENIC SHOCK

In contrast to septic shock, low $\dot{Q}_T$ is signaled by low PP indicating low SV (see Fig. 20-3), signs of increased systemic vascular resistance (e.g., cold, blue, damp extremities and poor return of color to the nail bed), and a history or presentation including features suggesting a cardiogenic or hypovolemic cause of hypotension. If $\dot{Q}_T$ is reduced in the hypotensive patient, then the heart may be too full.

A heart that is too full (see Table 20-2) is often signaled by symptoms of ischemic heart disease or arrhythmia, signs of cardiomegaly, the third and fourth sounds or gallop rhythm of heart failure, new murmurs of valvular dysfunction, increased jugular or CVP, and laboratory tests suggesting ischemia (e.g., electrocardiogram [ECG] or creatine phosphokinase determination) or ventricular dysfunction (e.g., chest x-ray suggesting cardiomegaly, a widened vascular pedicle, or cardiogenic edema or echocardiogram showing regional or global systolic dyskinesia). The most common cause of hypotension associated with a circulation that is too full on initial evaluation is cardiogenic shock due to myocardial ischemia (see Chaps. 22 and 25). Initial therapy treats this presumptive diagnosis with inotropic drug therapy (dobutamine 3 to 10 μg/kg per minute) to assist the ejecting function of the ischemic heart. Such therapy does not directly address the coronary insufficiency and may increase the myocardial O_2 demand, especially if it causes tachycardia. Concurrent sublingual, dermal, or intravenous nitroglycerin ameliorates elements of coronary vasospasm to increase blood flow and reduces preload to decrease myocardial O_2 consumption. Morphine also decreases pain, anxiety, and preload.[43]

In this situation, even a cautious volume challenge (250 mL 0.9% NaCl over 20 minutes) may be risky because ventricular function and $\dot{Q}_T$ are decreased as often as they are increased by this intervention, and the risk of pulmonary edema is increased. When signs of pulmonary edema are present on clinical and radiologic examinations of the thorax, diuretics, morphine, and nitroglycerin often reduce preload by relaxing the capacitance veins, associated with an increase in LV systolic performance. However, about 10% of patients with myocardial ischemia present with significant hypovolemia. Accordingly, the clinical assessment of hemodynamics should be supplemented as soon as possible with other means to exclude hypovolemia (e.g., right heart catheterization, empiric volume challenge, echocardiography, or dynamic tests of the adequacy of circulating volume) so that appropriate volume infusion or reduction can be titrated. When these measures are addressed adequately but the hypoperfusion state persists, early movement toward arteriolar vasodilator therapy or a balloon-assist device is indicated to reduce LV afterload and preserve coronary perfusion pressure (see Chap. 25). These latter interventions are not relegated to the last resort but are considered early in this initial stabilization of cardiogenic shock. Similarly, early elective intubation and mechanical ventilation allow effective sedation and reduce O_2 consumption,[41] and PEEP improves arterial oxygenation, often without reducing VR and with improvement of pumping function in the damaged left ventricle by reducing preload and afterload.[44]

HYPOVOLEMIC SHOCK

Beyond the absence of clinical features suggesting that the heart is too full in the hypotensive patient who is presenting reduced $\dot{Q}_T$ (see Table 20-2), hypovolemic shock is distinguished from cardiogenic shock by several positive clinical features. Often there is an obvious source of external bleeding (e.g., multiple trauma, hemoptysis, hematemesis, hematochezia, or melena); internal bleeding is often signaled by blood aspirated from the nasogastric tube or on rectal examination, by increasing abdominal girth, or by clinical and radiologic examinations of the thoracic cavity for pleural, alveolar, retroperitoneal, or periaortic blood. Each of these signals is often associated with a new reduction in the hematocrit. Nonhemorrhagic hypovolemia often presents with recognizable excess gastrointestinal fluid losses (e.g., vomiting, diarrhea, suctioning, and stomas), excess renal losses (e.g., osmotic or drug diuresis and diabetes insipidus), or third-space losses as in extensive burns. Physical examination shows dry mucous membranes with decreased tissue turgor, and routine laboratory tests often show increased serum urea nitrogen out of proportion to a relatively normal creatinine level and increased hematocrit due to hemoconcentration.

The initial management of patients with presumed hypovolemic shock necessitates early vascular access with two large-bore (14-gauge) peripheral intravenous catheters for rapid infusion of large volumes of warmed blood and fluids for hemorrhagic shock and the appropriate crystalloid solution for dehydration. Central venous access ensures adequate volume resuscitation and allows early measurement of CVP. An immediate response of increased BP and pulse volume supports the presumed diagnosis, whereas no improvement in these hemodynamic measurements necessitates emergent repair of the site of blood loss or a reevaluation of the working

diagnosis. Achieving hemostasis in hemorrhagic shock is a prerequisite for adequate volume resuscitation: urgent and simultaneous pursuit of hemostasis and fluid resuscitation is encouraged.[45] Vasoconstricting drugs such as norepinephrine should be used only as short-term antihypotensives to mobilize endogenous unstressed volume or enhance arteriolar vasoconstriction until the circulating volume is restored by transfusion; prolonged use of these drugs confounds the physician's assessment of the end point of volume resuscitation. Early endotracheal intubation and mechanical ventilation reduce the patient's work of breathing and allow respiratory compensation for lactic acidosis during volume resuscitation; warming the fluids and covering the patient with warm dry blankets prevent the complication of hypothermia, including cold coagulopathy and further bleeding (see Table 21-4).

OTHER COMMON CAUSES OF SHOCK: A SHORT DIFFERENTIAL DIAGNOSIS

The purpose of this initial schema is to formulate a working diagnosis for the most common presentations of shock so that early and rapid therapy can be initiated. The response to the initial therapy confirms or challenges the working diagnosis. When features of the initial clinical presentation or the response of the patient to appropriate management challenges the working diagnosis, early acquisition of more objective hemodynamic data is appropriate. In the interim, other features of the clinical presentation often suggest a cause of shock that falls outside this simplistic schema, or the possibility of overlapping or concurrent causes expands. This section briefly reviews several important differential diagnostic conditions for cardiogenic shock (e.g., tamponade or acute right heart syndromes) and hypovolemic shock (e.g., anaphylactic, neurogenic, or adrenal shock; (see Table 20-2, what does not fit?).

CARDIAC TAMPONADE

Pericardial effusion is often suggested early by the clinical setting (e.g., renal failure, malignancy, or chest pain), physical examination (e.g., elevated neck veins, systolic BP that decreases >10 mm Hg on inspiration, or distant heart sounds), or routine investigations (e.g., chest radiograph with "water bottle" heart, low voltage on the ECG, or electrical alternans). Such a constellation of clinical data requires early echocardiographic confirmation of pericardial effusion, and tamponade is signaled by right ventricular and right atrial collapse that worsens with inspiration, with a relatively small left ventricle (see Chap. 28). Tamponade requires urgent pericardiocentesis or operative drainage by pericardiostomy. While deciding on definitive treatment, one should remember that intravenous expansion of the circulating volume may produce small increases in BP, whereas reductions in circulating volume (e.g., diuretics, nitroglycerin, morphine, or intercurrent hemodialysis) are often associated with catastrophic reduction in $\dot{Q}_T$ by reducing the venous tone and volume necessary to maintain the Pms required to drive VR back to high Pra.

Right heart catheterization typically shows a Pra increased to about 16 to 20 mm Hg and equal to pulmonary arterial DP and the arterial Pwp; $\dot{Q}_T$ and SV are much reduced (see Chap. 28). This hemodynamic subset resembles that of cardiogenic shock (high Ppw and low SV). However, in the case of pericardial tamponade, Ppw is increased because pericardial pressure is increased, so the transmural pressure of the left ventricle approaches zero, a value consistent with the very low LVEDV accounting for the low SV. Other etiologies of hypotension associated with high cardiac pressures and small ventricular volumes include constrictive pericarditis, tension pneumothorax, massive pleural effusion, positive-pressure ventilation with high PEEP, and very high intraabdominal pressure (see Table 21-1). Up to 33% of patients presenting with cardiac tamponade have increased BP despite low $\dot{Q}_T$; this subset of patients has a high incidence of hypertension preceding the onset of tamponade.[46]

RIGHT VENTRICULAR OVERLOAD AND INFARCTION

Another clinical presentation that may fall outside the simplest scheme presented in Table 20-2 is the hypotension associated with acute or acute-on-chronic pulmonary hypertension. Shock after acute pulmonary embolism is often signaled by the clinical setting including risk factors (e.g., perioperative, immobilized, thrombophilia, or prior pulmonary embolisms); symptoms of acute dyspnea, chest pain, or hemoptysis; physical examination showing a loud P_2 with a widened and fixed split of the second heart sound; new hypoxemia without obvious radiologic explanation; and acute right heart strain on the ECG (see Chap. 27). Noninvasive Doppler studies of the veins in the lower extremities and helical computed tomographic angiography confirm the diagnosis. Anticoagulation or placement of a filter in the inferior vena cava reduces the incidence of subsequent emboli, and there may be some success with thrombolytic therapy (or, in some centers, surgical removal of the embolus) in patients with shock due to pulmonary embolism. Acute-on-chronic pulmonary hypertension causes shock in the setting of prior primary pulmonary hypertension, recurrent pulmonary emboli, progression of collagen vascular disease, or chronic respiratory failure (e.g., chronic obstructive pulmonary disease or pulmonary fibrosis) aggravated in part by hypoxic pulmonary vasoconstriction. In these circumstances, O_2 therapy and pulmonary vasodilator therapy combine to decrease pulmonary hypertension and increase $\dot{Q}_T$ in a small but significant proportion of patients (see Chap. 27).

Right heart catheterization shows a unique hemodynamic profile: a very high mean pulmonary artery pressure, pulmonary arterial DP considerably greater than the Pwp, and reduced $\dot{Q}_T$ and SV. Not uncommonly, arterial Pwp is normal or increased despite a small LVEDV on echocardiographic examination, which also shows a right-to-left shift of the interventricular septum; presumably, this causes stiffening of the diastolic V-P curve of the left ventricle. A complication of pulmonary vasodilator therapy is hypotension due to systemic arterial dilation unaccompanied by increased right heart output. Such effects aggravate the hypoperfusion state, perhaps by reducing coronary blood flow to the hypertrophied, dilated right ventricle. Some evidence suggests that shock associated with pulmonary hypertension is ameliorated by α-agonist therapy (e.g., norepinephrine or phenylephrine), which acts as a predominant systemic arteriolar constrictor to increase BP sufficiently to maintain right ventricular perfusion.[47,48]

Right ventricular infarction causes low pulmonary artery pressures and normal LV filling pressures because the dilated,

injured right ventricle is unable to maintain adequate flow to the left heart.[49] Elevated neck veins and Pra tend to decrease with dobutamine infusion, perhaps because the enhanced contractility of the left ventricle improves systolic function of the mechanically interdependent right ventricle.[45,46] Volume expansion often aggravates right ventricular dysfunction, and systemic vasoconstriction may preserve right ventricular perfusion.[50]

ANAPHYLACTIC, NEUROGENIC, AND ADRENAL SHOCK

Other etiologies of shock having unique clinical presentations that usually lead to early diagnosis are anaphylactic shock and neurogenic shock. Beyond identifying the etiology early through their association with triggering agents and trauma, respectively, the physician should note that the pathophysiology of each is a dilated venous bed with greatly increased unstressed volume of the circulation leading to hypovolemic shock. Accordingly, the mainstay of therapy for both conditions is adequate volume infusion; adjunctive therapy for anaphylaxis includes antihistamines, steroids, and epinephrine to antagonize the mediators released in the anaphylactic reaction (see Chap. 106), whereas a careful search for sources of blood loss and hemorrhagic shock is part of the early resuscitation of spinal shock in the traumatized patient (see Chap. 94).

Not uncommonly, the presentation of patients with nonhemorrhagic hypovolemic shock raises the concern of acute adrenal cortical insufficiency. When this possibility is not obviously excluded, it is appropriate to draw a serum cortisol level, provide adequate circulating steroids with dexamethasone, and conduct a corticotropin stimulation test to confirm or refute the diagnosis. Characteristically, hypotension and hypoperfusion in such patients will not respond to adequate vascular volume expansion until dexamethasone is administered (see Chap. 79).

MULTIPLE ETIOLOGIES OF SHOCK

With this differential diagnosis and management evaluation in mind, the initial approach to patients with hypoperfusion states should be completed in less time than it takes to read about it. The target is to distinguish among patients with septic shock, cardiogenic shock, and hypovolemic shock and to initiate an appropriate therapeutic challenge—antibiotics, inotropic agents, or a volume challenge—within 30 minutes of presentation. By the response, the diagnosis is confirmed or challenged, with special regard to equivocal responses to therapy or to several other diagnostic categories of shock. Sorting out the primary etiology of the hypoperfusion state often requires considerable additional data. This process is rendered more complex by concurrent etiologies contributing to the shock, for example, the patient with septic shock unable to increase $\dot{Q}_T$ due to intercurrent myocardial dysfunction, the patient with acute myocardial infarction who is hypovolemic, or the patient with hemorrhagic shock who becomes septic. Other combinations of these major categories overlap with confounding effects of tamponade, positive-pressure ventilation, pneumothorax, and pulmonary hypertension—all to challenge ongoing diagnostic and management approaches.

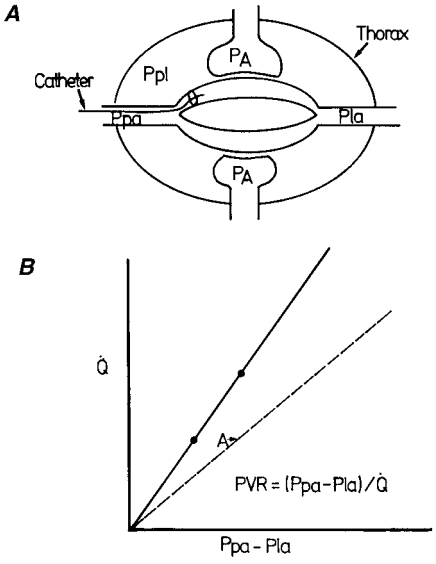

FIGURE 20-10 ***A.*** **Schematic of the pulmonary circulation illustrates a simple view of pulmonary vascular resistance (PVR). Pulmonary blood flows from the pulmonary arteries (Ppa) through branching vessels to the left atrium (Pla). This central circulation is enclosed by the thorax, which contains airspaces (Pa) that abut alveolar vessels. Between the airspaces and thorax is the pleural (pl) space, so pleural pressure (Ppl) approximates the pressure outside extraalveolar vessels, including the heart. A balloon-tipped catheter occludes the upper branch of the pulmonary artery so that the catheter tip sits in a stagnant column of blood, continuous with Pla, to provide an estimate of pulmonary wedge pressure (Ppw), unless alveolar pressure (P_A) exceeds Pla, when occlusion pressure exceeds Pla because P_A closes the alveolar vessels; in either case, when the balloon is deflated, the catheter tip measures Ppa, and a thermistor near the tip can measure pulmonary blood flow ($\dot{Q}$) by thermodilution.** ***B.*** **Plots of $\dot{Q}$ (*ordinate*) against Ppa 2 Pla (*abscissa*); the inverse of the slope of the continuous line drawn through the two P$\dot{Q}$ points is PVR; for a given $\dot{Q}$ at the lower point, Ppa 2 Pla increases to A on the interrupted P$\dot{Q}$ line, indicating increased PVR.**

The Pulmonary Circulation

PRESSURES, FLOW, AND RESISTANCE IN PULMONARY VESSELS

$\dot{Q}_T$ from the left heart is equal to VR to the right heart, so the entire $\dot{Q}_T$ traverses the pulmonary circulation in pulsatile fashion (Fig. 20-10). The right ventricle ejects blood into the pulmonary artery, thereby increasing its pressure (Ppa) to drive flow through a branching arteriolar system into the lung parenchyma, where a network of very small alveolar septal vessels or capillaries passes between the airspaces of the lung to effect pulmonary gas exchange. These septal vessels converge into pulmonary veins that empty into the left atrium, where the pressure (Pla) is often regarded as the outflow pressure of the pulmonary circulation. When this pressure gradient across the pulmonary circulation (Ppa − Pla) is divided by the pulmonary blood flow ($\dot{Q}$), the pulmonary vascular resistance is calculated (mm Hg/L per minute) and sometimes converted to metric units (dyn-s/cm^5) by multiplying by 80. By this analysis, increasing blood flow from one level to another is associated with decreasing pressure

across the pulmonary circulation (Ppa − Pla) along a unique pressure-flow relation given by the continuous line in Fig. 20-10B. Resistance to $\dot{Q}$ may be increased by smooth muscle constriction within the pulmonary arterioles and alveolar vessels by hypoxia, by compression of the alveolar septal vessels by elevated PA, by obstruction of larger pulmonary vessels by thromboembolism, or by obliteration of many of the parallel vascular channels as they traverse the lung so that the same blood must flow through fewer channels. Such an increase in pulmonary vascular resistance would be calculated as at point *A* on the interrupted line in Fig. 20-10, where the pressure difference across the lung (Ppa − Pla) has increased for the same amount of $\dot{Q}$. Pulmonary hypertension is a frequent abnormality in critical illness; its causes are listed in Table 22-4 and its treatment is discussed in Chaps. 22 and 26.

Figure 20-10 also depicts a common way to make these measurements with a pulmonary artery catheter (PAC) that is passed throurg systemic veins into the central circulation. When a small balloon near its tip is inflated, the balloon passes with the VR into the right atrium, right ventricle, and pulmonary artery until it wedges in a pulmonary artery branch, obstructing the flow there. Because there is no flow, the hole in the catheter tip is open to a stagnant column of blood extending through the pulmonary vessels to the left atrium. Accordingly, this Ppw approximates Pla, providing an estimate of LVEDP to evaluate ventricular function and an estimate of pulmonary microvascular pressure to help manage pulmonary edema (see below). When the balloon is deflated and flow resumes through that vessel, the pressure there is equal to pulmonary arterial pressure. Mixed venous blood drawn from the pulmonary artery provides a measure of O_2 content ($C\ ^{-}VO_2$); when related to the simultaneous measurement of arterial O_2 content (CaO_2) and $\dot{Q}T$, the patient's O_2 consumption ($\dot{V}O_2 = \dot{Q}T[CaO_2 - C\ ^{-}VO_2]$) can be calculated and interpreted in the context of the patient's O_2 transport ($D_{O_2} = \dot{Q}T \times CaO_2$). A sensitive thermistor at the tip of the catheter may be used to detect temperature changes after the injection of a cold saline bolus into the right atrium to allow estimation of $\dot{Q}T$ from the resulting thermodilution curve.

The pulmonary artery and the left atrium are surrounded by Ppl, so absolute values of Ppa and Pla change with respiration. When spontaneous active inspiration decreases Ppl, pulmonary arterial and left atrial pressures decrease, but the driving pressure of blood flow across the lung stays the same (Ppa − Pla); when positive-pressure inflation increases Ppl, Ppa and Pla increase. Accordingly, it is helpful to record pulmonary vascular measurements at end expiration when the mode of ventilation has minimally different effects; even this approach can be confounded when the patient exerts vigorous respiratory activity. When alveolar pressure (PA) exceeds Pla, the true driving pressure for pulmonary blood flow is Ppa − PA. One often overlooked adverse effect of positive-pressure ventilation with high PEEP or high tidal volume is the large increase in dead space (VD/VT) when pulmonary blood flow is interrupted by the high PA; not infrequently, alveolar ventilation can actually increase when tidal volume is reduced in these conditions, causing a paradoxical fall in $PACO_2$. A second consequence of PA being greater than Pla is an overestimation of Ppw; this can be detected when the respiratory fluctuation in Ppa is much less than that in Ppw.[51] Given these effects of respiration on measurements of Ppa and Ppw, it is not surprising that many physicians err in their interpretation of PAC data.[52,53] Further, PAC use is accompanied by complications, and it can be argued that the hemodynamic data obtained can be deduced by clinical examination, are not helpful in clinical decision making, or do not improve outcome.[54,55] However, physicians err in their clinical evaluations,[56–57] so it seems reasonable to encourage the informed use of PAC to obtain hemodynamic data when there is clinical uncertainty and when those data will be used to titrate aspects of the patient's management.

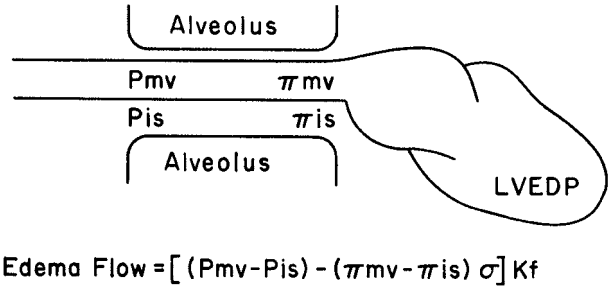

FIGURE 20-11 Schematic representation of Starling forces governing the flux of lung liquid from the intravascular to the extravascular space (for discussion, see text). is, interstitial space; LVEDP, left ventricular end-diastolic pressure; mv, microvessels of the lung; *p*, colloid osmotic pressure; *s*, reflection coefficient. (*Reproduced with permission from Hall and Wood.*[24])

PULMONARY EDEMA

Figure 20-11 shows a schematic diagram depicting the circulatory factors governing the movement of edema ($\dot{Q}E$) between the pulmonary vessels and the lung interstitial tissues; the Starling equation describing lung liquid flux is written beneath the figure. The hydrostatic pressure in the microvessels of the lung (Pmv = 12 mm Hg) lies about halfway between Ppa (normally about 15 mm Hg) and LVEDP (normally about 10 mm Hg). Hydrostatic pressure in the septal interstitial space (Pis = −4 mm Hg) is subatmospheric, in part because it drains into the peribronchovascular interstitium, which has a more negative pressure, and in part because lymph vessels, valved like veins for unidirectional flow, actively remove liquid from the interstitial spaces that have intrinsic structural stability to resist collapse.[58] Accordingly, there is a positive hydrostatic pressure (Pmv − Pis = 16 mm Hg) driving edema across the microvascular endothelium to the lung septal interstitium. The vascular wall presents a barrier to this bulk flow of liquid characterized by its permeability to water (K_f; mL edema/min per mm Hg); K_f includes surface area (S) and thus is heavily weighted by the characteristics of the alveolar vessels, where so much S resides.[58] The microvascular membrane is also characterized by its permeability to circulating proteins, dominated by albumin and globulin. If these plasma proteins were completely reflected ($\sigma = 1$), no protein would pass from lung blood to the interstitium; in contrast, if the microvascular membrane were freely permeable ($\sigma = 0$), interstitial protein concentration (CL), as measured in lung lymph, would equal that of plasma proteins (Cp). CL/Cp is about 0.6 in the normal steady-state edema flow in most

mammals; when $\dot{Q}E$, as estimated from lung lymph flow ($\dot{Q}L$), is progressively increased by elevating Pmv, C_L/Cp decreases to a plateau value of about 0.3. This plateau value indicates the microvascular protein reflection coefficient ($\sigma = 1\ 2\ C_L/Cp = 0.7$) measured in conditions of high edema flow; at lower $\dot{Q}E$ levels, water diffuses from the interstitium to the blood along the concentration gradient for water established by $Cp > C_L$.[58]

In cardiogenic pulmonary edema, $\dot{Q}E$ is increased by increasing Pmv. Several factors act to keep the lungs from accumulating excess liquid: lymphatic flow increases, C_L/Cp decreases, and Pis increases. The increased septal Pis drives edema through tissue planes toward the intraparenchymal peribronchovascular interstitium, where Pis is rendered even more subatmospheric (−10 mm Hg) by the outward pull of alveolar walls on the adventitia surrounding the relatively stiff bronchi and vessels.[58] This adventitial pull renders Pis even more negative with each inspiration, creating a cyclic suction to move edema from the alveolar septa toward the hilum of the lung, where peribronchovascular interstitial pressures are most negative, where the tissues have the largest capacity to accommodate the edema, and where the most dense accumulation of lymphatics is arranged to clear the edema to the systemic veins. This accounts for the Kerley lines, the bronchial cuffing, and the perihilar "butterfly" distribution of interstitial cardiogenic pulmonary edema on the chest radiograph. When edema genesis continues to fill these interstitial reservoirs, Pis rises at the alveolar septa, disrupting tight junctions between alveolar type I epithelium to flood the airspaces. Histologic morphometry of edematous lungs shows that flooded alveoli have about one-eighth the volume of unflooded alveoli, indicating that a relatively small volume of alveolar edema floods eight times that volume of airspace; for example, in a patient with an end-expired lung gas volume of 4 L, 250 mL of alveolar edema fills half the airspaces ($8 \times 250 = 2$ L), accounting for a large intrapulmonary shunt and for a large reduction in C_L because only half the lung is ventilated.[22]

In the exudative phase of ARDS, a greater proportion of noncardiogenic edema accumulates in airspaces, so there is a much greater shunt per edema volume than in cardiogenic edema. Presumably, this different distribution of edema occurs because the lung injury that increases K_f and decreases S also damages the alveolar epithelial barrier, so increased $\dot{Q}E$ has access to a low-resistance pathway to a very large reservoir for edema—the airspaces of the lung.[59] Often, the hydrostatic pressure driving edema from vessels to airspace is normal or reduced; as $\dot{Q}E$ increases at normal Pmv after an acute lung injury, C_L/Cp does not decrease as in cardiogenic edema but increases slightly to a value of about 0.8, so the reflection coefficient decreases ($\sigma = 1\ 2\ C_L/Cp = 0.2$ L). Accordingly, alveolar fluid protein concentration (C_A) approaches Cp in ARDS but is much lower than Cp in cardiogenic edema.[56] When the vascular membrane is repaired, alveolar edema is cleared very slowly from noninjured lungs by active transport of sodium; water follows the osmotic gradient through an intact alveolar membrane, and this clearance raises C_A above Cp as a clinical marker of recovery from ARDS.[60]

PEEP increases end-expired lung volume to decrease Pis and increase capacity in the peribronchovascular interstitium; this in turn redistributes much of the alveolar edema into this interstitial reservoir, associated with the aeration of flooded airspaces at a much larger alveolar volume to reduce shunt and to increase C_L without altering the amount of edema.[11,12,61] Because lung volume increases greatly when PEEP is effective in redistributing edema, Ppl must increase to push the chest wall to an equivalently higher volume (see Fig. 20-5). This raises Pra to reduce VR and BP[4,5,20] unless the patient's baroreceptor reflexes, iatrogenic infusions of fluid, or vasoactive drugs maintain Pms and $\dot{Q}T$.[25,62] As illustrated in Fig. 20-9, this recruitment of previously flooded airspaces occurs within the large P-V hysteresis of the edematous lung, so less PEEP is required than that indicated by the inflection point of the inflation P-V curve.[63]

TABLE 20-3 Therapeutic Goals in Acute Hypoxemic Respiratory Failure

1. Seek the least PEEP providing 90% saturation of an adequate hematocrit (>30%) on nontoxic F_{IO_2} (<.6)
2. Seek the least tidal volume providing adequate CO_2 elimination (pH > 7.2)
3. Seek the least circulatory volume or Ppw providing adequate CO and D_{O_2}

ABBREVIATIONS: D_{O_2}, O_2 delivery; F_{IO_2}, fraction inspired O_2; PEEP, positive end-expiratory pressure.

AN APPROACH TO MANAGING ACUTE HYPOXEMIC RESPIRATORY FAILURE

As with many therapeutic interventions in critical illness, too much can cause harm, so it is helpful to define the goal of each intervention and then use the mildest intervention to achieve that goal. Ventilator management of pulmonary edema causing AHRF is summarized in Table 20-3. Because the aim of PEEP therapy is to maintain arterial saturation (>90%) of an adequate circulating hemoglobin (<12 g%) on a nontoxic fraction inspired O_2 (F_{IO_2}; <0.6)—all to effect adequate D_{O_2} without aggravating the lung injury with oxygen toxicity—it is helpful to use the least PEEP to achieve these goals so as not to reduce $\dot{Q}T$. Because PEEP already increases end-expired lung volume, superimposed large tidal volumes cause pulmonary barotraumas, further reduce VR, and contribute to mortality; using the least tidal volume (e.g., 6 mL/kg ideal body weight) effecting adequate CO_2 elimination at an increased rate minimizes these complications. It is remarkable how rapidly PEEP redistributes edema to reduce hypoxemia (in minutes) and how rapidly the shunt returns when PEEP is removed. Accordingly, the informed physician can implement an effective, tolerable estimate of least PEEP in less than 15 minutes in ventilated patients in whom BP and pulse oximetry are being monitored continuously. Beginning with a small tidal volume (6 mL/kg), high respiratory rate (30 breaths/min), and F_{IO_2} of 1 in a well-sedated patient, PEEP is increased by 5 cm H_2O every minute from 0 to 20 minutes. If BP does not decrease and arterial O_2 saturation (Sa_{O_2}) remains 95%, F_{IO_2} is reduced to 0.8 for 5 minutes and then to 0.7 and 0.6 at 5-minute intervals. If Sa_{O_2} still exceeds 95%, PEEP is reduced by 5 cm H_2O every 5 minutes until Sa_{O_2} is greater than 90% and then increased by 2 to 3 cm H_2O to restore Sa_{O_2} to less than 90%. A decrease in BP as PEEP is initially increased

indicates relative circulatory hypovolemia, so PEEP must be reduced again until $\dot{Q}_T$ and BP are restored with volume infusion including packed red blood cells to achieve an adequate hematocrit or with an infusion of dobutamine titrated from 1 to 10 μg/kg per minute to maintain $\dot{Q}_T$ at a lower circulatory volume and Ppw. Similarly, if the initial $F_{I_{O_2}}$ reductions decrease Sa_{O_2} by less than 90%, PEEP should be increased in 2.5-cm H_2O increments above 20 cm H_2O until Sa_{O_2} is high enough to allow $F_{I_{O_2}}$ reduction; at this stage, it is prudent to reduce the tidal volume further. When PEEP is effective, plans to prevent its inadvertent removal, as during routine bedside suctioning, can prevent sudden hypoxemic cardiovascular catastrophe.

Cardiovascular management of cardiogenic and noncardiogenic edema aims to reduce edema formation and accumulation without inducing inadequate $\dot{Q}_T$ or D_{O_2} (see Table 20-3), thereby decreasing the duration and complications of intensive care.[62] Cardiogenic edema is caused by high Pmv, often related to acute or acute-on-chronic LV dysfunction that increases LVEDP. Reducing the central blood volume by venodilating agents (e.g., morphine, furosemide, or nitroglycerin) or procedures (e.g., rotating tourniquets, phlebotomy, or diuresis) reduces LVEDP and edema genesis, but excess preload reduction will adversely reduce $\dot{Q}_T$ from a poorly functioning ventricle that often requires a higher LVEDP (16 to 30 mm Hg) than normal (8 to 12 mm Hg). Where indicated, vasoactive drugs to enhance systolic function (e.g., dobutamine, milrinone, nitroglycerin, or oxygen) or reduce afterload (e.g., enalaprilat, calcium channel blockers, or nitroprusside) and measures to correct diastolic dysfunction (e.g., prolong filling time, maintain coordinated atrial contraction, or correct myocardial hypoxia and ischemia) act to reduce the LVEDP required for adequate $\dot{Q}_T$ and thus reduce cardiogenic edema formation by the Starling equation. Increasing π_{mv} by colloid infusion also reduces edema formation, provided Pmv is not increased; an albumin infusion that raises π_{mv} from 15 to 20 mm Hg and Pmv from 25 to 30 mm Hg causes more $\dot{Q}E$ because $\sigma = 0.7$.

Colloid infusion is even less helpful in reducing noncardiogenic edema, where σ is much reduced. In one study of oleic acid-induced noncardiogenic edema in dogs, raising π_{mv} by 5 mm Hg had no effect on edema when Pmv was not allowed to change, but lowering Pmv by 5 mm Hg (when π_{mv} did not change) reduced edema by 50% over the same 4 hours of treatment.[57] Compelling evidence in other animal[64–67] and clinical studies[31–33] of acute lung injury supports the therapeutic effect of reducing pulmonary vascular pressures in reducing pulmonary edema (Fig. 20-12), and this is currently being tested prospectively in patients with acute lung injury and ARDS (ARDS Network Fluid and Catheter Treatment Trial). When noncardiogenic edema occurs at normal or low Pmv, the reduction of LVEDP by only 5 mm Hg reduces LVEDV, SV, and $\dot{Q}_T$ by as much as a 20 mm Hg reduction in LVEDP in cardiogenic edema. Accordingly, reducing the measured Ppw in a patient with acute lung injury must avoid causing inadequate $\dot{Q}_T$ and D_{O_2}. As in cardiogenic edema, Ppw can be reduced considerably without evidence of inadequate output and D_{O_2}, and vasoactive drugs and increased hematocrit are effective in restoring adequacy of D_{O_2} at low Ppw when indicated. This approach constantly seeks the least Ppw associated with an adequate $\dot{Q}_T$ and D_{O_2} during the early stage of edema formation in ARDS. Of course, this is only

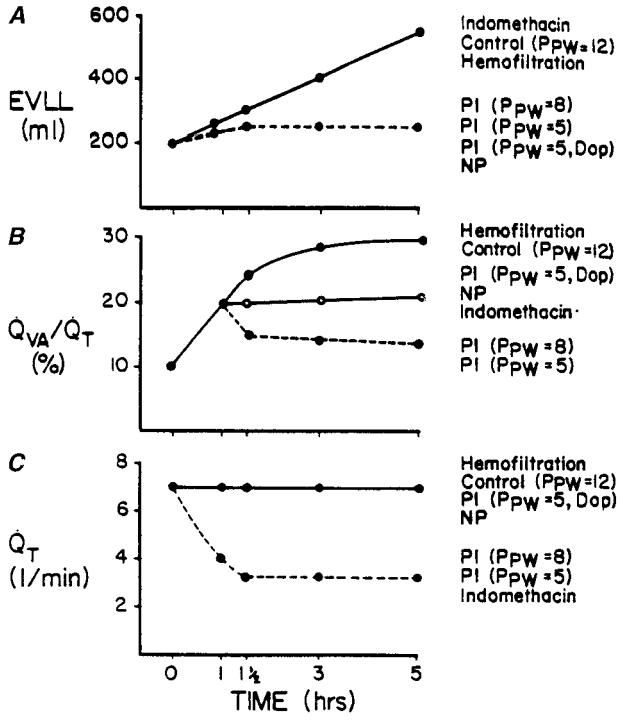

FIGURE 20-12 Schematic diagram illustrating the effects of reducing pulmonary wedge pressure (Ppw) 1 hour after hydrochloric acid or kerosene aspiration at time 0 hour (*abscissa*) on extravascular lung liquid (EVLL by thermal dilution; *A*), shunt ($\dot{Q}V_A/\dot{Q}_T$; *B*), and cardiac output ($\dot{Q}_T$; *C*). Data are compiled from six studies by the same group with similar experimental protocols. *A.* Edema increases linearly with time after injury in the control group (Ppw = 12 mm Hg, *continuous line*), but reduction of Ppw to 8 or 5 mm Hg at 1 hour by plasmapheresis (Pl) or sodium nitroprusside (NP) attenuates or stops edema accumulation (*interrupted line*) such that EVLL is less than half that in the control group by 5 hours; all EVLL values were confirmed by gravimetric edema measures in the lungs excised at 5 hours. Hemofiltration to a Ppw of 5 mm Hg did not reduce edema, and indomethacin had no effect on edemagenesis when Ppw was kept the same as in the control group. *B.* Shunt increased in a curvilinear manner to about 30% as EVLL increased with time in the control group (*continuous line through closed circles*); when Ppw was reduced by plasmapheresis, $\dot{Q}V_A/\dot{Q}_T$ stopped increasing and actually decreased to about 15% owing in part to reduced edema. Dopamine and NP also decreased $\dot{Q}_{VA}/\dot{Q}_T$ and edema; moreover, dopamine and NP also decreased $\dot{Q}_{VA}/\dot{Q}_T$ when they reduced edema (*continuous line through open circles*), but $\dot{Q}_{VA}/\dot{Q}_T$ was greater in these groups than in plasmapheresis alone (*interrupted line*) because the vasoactive drugs increased $\dot{Q}_T$; similarly, indomethacin reduced $\dot{Q}_{VA}/\dot{Q}_T$ compared with the control group despite similar edema because $\dot{Q}_T$ decreased (see *C*). *C.* $\dot{Q}_T$ did not change with time when Ppw was maintained in the control group; when Ppw was reduced by plasmaphereis, $\dot{Q}_T$ was maintained equal to the control group by dopamine and NP (*continuous line*). Plasmapheresis reduced $\dot{Q}_T$ by decreasing Ppw (*interrupted line*) but reduced oxygen delivery less by increasing the hematocrit. Indomethacin reduced $\dot{Q}_T$ at the same Ppw (*interrupted line*) but reduced oxygen delivery less by increasing the hemocrit. Indomethacin reduced $\dot{Q}_T$ at the same Ppw, suggesting decreased ventricular function; as a consequence, $\dot{Q}_{VA}/\dot{Q}_T$ decreased with no change in edema.

symptomatic treatment; as yet there are no specific therapies for the acute lung injury that correct an increased K_f and a reduced S. The aim is to minimize the edema consequences of vascular injury and thereby shorten duration of ventilation and care in the intensive care unit.[31–33]

Chapter 21
SHOCK

KEITH R. WALLEY

KEY POINTS

- *Shock is present when there is evidence of multisystem organ hypoperfusion; it often presents as decreased mean blood pressure.*
- *Initial resuscitation aims to establish adequate airway, breathing, and circulation. Rapid initial resusciation (usefully driven by protocol) is fundamental for improved outcome, since "time is tissue."*
- *A working diagnosis or clinical hypothesis of the cause of inadequate circulation should always be made immediately, while treatment is initiated, based on clinical presentation, physical examination, and by observing the response to therapy.*
- *Drug and/or definitive therapy for specific causes of shock must be considered and implemented early (e.g., thrombolysis for myocardial infarction, hemostasis for hemorrhage, appropropriate antibiotics, and activated protein C for severe sepsis, etc.).*
- *The most common causes of shock are high cardiac output hypotension, or septic shock; reduced pump function of the heart, or cardiogenic shock; and reduced venous return despite normal pump function, or hypovolemic shock. Overlapping etiologies can confuse the diagnosis, as can a short list of other less common etiologies, which are often separated by echocardiography and pulmonary artery catheterization.*
- *Shock has a hemodynamic component, which is the focus of the initial resuscitation, but shock also has a systemic inflammatory component (ameliorated by rapid initial resuscitation) that leads to adverse sequelae including subsequent organ system dysfunction.*

This chapter discusses shock with respect to the bedside approach: first with an early working diagnosis, then an approach to urgent resuscitation that confirms or changes the working diagnosis, followed by a pause to ponder the broader differential diagnosis of the types of shock and the pathophysiology of shock leading to potential adverse sequelae. Effective initial diagnosis and treatment at a rapid pace depend in large part on understanding cardiovascular pathophysiology.

Establishing a Working Diagnosis of the Cause of Shock

DEFINITION OF SHOCK

Shock is present if evidence of multisystem organ hypoperfusion is apparent. Evidence of hypoperfusion includes tachycardia, tachypnea, low mean blood pressure, diaphoresis, poorly perfused skin and extremities, altered mental status, and decreased urine output. Hypotension has special importance because it commonly occurs during shock, because blood pressure is easily measured, and because extreme hypotension always results in shock. Important caveats are: (1) relatively low blood pressure is normal in some healthy individuals and (2) systolic blood pressure may be preserved in some patients in shock by excessive sympathetic tone. In the latter case, it is important to anticipate that sedation will unmask hypotension. Further, cuff blood pressure measurements may markedly underestimate central blood pressure in low flow states.[1] The focus of initial resuscitation is reversing the hemodynamic component of shock, which leads to tissue hypoxia and lactic acidosis. However, all types of shock are also associated with a systemic inflammatory component that is a key contributor to subsequent multisystem organ failure and death. The development of the systemic inflammatory component is minimized by rapid and adequate (usefully driven by protocol) initial resuscitation.[2]

A QUESTIONING APPROACH TO THE INITIAL CLINICAL EXAMINATION

Mean blood pressure is the product of cardiac output and systemic vascular resistance (SVR). Accordingly, hypotension may be caused by reduced cardiac output or reduced SVR. Therefore, initial examination of the hypotensive patient seeks to answer the question: Is cardiac output reduced? High cardiac output hypotension is most often signaled by a high pulse pressure, a low diastolic pressure, warm extremities with good nail bed return, fever (or hypothermia), leukocytosis (or leukopenia), and other evidence of infection; these clinical findings strongly suggest a working diagnosis of septic shock (Table 21-1), the initial treatment for which is thoughtful antibiosis combined with rapid expansion of the vascular volume and subsequent vasopressors, inotropes, and blood transfusion as necessary to achieve an adequate mean arterial pressure (MAP) and central venous oxygen saturation (Scv_{O_2}; see below).

In contrast, low cardiac output is signaled by a low pulse pressure, mottled cyanotic skin, and cool extremities with poor nail bed return. In this case, clinical examination turns to a second question: Is the heart too full? A heart that is too full in a hypotensive patient is signaled by elevated jugular venous pressure, peripheral edema, crepitations on lung auscultation, a laterally displaced precordial apical impulse with extra heart sounds (S_3, S_4), chest pain, ischemic changes on the electrocardiogram, and a chest radiograph showing a large heart with dilated upper lobe vessels and pulmonary edema.[3] These findings suggest cardiogenic shock, most often caused by ischemic heart disease, and are generally absent when low cardiac output results from hypovolemia (see Table 21-1). Clinical examination then shows manifestations of blood loss (hematemesis, tarry stools, abdominal distention, reduced hematocrit, or trauma) or manifestations of dehydration (reduced tissue turgor, vomiting or diarrhea, or negative fluid balance). This distinction between cardiogenic and hypovolemic shock allows initial therapy to focus on vasoactive drugs and on volume infusions, respectively.

Whenever the clinical formulation is not obvious after answering the first two questions, ask a third: What does not fit? Most often, the answer is that the hypotension is due to overlap of two or more of these common etiologies of

TABLE 21-1 Rapid Formulation of an Early Working Diagnosis of the Etiology of Shock

Defining features of shock		
Blood pressure	↓	
Heart rate	↑	
Respiratory rate	↑	
Mentation	↓	
Urine output	↓	
Arterial pH	↓	
	High-Output Hypotension Septic Shock	Low Cardiac Cardiogenic and Hypovolemic Shock
Is cardiac output reduced?	No	Yes
Pulse pressure	↑	↓
Diastolic pressure	↓	↓
Extremities/digits	Warm	Cool
Nail bed return	Rapid	Slow
Heart sounds	Crisp	Muffled
Temperature	↑ or ↓	↔
White cell count	↑ or ↓	↔
Site of infection	++	—
	Reduced Pump Function, Cardiogenic Shock	Reduced Venous Return, Hypovolemic Shock
Is the heart too full?	Yes	No
Symptoms clinical context	Angina on electrocardiogram	Hemorrhage dehydration
Jugular venous pressure	↑	↓
S_3, S_4, gallop rhythm	+++	—
Respiratory crepitations	+++	—
Chest radiograph	Large heart ↑ Upper lobe flow Pulmonary edema	Normal
What does not fit?		
Overlapping etiologies (septic cardiogenic, septic hypovolemic, cardiogenic hypovolemic)		
Short list of other etiologies		
High-output hypotension	High right atrial pressure hypotension	Nonresponsive hypovolemia
Liver failure	Pulmonary hypertension (Most often pulmonary embolus)	Adrenal insufficiency
Severe pancreatitis	Right ventricular infarction	Anaphylaxis
Trauma with significant systemic inflammatory response	Cardiac tamponade	Spinal shock
Thyroid storm		
Arteriovenous fistula		
Paget disease

shock: septic shock complicated by myocardial dysfunction or hypovolemia, cardiogenic shock complicated by hypovolemia or sepsis, and hypovolemic shock masking sepsis or ischemic heart disease. At this time, more data are frequently needed, especially aided by echocardiography and pulmonary artery catheterization. Interpretations of the data and response to initial therapy frequently confirm the multiple etiologies or lead to a broader differential diagnosis of the etiologies of shock (see below). A short list of common etiologies other than septic, cardiogenic, or hypovolemic shock can be grouped as they present (see Table 21-1): high cardiac output hypotension that does not appear to be caused by sepsis, high right atrial pressure hypotension not caused by left ventricular ischemia, and poorly responsive hypovolemic shock.

Urgent Initial Resuscitation

PRIMARY SURVEY

Early institution of aggressive resuscitation improves a patient's chances of survival.[2,4] To improve efficiency at the necessarily rapid tempo, a systematic approach to initial evaluation and resuscitation is useful as it is during cardiac emergencies (advanced cardiac life support [ACLS]) and trauma (advanced trauma life support [ATLS]). In analogy to these systematic "ABC" approaches, a primary survey includes establishing an airway (*airway*), choosing a ventilator mode and small tidal volumes that minimize ventilator-induced lung injury (*breathing*), rapid (usefully protocol driven) resuscitation of the inadequate circulation

(*circulation*), and *drugs/definitive therapy* consisting of early consideration and implementation of definitive therapy for specific causes of shock (e.g., thrombolysis or angioplasty for myocardial infarction; hemostasis for hemorrhage; appropriate antibiotics, surgical drainage of abscess, activated protein C, and steroids for severe sepsis; etc.).

AIRWAY

Almost all patients in shock have one or more indications for airway intubation and mechanical ventilation (Table 21-2), which should be instituted early. Significant hypoxemia (based on blood-gas analysis, pulse oximetry, or high clinical suspicion) is one indication for airway intubation because external masks and other devices do not reliably deliver an adequate fraction of inspired O_2 ($F_{I_{O_2}}$). Initially, a high $F_{I_{O_2}}$ (100%) is used until blood-gas analysis or reliable pulse oximetry allows titration of the $F_{I_{O_2}}$ down toward less toxic concentrations.

Ventilatory failure is another indication for airway intubation and mechanical ventilation. Elevated and rising partial pressure of CO_2 in arterial blood reliably establishes the diagnosis of ventilatory failure but is often a late finding. In particular, young, previously healthy patients are able to defend partial pressure of CO_2 (P_{CO_2}) and pH up until a precipitous respiratory arrest. Therefore, clinical signs of respiratory muscle fatigue or subtle evidence of inadequate ventilation are more important early indicators.[5] Evidence of respiratory muscle fatigue, including labored breathing precluding more than rudimentary verbal responses, tachypnea greater than 40/minute or an inappropriately low and decreasing respiratory rate, abdominal paradoxical respiratory motion, accessory muscle use, and other manifestations of ventilatory failure such as inadequately compensated acidemia should lead to early elective intubation and ventilation of the patient in shock (see Chap. 31).

Obtundation, due to shock or other causes, resulting in inadequate airway protection is an important indication for intubation. In shock, airway intubation and mechanical ventilation should precede other complicated procedures, such as central venous catheterization, or complicated tests that require transportation of the patient because these procedures and tests restrict the medical staff's ability to continuously assess the airway and ensure adequacy of ventilation.

TABLE 21-2 Indications for Intubation in Shock Patients

Indication	Why
Hypoxemia	High $F_{I_{O_2}}$ is not guaranteed by oxygen masks; PEEP can be added
Ventilatory failure (inappropriately high P_{CO_2}, signs of ventilatory muscle fatigue)	Ensure adequate CO_2 removal Correct hypoxia due to hypoventilation Prevent sudden respiratory arrest
Vital organ hypoperfusion	Rest ventilatory muscles (and divert cardiac output to hypoperfused vital organs)
Obtundation	Protect and ensure an adequate airway

ABBREVIATIONS: $F_{I_{O_2}}$, fraction of inspired O_2; P_{CO_2}, partial pressure of CO_2; PEEP, positive end-expiratory pressure.

BREATHING

Initially, mechanical ventilation with sedation and, if necessary, paralysis are instituted to remove work of breathing as a confounding factor from the initial resuscitation and diagnostic pathway and to redistribute limited blood flow to vital organs.[6] The change from spontaneous breathing (negative intrathoracic pressure ventilation) to mechanical ventilation (positive intrathoracic pressure ventilation) leads to reduced venous return so that additional volume resuscitation must be anticipated when hypovolemia contributes to shock. Application of positive end-expiratory pressure (increases intrathoracic pressure) and administration of sedative or narcotic drugs (increases venous capacitance) similarly should be expected to reduce venous return and highlight the importance of aggressive volume resuscitation at the time of intubation and institution of mechanical ventilation in hypovolemic patients. Conversely, when hypovolemia is not a problem (e.g., cardiogenic shock), application of positive intrathoracic pressure may improve cardiac output and blood pressure.

A relatively small tidal volume (6 to 8 mL/kg) should be selected to minimize hypotension due to high intrathoracic pressures and, more importantly, to reduce ventilator-induced lung injury.[7] When arterial hypoxemia due to acute lung injury or frank adult respiratory distress syndrome (ARDS) complicates shock, adherence to tidal volumes of 6 mL/kg ideal body weight significantly decreases mortality rate and number of days on a ventilator in the intensive care unit.[8]

CIRCULATION

Just as low tidal volumes limit ongoing lung inflammation and injury, rapid resuscitation of the circulation limits ongoing generation of a systemic inflammatory response and multiple organ injury. Hence, rapid protocol-driven approaches with defined end points improve shock outcome.[4,9] For all types of shock, "time is tissue." Thus, for cardiogenic shock secondary to acute myocardial infarction, the early goal is immediate thrombolysis, angioplasty, or surgical revascularization.[3] For hypovolemic shock due to hemorrhage, the early goal is immediate hemostasis and rapid volume resuscitation. The early goals of volume resuscitation in hypovolemic or septic shock are incorporated in the Early Goal-Directed Therapy algorithm (Fig. 21-1), which was initially designed to aid resuscitation of septic shock.[2] This requires immediate monitoring (even before formal admission to the intensive care unit) of MAP (goal > 65 mm Hg), central venous pressure (CVP; goal 8 to 12 mm Hg), and Scv_{O_2} (goal > 70%).

Volume

Aggressive volume resuscitation up to the point of a heart that is too full is the first step in resuscitation of the circulation. The rate and composition of volume expanders must be adjusted in accord with the working diagnosis. The Early Goal-Directed Therapy algorithm for resuscitation of septic shock calls for 500 mL saline every 30 minutes, but this is much too slow in hypovolemic patients in whom 1 L every 10 minutes, or faster, is initially required. During volume resuscitation, infusions must be sufficient to test the clinical hypothesis that the patient is hypovolemic by effecting a short-term end point indicating benefit (increased blood pressure and pulse

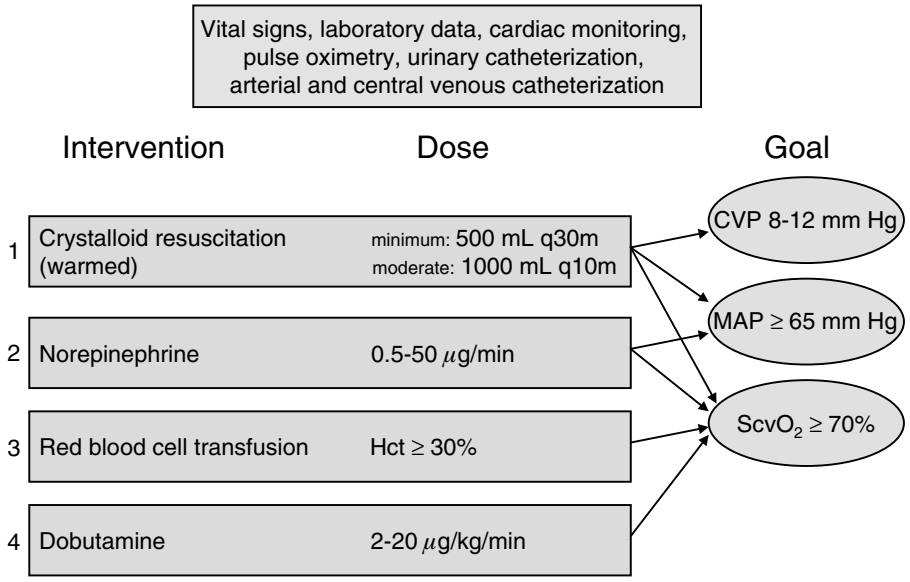

FIGURE 21-1 An approach to initial resuscitation of the circulation based on Early Goal-Directed Therapy. Cardiac monitoring, pulse oximetry, urinary catheterization, and arterial and central venous catheterizations must be instituted. Volume resuscitation is the initial step. If this is insufficient to raise mean arterial pressure (MAP) to 65 mm Hg, then vasopressors are the second step. Adequate tissue oxygenation (reflected by central venous O_2 saturation [Scv_{o_2}] > 70%) is a goal of all resuscitation interventions. If this Scv_{o_2} goal is not met by volume resuscitation and vasopressors, then red blood cell transfusion and inotrope infusion are the third and fourth interventions, respectively. When the goals of resuscitation are met, then reduction of vasopressor infusion, with further volume infusion if necessary, becomes a priority. CVP, central venous pressure; Hct, hematocrit. (*Adapted from Rivers et al.*[2])

pressure and decreased heart rate) or complication (increased jugular venous pressure and pulmonary edema). Absence of either response indicates an inadequate challenge, so the volume administered in the next interval must be greater than the previous one. In obvious hemorrhagic shock, immediate hemostasis is essential[10]; blood must be obtained early, warmed and filtered; blood substitutes are administered in large amounts (crystalloid or colloid solutions) until blood pressure increases or the heart becomes too full. At the other extreme, a working diagnosis of cardiogenic shock without obvious fluid overload requires a smaller volume challenge (250 mL NaCl in 20 minutes). In each case, and in all other types of shock, the next volume challenge depends on the response to the first; it should proceed soon after the first so that the physician does not miss the diagnostic clues evident only to the examining critical care team at the bedside during this urgent resuscitation (Table 21-3).

Role of Red Blood Cell Transfusion during Initial Resuscitation

Transfusion of red blood cells is a component of the initial volume resuscitation of shock when severe or ongoing blood loss contributes to shock. In addition, when anemia contributes to inadequate oxygen delivery so that mixed venous oxygen saturation or its surrogate Scv_{O_2} <70% despite an adequate CVP (8 to 12 mm Hg) and an adequate MAP (>65 mm Hg), then transfusion of red blood cells to hematocrit greater than 30% is a reasonable component of Early Goal-Directed Therapy and improves outcome.[2] After initial resuscitation and stabilization, transfusion of red blood cells to maintain a hemoglobin above 90 g/L is no more beneficial than maintaining a hemoglobin level above 70 g/L and only incurs additional transfusion risk.[11]

Is There a Role for Delayed Resuscitation of Hypovolemia?

During brisk ongoing hemorrhage, massive crystalloid or colloid resuscitation increases blood pressure and the rate of hemorrhage, so patient outcome may be worse.[12] This does not mean that resuscitation is detrimental; rather, control of active bleeding is more important than volume replacement. Preventing blood loss conserves warm, oxygen-carrying, protein-containing, biocompatible intravascular volume and is therefore far superior to replacing ongoing losses with fluids deficient in one or more of these areas. I and my colleagues believe that delayed or inadequate volume resuscitation, after blood loss is controlled, is a significant error that will have a detrimental effect on patient outcome.[10]

This approach of aggressive volume resuscitation avoids persistent hypovolemia as the cause for prolonged hypotension at the risk of causing pulmonary edema or aggravating the pumping dysfunction of the ischemic myocardium. We are not cavalier about fluid overload; just as soon as early resuscitation goals are met and as the heart becomes evaluated as too full, we shift goals to aim for the lowest circulating volume that provides adequate perfusion and O_2 delivery, but we emphasize that rational diagnosis and early resuscitation from shock require an adequate circulating volume before vasoactive drugs can be effective. Of course, the discerning intensivist is aware that the initial evaluation of some hypotensive patients demonstrates a heart that is too full, so vasoactive therapy starts immediately.

Vasopressors

Volume-resuscitated septic shock stands out as a challenging hemodynamic problem. Here the inflammatory component of shock is prominent; after vigorous volume resuscitation, right atrial pressure and cardiac output may be high, but MAP may be distressingly low and evidence of organ system hypoperfusion may persist (oliguria, impaired mentation, and lactic acidosis). Here there is a role for pressor agents. Whereas adequate cardiac output is more important than blood pressure (because adequate tissue oxygen delivery is the underlying issue), effective distribution of flow by the vascular system depends on an adequate pressure head. At pressures below an autoregulatory limit, normal flow distribution mechanisms are lost, so significant vital organ system hypoperfusion may persist in the face of elevated cardiac output

TABLE 21-3 Urgent Resuscitation of the Patient with Shock—Managing Factors Aggravating the Hypoperfusion State

Respiratory therapy
Protect the airway—consider early elective intubation
Prevent excess respiratory work—ventilate with small volumes
Avoid respiratory acidosis—keep Pa_{CO_2} low
Maintain oxygen delivery—FI_{O_2}, PEEP, hemoglobin
Infection in presumed septic shock (see Chap. 46)
Empirical rational antibiosis for all probable etiologies
Exclude allergies to antibiotics
Search, incise, and drain abscesses (consider laparotomy)
Arrhythmias aggravating shock (see Chap. 24)
Bradycardia
Correct hypoxemia—FI_{O_2} of 1.0
Atropine 0.6 mg, repeat × 2 for effect
Increase dopamine to 10 mg/kg per minute
Add isoproterenol (1–10 mg/min)
Consider transvenous pacer
Ventricular ectopy, tachycardia
Detect and correct K^+, Ca^{2+}, Mg^{2+}
Detect and treat myocardial ischemia
Amiodarone for sustained ventricular tachycardia
Supraventricular tachycardia
Consider defibrillation early
β blocker, digoxin for rate control of atrial fibrillation
Sinus tachycardia 140/min
Detect and treat pain and anxiety
Midazolam fentanyl drip
Morphine
Detect and treat hypovolemia
Metabolic (lactic) acidosis
Characterize to confirm anion gap without osmolal gap
Rule out or treat ketoacidosis, aspirin intoxication
Hyperventilate to keep Pa_{CO_2} of 25 mm Hg
Calculate bicarbonate deficit and replace half if pH <7.0
Correct ionized hypocalcemia
Consider early dialysis
Hypothermia
Maintain skin dry and covered with warmed blankets
Warm vascular volume expanders
Aggressive rewarming if temperature <35°C (95°F)

ABBREVIATIONS: FI_{O_2}, fraction of inspired O_2; P_{CO_2}, partial pressure of CO_2; PEEP, positive end-expiratory pressure.

due to maldistribution of blood flow. In this case, where inadequate pressure is the dominant problem, an assessment of organ system perfusion is made (urine output, mentation, and lactic acid concentration), and then a vasopressor agent such as noradrenaline is initiated to raise MAP.[13] The increased afterload will decrease cardiac output, so this intervention as single therapy is appropriate only when cardiac output is high. If cardiac output and oxygen delivery are inadequate, then combination of vasopressor therapy with inotropic agents should be considered (see below).

Too often, the blanket coverage of "pressor agents" is used early in all types of shock. Because some positive inotropic drugs can cause venoconstriction to increase cardiac output by endogenous volume shifts (dopamine and epinephrine), there is a rationale (like that of raising the patient's legs or applying military antishock trousers) for the common practice of starting these agents in some hypotensive patients while the volume resuscitation proceeds. However, this strategy often confounds the determination of an adequate circulating volume and the diagnosis of the etiology of shock. Thus, vasopressor use as part of Early Goal-Directed Therapy must be reassessed during ongoing volume resuscitation. Even when the numerical MAP and CVP goals have been attained, additional rapid volume challenge generally should be used to test for further clinical improvement (increased MAP, decreased heart rate, increased Scv_{O_2}, and increased urine output) and to determine whether this will allow titration of vasopressor use down or off.

Assessment of organ system perfusion is the most important component of vasopressor therapy; increase in blood pressure by itself is insufficient and can distract from careful reassessment of adequacy of oxygen delivery. If urine output increases, mentation improves, and lactate levels decrease, then vasopressor therapy has achieved its goals, and there is no need to increase MAP further even if the MAP that reverses these signs of hypoperfusion is 55 mm Hg. If the measures of organ system perfusion are not improved by vasopressor therapy, then arbitrarily driving MAP much above 70 mm Hg is rarely useful in septic shock and usually detrimental because cardiac output will decrease further and excessive vasoconstrictor tone will impair blood flow distribution. If evidence of hypoperfusion persists, then inadequate volume resuscitation, cardiac output, hemoglobin, and oxygen saturation are more likely problems.

Inotropes

If evidence of inadequate perfusion persists (assessed by clinical indicators, by direct measurement of cardiac output, or by Scv_{O_2}, etc.) despite adequate circulating volume (Early Goal-Directed Therapy goal: CVP 8 to 12 mm Hg) and vasopressors (Early Goal-Directed Therapy goal: >65 mm Hg), then inotropic agents are indicated.[13] Inotropes are not effective when volume resuscitation is incomplete. In this case, the arterial vasodilating properties of inotropes such as dobutamine and milrinone result in a drop in arterial pressure that is not countered by an increase in cardiac output because venous return is still limited by the inadequate volume resuscitation. The corollary is, if initiation of inotropes results in a significant drop in blood pressure, then adequate volume resuscitation is not complete.

The objective of inotrope use is to increase cardiac output to achieve adequate oxygen delivery to all tissues. Of the many clinical and laboratory indicators that should be measured, mixed venous O_2 saturation (when a pulmonary artery catheter is placed) or Scv_{O_2} are useful surrogate measures of adequacy of O_2 delivery.[14] Rapidly achieving a goal Scv_{O_2} greater than 70% results in a substantial improvement in survival and limits the systemic inflammatory response so that the subsequent need for further volume, red blood cell transfusion, vasopressor use, and mechanical ventilation is reduced.[2]

Accordingly, we encourage early aggressive volume resuscitation, judicious use of vasopressors to aid in rapidly achieving an adequate MAP in septic shock, titration of a positive inotropic agent (dobutamine 2 to 20 μg/kg per minute) to enhance myocardial contractility, and blood transfusion to hematocrit greater than 30, if necessary, to achieve Scv_{O_2} greater than 70%. Resuscitation of the circulation is often usefully driven by protocol. When numerical resuscitation goals are met, additional rapid volume infusions can be used to determine whether volume resuscitation is complete and to

help titrate vasopressor agents down and off. After a rapid and adequate resuscitation, timely reduction in vasopressor and inotrope use should be anticipated and is the next goal.

DRUGS/DEFINITIVE THERAPY

During the rapid initial assessment of the patient in shock and initial resuscitation aimed at supporting respiration and circulation, it is important to consider early institution of other definitive therapy for specific causes of shock and early input from consultant experts. When myocardial infarction is the cause of cardiogenic shock, immediate thrombolysis or angioplasty is considered, using intraaortic balloon pump support and coronary artery bypass surgery when necessary[3] (see Chap. 25). During resuscitation of hypovolemic shock, continuous and early application of techniques to anticipate, prevent, or correct hypothermia prevents secondary coagulopathy, coma, and nonresponsiveness to volume and pharmacologic resuscitation. Hemostasis is the immediate goal for hemorrhage[10] because it removes the cause of hypovolemic shock and lessens the need for further volume expanders, none of which are as effective as keeping the patient's own blood intravascular. Emergent radiologic and surgical consultation and intervention may be required. Similarly, when septic shock is secondary to a perforated viscus, an undrained abscess, or rapid spread of infection in devitalized tissue or in tissue planes (gas gangrene, necrotizing fasciitis, etc.), then immediate surgical intervention is fundamental to survival. Early institution of appropriate antibiotics has a profound effect on patient survival from septic shock.[15] Activated protein C decreases mortality for severe sepsis and is most effective when given early.[16] Low-dose steroid therapy of septic shock in patients who are unresponsive to corticotropin (ACTH) similarly improves survival in patients having septic shock.[17] Thus, an ACTH stimulation test should be conducted and low-dose steroid therapy should be initiated immediately thereafter. Steroid therapy can be discontinued as soon as the results of the ACTH stimulation test demonstrate adrenal responsiveness.[17]

CATHETERS AND FREQUENT MEASUREMENTS DURING INITIAL RESUSCITATION

After an airway is established and breathing ensured, correction of the circulatory abnormality always requires good intravenous access. For large-volume administration, two peripheral intravenous catheters of gauge 16 or larger or large-bore central venous access is required. Early Goal-Directed Therapy mandates immediate placement of a central venous catheter. Electrocardiographic monitoring is easily accomplished and usefully measures heart rate and rhythm for early detection and, hence, rational treatment of tachyarrhythmias or bradyarrhythmias aggravating the low-flow state.

The urinary bladder should be catheterized to measure urine output and to facilitate urine sampling. A nasogastric or orogastric tube to decompress the stomach and later to deliver medication and nutrition is generally required in the intubated patient. Measuring arterial pressure with a peripheral arterial or femoral arterial catheter is useful because, in the patient in shock with low cardiac output or low blood pressure, cuff pressures may be inaccurate.[1] Arterial blood-gas and other blood samples are then readily obtained.

Early echocardiography is a useful adjunct to Scv_{O_2} to distinguish poor ventricular pumping function from hypovolemia; a good study can exclude or confirm tamponade, right heart failure, pulmonary hypertension possibly due to pulmonary embolism, or significant valve dysfunction, all of which influence therapy, and can replace more invasive pulmonary artery catheterization.

Effective use and interpretation of Scv_{O_2} and echocardiography often obviate pulmonary artery catheterization when the clinical hypothesis of cardiogenic, hypovolemic, or septic shock is confirmed and corrected by initial therapeutic intervention. There is no role for pulmonary artery catheterization for routine monitoring or management of uncomplicated shock states.[18,19] Use of pulmonary artery catheterization should be restricted to circumstances in which the derived measurements will alter management or direct therapeutic interventions. For example, when confirmed septic shock does not respond fully, or as expected, to volume resuscitation and vasopressor use (e.g., persistent narrow pulse pressure, low Scv_{O_2}, and elevated lactate), then myocardial dysfunction contributes. When echocardiography excludes other causes (see above), then subsequent pulmonary artery catheterization guides the balance between vasopressor (to maintain an adequate MAP for blood flow distribution to vital organs) and inotrope use (to achieve an adequate cardiac output and oxygen delivery to maintain vital organ function).

TEMPO

One of the most important contributions the intensivist can make to the care of a shock patient is to establish an appropriately rapid management tempo. Rapid initial resuscitation improves survival ("time is tissue"). In many instances, resuscitation driven by protocol can achieve adequate resuscitation faster. Effective protocol-driven resuscitation requires significant preliminary discussion, buy in, and training of emergency room physicians, house staff, nurses, respiratory therapists, and others.

The mirror image of urgent implementation is rapid liberation of the resuscitated patient from excessive therapy. It is not uncommon for the patient with hypovolemic or septic shock to stabilize hemodynamically on positive-pressure ventilation with high circulating volume and several vasoactive drugs infusing at a high rate. Too often, hours or days of "weaning" pass, when a trial of spontaneous breathing, diuresis, and sequential reduction of the drug dose by half each 10 minutes can return the patient to a much less treated, stable state within the hour. Of course, this rapid discontinuation may be limited by intercurrent hemodynamic or other instability, but defining each limit and justifying ongoing or new therapy is the essence of titrated care in this postresuscitation period.

Types of Shock

We use cardiac function curves and venous return relations in the following discussion to compare and contrast cardiovascular mechanisms responsible for cardiogenic shock (Fig. 21-2), hypovolemic shock (Fig. 21-3), and septic shock (Fig. 21-4). The goal is to link pathophysiology of the circulation to the broader differential diagnosis of the types of shock

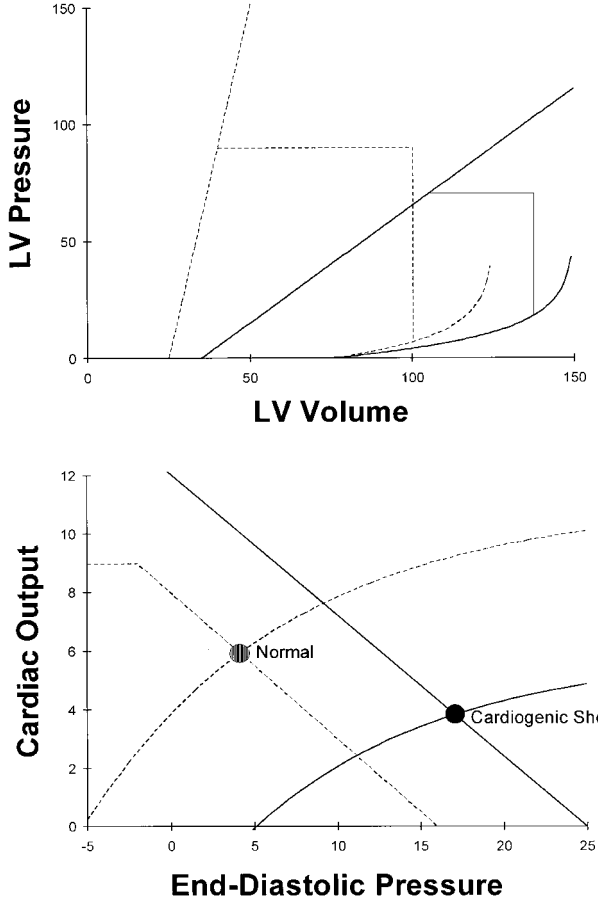

FIGURE 21-2 Cardiovascular mechanics in cardiogenic shock. ***Upper panel.*** **Abnormalities of systolic and diastolic left ventricular (LV) pressure and volume (*ordinate and abscissa*, respectively) relations during cardiogenic shock (*continuous lines*) with normal pressure-volume relations (*dashed lines*). The primary abnormality is that the end-systolic pressure-volume relation (*sloped straight lines*) is shifted to the right mainly by a marked reduction in slope (decreased contractility). As a result, at similar or even lower systolic pressures, the ventricle is not able to eject as far, so end-systolic volume is greatly increased and stroke volume is therefore decreased. To compensate for the decrease in stroke volume, the curvilinear diastolic pressure-volume relation shifts to the right, which indicates decreased diastolic stiffness (increased compliance). To maximize stroke volume, diastolic filling increases even further, associated with an increase in end-diastolic pressure.** ***Lower panel.*** **Why end-diastolic pressure increases is determined from the pump function and venous return curves as a plot of cardiac output (*ordinate*) versus right atrial end-diastolic pressure (*abscissa*). The decrease in contractility (*upper panel*) results in a shift of the curvilinear cardiac function curve from its normal position (*dashed curve, lower panel*) down and to the right (*continuous curve, lower panel*). Because end-diastolic pressure and cardiac output are determined by the intersection of the cardiac function curve (*curvilinear relations, lower panel*) with the venous return curve (*straight lines, lower panel*), the shift of the cardiac function curve immediately results in a decrease in cardiac output and an increase in end-diastolic pressure. Compensatory mechanisms (fluid retention by the kidneys, increased sympathetic tone) act to maintain venous return by increasing mean systemic pressure (venous pressure when cardiac output = 0) from 16 to 25 mm Hg as indicated by the rightward shift from the *dashed straight line* to the *continuous straight line* in the *lower panel*. The effect is that end-diastolic pressure increases so that stroke volume (*upper panel*) and cardiac output (*lower panel*) are increased toward normal.**

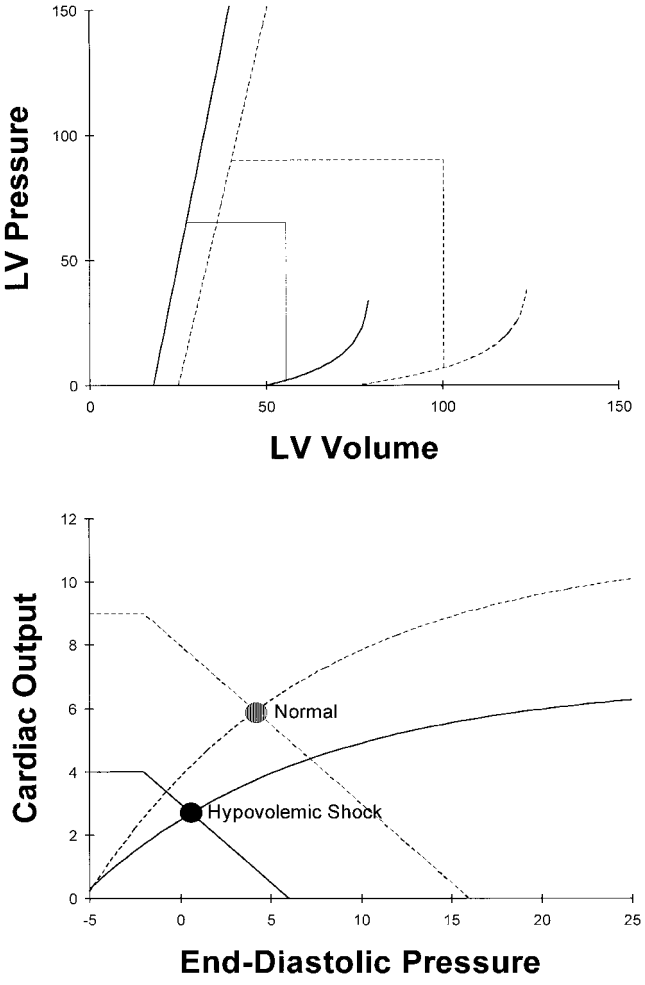

FIGURE 21-3 Cardiovascular mechanics in hypovolemic shock (axes as labeled as in Fig. 21-2). ***Lower panel.*** **During hypovolemic shock, the primary abnormality is a decrease in the intravascular volume so that mean systemic pressure decreases as illustrated by a shift of the venous return curves from the normal relation (*straight dashed line*) leftward (*straight continuous line*). This hypovolemic venous return curve now intersects the normal cardiac function curve (*dashed curvilinear relation*) at a much lower end-diastolic pressure so that cardiac output is greatly reduced.** ***Upper panel.*** **The increased sympathetic tone accompanying shock results in a slight increase in contractility, as illustrated by the slight left shift of the left ventricular end-systolic pressure-volume relation (*from the dashed straight line to the solid straight line*). However, because the slope of the end-systolic pressure-volume relation is normally quite steep, the increase in contractility cannot increase stroke volume or cardiac output much and is therefore an ineffective compensatory mechanism in patients with normal hearts. If volume resuscitation to correct the primary abnormality is delayed for several hours, the diastolic pressure-volume relation shifts from its normal position (*dashed curve, upper panel*), resulting in increased diastolic stiffness (*continuous curve, upper panel*). Increased diastolic stiffness results in a decreased stroke volume and therefore a depressed cardiac function curve (*continuous curve, lower panel*) compared with normal (*dashed curve, lower panel*). This decrease in cardiac function due to increased diastolic stiffness probably accounts for irreversibility of severe prolonged hypovolemic shock. LV, left ventricular.**

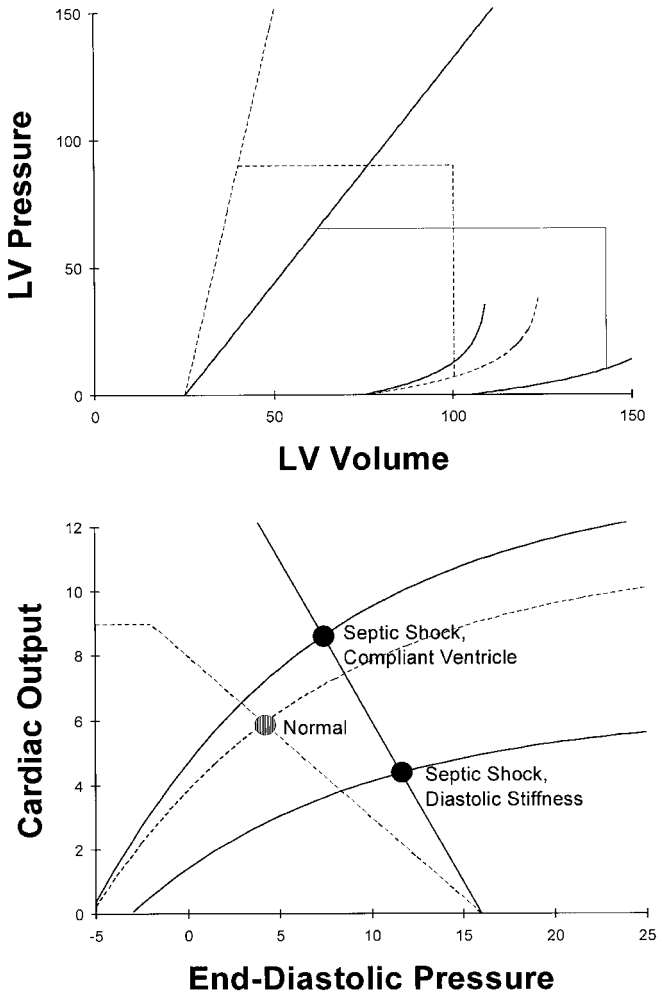

FIGURE 21-4 Cardiovascular mechanics in septic shock (axes as labeled as in Fig. 21-2). Septic shock has important independent effects on left ventricular (LV) pressure-volume relations, on the venous return curve, and on arterial vascular resistance. *Upper panel.* Depressed systolic contractility indicated by a decreased slope of the LV end-systolic pressure-volume relation from normal (*dashed sloped line*) to sepsis (*continuous sloped line*) is caused in part by a circulating myocardial depressant factor, but the end-systolic volume remains about normal owing to the reduced afterload. Survivors of septic shock have a large end-diastolic volume even at reduced diastolic pressure associated with dilation of their diastolic ventricles, indicated by a shift of the normal diastolic pressure-volume relation (*dashed curve*) to the right (*right-hand continuous curve*). As a result, stroke volume is increased. However, in nonsurvivors, stroke volume decreases because of a leftward shift of the diastolic pressure-volume relation (*left-hand continuous curve*), indicating increased diastolic stiffness and impaired diastolic filling. *Lower panel.* The cardiac function curve for survivors is normal (*dashed curvilinear relation*) or slightly increased (*continuous curvilinear relation* owing to reduced afterload). The peripheral *circulation* during septic shock is often characterized by high flows and low vascular pressures. It follows that the resistance to venous return is decreased as indicated by a steeper venous return curve (*continuous straight line*) compared with normal (*straight dashed lines*). This accounts for the high venous return and large end-diastolic volumes and stroke volumes. As with other interventions, resistance to venous return may be decreased in part by redistribution of blood flow to vascular beds with short time constants. However, the nonsurvivors may have significantly depressed cardiac function (*downward shifted continuous curve*) because of the additive effects of decreased systolic contractility and impaired diastolic filling. Depending on the relative contribution of the abnormalities of ventricular mechanics and peripheral vascular changes, cardiac output is usually normal or high even at relatively normal end-diastolic pressures until diastolic dysfunction limits cardiac output by reducing diastolic volume even at high diastolic pressures.

presented in Table 21-4 to facilitate the accurate etiologic diagnosis and management based on additional hemodynamic measures as required by the response to urgent resuscitation.

Shock caused by decreased pump function of the heart is commonly cardiogenic shock resulting from left ventricular ischemia. For high right atrial pressure hypotension not obviously caused by left ventricular ischemia, greatly elevated pulmonary arterial pressure (most commonly pulmonary embolism), right ventricular ischemia, and dysfunction of heart valves must be excluded. Of course, right atrial pressure may be increased by abnormal pressures surrounding the heart in the absence of ventricular dysfunction. Because of this clinical presentation, I have included cardiac tamponade in the category of high right atrial pressure hypotension. Tamponade and pulmonary embolism might have been classified as decreased venous return due to obstruction of the circulation (see Table 21-1). Decreased venous return despite normal pump function is most commonly due to hemorrhagic or dehydration hypovolemia, but I emphasize other mechanisms including decreased venous tone caused by drugs, neurologic injury, and adrenal insufficiency, particularly for nonresponsive hypovolemia. Septic shock is the most common cause of high cardiac output hypotension resulting from abnormal arterial tone and blood flow distribution, although other causes such as severe liver failure, severe pancreatitis, trauma with tissue damage eliciting a significant inflammatory response, anaphylactic shock, thyroid storm, Paget disease, and other peripheral shunts share this mechanism. Defining shock as anaerobic metabolism of multiple organ systems, often signaled by lactic acidosis, allows classification of the shock state associated with metabolic poisons such as carbon monoxide that results in histotoxic hypoxia caused by inadequate uptake of oxygen by the mitochondria (see Table 21-4). Other shock states, in particular septic shock, may also involve an inability of tissues to extract delivered oxygen, but the lactic acidosis of sepsis is not necessarily caused by anaerobic metabolism.

DECREASED PUMP FUNCTION—CARDIOGENIC SHOCK

Pump function is measured as the output of a pump for a given input. The diagnosis of decreased pump function as the cause of shock is made by finding evidence of inappropriately low output (cardiac output) despite normal or high input (right atrial pressure). Cardiac output is the most important "output" of the heart and is clinically assessed in the same way that perfusion was assessed during the urgent initial examination. Better estimates are later obtained by thermodilution measurement using a pulmonary artery catheter, nuclear medicine scans, and Doppler echocardiographic

TABLE 21-4 Causes of and Contributors to Shock

- Decreased pump function of the heart—cardiogenic shock
  - Left ventricular failure
    - Systolic dysfunction—decreased contractility
      - Myocardial infarction
      - Ischemia and global hypoxemia
      - Cardiomyopathy
      - Depressant drugs: β blockers, calcium channel blockers, antiarrhythmics
      - Myocardial contusion
      - Respiratory acidosis
      - Metabolic derangements: acidosis, hypophosphatemia, hypocalcemia
    - Diastolic dysfunction—increased myocardial diastolic stiffness
      - Ischemia
      - Ventricular hypertrophy
      - Restrictive cardiomyopathy
      - Consequence of prolonged hypovolemic or septic shock
      - Ventricular interdependence

ABBREVIATIONS: ARDS, acute respiratory distress syndrome; PEEP, positive end-expiratory pressure.

techniques. Right atrial pressure or CVP is the most easily measured "input" of the whole heart and is initially assessed by examination of jugular veins. After catheter insertion, CVP can be measured accurately. Other outputs, such as stroke work or left ventricular ejection fraction, and other inputs, such as left ventricular end-diastolic pressure (LVEDP) or volume (LVEDV), are useful to determine the specific cause of decreased pump function. Left and right ventricular dysfunction can be caused by decreased systolic contractility, increased diastolic stiffness, greatly increased afterload (including obstruction), valvular dysfunction, or abnormal heart rate and rhythm.

CAUSES OF LEFT VENTRICULAR FAILURE

Acute or acute-on-chronic left ventricular failure resulting in shock is the classic example of cardiogenic shock and is

identified as a subset of decreased pump function by evidence of a low cardiac output in relation to high left ventricular filling pressures. Clinical findings of low cardiac output and increased left ventricular filling pressures include, in addition to assessment of perfusion, pulmonary crackles in dependent lung regions, a laterally displaced and diffuse precordial apical impulse, elevated jugular veins, and presence of a third heart sound.[20] These findings are not always present or unambiguous. Therefore, echocardiography or pulmonary artery catheterization is helpful and often essential in establishing the diagnosis and titrating therapy. Cardiogenic shock then is usually associated with a cardiac index lower than 2.2 L/m^2 per minute when the pulmonary artery occlusion pressure has been raised above 18 mm Hg.[21]

Systolic Dysfunction

Figure 21-2 illustrates the pathophysiologic abnormalities of cardiogenic shock resulting from decreased left ventricular contractility. The primary abnormality is that the relation of end-systolic pressure to volume is shifted down and to the right (see Fig. 21-2, upper panel) so that, at the same afterload, the ventricle cannot eject as far (decreased contractility). It follows that pump function is also impaired, indicated by a shift down and to the right (see Fig. 21-2, lower panel) so that at similar preloads cardiac output is reduced. Three mechanisms that counter the decrease in cardiac output are illustrated. The diastolic ventricle becomes more compliant, possibly from stress relaxation of the pericardium and myocardium, so that stroke volume increases at the same end-diastolic pressure (rightward shift of the diastolic pressure-volume relation in the upper panel). Afterload decreases, resulting in increased stroke volume (see Fig. 21-2, upper panel). Mean systemic pressure rises (see Fig. 21-2, lower panel), aided by avid fluid retention by the kidneys and by increased venous tone mediated by the sympathetic nervous system. Thus, the Frank-Starling mechanism of increasing cardiac output by increasing diastolic filling is used.

As a result of a decrease in contractility, the patient presents with elevated left and right ventricular filling pressures and a low cardiac output. Mixed venous oxygen saturation may be well below 50% because cardiac output is low. In the presence of physiologic pulmonary shunt that accompanies pulmonary edema, the low saturation of mixed venous blood shunting by the lung contributes to substantial arterial desaturation. Accordingly, arterial desaturation aggravates the low oxygen delivery due to reduced cardiac output, as does intercurrent anemia.

Acute myocardial infarction or ischemia is the most common cause of left ventricular failure leading to shock. The principal effect of myocardial infarction is to depress systolic contractility, which in completely infarcted areas becomes zero or even negative (paradoxical regional wall motion). Earlier series described shock occurring in 10% to 20% of patients with transmural myocardial infarction.[22] However, the recent use of fibrinolytic therapy and early angioplasty or surgical revascularization has reduced the incidence of cardiogenic shock to less than 5%.[23] Infarction greater than 40% of the myocardium is often associated with cardiogenic shock;[24] anterior infarction is 20 times more likely to lead to shock than is inferior or posterior infarction.[25] Details of the diagnosis and management of ischemic heart disease are discussed in Chap. 25; other causes of decreased left ventricular contractility in critical illness are discussed in more detail in Chaps. 22 and 23, and each may contribute to shock.

Diastolic Dysfunction

Increased left ventricular diastolic chamber stiffness contributing to cardiogenic shock occurs during myocardial ischemia and in a range of less common disorders including late stages of hypovolemic shock and septic shock (see Table 21-4); all causes of tamponade listed in Table 21-4 need to be considered in a systematic review of causes of diastolic dysfunction.[26] Cardiac function is depressed because stroke volume is decreased by decreased end-diastolic volume caused by increased diastolic chamber stiffness. Diastolic dysfunction in a hypotensive patient with low cardiac output and high filling pressures is often identified by a small (rather than large) LVEDV by bedside echocardiography. Conditions resulting in increased diastolic stiffness are particularly detrimental when systolic contractility is decreased because decreased diastolic stiffness (increased compliance; see Fig. 21-2, upper panel) is normally a compensatory mechanism. Increased diastolic chamber stiffness contributing to hypotension in patients with low cardiac output and high ventricular diastolic pressures is best identified echocardiographically by small diastolic volumes.

Treatment of increased diastolic stiffness is approached by first considering the potentially contributing reversible causes. Acute reversible causes include ischemia and the many causes of tamponade physiology listed in Table 21-4. Fluid infusion results in large increases in diastolic pressure without much increase in diastolic volume. Positive inotropic agents and afterload reduction are generally not helpful and may decrease blood pressure further. If conventional therapy of cardiogenic shock aimed at improving systolic function is ineffective, then increased diastolic stiffness should be strongly considered as the cause of decreased pump function. Cardiac output responsiveness to heart rate is another subtle clue suggesting impaired diastolic filling. Heart rate does not normally alter cardiac output (which is normally set by and equal to venous return) except at very low heart rates (maximally filled ventricle before end diastole) or at very high heart rates (incomplete ventricular relaxation and filling). However, if diastolic filling is limited by tamponade or a stiff ventricle, then very little further filling occurs late in diastole. In this case, increasing heart rate from 80 to 100 or 110 beats/min may result in a significant increase in cardiac output, which may be therapeutically beneficial and also a diagnostic clue.

Valvular Dysfunction

Acute mitral regurgitation, due to cordal or papillary muscle rupture or papillary muscle dysfunction, most commonly is caused by ischemic injury. The characteristic murmur and the presence of large V waves on the pulmonary artery occlusion pressure trace suggest significant mitral regurgitation, which is quantified by Doppler echocardiographic examination. Rupture of the ventricular septum with left-to-right shunt is detected by Doppler echocardiographic examination or by observing a step-up in oxygen saturation of blood from the right atrium to the pulmonary artery.[27] Rarely, acute obstruction of the mitral valve by left atrial thrombus or myxoma may also result in cardiogenic shock. These conditions are generally surgical emergencies.

More commonly, valve dysfunction aggravates other primary etiologies of shock. Aortic and mitral regurgitation reduces forward flow and raises LVEDP, and this regurgitation is ameliorated by effective arteriolar dilation and by nitroprusside infusion. Vasodilator therapy can effect large increases in cardiac output without much change in mean blood pressure, pulse pressure, or diastolic pressure, so pulmonary artery catheterization and repeat echocardiography, to confirm increased cardiac output and reduced valvular regurgitation, are essential to titrating effective vasodilator doses. In contrast, occasional patients develop decreased blood pressure and cardiac output on inotropic drugs such as dobutamine; in this case, excluding dynamic ventricular outflow tract obstruction by echocardiography or treating it by increasing preload, afterload, and end-systolic volume are essential.

Cardiac Arrhythmias

Not infrequently, arrhythmias aggravate hypoperfusion in other shock states. Ventricular tachyarrhythmias are often associated with cardiogenic shock; sinus tachycardia and atrial tachyarrhythmias are often observed with hypovolemic and septic shock. Specific therapy of tachyarrhythmias depends on the specific diagnosis, as discussed in Chap. 24. Inadequately treated pain and unsuspected drug withdrawal should be included in the intensive care unit differential diagnosis of tachyarrhythmias; whatever their etiology, the reduced ventricular filling time can reduce cardiac output and aggravate shock. Bradyarrhythmias contributing to shock may respond acutely to atropine or isoproterenol infusion and then pacing; hypoxia or myocardial infarction as the cause should be sought and treated. Symptomatic hypoperfusion resulting from bradyarrhythmias, even in the absence of myocardial infarction or high-degree atrioventricular block, is an important indication for temporary pacemaker placement that is sometimes overlooked.

Treatment of Left Ventricular Failure

After initial resuscitation, which includes consideration of early institution of thrombolytic therapy in acute coronary thrombosis and revascularization or surgical correction of other anatomic abnormalities where appropriate,[3] management of patients with cardiogenic shock requires repeated testing of the hypothesis of "too little versus too much." Clinical examination is not accurate enough; when the response to initial treatment of cardiogenic shock is inadequate, a pulmonary artery catheter may be required. Therapy for cardiogenic shock follows from consideration of the pathophysiology illustrated in Fig. 21-2 and includes optimizing filling pressures, increasing contractility by improving the ratio of myocardial oxygen supply to demand, or by using inotropic drugs, and optimizing afterload. Temporary mechanical support using an intraaortic balloon pump is often extremely useful in cardiogenic shock and should be considered early as a support device in patients who may benefit from later surgical therapy.[28] Cardiac transplantation and mechanical heart implantation are considered when other therapy fails.

Filling pressures are optimized to improve cardiac output but avoid pulmonary edema. Depending on the initial presentation, cardiogenic shock frequently spans the spectrum of hypovolemia (so fluid infusion helps) to hypervolemia with pulmonary edema (where reduction in intravascular volume results in substantial improvement). If gross fluid overload is not present, then a rapid fluid bolus should be given. In contrast to patients with hypovolemic or septic shock, a smaller bolus (250 mL) of crystalloid solution should be infused as quickly as possible. Immediately after infusion, the patient's circulatory status should be reassessed. If there is improvement but hypoperfusion persists, then further infusion with repeat examination is indicated to attain an adequate cardiac output and oxygen delivery while seeking the lowest filling pressure needed to accomplish this goal. If there is no improvement in oxygen delivery and evidence of worsened pulmonary edema or gas exchange, then the limit of initial fluid resuscitation has been defined. Crystalloid solutions are used particularly if the initial evaluation is uncertain because crystalloid solutions rapidly distribute to the entire extracellular fluid compartment. Therefore, after a brief period only one-fourth to one-third remains in the intravascular compartment, and evidence of intravascular fluid overload rapidly subsides.

Contractility increases if ischemia can be relieved by decreasing myocardial oxygen demand, by improving myocardial oxygen supply by increasing coronary blood flow (coronary vasodilators, thrombolytic therapy, surgical revascularization, or intra-aortic balloon pump counterpulsation), or by increasing the oxygen content of arterial blood. Inotropic drug infusion attempts to correct the physiologic abnormality by increasing contractility (see Fig. 21-2). However, this occurs at the expense of increased myocardial oxygen demand. Afterload is optimized to maintain arterial pressures high enough to perfuse vital organs (including the heart) but low enough to maximize systolic ejection. When systolic function is reduced, vasodilator therapy may improve systolic ejection and increase perfusion, even to the extent that blood pressure rises.[29] In patients with very high blood pressure, end-systolic volume increases considerably so that stroke volume and cardiac output decrease unless LVEDV and LVEDP are greatly increased; this sequence is reversed by judicious afterload reduction.

Diagnosis and Management of Right Ventricular Failure

Right ventricular failure as a cause of cardiogenic shock is often identified by elevated right atrial pressure and low cardiac output not explained by left ventricular failure or cardiac tamponade. The most common causes of shock owing to right ventricular failure are right ventricular infarction and pulmonary embolism resulting in greatly increased right ventricular afterload.

Right ventricular infarction is found in approximately half of inferior myocardial infarctions and is complicated by shock only 10% to 20% of the time.[30] Isolated right ventricular infarction with shock is uncommon and has a mortality rate ~50% comparable to left ventricular infarction shock.[25] The hemodynamic findings of right ventricular infarction must be distinguished from cardiac tamponade and constrictive pericarditis and include Kussmaul sign, low cardiac output, high filling pressures, and often equalization of right atrial, right ventricular diastolic, pulmonary artery diastolic, and pulmonary artery occlusion pressures. Pulmonary crackles are classically absent. Early recognition of right versus left ventricular infarction as the cause of shock is important, so potentially dangerous therapy, including vasodilators, morphine, and β blockers, are avoided. Therapy includes infusion

of dobutamine and volume expansion, although excessive volume can aggravate shock by shifting the intraventricular septum from right to left.[31] Because bradyarrhythmias are common and atrioventricular conduction is frequently abnormal, atrioventricular sequential pacing may preserve right ventricular synchrony and often dramatically improves cardiac output and blood pressure in shock caused by right ventricular infarction.[31] Afterload reduction using balloon counterpulsation may also be useful,[25] as are early fibrinolytic therapy and angioplasty when indicated (see Chap. 25).

Right ventricular ischemia, with or without coronary artery disease, probably is a more important cause of right ventricular dysfunction than generally recognized. In shock states systemic arterial pressure is often low, and right ventricular afterload (pulmonary artery pressure) may be high owing to emboli, hypoxemic pulmonary vasoconstriction, acidemic pulmonary vasoconstriction, sepsis, or ARDS. Therefore, right ventricular perfusion pressure is low leading to right ventricular ischemia and decreased contractility, which, in the face of normal or high right ventricular afterload, results in right ventricular dilation. Subsequent right-to-left shift of the interventricular septum limits left ventricular filling. Cardiac output is then limited by right ventricular systolic ejection and left ventricular diastolic filling.

Therapy of right ventricular failure caused by decreased right ventricular perfusion and increased afterload is evolving. Animal studies suggest that, acutely in right ventricular shock caused by pulmonary embolism, interventions such as norepinephrine infusion may increase systemic arterial pressure more than pulmonary arterial pressure, resulting in improved right ventricular perfusion. Improved right ventricular function and total cardiac function may result. This approach has not been carefully tested in patients in shock owing to right ventricular failure.[32] Established approaches include verifying that pulmonary emboli are present and initiating therapy with anticoagulation, fibrinolytic agents for submassive pulmonary embolism or shock, or surgical embolectomy as necessary.[33] Hypoxic pulmonary vasoconstriction may be reduced by improving alveolar and mixed venous oxygenation. More aggressive correction of acidemia should be considered in this setting. Pulmonary vasodilator therapy may be useful in some patients if pulmonary artery pressures can be lowered without significantly lowering systemic arterial pressures. Inhaled nitric oxide, prostaglandin E_1, and many other agents have been variably successful. Measurements of pulmonary artery pressure, systemic pressure, cardiac output, and oxygen delivery before and after a trial of a specific potential pulmonary vasodilator are essential (see Chap. 26).

Compression of the Heart by Surrounding Structures

Compression of the heart (cardiac tamponade) limits diastolic filling and can result in shock with inadequate cardiac output despite very high right atrial pressures. Diagnosis of cardiac tamponade is made physiologically by using pulmonary artery catheterization to demonstrate a low cardiac output in addition to elevated and approximately equal right atrial, right ventricular diastolic, pulmonary artery diastolic, and pulmonary artery occlusion pressures (particularly their waveforms). The diagnosis is often best confirmed anatomically by using echocardiographic examination to demonstrate pericardial fluid, diastolic collapse of the atria and right ventricle, and right-to-left septal shift during inspiration. Septal shift during inspiration and increased afterload that accompany decreased intrathoracic pressure during inspiration account for the clinically observed pulsus paradoxus. Although pericardial tamponade by accumulation of pericardial fluid is the most common cause of cardiac tamponade, other structures surrounding the heart may also produce tamponade. Tension pneumothorax, massive pleural effusion, pneumopericardium (rarely), and greatly elevated abdominal pressures may also impair diastolic filling.

Decreasing the pressure of the tamponading chamber by needle drainage of the pericardium, pleural space, and peritoneum can rapidly and dramatically improve venous return, blood pressure, and organ system perfusion. Therefore, the goal of therapy is to accomplish this decompression as rapidly and safely as possible. In patients who are hemodynamically stable, fluid infusion is a temporizing therapy that increases mean systemic pressure so that venous return increases even though right atrial pressure is high. In hemodynamically stable patients, if it is safe to take the time needed to get ultrasonic guidance for needle aspiration or surgical drainage, then this should be done. Otherwise, in an emergency, blind needle drainage is necessary.

DECREASED VENOUS RETURN—HYPOVOLEMIC SHOCK

The pressure driving venous return to the right atrium is described as mean systemic pressure minus right atrial pressure, where the mean systemic pressure is determined by the vascular volume and by the unstressed volume and capacitance of the systemic vessels. Venous return to the heart when right atrial pressure is not elevated may be inadequate owing to decreased intravascular volume (hypovolemic shock), to decreased tone of the venous capacitance bed so that mean systemic pressure is low (e.g., drugs, neurogenic shock), and occasionally to increased resistance to venous return (e.g., obstruction of the inferior vena cava by abdominal compartment syndrome). In the presence of shock, decreased venous return is determined to be a contributor to shock by finding low left and right ventricular diastolic pressures, often in an appropriate clinical setting such as trauma or massive gastrointestinal hemorrhage.

HYPOVOLEMIC SHOCK

Hypovolemia is the most common cause of shock caused by decreased venous return and is illustrated in Fig. 21-3. Intravascular volume is decreased, so the venous capacitance bed is not filled, leading to a decreased pressure driving venous return back to the heart. This is seen as a left shift of the venous return curve in Fig. 21-3, lower panel, so that cardiac output decreases at a low end-diastolic pressure (intersection of the venous return curve and cardiac function curve). Endogenous catecholamines attempt to compensate by constricting the venous capacitance bed, thereby raising the pressure driving venous return back to the heart, so that 25% reductions in intravascular volume are nearly completely compensated for. Orthostatic decrease in blood pressure by 10 mm Hg or an increase in heart rate of more than 30 beats/min[34] may detect this level of intravascular volume reduction. When approximately 40% of the intravascular volume is lost, sympathetic stimulation can no longer maintain

mean systemic pressure, resulting in decreased venous return and clinical shock.

After sufficient time (>2 hours) and severity (>40% loss of intravascular volume), patients often cannot be resuscitated from hypovolemic shock.[35] This observation highlights the urgency with which patients should be resuscitated. A "no reflow" phenomenon is described in microvascular beds, gut ischemia with systemic release of inflammatory mediators,[36] and increased diastolic stiffness (see Fig. 21-3) contribute to the pathophysiology.[37]

Shock after trauma is a form of hypovolemic shock in which a significant systemic inflammatory response, in addition to intravascular volume depletion, is present. Intravascular volume may be decreased because of loss of blood and significant redistribution of intravascular volume to other compartments, i.e., "third spacing." Release of inflammatory mediators may result in pathophysiologic abnormalities resembling septic shock. Cardiac dysfunction may be depressed from direct damage from myocardial contusion, from increased diastolic stiffness, from right heart failure, or even from circulating myocardial depressant substances. Shock related to burns similarly is multifactorial with a significant component of intravascular hypovolemia and a systemic inflammatory response (see Chaps. 98 to 100).

Other causes of shock caused by decreased venous return include severe neurologic damage or drug ingestion resulting in hypotension caused by loss of venous tone. As a result of decreased venous tone, mean systemic pressure decreases, thereby reducing the pressure gradient driving blood flow back to the heart so that cardiac output and blood pressure decrease. Obstruction of veins owing to compression, thrombus formation, or tumor invasion increases the resistance to venous return and occasionally may result in shock.

The principal therapy of hypovolemic shock and other forms of shock caused by decreased venous return is rapid initial fluid resuscitation. Warmed crystalloid solutions are readily available. Colloid-containing solutions result in a more sustained increase in intravascular volume. However, in the setting of demonstrated or potential leaking endothelial surfaces (e.g., ARDS), the colloid rapidly redistributes into the entire extravascular water compartment. Pulmonary edema and tissue edema may be aggravated. Overall, no benefit of colloid over crystalloid has been convincingly demonstrated. The role of hypertonic saline and other resuscitation solutions is currently uncertain. Alternatively, transfusion of packed red blood cells increases oxygen-carrying capacity and expands the intravascular volume and is therefore a doubly useful therapy. In an emergency, initial transfusion often begins with type-specific blood before a complete cross-match is available. During initial resuscitation, the Early Goal-Directed Protocol suggests that achieving a hematocrit greater than 30% may be beneficial when Scv_{O_2} is less than 70%. However, after initial resuscitation, maintaining hemoglobin above 90 g/L does not appear to be better than maintaining hemoglobin above 70 g/L. After a large stored red blood cell transfusion, clotting factors, platelets, and serum ionized calcium decrease and therefore should be measured and replaced if necessary (see Chap. 68).

Recognizing inadequate venous return as the primary abnormality of hypovolemic shock alerts the physician to several commonly encountered and potentially lethal complications of therapy. Airway intubation and mechanical ventilation increase negative intrathoracic pressures to positive values and thus raise right atrial pressure. The already low pressure gradient driving venous return to the heart worsens, resulting in marked reduction in cardiac output and blood pressure. However, ventilation treats shock by reducing the work of respiratory muscle, so ventilation should be implemented early with adequate volume expansion. Sedatives and analgesics are often administered at the time of airway intubation, resulting in reduced venous tone because of a direct relaxing effect on the venous capacitance bed or because of a decrease in circulating catecholamines. Thus, the pressure gradient driving venous return decreases. Therefore, in the hypovolemic patient, these medications may markedly reduce cardiac output and blood pressure and should be used with caution and with ongoing volume expansion.

HIGH CARDIAC OUTPUT HYPOTENSION—SEPTIC SHOCK

Septic shock is the most common example of shock that may be caused primarily by reduced arterial vascular tone and reactivity, often associated with abnormal distribution of blood flow. Gram-negative bacilli account for half of all cases of sepsis and approximately 50% of these patients develop septic shock.[38] In contrast, shock accompanies only 5% to 10% of gram-positive or fungal bloodstream infections,[38] although candida infections are emerging as an important cause of attributable mortality.[39] Evidence of end-organ hypoperfusion and dysfunction may be present at low, normal, and high cardiac outputs and oxygen deliveries. During evaluation and resuscitation, normal or increased cardiac output with low SVR hypotension is manifested by a high pulse pressure, warm extremities, good nail bed capillary filling, and low diastolic and mean blood pressures. This high cardiac output hypotension is often accompanied by an abnormal temperature and white blood cell count and differential and an evident site of sepsis. However, the diagnosis is sometimes initially unclear when septic shock is combined with cardiogenic or hypovolemic shock, which limit the usual increase in cardiac output, oxygen delivery, and mixed-venous oxygen saturation.

Several pathophysiologic mechanisms contribute to inadequate organ system perfusion in septic shock. There may be abnormal distribution of blood flow at the organ system level, within individual organs, and even at the capillary bed level. The result is inadequate oxygen delivery in some tissue beds.

The cardiovascular abnormalities of septic shock (see Fig. 21-4) are extensive and include systolic and diastolic abnormalities of the heart, abnormal arterial tone, decreased venous tone, and abnormal distribution of capillary flow leading to regions of tissue hypoxia. In addition, there may be a cellular defect in metabolism so that even cells exposed to adequate oxygen delivery may not maintain normal aerobic metabolism. Depressed systolic contractility illustrated as a rightward shift of the end-systolic pressure-volume relation in Fig. 21-4, upper panel, occurs in septic shock[40] due to circulating proinflammatory cytokines and other mediators, nitric oxide production by activated endothelial cells and cardiomyocytes, and reactive oxygen intermediate generation by retained leukocytes and other cells.[41] Decreased systolic contractility associated with septic shock is reversible over 5 to 10 days as the patient recovers.[40] Systolic and diastolic

dysfunctions during sepsis that progress to the point that high cardiac output (hyperdynamic circulation) is no longer maintained (normal or low cardiac output is observed) are associated with poor outcome.[40]

Decreased arterial resistance is almost always observed in septic shock. Early in septic shock, a high cardiac output state exists with normal or low blood pressure. The low arterial resistance is associated with impaired arterial and precapillary autoregulation and may be due to increased endothelial nitric oxide production and opening of potassium adenosine triphosphate channels on vascular smooth muscle cells. Redistribution of blood flow to low-resistance, short time-constant vascular beds (such as skeletal muscle) results in decreased resistance to venous return, as illustrated in Fig. 21-4 (lower panel) by a steeper venous return curve. As a result, cardiac output may be increased even when cardiac function is decreased (see Fig. 21-4, lower panel) because of decreased contractility (see Fig. 21-4, upper panel). Hypovolemia, caused by redistribution of fluid out of the intravascular compartment and to decreased venous tone, impedes venous return during septic shock.

Early institution of appropriate antibiotic therapy and surgical drainage of abscesses or excision of devitalized and infected tissue is central to successful therapy. Activated protein C and low-dose steroids therapy in patients with inadequate adrenal responses to ACTH stimulation improve outcome. Many other anticytokine and anti-inflammatory therapies and inhibition of nitric oxide production have not been successful in improving outcome.

OTHER TYPES OF SHOCK

As detailed in Table 21-4, there are many less common etiologies of shock, and the diagnosis and management of several causes of high right atrial pressure hypotension are discussed elsewhere in this book (see Chaps. 22, 26, and 28). A few other types of hypovolemic shock merit early identification by their characteristic features and lack of response to volume resuscitation including neurogenic shock and adrenal insufficiency. Anaphylactic shock results from the effects of histamine and other mediators of anaphylaxis on the heart, circulation, and the peripheral tissues (see Chap. 106). Despite increased circulating catecholamines and the positive inotropic effect of cardiac H_2 receptors, histamine may depress systolic contractility via H_1 stimulation and other mediators of anaphylaxis. Marked arterial vasodilation results in hypotension even at normal or increased cardiac output. Like septic shock, blood flow is redistributed to short time-constant vascular beds. The endothelium becomes more permeable, so fluid may shift out of the vascular compartment into the extravascular and intracellular compartments, resulting in intravascular hypovolemia. Venous tone and therefore venous return are reduced, so the mainstay of therapy of anaphylactic shock is fluid resuscitation of the intravascular compartment and includes epinephrine and antihistamines as adjunctive therapy.[42]

Neurogenic shock is uncommon. In general, in a patient with neurologic damage that may be extensive, the cause of shock is usually associated with blood loss. Patients with neurogenic shock develop decreased vascular tone, particularly of the venous capacitance bed, which results in pooling of blood in the periphery. Therapy with fluid will increase mean systemic pressure. Catecholamine infusion also will increase mean systemic pressure, and stimulation of α receptors will increase arterial resistance, but these are rarely needed once circulation volume is repleted.

Several endocrinologic conditions may result in shock. Adrenal insufficiency (Addison disease, adrenal hemorrhage and infarction, Waterhouse-Friderichsen syndrome, adrenal insufficiency of sepsis, and systemic inflammation) or other disorders with inadequate catecholamine response may result in shock or may be important contributors to other forms of shock.[17] Whenever inadequate catecholamine response is suspected, diagnosis should be established by measuring serum cortisol and conducting an ACTH stimulation test, whereas presumptive therapy proceeds using dexamethasone (see Chap. 79). Hypothyroidism and hyperthyroidism may in extreme cases result in shock; thyroid storm is an emergency requiring urgent therapy with propylthiouracil or other antithyroid drug, steroids, propranolol, fluid resuscitation, and identification of the precipitating cause[43] (see Chap. 80). Pheochromocytoma may lead to shock by markedly increasing afterload and by redistributing intravascular volume into extravascular compartments.[44] In general, the therapeutic approach involves treating the underlying metabolic abnormality, resuscitating with fluid to produce an adequate cardiac output at the lowest adequate filling pressure, and infusing inotropic drugs, if necessary, to improve ventricular contractility if it is decreased. Details of diagnosis and therapy of shock associated with poisons (carbon monoxide, cyanide) are discussed in Chap. 102.

Organ System Pathophysiology of Shock

INFLAMMATORY COMPONENT OF SHOCK

Shock has a hemodynamic component that has been the focus of much of the preceding discussion. In addition, shock is invariably associated with some degree of inflammatory response, although this component of shock varies greatly. A severe systemic inflammatory response (e.g., sepsis) can result primarily in shock. Conversely, shock results in an inflammatory response because ischemia-reperfusion injury[45] will be triggered to some extent after successful hemodynamic resuscitation of shock of any kind. Ischemia-reperfusion causes release of proinflammatory mediators, chemotactic cytokines, and activation of endothelial cells and leukocytes. Because of the multiorgan system involvement of shock, the inflammatory response of ischemia-reperfusion involves many organ systems. Rapid hemodynamic correction of hypovolemic or cardiogenic shock may result in a minimal systemic inflammatory response. However, trauma with significant tissue injury or prolonged hypoperfusion states usually elicit marked systemic inflammatory responses. Because the resolution and repair phases of the inflammatory response are complex and take time, this component of shock is important to recognize and characterize clinically because it has prognostic value with profound effects on the subsequent clinical course.

A systemic inflammatory response results in elevated levels of circulating proinflammatory mediators (tumor necrosis alpha, interleukins, prostaglandins, etc.) that activate endothelial cells and leukocytes. Subsequent production of nitric oxide by activated vascular endothelial cells via inducible nitric oxide synthase results in substantial vasodilation. Products of the arachidonic acid pathway generated during

the systemic inflammatory response contribute to systemic vasodilation (prostaglandin I_2) and pulmonary hypertension (thromboxane A_2). Activated endothelial cells and leukocytes upregulate expression of cellular adhesion molecules and their corresponding ligands, resulting in accumulation of activated leukocytes in pulmonary and systemic capillaries and postcapillary venules. Expression of chemotactic cytokines by endothelial and parenchymal cells contributes to flow of activated leukocytes into the lungs and systemic tissues. Activated leukocytes release destructive oxygen free radicals, resulting in further microvascular and tissue damage. Damaged and edematous endothelial cells, retained leukocytes, and fibrin and platelet plugs associated with activation of the complement and coagulation cascades block capillary beds in a patchy manner, leading to increased heterogeneity of microvascular blood flow. As a result of the significant damage to the microvasculature, oxygen uptake by metabolizing tissues is further impaired.[46] A severe systemic inflammatory response leads to very high levels of circulating proinflammatory mediators, leukopenia, and thrombocytopenia owing to uptake in excess of production, disseminated intravascular coagulation owing to excessive activation of the coagulation cascades, diffuse capillary leak, marked vasodilation that may be quite unresponsive to high doses of vasopressors, and generalized organ system dysfunction.

Whereas the hemodynamic component of shock is often rapidly reversible, the resolution and repair phases of an inflammatory response follow a frustratingly slow time course: recruitment of adequate and appropriate leukocyte populations, walling off or control of the initial inciting stimuli, modulation of the subsequent inflammatory response toward clearance with apoptosis of inflammatory and damaged cells (T-helper 1 type of response), or, when the inflammatory stimulus is not as easily cleared, toward a more chronic response with recruitment of new populations of mononuclear leukocytes and fibrin and collagen deposition (T-helper 2 type of response). During this repair and resolution phase, current therapy involves vigilant supportive care of the patient to prevent and avoid the common multiple complications associated with multiple organ system dysfunction and mechanical ventilation.

INDIVIDUAL ORGAN SYSTEMS

Altered mental status, ranging from mild confusion to coma, is a frequently observed effect of shock on neurologic function, when brain blood flow decreases by approximately 50%.[47] Autoregulation of cerebral blood flow is maximal, and decreased neurologic function ensues, when MAP decreases to below 50 to 60 mm Hg in normal individuals. Elevated P_{CO2} transiently dilates and decreased P_{CO2} transiently constricts cerebral vessels. Profound hypoxia also results in markedly decreased cerebral vascular resistance. Patients recovering from shock infrequently suffer frank neurologic deficit unless they have concomitant cerebrovascular disease. However, subsequent subtle neurocognitive dysfunction is now increasingly recognized.

Systolic and diastolic myocardial dysfunction during shock have been discussed above. Myocardial oxygen extraction is impaired during sepsis and myocardial perfusion is redistributed away from the endocardium. This maldistribution is further aggravated by circulating catecholamines. Segmental and global myocardial dysfunction occur with ST and T-wave changes apparent on the electrocardiogram, and elevations in creatine kinase and troponin concentrations may be observed[48] in the absence of true myocardial infarction. In addition, the metabolic substrate for myocardial metabolism changes so that free fatty acids are no longer the prime substrate and more lactic acid and endogenous fuels are metabolized.

More than any other organ system, the lungs are involved in the inflammatory component of shock. ARDS is the acronym given to lung injury caused by the effect of the systemic inflammatory response on the lung and has aptly been called "shock lung." Inflammatory mediators and activated leukocytes in the venous effluent of any organ promptly affect the pulmonary capillary bed, leading to activation of pulmonary vascular endothelium and plugging of pulmonary capillaries with leukocytes. Ventilation perfusion matching is impaired and shunt increases. High tidal volume ventilation induces a further intrapulmonary inflammatory response and lung damage. Increased ventilation associated with shock results in increased work of breathing to the extent that a disproportionate amount of blood flow is diverted to fatiguing ventilatory muscles.

Early in shock, increased catecholamines, glucagon, and glucocorticoids increase hepatic gluconeogenesis leading to hyperglycemia. Later, when synthetic function fails, hypoglycemia occurs. Clearance of metabolites and immunologic function of the liver are also impaired during hypoperfusion. Typically, centrilobular hepatic necrosis leads to release of transaminases as the predominant biochemical evidence of hepatic damage, and bilirubin levels may be high. Shock may lead to gut ischemia before other organ systems become ischemic, even in the absence of mesenteric vascular disease. Mucosal edema, submucosal hemorrhage, and hemorrhagic necrosis of the gut may occur. Hypoperfusion of the gut has been proposed as a key link in the development of multisystem organ failure after shock, particularly when ARDS precedes sepsis[49]; that is, loss of gut barrier function results in entrance of enteric organisms and toxins into lymphatics and the portal circulation. Because the immunologic function of the liver is impaired, bacteria and their toxic products, particularly from portal venous blood, are not adequately cleared. These substances and inflammatory mediators produced by hepatic reticuloendothelial cells are released into the systemic circulation and may be an important initiating event of a diffuse systemic inflammatory process that leads to multisystem organ failure or to the high cardiac output hypotension of endotoxemia. Decreased hepatic function during shock impairs normal clearance of drugs such as narcotics and benzodiazepines, lactic acid, and other metabolites that may adversely affect cardiovascular function. In addition, pancreatic ischemic damage may result in the systemic release of a number of toxic substances including a myocardial depressant factor.

The glomerular filtration rate decreases as renal cortical blood flow is reduced by decreased arterial perfusion pressures and by afferent arteriolar vasoconstriction owing to increased sympathetic tone, catecholamines, and angiotensin. The ratio of renal cortical to medullary blood flow decreases. Renal hypoperfusion may lead to ischemic damage with acute tubular necrosis, and debris and surrounding tissue edema obstruct tubules. Loss of tubular function is compounded by

loss of concentrating ability because medullary hypertonicity decreases. Impaired renal function or renal failure leads to worsened metabolic acidosis, hyperkalemia, impaired clearance of drugs and other substances; all contribute to the poor outcome of patients in shock with renal failure.

Shock impairs reticuloendothelial system function, leading to impaired immunologic function. Coagulation abnormalities and thrombocytopenia are common hematologic effects of shock. Disseminated intravascular coagulation occurs in approximately 10% of patients with hypovolemic and septic shock. Shock combined with impaired hematopoietic and immunologic function seen with hematologic malignancies or after chemotherapy is nearly uniformly lethal. Endocrine disorders, from insufficient or ineffective insulin secretion to adrenal insufficiency, adversely affect cardiac and other organ system function. Conceivably, impaired parathyroid function is unable to maintain calcium homeostasis. As a result, ionized hypocalcemia is observed during lactic acidosis or its treatment with sodium bicarbonate infusion.[50]

SHOCK AND THERAPEUTIC INTERVENTIONS

Hypoperfusion alters the efficacy of drug therapy by slowing delivery of drugs, altering pharmacokinetics once delivered, and decreasing the clearance of drugs. For example, subcutaneous injection of medications may fail to deliver useful quantities of a drug in the setting of decreased perfusion. When adequate perfusion is re-established, the drug may be delivered in an unpredictable way at an inappropriate time. Thus, parenteral medications should be given intravenously to patients with evidence of hypoperfusion. In marked hypoperfusion states, peripheral intravenous infusion also may be ineffective, and central venous administration may be necessary to effectively deliver medications. Once the drug is delivered to its site of action, it may not have the same effect in the setting of shock. For example, catecholamines may be less effective in an acidotic or septic state. Because there may be significant renal and hepatic hypoperfusion, drug clearance is frequently greatly impaired. With these observations in mind, it is appropriate to consider, for each drug, necessary changes in route, dose, and interval of administration in shock patients.

Bicarbonate therapy of metabolic acidosis associated with shock may have adverse consequences.[50] Bicarbonate decreases ionized calcium levels further, with a potentially detrimental effect on myocardial contractility. Because bicarbonate and acid reversibly form carbon dioxide and water, a high P_{CO_2} is observed. Particularly during bolus infusion, acidotic blood containing bicarbonate may have a very high P_{CO_2}, which readily diffuses into cells, resulting in marked intracellular acidosis; recall that hypoperfusion increases tissue P_{CO_2} by carrying off the tissue CO_2 production at a higher mixed venous P_{CO_2} owing to reduced blood flow. Intracellular acidosis results in decreased myocardial contractility. These adverse consequences of bicarbonate therapy may account in part for the lack of benefit observed with bicarbonate therapy of metabolic acidosis.[50]

Outcome

Untreated, shock leads to death. Even with rapid, appropriate resuscitation, shock is associated with a high initial mortality rate, and tissue damage sustained during shock may lead to delayed sequelae. Several studies have identified important predictors. For cardiogenic shock, 85% of the predictive information is contained in age, systolic blood pressure, heart rate, and presenting Killip class.[3] A blood lactic acid level in excess of 5 mmol/L is associated with a 90% mortality rate in cardiogenic shock[51] and a high mortality rate in other shock states. These mortality rates have decreased during the past decade of interventional cardiology and aggressive antibiosis (see Chaps. 25 and 46). In septic shock, decreasing cardiac output predicts death, and high concentrations of bacteria in blood and a failure to mount a febrile response predict a poor outcome. Age and pre-existing illness are important determinants of outcome. Multisystem organ failure is an important adverse outcome, leading to a mortality rate in excess of 60%.

Chapter 22

VENTRICULAR DYSFUNCTION IN CRITICAL ILLNESS

KEITH R. WALLEY

KEY POINTS

- *Understanding cardiovascular dysfunction in a critically ill patient requires consideration of cardiac function and systemic vascular factors controlling venous return.*
- *Compression by surrounding structures (cardiac tamponade) and increased afterload must be considered as external causes or contributors to cardiac dysfunction.*
- *Decreased ventricular pump function may be due to decreased systolic contractility, increased diastolic stiffness, abnormal heart rate and rhythm, or valvular dysfunction.*
- *Management of ventricular dysfunction aims to reverse the cause by optimizing preload and afterload and correcting abnormalities in heart rhythm, valve function, and contractility.*
- *Acute reversible contributions to depressed contractility result from ischemia, hypoxemia, acidosis, ionized hypocalcemia and other electrolyte abnormalities, myocardial depressant factors, and hypo- and hyperthermia.*
- *Management of acute-on-chronic heart failure progressively includes oxygen; optimizing preload with diuretics, morphine, and nitrates or fluid infusion for hypovolemia; afterload reduction; increasing contractility using catecholamines or phosphodiesterase inhibitors; antiarrhythmic drugs and resynchronization using biventricular pacing; intraaortic balloon counterpulsation; and cardiac transplantation.*

This chapter reviews the etiology and management of circulatory disturbances arising in critically ill patients whose primary cause for ventricular dysfunction is more related to complications of other multisystem organ failures without diminishing the possibility that occult ischemic heart disease (see Chap. 25) might be unmasked by the stress imposed by multisystem organ failure or its diverse treatments. I emphasize how critical illness disturbs ventricular function and the systemic factors governing venous return and refer the reader to Chap. 25 for the detailed diagnosis and management of ischemic heart disease. To avoid redundancy, I refer liberally to other chapters in this book that discuss mechanisms for ventricular dysfunction in the context of other diseases (see Chaps. 20, 21, 26, 28, and 29).

Assessment of Cardiovascular Dysfunction

Cardiac pump function can be defined by the relation of the heart's output to its input.[1] Cardiac output is the most important output of the entire heart, and right atrial pressure (Pra) is an easily measured input of the entire heart. Cardiac output is initially assessed as high, adequate, or inadequate by cardiovascular examination and by clinical evaluation of perfusion. Later, after placement of a central venous catheter to allow measurement of central venous pressure (CVP) and central venous oxygen saturation, after placement of a pulmonary artery catheter, or after echocardiography, cardiac output can be more accurately quantitated. Pra is initially evaluated by clinical examination of distention of the jugular veins and later may be more accurately measured as the CVP. Other outputs, such as stroke work, and other inputs, such as pulmonary artery occlusion (or wedge) pressure (Ppw), serve to quantitate cardiac dysfunction and to determine the specific cause of cardiac dysfunction.

Depressed cardiac function may be due to left ventricular dysfunction, right ventricular dysfunction, external compression (cardiac tamponade), or excessively elevated right or left ventricular afterload. I focus on left ventricular and right ventricular dysfunction because cardiac tamponade is discussed in Chap. 28 and pulmonary embolism in Chap. 27. Yet in every case one should consider whether the pericardium and other structures surrounding the heart or right- and left-side afterloads are affecting cardiac function. The specific causes of ventricular dysfunction, right and left, are decreased contractility (a shift down and to the right of the end-systolic pressure-volume relation), increased diastolic stiffness (a shift up and to the left of the diastolic pressure-volume relation), a change in heart rhythm and rate, and abnormal valvular function. How can one determine the presence of depressed ventricular pump function, distinguish between right and left ventricular dysfunction, and then identify the specific cause?

THE CLINICAL EXAMINATION

Left ventricular dysfunction is characterized by high left ventricular filling pressures in relation to cardiac output. Likewise, right ventricular dysfunction is characterized by high right ventricular filling pressures in relation to cardiac output. Importantly, there is a close interaction between the left and right ventricles so that, most commonly, left and right ventricular dysfunction coexist. Initially, clinical examination attempts to identify the presence and severity of depressed cardiac pump function and to distinguish the contributions of right and left ventricular dysfunction. Evaluation of perfusion and mean blood pressure, pulse pressure, and heart rate provide a clinical estimate of whether or not cardiac output is decreased (see Table 21-1). Right ventricular filling pressure may be judged by distention of jugular veins. Evidence of dependent pulmonary crackles on physical examination due to heart failure suggests that left ventricular filling pressure is elevated, usually above 20 to 25 mm Hg. However, in chronic congestive heart failure, where pulmonary lymphatic drainage increases, crackles may not be present even at filling pressures as high as 30 mm Hg. Interstitial edema clearance lags decreases in left atrial pressure (Pla) by hours, so rapid decreases in Pla are not accurately reflected by pulmonary auscultation. An audible third heart sound suggests an elevated Pla in the presence of a dilated left ventricle.[2]

CENTRAL VENOUS AND RIGHT HEART CATHETERS

In severe ventricular dysfunction or in critical illness, where even mild ventricular dysfunction contributes significantly to severity of illness, more accurate measures of ventricular

function than can be determined by clinical examination are required to test and titrate therapy. Important tools in the intensive care unit (ICU) are central venous catheterization, pulmonary artery catheterization, and echocardiographic evaluation (see Chap. 13). Central venous catheterization allows measurement of right ventricular filling pressure (CVP) and central venous oxygen saturation, which can be used to estimate cardiac output by using the Fick equation. Pulmonary artery catheterization, using a thermistor-tipped catheter with a distal port at the tip and a proximal port 30 cm from the tip, can accurately determine cardiac output by using the thermodilution technique. Right ventricular filling pressure (CVP) can be measured with the proximal port. Left ventricular filling pressure may be estimated as the Ppw (with important limitations discussed in Chap. 13). Therefore, the separate contributions of right ventricular and left ventricular dysfunction can be distinguished. Right ventricular afterload can be measured as pulmonary artery pressure (Ppa) by using the distal port of the pulmonary artery catheter, and left ventricular afterload is reflected by measuring systemic arterial pressure. Uncritical use of a pulmonary artery catheter may be associated with no benefit or even an increased mortality rate.[3,4] Nonetheless, thoughtful use of a pulmonary artery catheter in the most severely ill may decrease mortality rate.[5]

INTEGRATING HEMODYNAMICS WITH IMAGING STUDIES

The distinction between decreased contractility and increased diastolic stiffness cannot be determined by right heart catheterization alone. Accordingly, techniques that image ventricular diastolic and systolic volumes contribute substantially to the information obtained from pulmonary artery catheterization. The presence of enlarged v waves on the Pra trace or on the Ppw trace indicates tricuspid and mitral regurgitation, respectively. However, the size of the v waves depends on a number of factors, including compliance of the atria and ventricles so that accurate assessment of valvular dysfunction using a pulmonary artery catheter alone is impossible. Thus, additional imaging techniques are required to assess valvular function.

The most readily available and useful imaging technique is echocardiography, which can be used to evaluate ventricular function and valvular function (see Chap. 29). An estimated ejection fraction smaller than 0.4 is generally an excellent indicator of decreased contractility in hemodynamically stable patients. However, ejection fraction and related fractional shortening measurements are sensitive to changes in preload and afterload.[6,7] In the hemodynamically unstable patient, ejection fraction must be interpreted in conjunction with hemodynamic measurements from systemic and pulmonary artery catheters. Alternatively, echocardiography can be used to estimate ventricular diastolic and systolic volumes and filling of surrounding venous structures. Two distinctions are evident: a small end-diastolic volume (EDV) when filling pressures are normal or high indicates that increased diastolic stiffness contributes to decreased ventricular pump function,[8] and a large end-systolic volume (ESV) when afterload is normal or low indicates that depressed contractility contributes to decreased ventricular pump function. Therefore, end-diastolic and end-systolic diameters should be determined separately and interpreted in the light of measured pressures and flows.

Doppler echocardiographic examination allows measurement of the pressure gradient across valves, which is proportional to four times velocity squared, because blood flow across valves is turbulent. For example, it is usually possible to estimate Ppa from the tricuspid regurgitation velocity and CVP. Valvular insufficiency is also identified using Doppler and color Doppler echocardiographic imaging of blood velocities. The major limitation of conventional transthoracic echocardiographic examinations is that critically ill patients frequently are on positive-pressure mechanical ventilation and have lung disease, so lung shadows obscure echocardiographic views, thus making accurate examination difficult. Transesophageal echocardiographic examination circumvents this problem and is therefore an important tool for evaluating ventricular pump function in critically ill patients.[9–11]

DEFINITION OF CARDIAC FUNCTION AND ITS RELATION TO VENOUS RETURN

The pump function curve of the entire heart is illustrated as the relation between cardiac output and Pra over a range of values (Fig. 22-1A). Sometimes this relation is called a *Starling function curve*, although this term has been applied historically to a pump function curve where stroke work is the output.[12] The relation between cardiac output and Pra importantly illustrates that increasing Pra is more effective in increasing cardiac output at low values than at high values of Pra.

Most physicians are aware that increased contractility improves cardiac and ventricular pump function by shifting the pump function curve upward and to the left so that, at the same filling pressure, an increased cardiac output is generated. It is equally important to realize that abnormalities in diastolic stiffness, afterload, valve function, and heart rate can shift this relation, and these factors are often more important than changes in systolic function in modulating ventricular dysfunction encountered in the noncoronary care ICU.

CONTROL OF VENTRICULAR PUMPING FUNCTION

The ventricular pump function curve can be altered by changes in contractility, preload, afterload, heart rate and rhythm, and valvular function. Consider the pressure-volume relation of the left ventricle shown in Fig. 22-2. All end-systolic pressure-volume points lie along a line, the end-systolic pressure-volume relation (ESPVR). All ejections from different diastolic volumes end on the ESPVR.[13] The ESPVR shifts to the left when contractility increases, resulting in increased ejection at any given afterload; conversely, a shift to the right of the ESPVR indicates decreased contractility. Because of these characteristics, the ESPVR is a good index of ventricular contractility independent of changes in preload and afterload; because this slope is maximal at end systole and has the units of elastance ($E = \Delta P/\Delta V$), it has been denoted E_{max} or E_{es}.[13]

This pressure-volume representation of ventricular function is related to the ventricular pump function curve in a straightforward manner (Fig. 22-3). If the diastolic pressure-volume relation is constant, afterload is constant and if heart rate is constant, an increase in contractility decreases ESV and results in an increased stroke volume and cardiac output at the same filling pressure. Accordingly, an increase in

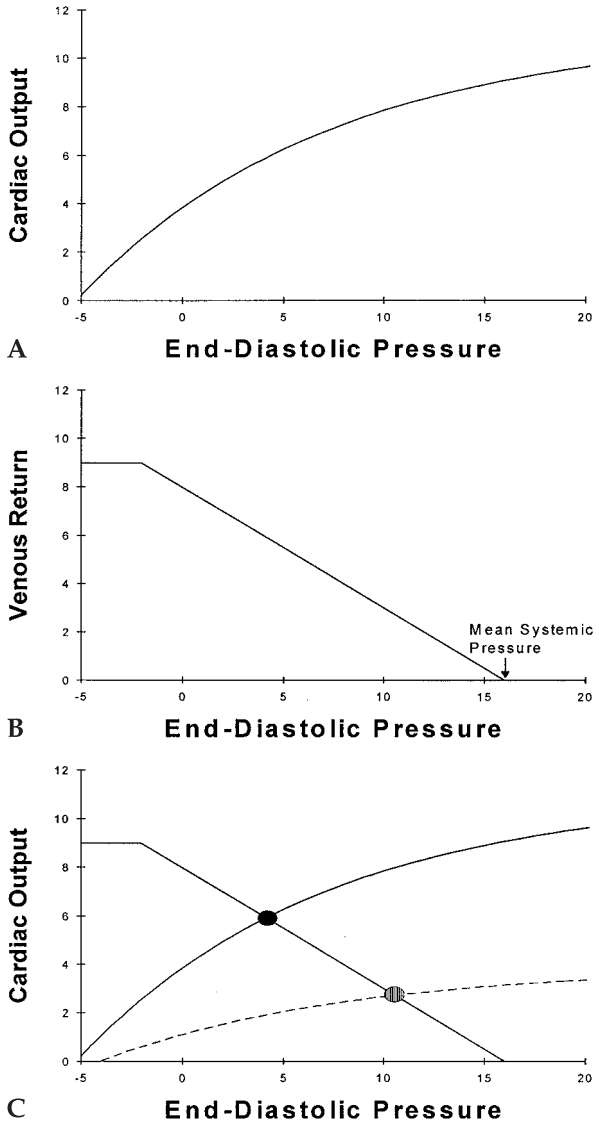

FIGURE 22-1 ***A*****. The cardiac function curve relates right atrial pressure (Pra) or end-diastolic pressure (EDP;** ***abscissa*****) to cardiac output (***ordinate***). As EDP increases, cardiac output increases; however, at high EDPs, further increases cause less increase in cardiac output.** ***B*****. The relation between EDP (Pra,** ***abscissa*****) and venous return (***ordinate***) is illustrated. When EDP equals mean systemic pressure (Pms), there is no pressure gradient (Pms-Pra) driving the blood flow back to the heart, so venous return is zero. As EDP (Pra) decreases, the gradient from the veins to the heart to drive blood flow back to the heart increases, so venous return increases. At very low EDPs (Pra 0 mm Hg), central veins collapse and act as Starling resistors, so further decreases in EDP do not increase venous return.** ***C*****. The cardiac function curve and the venous return curve are drawn on the same axes (***continuous lines***). The intersection of the cardiac function curve and the venous return curve defines the operating point of the circulation, here at an EDP (Pra) of approximately 5 mm Hg and a cardiac output of approximately 5 L/min. The interrupted cardiac function curve illustrates decreased cardiac function, causing decreased cardiac output (~3 L/min) at a higher EDP (Pra = 10 mm Hg).**

ventricular contractility results in a leftward and upward shift of the ventricular pump function curve. An increase in contractility from a normal steep ESPVR does not decrease ESV much and therefore does not improve the ventricular pump function much (Fig. 22-4). This explains why increased contractility is only a minor contributor to regulation of ventricular function in normal human beings. In contrast, when ventricular contractility is decreased, as indicated by a decrease in slope of the ESPVR, an increase in contractility significantly decreases ESV to improve ventricular pump function (see Fig. 22-4), thereby explaining why positive inotropic agents are useful in acute treatment of dilated cardiomyopathies.

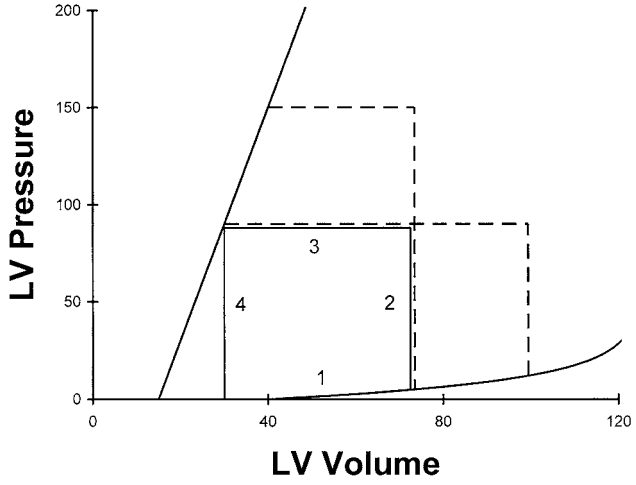

FIGURE 22-2 Left ventricular pressure-volume relations. The continuous thick lines represent a single cardiac cycle as a pressure-volume loop. During diastole, the ventricle fills along a diastolic pressure-volume relation (1). At the onset of systole, left ventricular pressure rises with no change in volume (2). When left ventricular pressure exceeds aortic pressure, the aortic valve opens, and the left ventricle ejects blood (3) to an end-systolic pressure-volume point. The ventricle then relaxes isovolumically (4). At a higher-pressure afterload, the left ventricle is not able to eject as far (*short interrupted lines*). Conversely, at a lower afterload, the left ventricle is able to eject farther, so that all end-systolic points lie along and define the end-systolic pressure-volume relation (ESPVR or E_{max}, *sloped solid line*). Increased diastolic filling (*long interrupted lines*) results in increased stroke volume from the larger end-diastolic volume to an endsystolic volume that lies on the same ESPVR; accordingly, increased afterload reduces stroke volume unless preload increases to compensate.

A decrease in pressure afterload will result in a decrease in ESV, so stroke volume and cardiac output increase when contractility, the diastolic pressure-volume relation, and heart rate are constant.[13] Thus, decreased afterload also improves ventricular pump function by shifting the function curve up and to the left. Analogous to the effects of changing contractility, normal hearts with steep ESPVRs do not eject substantially further with a decrease in afterload because ESV does not decrease much (Fig. 22-5). This explains the observation that decreasing afterload in normal patients does not substantially increase cardiac function and output but leads to hypotension. However, in patients with depressed contractility, as signaled by a decreased slope of the ESPVR, a small decrease in afterload causes greater ejection to a smaller ESV so that stroke volume and cardiac output are substantially increased at the same ventricular filling pressure (see Fig. 22-5). Therefore, in patients with depressed systolic contractility, afterload reduction is an effective means for improving ventricular pump function.[14,15]

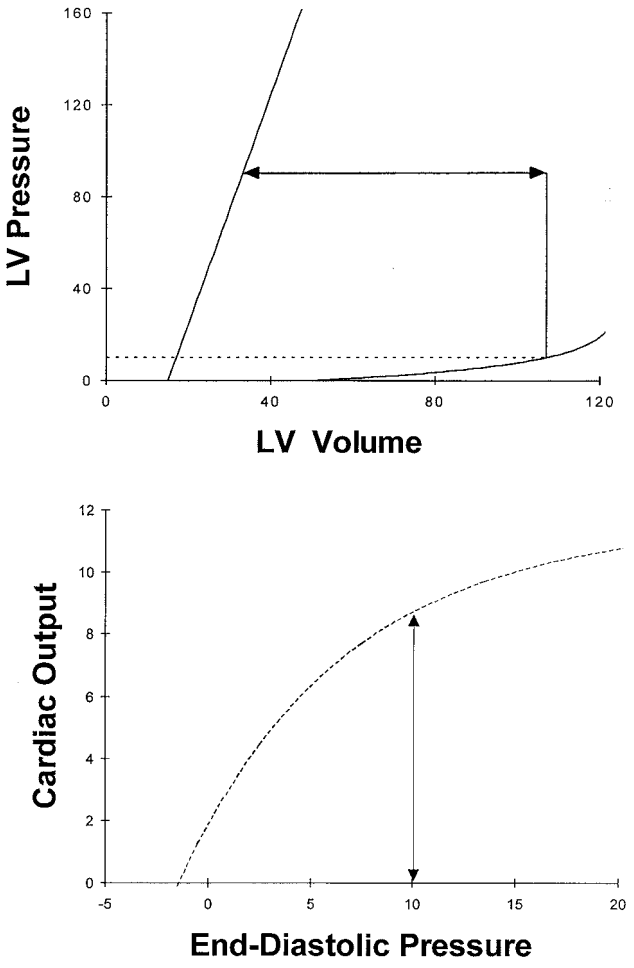

FIGURE 22-3 The cardiac function curve (*bottom*) is related to the left ventricular pressure-volume relations (*top*). *Top*. Stroke volume (*double-headed arrow*) is the difference between end-systolic volume (ESV) and end-diastolic volume (EDV). EDV at end-diastolic pressure (EDP = 10 mm Hg) is illustrated on the diastolic pressure-volume relation; ESV is determined by the end-systolic pressure (ESP) and the end-systolic pressure-volume relation (ESPVR or E_{max}). Therefore, for any EDP, cardiac output can be calculated if heart rate is known. *Bottom.* An increase in EDP increases EDV and cardiac output. At an EDP of 510 mm Hg, an increase in contractility would result in an increased stroke volume because the ESPVR shifts to the left; therefore, cardiac output increases at the same EDP and the cardiac function curve shifts up.

Increased stiffness of the diastolic pressure-volume relation reduces stroke volume because EDV is decreased at the same ventricular filling pressure independent of contractile state, afterload, and heart rate (Fig. 22-6). Therefore, an increase in stiffness of the diastolic left ventricle leads to a rightward and downward shift of the ventricular pump function curve.[16] This may be erroneously interpreted as decreased ventricular contractility when, in this case, depressed ventricular function is completely accounted for by increased ventricular diastolic stiffness. An increase in heart rate also may shift the ventricular pump function curve to the left and upward. However, when heart rate increases, stroke volume often decreases because there is less time for the ventricle to fill during diastole, so EDV decreases. Ultimately, when there is no other change in the factors driving venous return, heart rate increases cardiac output only slightly at heart rates slower than 100 beats/min and has essentially no effect on cardiac output at faster heart rates.[17] At very fast heart rates exceeding 150 beats/min, diastolic filling becomes markedly impaired, and cardiac output decreases as heart rate quickens further. When control of heart rate is abnormal due to abnormal pacemaker function or abnormal cardiac rhythm, inappropriately slow heart rates become important and can limit cardiac output. For example, if a patient is hypotensive and critically ill to the extent that heart rate is expected to be 100 beats/min but the patient is able to generate a heart rate of only 50 beats/min, then artificially increasing heart rate will substantially improve cardiac output.

CONTROL OF VENOUS RETURN BY THE SYSTEMIC VESSELS

Cardiac function is tightly coupled to venous return, and many patients with presumed cardiac dysfunction instead have abnormalities of the factors driving venous return.[18] Pra and cardiac output define the cardiac function curve and define the venous return relation.[19] Figure 22-1B shows that, as Pra is decreased, venous return increases, because the pressure driving venous return back to the heart, mean systemic pressure (Pms) minus Pra, increases. The factors that determine venous return are Pms, Pra, and resistance to venous return (RVR).

$$\text{Venous return (VR)} = \frac{\text{Pms} - \text{Pra}}{\text{RVR}}$$

In steady state, the cardiac function curve and the venous return curve are necessarily coupled because cardiac output must equal venous return. Thus the operating point of the heart is not defined by the cardiac function curve or by the venous return curve but by the intersection of these two curves (see Fig. 22-1C). Accordingly, patients with cardiovascular dysfunction having abnormal values of heart rate, Pra, aortic pressure, and cardiac output may have cardiac dysfunction that accounts for these abnormalities or may have abnormalities of venous return. It follows that, in every patient with suspected abnormal cardiovascular function, one should consider cardiac function and venous return in attempting to understand the abnormality.[18,20]

In health, cardiac output is controlled by mechanical properties of the systemic vessels adjusted by neurohumoral reflexes; when output and blood pressure decrease, baroreceptor reflexes act to increase flow by raising Pms by sympathetic nervous and humoral output. The importance of factors driving venous return is evident during exercise or even during the act of standing up. Without increased venous tone (as can occur with some spinal cord injuries) or increased muscle activity aided by venous valves, cardiac output and therefore blood pressure decrease precipitously in changing from a recumbent to an upright position. As an extension of normal physiology, in critically ill patients without a previous history of cardiac dysfunction, the major factor limiting cardiac output is often limited venous return. Only in patients with marked ventricular dysfunction is cardiac output limited by decreased pump function. Knowing this avoids incorrect diagnosis and treatment. For example, positive inotropic drugs (dopamine and epinephrine) increase cardiac output even in

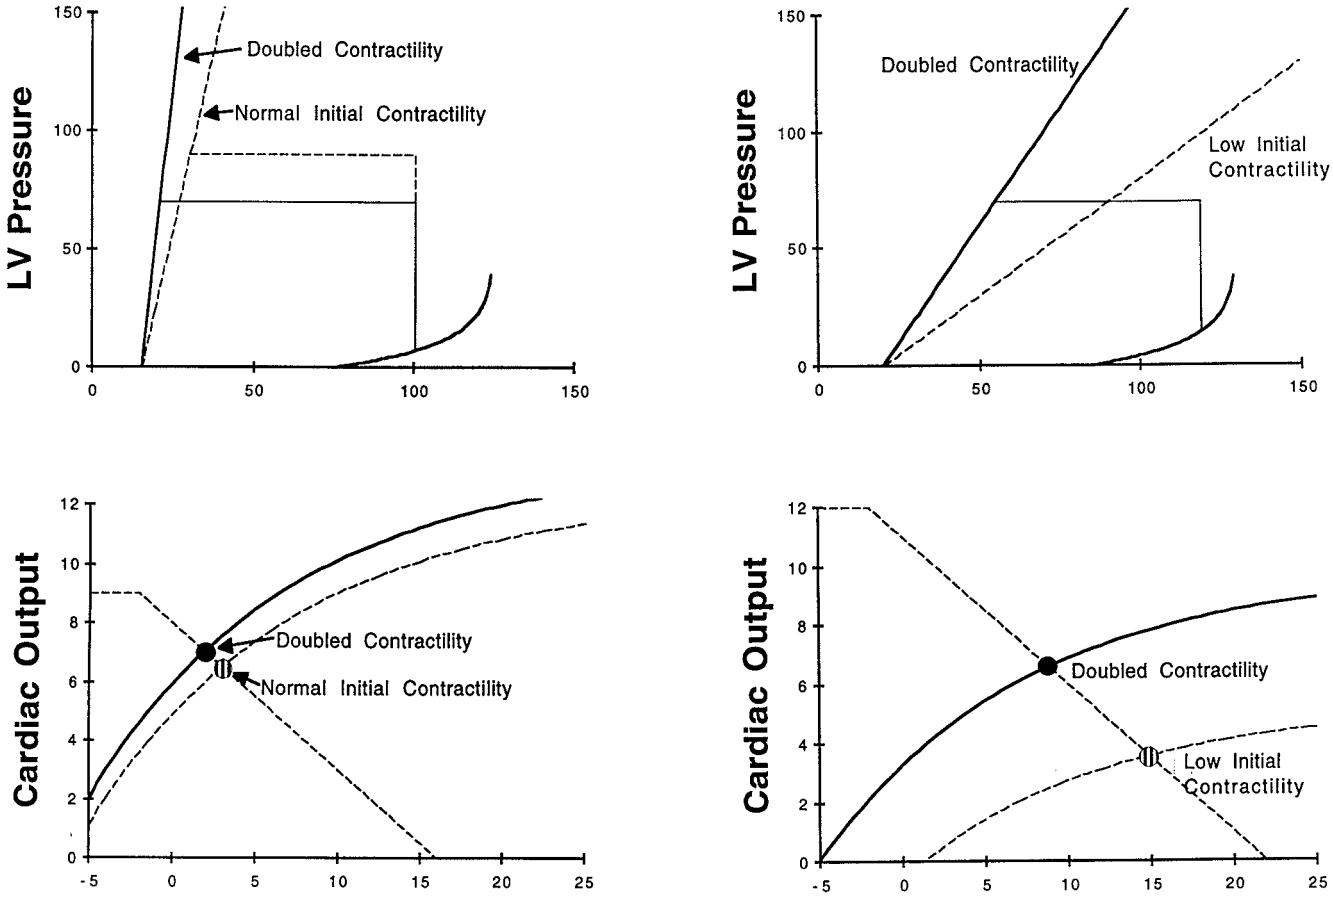

FIGURE 22-4 The *bottom two panels* show cardiac function curves derived (see Fig. 22-3 for derivation) from the pressure-volume relations illustrated in the *top panels*. The *left-hand panels* show that, when contractility is initially normal, then greatly increasing it does not improve cardiac function very much (*dashed and solid cardiac function curves* in the *lower left-hand panel* are similar). Flogging a normal heart with inotropic agents is ineffective, although vasoactive agents with effects on the venous circulation can increase venous return without correcting underlying pathophysiology. Conversely, the *right-hand panels* show that, when contractility is initially low, then inotropic agents substantially improve cardiac function (from the *dashed cardiac function curve to the solid cardiac function curve* in the *lower right-hand panel*). For the same venous return curve (*dashed biphasic line* in the *lower right-hand panel*), cardiac output increases at a lower left ventricular end-diastolic pressure (*black dot* versus *striped dot* in *lower right-hand panel*).

patients with no ventricular dysfunction by increasing venous return due to increased Pms and decreased resistance to venous return (by redistributing blood flow to vascular beds with short transit times). This improvement in cardiovascular function is often attributed to improved cardiac function. Yet this interpretation is often incorrect and may delay therapy aimed at correcting factors governing venous return, such as plasma volume expansion, whereas the vasoactive drugs ineffectively flog the empty heart.

In summary, a complete evaluation of the contribution of ventricular dysfunction to cardiovascular performance in critical illness acknowledges that cardiac output and ventricular filling pressures depend as much on factors driving venous return as on cardiac function. Most critically ill patients without a history of cardiac disease have abnormalities of venous return in excess of abnormalities of cardiac function. Accordingly, cardiac output is limited by the heart only in patients with marked ventricular dysfunction, and the ventricular pump function curve is dependent not only on contractility but also on afterload, the diastolic ventricular pressure-volume relation, and heart rate.

Mechanisms and Management of Left Ventricular Dysfunction

This section addresses the diverse acute and chronic etiologies of left ventricular dysfunction and concludes with principles of management for each.

DECREASED LEFT VENTRICULAR SYSTOLIC FUNCTION

CHRONIC CAUSES

Dilated cardiomyopathies are the best-known chronic causes of decreased left ventricular contractility.[21] Dilated cardiomyopathy is often idiopathic with evidence that genetic, viral, and immune factors contribute. Dilated cardiomyopathy may also be associated with coronary artery disease, presumably due to previous ischemic events and subsequent adverse remodeling and apoptosis of cardiomyocytes leading to a dilated, poorly functional left ventricle.[22] Alcoholic cardiomyopathy is an important cause of chronic dilated ventricular

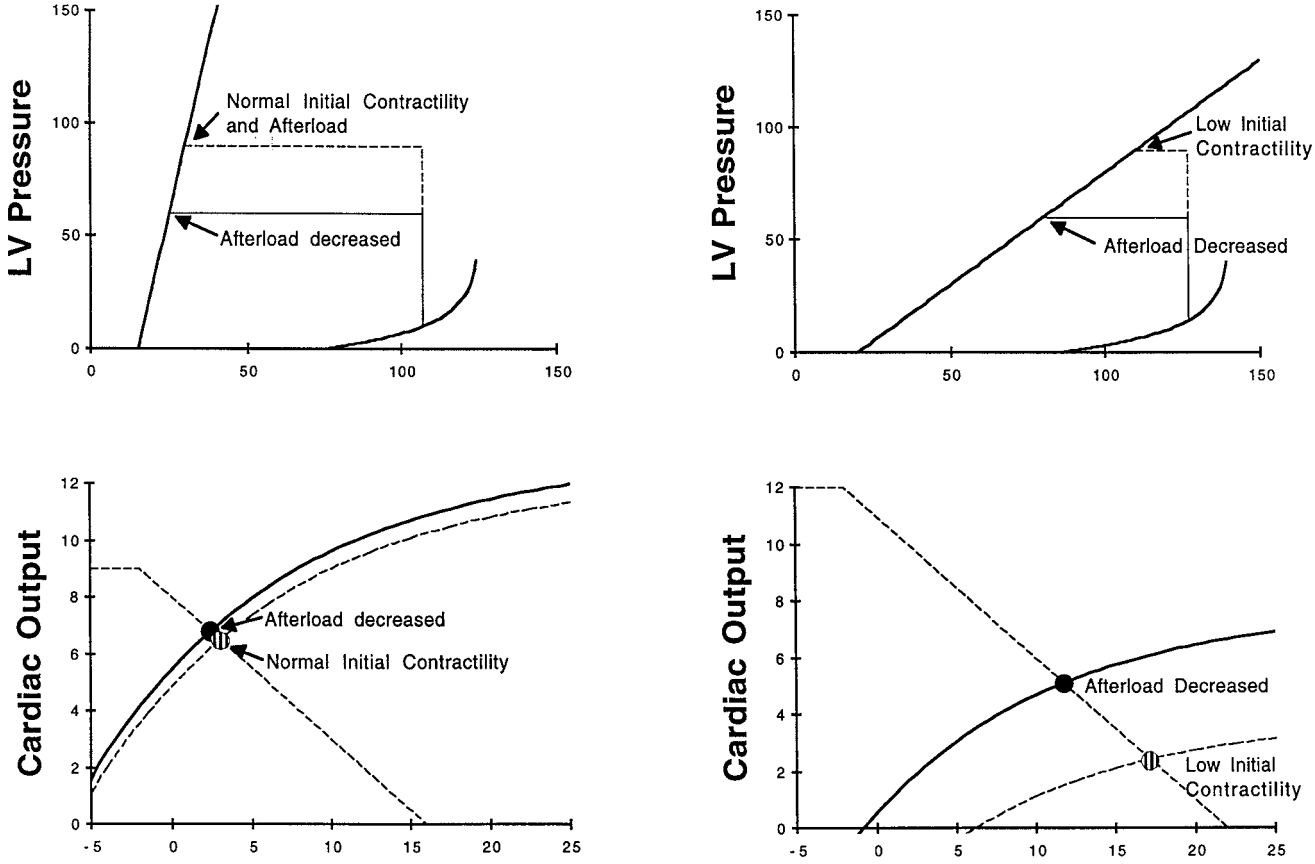

FIGURE 22-5 The *bottom two panels* show cardiac function curves derived (see Fig. 22-3 for derivation) from the pressure-volume relations illustrated in the *top panels*. The *left-hand panels* show that, when contractility is initially normal, then afterload reduction does not improve cardiac output or cardiac function (*dashed and solid cardiac function curves* in the *lower left-hand panel* are similar) and serves only to produce hypotension. Conversely, the *right-hand panels* show that, when contractility is initially reduced (*dashed cardiac function curve* in the *lower right-hand panel*), then afterload reduction substanially improves cardiac function (*solid cardiac function curve* in the *lower right-hand panel*). For the same venous return curve (*dashed biphasic line* in the *lower right-hand panel*), cardiac output increases at a lower left ventricular end-diastolic pressure (*black dot* versus *striped dot* in the *lower right-hand panel*).

dysfunction to be considered in critically ill patients.[21] Particularly in younger patients, inflammatory cardiomyopathy (myocarditis), usually viral, is an important cause of acute dilated cardiomyopathy that may lead to a chronic dilated cardiomyopathy in 10% of cases. Evidence of familial occurrence of similar disease is common, suggesting a genetic contribution in up to 25% of cases.[21,23] Rare causes such as the glycogen storage diseases also may be found in young patients. Multiple, less common causes may be encountered (Table 22-1).

These multiple, different etiologies of dilated cardiomyopathy lead to decreased ventricular contractility in a number of ways. Loss of myocardium with degradation of the normal collagen architecture by matrix metalloproteinases and replacement with fibrous connective tissue leads to remodeling and decreased contractility.[24] Increased levels of circulating renin, angiotensin II, endothelin, and norepinephrine promote cardiomyocyte hypertrophy, apoptosis, myocardial fibrosis, and vascular cell hypertrophy. Myocardial norepinephrine stores are depleted and β-receptor density is reduced in chronic dilated cardiomyopathy.[24,25] Biochemical changes that may contribute to decreased contractility include decreased efficiency of the sarcoplasmic reticulum calcium pump, decreased actin-myosin adenosine triphosphatase activity, and change in myosin isoenzyme composition.

ACUTE CAUSES

In the ICU, acute causes of decreased left ventricular contractility are important because the acute causes are potentially reversible (Table 22-2). Acute causes of depressed left ventricular contractility include ischemia, hypoxemia, respiratory acidosis, metabolic acidosis, ionized hypocalcemia, hypo- and hyperthermia, exogenous toxins such as alcohol and drugs, endogenous toxins such as circulating depressant factors of sepsis, inflammatory cytokines, and increased nitric oxide (NO) production.

Myocardial Ischemia

Transient ischemic episodes occur frequently in critically ill patients. The onset of ischemia is due to myocardial oxygen demand exceeding the ability of the myocardium to extract oxygen from the oxygen supply (coronary blood flow multiplied by arterial oxygen content). Myocardial oxygen demand is increased by increasing heart rate, contractility, afterload, preload, and the basal metabolic rate of the myocardium (which increases with increased sympathetic

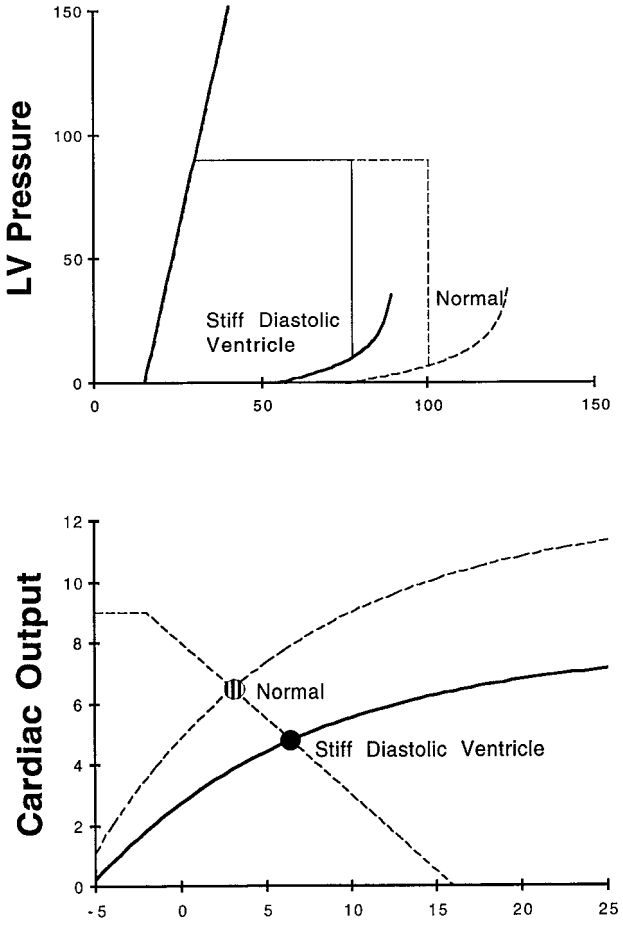

FIGURE 22-6 The *bottom panel* shows a cardiac function curve derived (see Fig. 22-3 for derivation) from the pressure-volume relations illustrated in the *top panel*. An increase in diastolic stiffness results in a decrease in end-diastolic volume (EDV) and in stroke volume at the same EDP, end-systolic pressure, and end-systolic pressure-volume relation, so increased diastolic stiffness shifts the cardiac function curve down and to the right (*dashed cardiac function curve* to the *solid cardiac function curve* in the *bottom panel*).

tone and catecholamines).[26] Many of the underlying illnesses encountered in the critically ill and many of the therapies, including fluid and inotropic or vasoactive drug infusion, contribute to markedly increased oxygen demand. Because of the prevalence of coronary artery disease in older patient populations, ischemia in the ICU is frequently regional with associated wall motion abnormalities. Accordingly, a high index of suspicion and an early aggressive diagnostic approach are indicated and facilitate the early treatment of ischemic coronary artery disease, as discussed in more detail in Chap. 25.

TABLE 22-1 Chronic Causes of Decreased Contractility (Dilated Cardiomyopathies)

Coronary artery disease
Idiopathic
Inflammatory (viral, toxoplasmosis, Chagas disease)
Alcoholic
Infection with the human immunodeficiency virus
Postpartum
Uremic
Diabetic
Nutritional deficiency (selenium deficiency)
Metabolic disorder (Fabry disease, Gaucher disease)
Toxic (Adriamycin, cobalt)

TABLE 22-2 Acute Reversible Contributors to Decreased Contractility

Ischemia
Hypoxia
Respiratory acidosis
Metabolic acidosis
Hypocalcemia
Hypophosphatemia
Possibly other electrolyte abnormalities (Mg^{2+}, K^+)
Exogenous substances (alcohol, β blockers, calcium channel blockers, antiarrhythmics)
Endogenous substances (endotoxin, histamine, tumor necrosis factor, interleukin 1, platelet-activating factor)
Hypo- and hyperthermia

Myocardial Hypoxia

In the absence of coronary artery disease, critically ill patients with sepsis also may manifest global heterogeneous left ventricular hypoxia with increased creatine kinase MB and troponin levels. The heart consumes less lactic acid and may produce lactic acid.[27] If inadequate oxygen delivery in relation to demand is not corrected quickly, then the heart may enter a detrimental positive-feedback loop of decreasing contractility, decreasing cardiac output and coronary perfusion, and, hence, decreasing contractility leading to precipitous cardiac arrest.[28] In the canine model, this vicious cycle occurred when arterial O_2 saturation decreased below 75% (arterial partial pressure of $O_2 = 40$ mm Hg) when hemoglobin concentration was 14 g/dL. Accordingly, aggressive measures to prevent this level of hypoxemia by keeping arterial O_2 saturation above 85% to 90% are indicated; maintaining a reasonable hematocrit in hypoxic critically ill patients with risks for myocardial ischemia is part of this therapy.

Myocardial Acidosis

Respiratory acidosis results in myocardial intracellular acidosis, and intracellular acidosis decreases the effect of intracellular calcium on the contractile proteins so that contractility is decreased.[29] In critically ill patients, respiratory acidosis may significantly contribute to depressed contractility and reduced cardiac output at partial pressure of CO_2 (P_{CO_2}) levels of 60 mm Hg and certainly by P_{CO_2} levels of 90 mm Hg.[30] Whether long-term elevations in P_{CO_2} have the same myocardial depressant effect is uncertain because intracellular pH will normalize, despite high P_{CO_2}, over time. These considerations may be particularly important in patients in whom the clinician actually seeks a high P_{CO_2} during mechanical ventilation (permissive hypercapnia) to minimize ventilator-associated lung injury (see Chaps. 37, 38, and 40).

Metabolic acidosis also may decrease left ventricular contractility, but its effects are less marked. Arterial blood gas measurement identifies metabolic acidosis in the extracellular compartment. The intracellular compartment is affected to the extent that the metabolic acid anion permeates the cell. Common organic acids such as lactic acid and ketoacids have

anions that do not easily cross into the intracellular compartment, so a severe metabolic acidosis may not be associated with significant intracellular acidosis and therefore may not depress ventricular contractility much. For example, lactic acidosis at a normal P_{CO_2} begins to depress contractility at pH 7.1 to 7.2, but even at a pH of 7.0 the depression in contractility remains quite small.[31]

Ionized Hypocalcemia

During septic shock and in patients critically ill from diverse causes, serum ionized calcium levels are often low.[32] Further acute reductions may result in a substantial decrease in left ventricular contractility. Decreased extracellular ionized calcium concentration results in decreased calcium flux during systole and decreased contractility.[33] After transfusion of red blood cells stored in standard citrated media, serum ionized calcium levels can decrease dramatically because calcium is bound by citric acid. During shock and other conditions, lactic acid, like citric acid, also appears to bind ionized calcium.[34] Bicarbonate infusion also can rapidly decrease ionized calcium levels and, as a result, may depress ventricular contractility.[35] In addition to ionized hypocalcemia, other electrolyte abnormalities, including hypophosphatemia, hypomagnesemia, and hypokalemia or hyperkalemia, may contribute to decreased contractility or, more importantly, to arrhythmias.

Side Effects of Common Drugs

Exogenous toxins may result in acutely depressed myocardial contractility. Ethanol is a commonly encountered substance that acutely depresses contractility. Drugs commonly used in the ICU that significantly depress contractility include β blockers, calcium channel blockers, and antiarrhythmics such as disopyramide and procainamide.

Septic Shock and Systemic Inflammatory Responses

Many inflammatory pathways triggered by bacterial endotoxins and sepsis have been suggested to contribute to myocardial dysfunction of sepsis. A number of proinflammatory cytokines, including tumor necrosis factor α (TNF), interleukin (IL)–1, IL-2, and IL-6, decrease myocardial contractility in humans and in animal models of sepsis.[36,37] Proinflammatory cytokines trigger increased NO production. NO is normally an important regulator of beat-to-beat contractility and, in the setting of enhanced NO production, becomes an important myocardial depressant factor.[37] Reactive oxygen intermediates released by leukocytes and cardiomyocytes contribute directly, and by formation of peroxy nitrite radicals, to myocardial damage and dysfunction. Coronary capillary endothelial activation, damage, and dysfunction also contribute, in part due to impaired regulation of coronary microvascular blood flow, which impairs myocardial oxygen extraction.[38] Thus, multiple pathways of the intramyocardial inflammatory response may contribute to myocardial dysfunction of systemic inflammation and sepsis.

During hyperdynamic sepsis, the etiology of the hypoperfusion state likely resides in the septic paralysis of arteriolar (and in part venular) smooth muscle, with a minor contribution from decreased contractility, because cardiac output is maintained or elevated. However, the late decrease in cardiac output leading to death involves significant decreases in systolic contractility and increases in diastolic stiffness.

During anaphylactic shock, histamine depresses left ventricular contractility in human beings,[39] although the primary cause of hypoperfusion is hypovolemia (see Chap. 106). Hyperthermia and hypothermia may decrease myocardial contractility and contribute to depressed left ventricular function observed during sepsis and other critical illnesses associated with marked abnormalities of body temperature (see Chaps. 110 and 111).

MANAGEMENT OF DECREASED LEFT VENTRICULAR CONTRACTILITY IN CRITICAL ILLNESS

Identify and Correct Acute Reversible Causes

It is important to identify the multiple, different potentially reversible causes for depressed contractility in critically ill patients because, although alone they may be insufficient to account for the left ventricular dysfunction, together they may significantly depress function. For example, if ischemia or hypoxemia is present, aggressive attempts to correct it should be instituted. In the presence of coronary artery disease, standard care including heparin, antiplatelet therapy (when indicated), β blockade, and coronary vasodilation using nitrates may be helpful. Thrombolytic therapy within 4 to 6 hours of acute coronary thrombosis or emergency angioplasty decreases the incidence of congestive heart failure and improves outcome (see Chap. 25). Correction of hypoxemia and anemia may result in substantial improvement in ventricular function. Attention should be paid to decreasing factors that increase myocardial oxygen demand. Therefore, when β blockade is not feasible, choosing the lowest level of inotropic and vasoactive drugs that produces the desired therapeutic effect will minimize their contribution to myocardial oxygen demand. Likewise, alleviating pain is important to diminish the associated tachycardia and increased sympathetic tone.

In ventilated patients with left ventricular dysfunction, the detrimental effects of acute respiratory acidosis should be considered; mixed venous and, hence, tissue P_{CO_2} is much higher than the arterial partial pressure of CO_2 when the cardiac output is low. In general, metabolic acidosis should be treated by reversing its etiology. Alkali therapy for increased anion gap metabolic acidosis is of no benefit and may be dangerous even at pH values as low as 7.0 for a number of reasons.[35] Bicarbonate infusion results in an increase in P_{CO_2} due to chemical equilibrium of HCO_3^- with H_2O and CO_2 unless compensatory hyperventilation is also instituted. Particularly during rapid bolus injection, local P_{CO_2} may climb to extremely high values so that myocardial intracellular acidosis transiently may be severe, leading to decreased ventricular contractility.[30] Bicarbonate therapy is associated with an increase in lactic acid production because bicarbonate increases the rate-limiting step of glycolysis. Bicarbonate therapy also decreases blood levels of ionized calcium.[34,35]

Decreased contractility due to ionized hypocalcemia can be corrected with an intravenous infusion of calcium. After approximately 6 U of transfusion, ionized hypocalcemia should be measured and corrected, if necessary. Hypophosphatemia, hypomagnesemia, hypokalemia, hyperkalemia, and other metabolic disturbances also should be corrected because they may lead directly or indirectly to altered cardiovascular function.

Treatment of myocardial depression due to circulating myocardial depressant factors has been attempted with antibodies to endotoxin and TNF, naloxone, and dialysis, but these

TABLE 22-3 Effect of Direct-Acting Vasodilators

Drug	Route of Administration	Dosage	Onset of Effect	Duration of Effect	Large Arteries	Arterioles	Veins
Sodium nitroprusside (Nipride)	Intravenous	25–400μg/min	Immediate	—	+	+++	+++
Nitroglycerin (Tridil)	Intravenous	10–200μg/min	Immediate	—	++	+	+++
Isosorbide dinitrate (Isordil; Sorbitrate, Isobid; Isotrate; Sorate, Sorbide; Dilatrate)	Oral	20–60 mg	30 min	4–6 h	++	+	+++

investigational treatments have not led to improved clinical outcomes. Inhibitors of circulating inflammatory mediators appear to be beneficial in severe sepsis but are limited in less severe sepsis,[40] possibly because circulating factors (endotoxin, TNF, and IL-1) are present for only limited periods early in the course of sepsis. Naloxone administered over short periods is not consistently effective, but longer-duration infusions of 1 or more days may result in improvement of hemodynamic measurements. Dialysis, hemofiltration, and plasmapheresis have not been tested adequately in human septic shock, but preclinical evidence suggests that depressed left ventricular contractility due to a myocardial depressant factor of sepsis can be reversed with these treatments.[41]

Managing the Depressed Heart

Having reversed the acute contributors to depressed left ventricular contractility, standard therapy of decreased left ventricular contractility includes optimizing ventricular filling pressure, decreasing afterload using angiotensin-converting enzyme inhibitors or alternatives when arterial pressure is adequate, increasing contractility using inotropic agents, resynchronization therapy using biventricular pacing,[42,43] and, when appropriate, using intraaortic balloon counterpulsation followed by surgical correction of coronary artery stenosis or other surgically correctable lesions[24,44] (see Chap. 23).

The ventricular pump function curve illustrates the Frank-Starling mechanism, which shows that increased ventricular filling results in increased ejection even when contractility is depressed. The limit to increased ventricular filling is generally set by the onset of pulmonary edema. Pulmonary edema fluid enters the lung interstitium according to the Starling equation. At normal protein osmotic pressures (largely due to albumin) and normal permeability of the pulmonary endothelium, pulmonary edema starts to develop at Ppw values of at least 20 to 25 mm Hg.[45] In the presence of decreased oncotic pressure due to decreased albumin or in the presence of a leaky pulmonary endothelium, pulmonary edema may form at considerably lower Ppw values; in acute respiratory distress syndrome (ARDS) or pneumonia, pulmonary edema may form at very low Ppw values. With this in mind, it is appropriate to search for the Ppw that produces the highest cardiac output without resulting in substantial pulmonary edema. Most often, this search necessitates preload reduction using diuretics and vasodilating agents (Table 22-3). However, when pulmonary edema does not limit oxygenation, it is appropriate to consider increasing cardiac output by intravascular fluid expansion.

Further management of decreased ventricular contractility then proceeds with afterload reduction[14] and inotropic agents.[46,47] These therapies are considered in detail below (Acute on Chronic Heart Failure). When vasodilator and inotropic therapy is insufficient, temporary support using intraaortic balloon counterpulsation is appropriate when damaged myocardium is expected to recover or as supportive therapy leading to surgical correction of an anatomic abnormality.[24,44] Balloon inflation during diastole improves diastolic perfusion of the coronary and systemic arterial beds. During systole, deflation of the balloon reduces afterload, allowing for increased ejection by a ventricle with markedly decreased contractility (see Chap. 25). Stem cell transplantation is a promising new approach under investigation to repair damaged myocardium.[48]

INCREASED DIASTOLIC STIFFNESS

In normal hearts and in hearts with depressed ventricular function, increasing preload is an important mechanism of increasing cardiac output. For hearts with normal systolic function, left ventricular end-diastolic filling pressures are often in the range of 0 to 10 mm Hg and result in an adequate cardiac output. For hearts with depressed contractility, higher filling pressures are usually required for an adequate cardiac output. Therefore, there is no uniformly optimal filling pressure. Left ventricular function may be substantially impaired by increased diastolic stiffness of the left ventricle—a shift up and to the left of the diastolic pressure-volume relation.[16,49] This is a problem whose importance is equal at least to depressed contractility in the critically ill patient.[8] Depressed systolic function reduces stroke volume because ESV increases; in contrast, increased diastolic stiffness reduces stroke volume because EDV decreases. Increased diastolic stiffness is a relatively frequent problem encountered in critically ill patients. It differs from depressed ventricular contractility because it is much more difficult to treat and does not

respond to conventional therapy of decreased left ventricular pump function.[50] In fact, in the absence of an imaging study that demonstrates increased diastolic stiffness (small EDV in relation to the end-diastolic pressure [EDP]), the diagnosis of increased diastolic stiffness is suggested by finding depressed ventricular pump function unresponsive to fluid loading, afterload reduction, and inotropic agents. Occasionally, the diagnosis of increased diastolic stiffness is suggested by the observation that cardiac output is unusually sensitive to changes in heart rate.

CHRONIC CAUSES

Chronic diseases that increase diastolic stiffness include concentric left ventricular hypertrophy due to hypertensive cardiovascular disease, hypertrophic cardiomyopathy, and restrictive myocardial diseases. In addition, diseases of the pericardium, including constriction and effusion, and other processes that increase intrathoracic pressure result in increased diastolic stiffness, as discussed in Chap. 28. Concentric hypertrophy due to chronic hypertension is very common; although it seldom primarily accounts for severe depression in ventricular pump function, it may be an important contributor in combination with acute diseases depressing systolic function. Hypertrophic cardiomyopathy results in increased diastolic stiffness and, in the setting of hypovolemia, may also result in greatly increased afterload due to dynamic aortic outflow obstruction. Over a period of days and months, β blockers and calcium channel blockers, in particular verapamil, may reduce evidence of increased diastolic stiffness. More rapidly, these agents alleviate dynamic outflow obstruction in patients with hypertrophic cardiomyopathy due to their negative inotropic effect.[51] Restrictive cardiomyopathies include amyloidosis, hemochromatosis, sarcoidosis, endomyocardial fibrosis, some glycogen storage diseases, and restriction because of surgical correction of acquired and congenital abnormalities. Amyloidosis is uncommon at age 40 but by age 90 has a prevalence of 50%.

Clinical examination may show a Kussmaul sign, rapid x and y descents in the jugular venous pressure waveform so that a and v waves are prominent, and a fourth heart sound. Hepatojugular reflux may be prominent because the increased venous return produced by this maneuver cannot be accommodated by the stiff heart. Diastolic ventricular pressure measurements may show a square root sign, which is a rapid early rise in diastolic pressure to a relatively constant plateau. Echocardiographic evaluation may demonstrate rapid early diastolic filling to a relatively fixed diastolic diameter similar to the square root sign, and increased myocardial echogenicity may be observed in amyloidosis.[52,53]

ACUTE CAUSES

As with diseases resulting in depressed left ventricular systolic function, it is important to consider the acute, potentially reversible causes of increased diastolic stiffness.[8] Regional or global ischemia results in delayed systolic relaxation, contributing to increased diastolic stiffness. This change in diastolic stiffness usually precedes depressed contractility because the sarcoplasmic reticulum calcium pump has a lower affinity for adenosine triphosphate than do the contractile proteins. In addition, ischemia may result in increased diastolic stiffness by increasing pericardial pressure as a result of increased CVP.[54] Therefore, in the setting of increased diastolic stiffness, any ischemia should be treated aggressively.[55] Nitrates increase coronary blood flow and decrease tone in the venous capacitance bed, thereby reducing pericardial pressure; nitroprusside also decreases diastolic stiffness.

Increased intrathoracic or intrapericardial pressure is a common reversible cause of apparent increased diastolic stiffness in critical illness. Intrathoracic pressure is increased by positive-pressure mechanical ventilation and more so by the addition of positive end-expiratory pressure (PEEP). Positive airway pressures and PEEP are variably transmitted to the heart, depending on the distensibility of the lungs and chest wall. If the lungs are very distensible and the chest wall is relatively rigid (as with a tense abdomen), then most of an increase in airway pressure will be transmitted to the heart; to maintain the same chamber volumes, the atrial and ventricular pressures have to increase as much. This accounts for part of the reduction in venous return and cardiac output if and when Pms does not increase by a similar amount. A common misconception is that, if the lungs are very stiff, as in the early exudative phase of ARDS, then less of an increase in airway pressures will be transmitted to the heart. However, because PEEP reduces shunt by re-aerating flooded lung regions, the chest wall volume and pleural pressure increase as much or more in ARDS, so the increase in Pra with PEEP may be just as much as in patients with normal lungs. Increased intrathoracic pressure due to pneumothorax or massive pleural effusion may tamponade the heart and thereby result in apparent increased diastolic stiffness. Greatly increased intraabdominal pressure may elevate the diaphragm and similarly increase diastolic stiffness. Pericardial pressure may be increased by pericardial effusion and rarely by massive pneumopericardium. Because all these causes of increased intrathoracic or intrapericardial pressure leading to apparent increased diastolic stiffness are treatable, they must be identified or excluded early in critically ill patients.

Hypovolemic shock and septic shock may result in increased diastolic stiffness.[56] The increased diastolic stiffness associated with these kinds of shock is associated with irreversibility of the shock state and increased mortality rate. In septic shock, when depressed left ventricular systolic contractility occurs, the response of surviving patients is that of decreased diastolic stiffness or increased diastolic ventricular compliance.[57] This is the usual response to decreased left ventricular systolic contractility seen with other dilated cardiomyopathies.[58] However, in patients with septic shock who do not survive, the diastolic left ventricles do not dilate to increase EDV and, hence, do not compensate normally for decreased systolic contractility. The diastolic ventricles of those who do not survive are therefore much stiffer than the ventricles of those who do survive.[59] Infusion of catecholamines and calcium may further contribute to increased diastolic stiffness by contraction band formation.

Hypothermia with body temperature falling below 35.8°C (95.8°F) also results in increased left ventricular diastolic stiffness. This is a reversible phenomenon as temperature is increased. This is an important consideration during massive fluid resuscitation and mandates resuscitation with warmed infusions.

MANAGEMENT OF DIASTOLIC DYSFUNCTION

Whereas acute diastolic stiffness due to ischemia, tamponade, and tension pneumothorax are readily treated, acute therapy

to reverse diastolic stiffness in the critical care setting is limited. Therefore, searching for an optimal filling pressure that maximizes ventricular diastolic filling without resulting in substantial pulmonary edema is a critically important component of care in these patients. In addition, hypovolemia and sepsis should be treated aggressively and promptly, inotropic agents should be avoided or used at the smallest dose that results in the desired systolic or vascular effect, hypothermia should be prevented and treated, and tachycardia or atrioventricular arrhythmias should be treated early (see below). Intrathoracic pressure is minimized by appropriate ventilator management and by decompressing surrounding compartments (pericardial, pleural, and abdominal) when these cause cardiac tamponade.

SPECIAL EFFECTS OF ALTERED AFTERLOAD ON VENTRICULAR FUNCTION IN CRITICAL ILLNESS

An increase in afterload decreases left ventricular pump function because stroke volume is reduced as a result of increased ESV (see Fig. 22-2). In malignant hypertension, elevated aortic pressure results in decreased cardiac output and elevated left ventricular filling pressures leading to pulmonary edema even if contractility is normal. Antihypertensive therapy results in rapid improvement. When contractility is depressed, increased afterload may worsen cardiac function even more. This is particularly important in dilated cardiomyopathies, in which increased afterload may be observed due to increased sympathetic tone, activation of the renin-angiotensin-aldosterone axis, and abnormally increased vascular smooth muscle tone.

Aortic valvular stenosis or dynamic obstruction of the aortic outflow tract also may increase afterload and contribute to decreased left ventricular pump function[14] (see Chap. 29). Dynamic outflow tract obstruction is most commonly due to hypertrophic cardiomyopathy. However, patients with preexisting concentric hypertrophy due to chronic hypertension who have a decrease in intravascular volume may develop dynamic aortic outflow tract obstruction with the classic findings of systolic anterior motion of mitral valve leaflet, increased ejection velocities signifying increased gradients across the aortic outflow tract, and cavity obliteration at end systole. This appears to occur most commonly in elderly patients with previously treated hypertension. Volume infusion to reverse intravascular hypovolemia may prevent left ventricular cavity obliteration and outflow tract obstruction and thereby reduce ventricular afterload. It is important to identify outflow tract obstruction as the cause of increased afterload because this cause of increased afterload is worsened by conventional afterload reduction therapy.

When afterload is reduced dramatically, or when intravascular volumes are expanded, the resulting high cardiac output state is sometimes called *high-output cardiac failure.* Actually, cardiac function still lies on a normal cardiac function curve, but the greatly increased venous return associated with low afterload results in high right- and left-side filling pressures with the appearance of right- and left-side congestion. This is particularly apparent in the presence of atrioventricular valvular stenosis, which previously may have been occult. Causes of high-output failure include anemia, arteriovenous fistulas, hepatic failure, Paget disease, thyrotoxicosis, pregnancy, carcinoid syndrome, and renal cell carcinoma.

ABNORMAL HEART RATE AND RHYTHM

Normally, heart rate and contractile states are matched to venous return and afterload to maximize the efficiency of the cardiovascular system. Even though heart rate is often of lesser importance in trying to increase cardiac output, excessively fast or excessively slow heart rates may limit cardiac output. Bradycardia is an important abnormal rhythm in a critically ill patient. Primarily, it is important to determine whether hypoxemia, drugs such as acetylcholinesterase inhibitors, or other reversible insults are the cause of bradycardia. In these cases, treatment consists of rapid reversal of the cause. In other cases in which bradycardia is due to primary cardiac disease, including myocardial infarction with involvement of the conducting system, therapy is directed at increasing heart rate by other means. Acutely, bradycardia may be treated with atropine and, if necessary, by isoproterenol or epinephrine infusion titrated to heart rate response. These temporizing measures allow placement of temporary or permanent pacemakers. In addition to the well-known indications for temporary pacing after myocardial infarction, it should be recognized that symptomatic bradycardia from any cause is an indication for pacing.

Tachycardia at sufficiently high rates results in an inadequate diastolic filling time, so stroke volume is reduced because adequate diastolic filling does not occur and the contribution to ventricular diastolic filling by the atria is less efficient, particularly in atrial fibrillation. An end-diastolic gradient across the mitral valve develops at fast heart rates. Hypoxemia and acidosis encountered in critically ill patients are frequently associated with ventricular and, even more commonly, supraventricular tachyarrhythmias. Hyperkalemia and hypokalemia, hypocalcemia, and hypomagnesemia are common electrolyte disturbances associated with increased incidence of ventricular arrhythmias. Accordingly, management of atrial and ventricular tachyarrhythmias involves correcting these potential contributing abnormalities.

Cardiac resynchronization therapy using biventricular pacing appears to improve cardiac function in patients having a decreased ejection fraction, bundle branch block, and New York Heart Association class III or IV heart failure.[42,43] The role for resynchronization therapy in the critical care setting has not been fully defined.

Arrhythmias including atrial fibrillation, atrial flutter, and ventricular tachycardia should be immediately cardioverted if they are contributing to a shock state. Otherwise, rapid heart rate due to atrial fibrillation is slowed using β blockers or second-line agents including calcium channel blockers. Adenosine, verapamil, and maneuvers to increase vagal tone may be useful in the diagnosis of tachyarrhythmias and in treating paroxysmal supraventricular tachycardia.[60] Multifocal atrial tachycardia responds to correction of underlying pulmonary disease and to verapamil.[61] Ventricular dysrhythmias contributing to altered hemodynamic function must be treated. Specific management of ventricular arrhythmias is detailed in Chap. 24.

VALVULAR DYSFUNCTION

The valves regulate preload and afterload and are therefore important determinants of left ventricular pump function (see Chap. 29). In critically ill patients, the effect of preexisting valvular disease may change with altered hemodynamics,

or the extent of valvular disease may change primarily. For example, aortic and mitral insufficiencies contribute to low cardiac output at high ventricular filling pressures in critical illness, and both respond quickly to afterload reduction. Moreover, mitral regurgitation may worsen acutely due to increased EDV and expansion of the mitral annulus. In contrast, mitral valve prolapse may worsen at low ventricular volumes due to hypovolemia. In high cardiac output states, previously insignificant mitral stenosis may result in a high Pla and pulmonary edema. The gradient across the stenotic aortic valve may increase in high-flow states and conversely decrease in low-flow states, so that, without considering the flow across the valve, an incorrect judgment of the functional significance of the valvular disease may be made. Dysfunction of prosthetic valves is important to identify and may be a surgical emergency.

Mechanisms and Management of Right Ventricular Dysfunction

Right ventricular pump function also depends on contractility, afterload, preload (the diastolic pressure-volume relation), heart rhythm, and valve function. However, the right ventricle differs from the left ventricle, so the relative importance of each of these components is different. The left ventricle is well designed to generate high pressures. Its thick walls and small chamber volume result in manageable levels of wall stress despite high intracavitary pressures. The helical arrangement of muscle fibers changing from endocardium to epicardium in concentric layers results in a strong wall with an efficient distribution of wall stress.[62] In contrast, the right ventricle is a thin-walled pump whose surface has a large radius of curvature and it is not suited as a high-pressure generator. Instead, the right ventricle functions as an excellent flow generator at low pressures. Right ventricular contraction moves sequentially from the apex to the pulmonary outflow tract, giving it features of a peristaltic volume pump. During diastole, the right ventricle at normal diastolic pressure lies below its stressed volume, a feature that allows it to accommodate a large filling volume without an elevation in EDP. Because of these features, volume preload and, most importantly, pressure afterload become even more important determinants of right ventricular function than they are in the left ventricle.

DECREASED RIGHT VENTRICULAR SYSTOLIC FUNCTION

Contractility of the right ventricle is decreased approximately to the same extent as in the left ventricle by the many causes listed for the left ventricle (see Tables 22-1 and 22-2). Occasionally, right ventricular contractility is disproportionately reduced as in right ventricular infarction, right ventricular dysplasia, Uhl anomaly, isolated right ventricular myopathy, and myopathy associated with uncorrected atrial septal defect. Right ventricle ischemia in the absence of coronary artery disease is very important during critical illness. When afterload is elevated, the right ventricle responds along a preload-dependent right ventricular systolic pressure-volume relation, so right ventricular ESV increases.[63] Right ventricular chamber pressures are increased, the radius of curvature is increased, and, hence, the wall stress in the thin right ventricular wall increases dramatically. Therefore, right ventricular myocardial oxygen demand increases proportionately. At increased right ventricular pressures, the right ventricular intramural pressure increases, and hence, the gradient for right ventricular coronary blood flow decreases. Oxygen supplied to the right ventricular myocardium may not meet oxygen demand, so contractility decreases, further worsening right ventricular function.[64]

DISORDERS OF RIGHT VENTRICULAR PRELOAD, AFTERLOAD, RHYTHM, AND VALVES

Increasing right ventricular EDV results in an increase in right ventricular stroke volume, even though right ventricular EDP may not increase much because normally EDV is below the right ventricular diastolic stressed volume. Because of this, and because Pra is heavily influenced by intraabdominal, intrathoracic, and intrapericardial pressures, Pra (CVP) is probably a poor indicator of right ventricular preload.

The afterload of the right ventricle is the Ppa (Table 22-4). This may be elevated long term by emphysematous destruction of small pulmonary vessels, chronic hypoxic pulmonary vasoconstriction due to obstructive pulmonary disease and restrictive chest wall diseases, recurrent pulmonary embolism, chronically elevated Pla due to mitral stenosis or left ventricular congestive failure, primary pulmonary hypertension, and several connective tissue and inflammatory diseases that involve the pulmonary vasculature. The acute pulmonary vasodilator response to nitroglycerin infusion is useful for predicting which patients will do well.[15] Acute causes of pulmonary hypertension are also important to identify because they are more often reversible. In addition, whereas the right ventricle may hypertrophy and accommodate severe chronically increased afterload, moderate acute pulmonary hypertension may rapidly lead to right ventricular decompensation. Important causes of acute pulmonary hypertension in critically ill patients include pulmonary embolism, hypoxic pulmonary vasoconstriction, acidemic pulmonary vasoconstriction, pulmonary infection, ARDS, sepsis, and acutely elevated Pla (see Chap. 26).

As with the left ventricle, the right ventricle depends on normal rate and rhythm to attain optimal function. Right ventricular valvular disease is less common and less important

TABLE 22-4 Causes of Elevated Right Ventricular Afterload

Chronic
Chronic hypoventilation
Recurrent pulmonary emboli
Primary pulmonary hypertension
Associated with connective tissue diseases
Chronically elevated left atrial pressure (mitral stenosis, left ventricular failure)
Acute
Pulmonary embolus
Hypoxic pulmonary vasoconstriction
Acidemic pulmonary vasoconstriction
ARDS
Sepsis
Acute elevation in left atrial pressure
Positive-pressure mechanical ventilation

ABBREVIATION: ARDS, acute respiratory distress syndrome.

than left ventricular valvular disease because right ventricular pressures are much less than left ventricular pressures, so gradients across the valves are considerably less. In critically ill patients, tricuspid valve disease with endocarditis is common as a preexisting condition such as endocarditis or as a result of instrumentation with a pulmonary artery catheter or other right heart catheters.

VENTRICULAR INTERACTION

DIAGNOSIS OF VENTRICULAR INTERDEPENDENCE

Combined pump dysfunction of the right and left ventricles is more common than isolated right or left ventricular pump dysfunction. Part of the explanation is that the diseases resulting in decreased pump function more commonly involve both ventricles. However, the right and left ventricles interact in important ways that, when recognized, may lead to a more effective therapeutic approach. The right and left ventricles are contained inside the same pericardial cavity within the chest wall, and the right and left ventricles share the interventricular septum. Accordingly, much of the interaction between the right and left ventricles is mediated by the parallel coupling produced by the pericardium and septal shift. The right ventricle is also connected in series with the left ventricle so that a substantial rise in Pla is transmitted back through the pulmonary vasculature and results in an increase in right ventricular afterload. In addition, the left ventricle is the pump that perfuses the right and left coronary circulations; hence, decreased systemic pressure combined with elevated right ventricular pressures may result in hypoperfusion of the right ventricle.

Detrimental ventricular interaction is generally only a problem when right heart and pulmonary circulation pressures are high. Table 22-4 lists a number of important and common causes in critically ill patients. Pulmonary embolus is a common and often missed diagnosis requiring helical computed tomography or pulmonary angiography. Right ventricular pressure and Pra rise. Elevated right ventricular pressure shifts the interventricular septum from right to left during diastole, resulting in increased left ventricular diastolic stiffness. During systole, left ventricular pressure usually is sufficiently greater than right ventricular pressure, so the septum shifts back. This change in systolic shape means that the myocardium of the left ventricular free wall must shorten even more for less of an ejected stroke volume. The rise in Pra is transmitted through the compliant right atrium to the pericardial space. The increase in pericardial pressure tamponades all other cardiac chambers. When pericardial effusion is present, these effects are magnified. When Pla is high due to mitral stenosis or decreased left ventricular pump function, Ppa values rise. In the long term, this also may result in increased pulmonary vascular resistance. The resulting right ventricular failure with right-to-left septal shift impairs left ventricular filling, which may be a critical insult in these diseases.

TREATMENT OF VENTRICULAR INTERDEPENDENCE

Management aims to decrease Ppa values and to decrease parallel coupling of the left and right ventricles. Reversible contributions to pulmonary hypertension are treated as outlined in the discussion of right ventricular afterload. Parallel coupling by elevated pericardial pressure is decreased by relieving pericardial tamponade, if present; by decreasing intrathoracic pressures by decompressing thoracic and abdominal fluid and air collections; by airway management to reduce Ppa; in select patients by surgically opening or removing the pericardium; and in patients after sternotomy, by leaving a sternal incision open and closing only the overlying skin.

Unresuscitatable cardiac arrest is a common outcome when perfusion of the right ventricle is threatened because right ventricular pressures are high relative to left ventricular pressures. This happens in massive pulmonary embolism and in cases of severe pulmonary hypertension. Thrombolytic therapy and pulmonary vasodilator therapy attempt to reverse the cause. Animal models of massive pulmonary embolism suggest that successful acute cardiovascular management attempts to raise systemic pressures more than right-side pressures.[64] Therefore, norepinephrine or epinephrine, both of which have a substantial α-agonist effect, improves right ventricular perfusion and is more successful in immediate resuscitation than is isoproterenol or fluid infusion.

Acute on Chronic Heart Failure

Heart failure affects almost 5 million Americans, with more than half a million new cases each year. Seventy-five percent of heart failure hospitalizations involve patients older than 65 years. Heart failure carries a poor prognosis, with a survival rate of less than 50% after 5 years.[24] Mortality rate is often related to episodes of acute decompensation that punctuate the course of heart failure. Important precipitating causes of acute decompensation are listed in Table 22-5. A review of these causes shows why chronic heart failure is often exacerbated in the course of critical illness, so early detection and management of acute-on-chronic heart failure are essential components of critical care.[65]

PRECIPITATING FACTORS

Poor compliance with medications and new medications are common precipitating events. Dietary indiscretions with increased sodium load and alcohol ingestion leading to a further acute depression in systolic contractility are seen frequently. Intercurrent illness such as a urinary tract infection or viral

TABLE 22-5 Common Precipitating Factors of Acute on Chronic Heart Failure

Poor compliance with medications
Dietary indiscretion (salt load, alcohol)
Infection
Fever
High environmental temperature
Effect of a new medication (β blocker, calcium channel blocker, antiarrhythmic, nonsteroidal anti-inflammatory)
Arrhythmia (typically, new atrial fibrillation)
Ischemia or infarction
Valve dysfunction (endocarditis, papillary muscle dysfunction)
Pulmonary embolism
Surgical abdominal event (cholecystitis, pancreatitis, bowel infarct)
Worsening of another disease (diabetes, hepatitis, hyperthyroidism, hypothyroidism)

syndrome, fever, or high ambient temperatures may make greater demands on cardiac output than can be met. Onset may be slow, and patients complain of decreased exercise tolerance, dyspnea, paroxysmal nocturnal dyspnea, and swelling of ankles and abdomen worsening over days and weeks. Rapid onset suggests that ischemia or arrhythmia may be the cause. Cardiac output may be depressed, so the kidneys are hypoperfused. The response of the kidneys is to avidly retain sodium and water, which may further worsen volume overload. Volume overload leads to elevated venous pressures with subsequent pulmonary edema due to elevated Pla and peripheral edema due to elevated systemic venous pressures. There is an excessive reflex release of catecholamines leading to tachycardia and increased arterial tone, so arterial resistance rises. Increased arterial resistance as afterload may be detrimental to left ventricular pump function. Activation of the renin-angiotensin axis accounts for avid renal absorption of sodium. Vasopressin release increases water retention. Coronary artery disease is common in this population, so decompensation may have followed an acute ischemic coronary event or coronary ischemia may be precipitated by worsened congestive heart failure.

CLINICAL FEATURES

Patients are often anxious, tachycardic, and tachypneic, with evidence of hypoperfused extremities and possibly cyanosis. Jugular veins are distended, and hepatojugular reflux may be demonstrable on physical examination. Typically the sternal angle is approximately 5 cm above the right atrium when the patient's torso is at a 30- to 45-degree angle. Jugular venous distention is usually no higher than 1 to 3 cm above the sternal angle in normal patients, but it is elevated during acute heart failure. An apical impulse lateral to the midclavicular line or farther than 10 cm from the midsternal line is a sensitive but not specific indicator of left ventricular enlargement, whereas an apical diameter larger than 3 cm indicates left ventricular enlargement.[66] A sustained apical impulse suggests left ventricular hypertrophy or aneurysm. A third heart sound or summation gallop is often present but may be obscured by increased respiratory sounds. Pulse pressure is often reduced, so peripheral pulses are "thready." Crackles are heard in dependent lung fields but in severe cardiac failure are heard in all zones. Wheezes and a prolonged expiratory phase may be noted, suggesting edema surrounding the airways. Hepatomegaly, which may be pulsatile particularly with tricuspid valve insufficiency, may be present, and there is evidence of dependent edema in the lower extremities and over the sacrum.

Chest radiographic findings suggesting elevated left ventricular filling pressures include upper zone redistribution of vascular markings, septal lines (Kerley B lines), loss of pulmonary vascular definition, perivascular and peribronchial cuffing, perihilar interstitial and then alveolar filling patterns, and pleural effusions. The cardiopericardial silhouette may be enlarged, suggesting enlarged cardiac chambers, and the azygos vein may be enlarged, suggesting elevated Pra.

MANAGEMENT

Therapy of acute-on-chronic heart failure initially aims to treat intravascular overload and improve gas exchange. Therefore, the patient is positioned with the torso elevated at least 45 degrees, and oxygen is administered. Good intravenous access, optimally central venous, is established. Furosemide (20 to 40 mg initially, followed by increasing doses as required) induces a rapid diuresis. Even before diuresis is established, furosemide reduces Pla by a venodilation effect and also reduces intrapulmonary shunt.[67] Titrated morphine doses decrease venous tone and thereby decrease left ventricular filling pressures and improve pulmonary edema. In addition, morphine may make the patient less anxious, thereby decreasing whole-body oxygen demand. Nitrates are venodilators that serve to decrease left ventricular filling pressure and mild arterial vasodilators, resulting in decreased afterload. Nitrates have the additional benefit of being coronary vasodilators.

Afterload reduction is an important therapeutic intervention in patients with depressed left ventricular systolic contractility[14] due to a decrease in the slope of the ESPVR. Because there is a decrease in the slope of this relation, small reductions in pressure afterload can result in improved ejection to smaller ESVs. The reduction in ESV results in increased stroke volume and in substantially decreased end-systolic wall stress because, by the Laplace relation, wall stress is proportional to the product of cavity pressure and radius. The decrease in wall stress reduces myocardial oxygen demand. Afterload reduction in some critically ill patients may result in unacceptable hypotension. For this reason, it is best to start with an easily titratable medication with a very short half-life such as nitroprusside or, in the setting of ischemia, intravenous nitroglycerin (see Chap. 25). Nitroprusside is infused at an increasing dose while the response of cardiac output and blood pressure is measured repeatedly, so that an optimal dose resulting in maximum cardiac output with adequate perfusing pressures is chosen. Nitroprusside and other nitrates are direct or indirect NO donors that cause vascular smooth muscle relaxation. Nitroprusside at larger doses can result in significant toxicity, with cyanide formation and methemoglobinemia. When circulatory stability is achieved, other, longer-acting agents are substituted; angiotensin-converting enzyme inhibitors are particularly useful,[21,24] as are alternative drugs (see Table 22-3).

Inotropic or vasoactive agents are extremely useful in reversing depressed systolic contractility, but routine use of inotropes is not indicated for heart failure because inotropic use may increase mortality rate.[47,68] Dobutamine acts mainly on β_1 receptors and results primarily in increased ventricular contractility and in mild peripheral vasodilation. Doses from 2 to 15 μg/kg per minute are infused through a central venous line. Particularly in the presence of intravascular hypovolemia, the vasodilating effect of dobutamine may exceed its effect on increasing cardiac output, so blood pressure may decrease unacceptably. Dopamine has significant adverse effects that should limit its use. Low-dose dopamine has been clearly shown not to be beneficial. Dopamine is predominantly a β agonist in doses of 5 to 10 μg/kg per minute; at doses exceeding 10 μg/kg per minute, dopamine is an α agonist and therefore increases arterial resistance. Dopamine increases Pms and, hence, venous return increases, resulting in increased left ventricular filling pressures. The increased afterload at large doses and increased filling pressures associated with dopamine are often undesirable in treating decreased contractility. Milrinone and enoximone are phosphodiesterase inhibitors that increase contractility by increasing

intracellular calcium during systole. These agents also may result in afterload reduction and therefore may be particularly beneficial in short-term treatment of depressed contractility. The use of digoxin to increase contractility is not generally helpful in the acute setting.[69]

In general, although positive inotropic agents improve contractility, they do so at the cost of increased myocardial oxygen demand and decreased efficiency of oxygen use and therefore may precipitate ischemia, arrhythmias, and other adverse outcomes. Dobutamine and milrinone are superior to dopamine, epinephrine, and isoproterenol for minimizing this adverse effect. If acute decompensation leads to cardiogenic shock and recovery is anticipated after medical or surgical intervention, then intraaortic balloon counterpulsation should be instituted when afterload reduction and inotropic therapy are insufficient.

Chapter 23

DIAGNOSTIC AND MANAGEMENT STRATEGIES FOR ACUTE HEART FAILURE IN THE INTENSIVE CARE UNIT

GERASIMOS S. FILIPPATOS
GEORGE BALTOPOULOS
ELIAS KARAMBATSOS
MARKKU S. NIEMINEN

KEY POINTS

- *Patients are admitted to the intensive care unit (ICU) with manifestations of acute heart failure (AHF) that arise in three general contexts: decompensation of chronic heart failure, as a complication of a cardiac process such as ischemia or valve incompetence, and when cardiomyopathy complicates other critical illness.*
- *Determining which of the contexts of AHF is present is invaluable to guide therapy.*
- *Predominant signs and symptoms arise from venous congestion after elevation of ventricular end-diastolic pressure and hypoperfusion; in a given patient, different contributions of these processes may be present.*
- *Measurement of brain natriuretic peptide has been a useful addition to the diagnostic armamentarium to determine whether heart failure is a cause of acute dyspnea; this measurement is most useful when obtained acutely and before initiation of therapies and, hence, has a limited role for assessing patients after admission to the ICU.*
- *Echocardiography is an extremely useful tool to assess ventricular function and define cardiac anatomy; on occasion, information from invasive measurement of intravascular pressure or venous oxygen saturation is also required to guide therapy.*
- *Many patients will exhibit respiratory distress and different degrees of impaired oxygenation; whereas many, if not most, patients can be managed with oxygen for this component of AHF, ventilatory support in the form of continuous positive airway pressure or bilevel airway support (BiPAP) should be considered for patients not responding adequately to oxygen therapy alone or whose respiratory symptoms and findings are severe from the onset.*
- *Diuretics are useful for treating venous congestion and inotropes for inadequate perfusion, but each carry risk of excessive dosing; the mainstay of therapy for most patients should be afterload reduction and search for the underlying causes of ventricular dysfunction and decompensation.*
- *Vasoconstrictive agents should be used only when and as long as truly life-threatening hypotension is present*

Acute heart failure (AHF) is the primary or an underlying diagnosis in many patients admitted to the intensive care unit (ICU), but its exact incidence is unknown. The cause of heart failure (HF) in 60% to 70% of hospitalized patients is ischemic heart disease,[1–3] but many diagnoses, including arrhythmias, idiopathic dilated cardiomyopathy, systemic or pulmonary hypertension, congenital and valvular heart disease, or myocarditis, should be considered (see Chap. 24). HF is complicated by diabetes in 27% of hospitalized patients, renal dysfunction in 17%, and respiratory disease in 32%, and the vast majority of individuals hospitalized for AHF are older than 70 years.[3]

AHF may present with left or right HF or the combination of these conditions. The cardiac dysfunction may be systolic or "diastolic" (with preserved ejection fraction), and the underlying pathogenetic mechanism may be cardiac or extracardiac and may induce transient or permanent cardiac damage.[4] Especially in the ICU, multiple extracardiac pathologies may result in AHF by changing preload, afterload, or contractility, including pericardial disease, renal failure, endocrinopathy, sepsis, thyrotoxicosis, anemia, end-stage liver disease, and central nervous system lesions. Some rare cardiac pathologies also may be responsible for AHF, such as tumors of the heart and cardiac contusion.

Mortality rate is high, with as many as 13.5% of patients succumbing in the first 3 months after an episode of AHF in some series.[3] The incidence of hospitalizations for HF as a primary diagnosis have increased recently, and 24% of patients will be rehospitalized within 90 days. Most patients hospitalized for management of HF represent cases of decompensation of chronic HF.[3,5–7]

This chapter offers a definition of the clinical syndrome of HF and then describes the underlying pathophysiology. Diagnostic and therapeutic approaches to patients admitted to the ICU with HF are described. The definitions and diagnostic and management strategies described in this chapter have been recently formulated as Guidelines of the Task Force on Acute Heart Failure by the European Society of Cardiology.[1]

Definition

The clinical syndrome of AHF may occur with or without previous cardiac disease. The time needed to characterize HF as acute has not been defined. The different clinical presentations of AHF are:[1,8]

1. Pulmonary edema: AHF accompanied by severe respiratory distress and O_2 saturation (Sa_{O_2}) less than 90% with room air before treatment.
2. Cardiogenic shock: Tissue hypoperfusion, after correction of preload, induced by cardiac disease. There is no simple and precise definition for cardiogenic shock. It is characterized by decreased systolic blood pressure (<90 mm Hg; or a drop of mean arterial blood pressure >30 mm Hg) and/or low urine output (<0.5 mL/kg per hour) with a pulse rate faster than 60 beats/min with or without evidence of organ congestion.
3. Hypertensive AHF: Signs and symptoms of HF accompanied by extremely high blood pressure and relatively preserved left ventricular systolic function.
4. Acute decompensation of heart function, occurring de novo or as deterioration of chronic HF: Signs and symptoms of AHF that do not fulfill criteria for cardiogenic shock, pulmonary edema, or hypertensive HF.

5. High-output failure: Characterized by warm periphery, pulmonary congestion, and sometimes low blood pressure, as seen in thyrotoxicosis.
6. Right HF: Characterized by low-output syndrome with increased jugular venous pressure, peripheral edema, and sometimes hypotension. It is often associated with left HF but may occur in isolation as a result of lung or pulmonary vascular disease or ischemia largely limited to the right ventricle.

Many other classifications for AHF have been used in the ICU. The most widely recognized are the Killip and the Forrester classifications originally designed to provide a clinical estimate of prognosis in acute myocardial infarction.[9,10] The Forrester classification categorizes patients by clinical and hemodynamic criteria to four different subsets:

1. No evidence of pulmonary congestion or peripheral hypoperfusion (normal cardiac index and pulmonary capillary pressure).
2. Pulmonary congestion only (elevated pulmonary capillary wedge pressure [PCWP]).
3. Hypoperfusion only (depressed cardiac index).
4. Pulmonary congestion and hypoperfusion (depressed cardiac index and elevated PCWP).

These definitions have been used to classify AHF patients in an attempt to improve prognostic information and management. However, AHF is a continuum, and this should be taken into consideration during the diagnostic and therapeutic assessments.

Practical Issues in the Pathophysiology of Acute Heart Failure

AHF is characterized by a relatively sudden inability of the heart to maintain cardiac output adequate for the demands of the circulation. Cardiac output is reduced with associated tissue hypoperfusion, usually with increased cardiac filling pressures (as reflected by an elevated PCWP) and associated tissue congestion. The primary response to this state is neuroendocrine activation, such as the renin-angiotensin-aldosterone axis, sympathetic system activation, cytokine and endothelin release, and peptide release, including vasopressin and natriuretic peptides.[11,12] Natriuretic peptides cause vasodilation, inhibit endothelin release, and counterbalance the effects of the sympathetic and renin-angiotensin-aldosterone systems. Moreover, they have diuretic, lusitropic (ventricular relaxation), and antifibrotic properties.[13,14]

Although activation of these pathways is no doubt an attempt to maintain homeostasis, the final result of neuroendocrine activation is vasoconstriction leading to retention of sodium and water, increased left ventricular filling pressures, and increased ventricular wall tension. This in turn causes myocardial oxygen demand to increase, unfortunately in a circumstance in which coronary blood flow cannot be increased in a commensurate fashion because of associated coronary artery disease or primary myocardial dysfunction and pump failure. In addition to renal and vascular effects, neurohormonal activation and hypoperfusion exert direct effects on the cardiac cells, leading to further deterioration of myocardial function within hours by induction of apoptosis and necrosis.[15–17] The significance of myocardial cell regeneration, which has been recently described in humans, is not known.[18] Large-dose catecholamine treatment can further induce cell death and desensitization of the β-adrenergic system,[19] leading to tolerance to inotropic stimulation by therapeutic catecholamines.[20] Oxygen free radical formation and endothelial injury have been implicated in AHF pathophysiology and may not only lead to abnormalities in the peripheral circulation but may also contribute to the pathogenesis of myocardial stunning and hibernation.

In patients with ischemic heart disease and acute coronary syndromes, the AHF syndrome may persist for hours to days after the restoration of coronary blood flow. This transient reduction in myocardial function, which may occur also after cardiac arrest, is called *myocardial stunning*.[21] A mechanism of depressed myocardial function that is also important in the ICU is *myocardial hibernation*. This impaired myocardial function is a result of severe chronic hypoperfusion and decreased coronary blood flow due to coronary artery stenosis. It appears to be a protective mechanism aimed at limiting myocardial cell injury and death under conditions of excessive load and inadequate perfusion.[22] These mechanisms may be particularly important in the ICU patient with a history of ischemic heart disease and myocardial dysfunction, even when AHF is not the primary admission diagnosis. Patients with stunned and hibernating myocardium can return to normal cardiac function when appropriately treated. Hibernating myocardium improves when coronary blood flow is restored, whereas stunned myocardium responds to inotropic stimulation.[23,24] However, the exact role of treatment on the outcome of critically ill patients with coexisting coronary artery disease is unknown.

Diagnosis of Heart Failure

Etiologic diagnosis of AHF based on history and on clinical findings is difficult in the ICU. A 12-lead electrocardiogram is useful to identify acute myocardial infarction. It may also help in the diagnosis of acute right ventricular strain; ST elevation of the V4R lead is characteristic of right ventricular myocardial infarction, which is present in 30% to 50% of patients with an inferior myocardial infarction.

Chest radiography is necessary to evaluate cardiac size and shape and to assess pulmonary congestion. Blood count and biochemical tests, including calcium and thyroid function, are necessary in the initial evaluation of AHF patients. Troponin and creatinine kinase MB fractions have been used to evaluate acute myocardial injury, but these standard markers often lose sensitivity and specificity in complex ICU patients with confounding effects of renal failure, trauma, and recent surgery.[25,26] Arterial blood gas analysis is extremely helpful to identify oxygenation abnormalities associated with pulmonary edema and metabolic acidosis resulting from hypoperfusion. Pulse oximetry and end-tidal CO_2 are helpful monitoring tools but are less reliable in shock states.

Natriuretic peptides and especially B-type natriuretic peptide (BNP) play a significant role as adaptive mechanisms in AHF. BNP is released from the cardiac ventricles in response to increased wall stretch resulting from pressure and volume overload.[27] BNP and NT-BNP (the product of the

posttranslational processing of the pro-BNP molecule) have been used for the diagnosis of decompensated HF in patients with dyspnea in the emergency department[1,28] and increased levels of plasma BNP and NT-BNP carry important prognostic information in patients with decompensated HF.[29,30] Moreover, it has been suggested that increased BNP level is a strong predictor for cardiac dysfunction in ICU patients.[31] However, the exact time of BNP rise in patients with AHF is not known, and BNP levels may be normal at the time of admission. BNP has a half-life of 22 minutes and NT-BNP has a half-life of 120 minutes, suggesting that meaningful hemodynamic changes could be reflected after 2 to 12 hours.[32] Many of the interventions used to treat AHF no doubt rapidly influence BNP levels, thus making use of this test questionable once the patient has had treatment initiated. Moreover, BNP concentration increases in patients with chronic renal failure, pulmonary embolism, pulmonary hypertension, and chronic obstructive pulmonary disease with right heart strain. Thus, an elevated level cannot be taken as unequivocal evidence of left HF, and patients with findings consistent with acute right heart strain require further diagnostic workup.[33–38] The effect of acute lung injury or ARDS with or without right HF upon BNP serum levels has not been evaluated. Plasma BNP is also increased after acute myocardial infarction[39] and is a predictor of major adverse events independent of ejection fraction.[40,41]

Although it has been suggested that increased plasma BNP concentrations are a useful marker for predicting cardiac rupture after acute myocardial infarction, the exact role of BNP in patients with cardiogenic shock or pulmonary edema from a mechanical complication after an acute myocardial infarction has not been extensively evaluated.[42]

Echocardiography is essential for the evaluation of the patient with AHF. Transthoracic echocardiography can be used to evaluate left and right ventricular functions, valvular integrity, pericardial pathology, and mechanical complications of acute myocardial infarction and is useful to identify intracavitary lesions. An echo Doppler study can be used for the hemodynamic evaluation of the HF patient, although in the ICU transesophageal echocardiography is often used because of the limited quality of the transthoracic images, particularly in patients undergoing mechanical ventilation.[43–45] Echocardiography has not been compared with right heart catheterization in patients with AHF, but the information from these two tools would likely be complementary by providing pressure and volume assessments of ventricular function.

Insertion of a pulmonary artery catheter for the diagnosis of AHF is usually unnecessary but can be helpful in complex patients with concurrent cardiac and pulmonary disease.[45] The measurement of mixed venous saturation or even of superior vena caval blood saturation as a surrogate measure (obtainable from a standard central venous catheter) is very useful to determine the adequacy of the cardiac output; saturations less than 60% strongly suggest inadequate tissue perfusion apart from the cardiac output measured by other means.

Monitoring the Patient with Acute Heart Failure

There are no prospective randomized clinical trials assessing the efficacy of different monitoring devices in AHF patients. However, as in all critically ill patients, temperature, respiratory rate, heart rate, electrocardiogram, and blood pressure should be monitored. The frequency with which these observations need to be taken depends on the severity of decompensation. Blood pressure should be checked regularly until the patient has demonstrated stability on a given dosage of vasodilators, diuretics, or inotropes. Noninvasive blood pressure monitoring is usually sufficient. An arterial catheter is sometimes used in shock states or when continuous analysis of arterial blood pressure or multiple arterial blood analyses are necessary. The Sa_{O2} of hemoglobin should be checked by pulse oximetry, continuously, or at regular intervals in any patient receiving oxygen therapy for AHF. The Sa_{O2} estimate by pulse oximetry is of limited value when the patient is in cardiogenic shock.

Many different noninvasive hemodynamic monitoring devices have been used in the ICU, but their exact role in the management of an AHF patient has not been definitively determined. Central venous lines can be used for the delivery of fluids and drugs to the central venous circulation and for monitoring right atrial pressure. However, right atrial pressure correlates poorly to preload in HF patients.

Pulmonary artery catheters (PACs) can measure intracardiac pressures, cardiac output, right ventricular end-diastolic volume and ejection fraction, and mixed venous saturation (see Chap. 13). Several retrospective studies have demonstrated an increased mortality rate associated with the use of this technology, including in patients with acute myocardial infarction.[46,47] These observations have been ascribed to limitations of the retrospective study, but the consistency of this association in other patient groups raises concern regarding the value of this mode of monitoring.[48–50] Recently, a prospective study randomized critically ill patients to a PAC group or to treatment without the use of data from a PAC. In this study, management with the PAC led to increased fluid resuscitation within the first 24 hours but no long-term differences in patient outcome.[51] Other studies evaluating the utility of PAC monitoring in patients with AHF and other causes of critical illness are currently underway.

Treatment of Acute Heart Failure

AHF is a complex and heterogeneous syndrome, with only a few randomized controlled trials that have assessed treatment approaches. The comorbidities that are common in ICU patients make management more difficult and complicated. The immediate goals of treatment include improvement of tissue perfusion and oxygenation, correction of underlying hemodynamic abnormalities and the causes of cardiac decompensation, and control of symptoms. These short-term goals should then be linked to longer-term management strategies that ideally improve morbidity and mortality rates.

RESPIRATORY THERAPY AND VENTILATORY SUPPORT

A priority in treating patients with acute cardiac failure is the maintenance of arterial oxygen saturation (SaO_2) within the normal range to improve tissue oxygenation. This can be achieved by using supplemental oxygen in most patients and by the use of noninvasive (see Chap. 33) or invasive (see Chap. 36) ventilatory strategies for patients with greater degrees of respiratory compromise.

Several trials have suggested a benefit of continuous positive airway pressure (CPAP) in patients with AHF, in particular a reduction in the need for endotracheal intubation.[52–56] These investigations have been criticized for their small size and a failure to demonstrate a difference in mortality rate, but a recent meta-analysis showed a trend to decreased hospital mortality rate when CPAP was used as a routine measure for patients with AHF.[57]

Other forms of noninvasive ventilatory support have been studied, most often bilevel support delivered by nasal or full-face mask. Three randomized trials compared this approach with conventional oxygen therapy, large-dose nitrate therapy, or CPAP,[58–60] with mixed results. A recent multicenter study of treatment of patients in pulmonary edema secondary to AHF showed no benefit for the general population of patients but did show a trend toward improvement by subset analysis of the more severely compromised patients.[61]

Analysis of these studies suggests that benefit is likely to be seen in more severely ill patients not stabilized with oxygen therapy alone. One approach is to use CPAP or other forms of support in patients with pulmonary edema, an elevated arterial partial pressure of CO_2 (suggesting impending ventilatory failure) and a low pH even when an arterial pressure of CO_2 is normal (suggesting more severe hypoperfusion).

MEDICAL TREATMENT

Vasodilators are the first line therapy in patients with pulmonary congestion and adequate blood pressure. Nitrates relieve pulmonary congestion by reducing left ventricular preload and afterload. The highest tolerable dose of nitrates with low dose furosemide should be administered since it is more effective than furosemide treatment alone in acute pulmonary edema.[62] However, close monitoring during intitiation of therapy is necessary because excessive vasodilation may induce a steep reduction in blood pressure, ischemia, sometimes shock and renal failure. Moreover, rapid development of tolerance to nitrates, especially when they are given intravenously, limits their effectiveness after 16 to 24 hours.

Sodium nitroprusside (SNP) has been also used for patients with acute heart failure and has found its widest application in patients with hypertensive crisis and ventricular decompensation. Controlled trials of its use are lacking in heart failure per se. Use of SNP requires close blood pressure monitoring. Prolonged administration can be associated with thiocyanate and/or cyanide toxicity and patients should be converted early to alternative agents to avoid these problems, particularly when renal and/or hepatic dysfunction are present.

Diuretics are indicated in patients with symptoms secondary to fluid retention. Diuretics increase the urine volume by enhancing the excretion of water and sodium chloride leading to decreased plasma and extracellular fluid volume and a decrease in peripheral and pulmonary edema. The acute hemodynamic effect of the intravenous administration of loop diuretics is vasodilation manifested by a reduction in ventricular filling pressures and in pulmonary vascular resistance.[63] With high doses reflex vasoconstriction has been reported. In acutely decompensated heart failure the use of diuretics normalizes loading conditions and may reduce neurohormonal activation in the short term.[64,65]

Intravenous administration of loop diuretics (furosemide, bumetanide, torasemide) is preferred in acute heart failure. The dose should be titrated according to the diuretic response and relief of congestive symptoms. Administration of a loading dose followed by continuous infusion has been shown to be more effective than bolus alone with a lower incidence of toxicity.[65–69] Diuretic resistance has been described and when present alternative means of fluid removal by dialysis or ultrafiltration should be considered.

Morphine can be used in the treatment of patients with pulmonary edema although its effectiveness has not been studied in clinical trials. Morphine induces venodilation and mild arterial dilation, reduces heart rate[70] and relieves breathlessness in patients with acute pulmonary edema.

There is no evidence from clinical trials to support the use of anticoagulants in critically ill patients with AHF without myocardial ischemia or atrial flutter/fibrillation. However, the morbidity and mortality from thromboembolic disease in the ICU warrants the consideration of prophylactic anticoagulation in patients with AHF. A placebo controlled study evaluating enoxaparine in acutely ill patients, which included patients with AHF, demonstrated a reduction in the incidence of complicating venous thromboembolism but no improvement in survival or duration of hospitalization.[71]

Nesiritide, a recombinant human BNP, has been used for the treatment of AHF. Nesiritide reduces right atrial pressure, pulmonary capillary wedge pressure and increases stroke volume. Additional beneficial actions include coronary artery vasodilation, diuresis, natriuresis and neurohormonal suppression.[72] The drug has been shown to be more efficacious than placebo in symptom improvement without a pro-arrhythmic effect. When compared to intravenous nitroglycerin neseritide results in a more rapid improvement in hemodynamic profile in patients with AHF.[73] In an open-label randomized trial of nesiritide and standard care versus standard care alone, patients treated with nesiritide exhibited a trend toward decreased readmissions and six-month mortality.[74] Nesiritide is administered as a 2 μg/kg bolus followed by a fixed dose infusion of 0.01 μg/kg per minute. The dose can be increased every three hours, to a maximum of 0.03 μg/kg/min, if the pulmonary capillary wedge pressure is more than 20 mm Hg and systolic blood pressure is more than 100 mm Hg (using a 1 μg/kg bolus followed by an increase of 0.005 μg/kg/min over the previous infusion rate). If hypotension occurs, the infusion should be discontinued and restarted after blood pressure stabilization, at a 30% lower infusion rate without bolus. Hypotension is a significant adverse effect of the drug, and may persist despite immediate cessation of infusion. Accordingly, nesiritide should not be employed in patients with extremely labile blood pressure dipping below a level of 90 mm Hg systolic.

In the near future, therapies directed at potentiating the beneficial effects of endogenous natriuretic peptides by reducing their degradation may find clinical application. A target under current investigation is neutral endopeptidase, the primary enzyme involved in their degradation. However, preliminary studies of inhibitors of neutral endopeptidase showed increased neurohormonal activation with increased levels of angiotensin II and endothelin-1 after enzyme inhibition.[75] Thus, vasopeptidase inhibitors, which could provide simultaneous inhibition of angiotensin converting enzyme and neutral endopeptidase have been developed. Early

use of such agents has been confounded by a high incidence of angioedema.[76,77]

Beta-blocking agents are contraindicated in patients with AHF, at least if it is clear that systolic dysfunction of the left ventricle is significant. Among patients in whom ischemia and tachycardia per se are felt to contribute significantly to their deterioration, beta blockade may be required; under such circumstances a short acting agent such as esmolol or metoprolol may given intravenously to permit cessation of therapy if adverse effects are encountered. Patients admitted to the ICU with AHF already receiving beta blockers should be continued on this therapy unless inotropic support is needed or excessive dosages is suspected.

In the initial management of the patient with acute heart failure, ACE inhibitors are not recommended and calcium antagonists are contraindicated. ACE inhibitors have an important role in the patient with systolic heart failure early after stabilization. Some new compounds with diuretic effect and vasodilating properties are under investigation, including vasopressin receptor antagonists.

Inotropic agents are indicated in the presence of hypotension and low cardiac output, with or without pulmonary congestion, refractory to optimal doses of diuretics and vasodilators (see Table 23-1). Inotropes are potentially harmful in chronic HF as they increase oxygen demand and calcium loading and should be used with caution.[78–80] However, in patients with AHF, symptom relief and prognosis appear dependent on correction of grossly deranged hemodynamics. Only a few controlled trials assessing specific inotropic regimens have been performed and thus rigid guidelines for drug administration do not exist.[80]

Dopamine is an endogenous cathecolamine and a precursor of norepinpehrine. Its effects differ according to dosage. At low doses ($\leq$2 to 3 μg/kg/min) activation of dopaminergic DA1 and DA2 receptors predominates with vasodilation in renal, mesenteric, coronary and cerebral vascular beds. The activation of DA2 receptors inhibits norepinephrine release from nerve terminals, activates the emetic center, decreases prolactin release and inhibits angiotensin II mediated aldosterone secretion. In the past, dopamine was widely used in the ICU to improve renal blood flow and diuresis in AHF patients with hypotension and low urine output. However, administration of low-dose dopamine to critically ill patients at risk of renal failure does not confer clinically significant protection from renal dysfunction.[81,82] Small trials suggested some benefit of dopamine at low doses in patients with AHF but this general practice is not strongly supported by existing literature.[83] In AHF with hypotension dopamine can be used at higher doses for both inotropic and vasoconstrictive purposes but adverse effects of increased afterload or mismatch of oxygen supply to myocardial demand should be anticipated.

Dobutamine is a synthetic, sympathomimetic agent with substantial beta agonist activity resulting in significant inotropic and chronotropic effects on the heart.[84] It is usually initiated with a 2 to 3 μg/kg/min infusion rate without a loading dose. The infusion rate may be progressively titrated according to symptoms, diuretic response or assessments of hemodynamics (cardiac output, mixed venous oxygen saturation). The dose may be initially increased to 20 μg/kg/min as required. When undesirable side effects are encountered (tachycardia, hypotension, chest pain, arrhythmia), discontinuation of the drug is usually associated with reversal of effect due to short half life. Dobutamine may have an additive effect when given concurrently with phosphodiesterase inhibitors (see below). Prolonged infusion of dobutamine (above 48 hours) is associated with tolerance effects.[85,86]

Type III phosphodiesterase inhibitors (PDEI) are drugs with hemodynamic activity intermediate between that of a pure vasodilator and that of an inotrope.[85] They are mainly used in patients with AHF and peripheral hypoperfusion, refractory to optimal diuretic and vasodilating therapy. Milrinone and enoximone are the PDEIs used in clinical practice. They act by inhibiting the breakdown of cyclic-AMP (cAMP) into AMP in both the vascular and myocardial smooth muscle. As a result, contractility improves in cardiomyocytes and relaxation in the smooth muscle cells. Because their site of action is distal to the beta-adrenergic receptors PDEIs maintain their effects even during concomitant beta-blocker therapy. When administered to patients with advanced HF, milrinone improves hemodynamics without tolerance development.[86] Hypotension may be caused by excessive peripheral vasodilation and is observed mainly in the patients with low intravascular volume. Therefore PDEIs are used in patients with preserved systemic blood pressure. Outcome data

TABLE 23-1 Inotropic Agents

	Indication	Bolus	Infusion Rate
Dobutamine	Hypotension, hypoperfusion	No	2 to 20–40 μg/kg per minute (predominant β-agonist effect throughout this range)
Dopamine	Hypotension, hypoperfusion	No	<3 μg/kg per minute: dopaminergic effect 3–5 μg/kg per minute: β-agonist effect predominant >5 μg/kg per minute: α agonist, vasoconstriction predominant
Milrinone	Hypoperfusion with preserved blood pressure, patients on β blockers	25–75 μg/kg per minute over 10–20 min	0.375–0.75 μg/kg per minute
Norepinephrine	Severe hypotension refractory to dobutamine		0.2–1.0 μg/kg per minute

regarding PDE-I administration in patients with acute HF are limited but not encouraging especially in patients with ischemic cardiomyopathy. Based on hemodynamic data alone, the combination of milrinone and dobutamine has a greater positive inotropic effect than each drug alone. However, the pharmacokinetic profile of milrinone is not optimal for ICU patients because individual responses to milrinone vary considerably.

A new class of medications which enhance calcium sensitization of the contractile proteins has found application in Europe and agents are in survival clinical trials in Europe and North America. Levosimendan is such an agent, and has been used in patients with symptomatic low cardiac output secondary to cardiac systolic dysfunction without severe hypotension. Levosimendan improves cardiac contractility by increasing the sensitivity of troponin C to calcium although is also type III PDE inhibitor.[87–91] Activation of adenosine triphosphate (ATP) sensitive potassium channels are responsible for its vasodilatory properties. Levosimendan has an active, potent, acetylated metabolite with half-life of approximately 80 hours, which probably explain the prolonged hemodynamic effects of a 24-hours levosimendan infusion.[88–91] Levosimendan has not been used extensively in patients with AHF. In patients with decompensated chronic systolic HF increases cardiac output, heart rate and stroke volume and decreases the pulmonary capillary wedge pressure and systemic and pulmonary vascular resistance.[88–91] An improvement in symptoms and decreased mortality has been shown in trials comparing levosimendan with dobutamine in patients with advanced chronic HF.[91] The hemodynamic effect of levosimendan is maintained in heart failure patients on concomitant beta-blocker therapy. Tachycardia and hypotension are its main side effects and levosimendan is not recommended in patients with low systolic blood pressure.

When the combination of inotropic agent and fluid challenge fails to restore organ perfusion and blood pressure, therapy with vasoconstrictors may be needed. Since this treatment may result in excessive afterload applied to a failing ventricle, it should be used as an emergency measure to sustain life and maintain perfusion in the face of life-threatening hypotension. Recent data indicate that if a vasopressor is needed, norepinephrine may be used because epinephrine has more negative effects on splanchnic circulation and on lactate metabolism.[92,93]

Cardiac glycosides inhibit sodium-potassium ATPase, thereby increasing calcium-sodium exchange with resulting positive inotropic effects. In AHF, cardiac glycosides produce a small increase in cardiac output and a reduction of filling pressures.[94,95] However, in patients with heart failure following myocardial infarction, increase of creatine kinase was more pronounced in patients receiving cardiac glycosides,[96,97] and in some studies a proarrhythmic effect and an adverse effect on outcome have been described. Accordingly, cardiac glycosides are not recommended for the acute management of AHF especially after acute myocardial infarction.

MECHANICAL ASSIST DEVICES

Mechanical circulatory support may be used in patients with AHF without permanent end-organ dysfunction, nonresponding to conventional therapy, as a bridge to recovery or as a bridge to heart transplant. In clinical trials left ventricular assist devices have been used as destination therapy for patients with advanced chronic heart failure but device related complications limit their use for this indication.

INTRAAORTIC BALLOON PUMP (IABP)

IABP is most frequently used in patients with cardiogenic shock or ongoing severe myocardial ischemia, refractory to initial medical therapy, in preparation for revascularization. It is also useful in patients with acute myocardial infarction complicated by significant mitral regurgitation or rupture of the interventricular septum, to obtain hemodynamic stabilization for definitive diagnostic studies and treatment or after cardiac surgical procedures for patients with low cardiac output states.[98] The IABP has obvious advantages over other cardiac assist devices because of the rapidity and ease of insertion, accomplished through a femoral artery and performed at the bedside of the ICU patient. However, IABP does not augment forward flow to the extent achieved with ventricular assist devices (see below).

IABP operation is based on the principle of counterpulsation. A balloon is positioned in the descending aorta just distal to the left sublavian artery. The balloon deflates at the onset of systole immediate prior to the ejection of blood from the left ventricle. Thus reduces afterload, thereby decreasing left ventricular work and myocardial oxygen consumption. It inflates in diastole, increasing diastolic pressure resulting in increased coronary artery perfusion. In the setting of nonischemic heart failure the afterload reduction may be still useful but the benefits of increased coronary flow are not clear. Vascular complications are common and careful monitoring of lower extremity perfusion is necessary. Intraabdominal (mesenteric ischemia, pancreatitis, splenic infarction), neurologic (stroke, paraplegia) and infectious complications have been described. Balloon rupture with helium embolization and balloon entrapment has been also reported. IABP is contraindicated in patients with aortic dissection or significant aortic insufficiency and its use should be restricted to patients with a correctable underlying condition.

VENTRICULAR ASSIST DEVICES

AHF patients not responding to conventional treatment including intra-aortic balloon pumping are candidates for mechanical circulatory support with ventricular assist devices (VAD).[99–101] This situation should be understood as one of bridging the patient ventricular function is expected to improve or transplantation is planned. VAD has been used after acute myocardial infarction, in post cardiac surgery low cardiac output syndrome and in acute myocarditis. Specific hemodynamic criteria have been used for patient selection in decompensated chronic heart failure but patient selection is more difficult in AHF. Patients with right heart failure are candidates for biventricular support, patients with aortic valve prosthesis are at increased risk for thromboembolism with some systems and aortic regurgitation is exaggerated after left VAD insertion because of the lowered left ventricular end diastolic pressure. An incompetent aortic valve may need repair or replacement before VAD insertion.

Many VAD are currently available and can be categorized in several different ways including: (a) left versus right VAD; (b) pulsatile versus non pulsatile flow; (c) internal versus external placement. No current single VAD is appropriate for the management of all AHF patients. Selection of the device is determined by the expected duration of support, the specific cardiac pathology, type of support needed (right, left or

biventricular), the device availability and surgical team experience. It is not possible for all cardiac surgery centers to use all available systems. Ideally, a center should have access to a short term support system for AHF, a long term support system and a system capable of providing support to the right ventricle.[101]

The patient with a VAD is a challenge for the ICU team because thromboembolism, bleeding, infection, hemolysis and device malfunction are common complications associated with the use of these systems.

Management of Specific Diseases in Acute Heart Failure

ACUTE MYOCARDIAL INFARCTION

In all patients with acute myocardial infarction and signs and symptoms of heart failure echocardiography is necessary for assessment of ventricular function and mechanical complications (see Table 23-2). In acute myocardial infarction complicated by cardiogenic shock emergency percutaneous intervention or surgery improves prognosis and should be considered at an early state. If neither of these are available, or can be only provided after long delay, fibrinolytic therapy should be considered.[102,103] Temporary stabilization of the patient can be achieved by adequate fluid and pharmacological support, intra aortic balloon pump and mechanical ventilation.

Acute right heart failure after myocardial infarction is usually related to acute right ventricular infarction with a typical electrocardiogram and echocardiogram. Early revascularization of the culprit coronary artery may improve prognosis.

FREE WALL RUPTURE

The incidence of cardiac wall rupture after an acute myocardial infarction is 0.8–6.2%.[104–107] Recent studies have shown that percutaneous intervention decreased the incidence of cardiac rupture, compared with the thrombolytic era. Older age, female gender, anterior location of the infarct and longer time to reperfusion carry an increased risk of cardiac rupture. Usually, death occurs within minutes due to cardiac tamponade and the diagnosis is established in autopsy. However, in around 30% of cases thrombus seals the rupture giving an opportunity for intervention, if the condition is recognized. Most of these patients have signs of hemodynamic collapse and in some patients rupture is preceded by chest pain, nausea and T wave changes or new ST segment elevation in the infarct related leads. All these patients should undergo immediate echocardiography. The clinical presentation, pericardial effusions more than 10 mm and intrapericardial echo densities consistent with thrombus confirm the diagnosis. Pericardiocentesis, fluids and positive inotropes have been used for temporary hemodynamic stabilization. However, the patients should be immediately transferred to the operating room for surgical repair of the rupture. Free wall rupture has been also described during dobutamine stress echocardiography after acute myocardial infarction.[107]

TABLE 23-2 Cardiac Disorders with Acute Heart Failure that Require Surgical Treatment

After Acute Myocardial Infarction
Cardiogenic shock and multi-vessel coronary artery disease
Ventricular septal defect
Free wall rupture
Acute mitral regurgitation
Valvular Disease
Acute decomposition of preexisting heart valve disease
Prosthetic valve failure or thrombosis
Acute mitral regurgitation (myxomatous degenerative lesions, endocarditis, trauma)
Acute aortic regurgitation (endocarditis, aortic dissection, trauma)
Ruptured sinus of Valsalva aneurysm
Acute heart failure requiring support by mechanical assist devices

Modified from Nieminen MS, Bohm M, Drexler H, et al.[1]

POST-INFARCTION VENTRICULAR SEPTAL RUPTURE (VSR)

Acute rupture of the interventricular septum occurs in 1–2% of all infarcts. VSR usually occurs in the first 5 days after an acute myocardial infarction. However, in the thrombolytic era the incidence has decreased and the median time of VSR is 1 day.[108–111] Septal rupture is more frequent in patients with transmural anterior myocardial infarction but in these patients VSR is generally apical and simple. In patients with an inferior myocardial infarction ruptures are in the basal inferoposterior septum and are more complex. The VSR is typically presented as acute pulmonary edema or cardiogenic shock in a patient with right-sided ventricular failure and a harsh, loud, holosystolic murmur usually at the left lower sternal border. With low output state the murmur is difficult to identify. Echocardiography is generally diagnostic. It will identify the site of the ventricular rupture, the size of the left to right shunt, left and right ventricular function and the existence of mitral incompetence. Severe mitral regurgitation coexists in 20 percent of patients with VSR. Pulmonary artery catheterization can be helpful if echocardiography is not diagnostic. It will document the increase in oxygen saturation in the right ventricle and the pulmonary to systemic blood flow ratio (usually more than 2). Temporary medical therapy consists of diuretics, vasodilators, inotropes, intraaortic balloon pump, oxygen and in some patients positive pressure ventilation. However, surgical repair should be performed soon after the diagnosis in most patients.[108] The timing of the surgical repair has been an issue of debate. It was believed that in the acute phase of the myocardial infarction the myocardium was too fragile for the safe repair of the VSR. However, current Guidelines recommend immediate surgical repair, regardless of the clinical status of the patient, because the rupture can abruptly expand even in stable patients.[1,111]

In some small, retrospective clinical studies has been supported that concomitant coronary artery bypass grafting improves late functional status and survival.[109] Thus, revascularization is usually performed although the number of patients in these studies was too small to draw any firm conclusions.[109] Percutaneous closure of the VSR has been used to stabilize selected patients but more experience is needed before it can be recommended. VSR has been also described in patients with normal coronary arteries and myocardial bridge.

Moreover, a new systolic murmur and cardiogenic shock have been described in some patients with anterior myocardial infarction.[112] In these patients with apical anterior myocardial infarction compensatory hyperkinesis of the basal segments of the heart induces left ventricular outflow tract (LVOT) obstruction. The syndrome persists until appropriate therapy decreases the LVOT obstruction.

ACUTE MITRAL REGURGITATION (MR)

Mild MR is common after an acute myocardial infarction and is not usually associated with hemodynamic compromise. However, acute severe MR is the cause of shock in approximately 10% of patients with cardiogenic shock after an acute myocardial infarction.[113,114] It occurs 1–10 days after the infarction. Successful reperfusion by thrombolytic therapy or percutaneous intervention probably reduces the incidence of acute MR and is associated with an earlier occurrence (median 1 day). Several different mechanisms are responsible for acute MR after an acute myocardial infarction. The most dramatic is complete papillary muscle rupture where most of the non operated patients die in the first 24 hours. Cordae tendineae rupture, partial papillary muscle rupture or dysfunction of the papillary muscle are more common and with better survival. In most patients posteromedial papillary muscle is involved because of its single blood supply from the posterior descending coronary artery.

Acute severe MR is manifested by flash pulmonary edema and shock. The characteristic apical systolic murmur may be absent, due to the acute elevation of pressure in the non compliant left atrium and the rapid pressure equalization between left atrium and left ventricle. Moreover, auscultatory finding of pulmonary edema may mask the MR murmur. Chest radiograph shows pulmonary edema (might be unilateral). Echocardiography is the standard diagnostic tool for detecting the presence and severity of mitral regurgitation. The left atrium is usually small or slightly enlarged. Transesophageal echocardiography may be needed to establish the diagnosis in some patients with not adequate transthoracic images. However, when the mitral valve is not well visualized, the demonstration of preserved systolic function in a patient with acute myocardial infarction and pulmonary edema is helpful. A pulmonary artery catheter is rarely needed for diagnostic purposes but it may be useful in monitoring the effects of therapy.

The patients with severe acute MR and pulmonary edema or shock from papillary muscle or chordal rupture require emergency surgical repair. Even if medical therapy and intra aortic balloon pumping result in hemodynamic stabilization operation should be done early because many patients deteriorate suddenly.

MANAGEMENT OF ACUTE HEART FAILURE FROM PROSTHETIC VALVE THROMBOSIS

The incidence of prosthetic valve thrombosis depends on valve location and type and the adequacy of anticoagulation. It is from 0.2–6% per patient year in patients with mitral or aortic valve prostheses up to an overall 20% in patients with prostheses in the tricuspid valve.[115–121] Clinical presentation of patients with prosthetic valve thrombosis (PVT) includes patients with clinically silent PVT, patients with stroke or peripheral embolism and patients with hemodynamic compromise and signs and symptoms of heart failure. All patients with a prosthetic valve and heart failure symptoms should undergo immediately a transthoracic and/or transesophageal echocardiographic study. Thrombolytic therapy is considered the treatment of choice for tricuspid valve thrombosis. The ideal therapy for left sided PVT remains controversial.[116–118] Surgical mortality is high for emergency operations in critically ill patients with hemodynamic instability (New York Heart Association functional class III or IV symptoms, pulmonary edema, hypotension). Thus, thrombolytic therapy was recommended for high risk surgical candidates.[116] However, thrombolysis takes several hours to be effective and this delay may lead to further deterioration in critically ill patients. The recommended dose of rtPA is 10 mg intravenous bolus followed by 90 mg infused over 90 min or 250–500,000 IU of streptokinase infused over 30 min followed by 100.000 IU per hour for 10 hours. Urokinase can be also used in a dose of 4,400 IU/kg/h for 12 hours without heparin or 2000 IU/kg/h with heparin for 24 hours. Echocardiography should be repeated in all patients after thrombolytic therapy. Thrombolysis is ineffective in approximately 18% and in these patients surgical intervention is indicated, although repeated infusions of thrombolytic therapy have been used in some studies.[118,119] Moreover, mortality is 6% and the risk of thromboembolism is 12%. Patients with aortic PVT and patients with large or mobile thrombi have a higher risk for thromboembolic complications after thrombolytic therapy and surgical intervention should be considered in these patients. Moreover, thrombolysis is not effective when fibrous tissue ingrowth (pannus) is implicated in the obstruction of the prosthetic valve. Clinical history, presentation and transesophageal echocardiography are helpful in the differential diagnosis but sometimes the distinction is still difficult.[120] Patients who are in stable clinical condition usually are not admitted in the ICU. Their management is also controversial. Small retrospective studies suggest that fibrinolytic therapy may be equally effective and in these patients.[116,118]

In conclusion, the clinical presentation of the individual patient, the characteristics of the PVT and the expertise at each center should be used to arrive at a therapeutic decision.

Chapter 24

CARDIAC ARRHYTHMIAS, PACING, CARDIOVERSION, AND DEFIBRILLATION IN THE CRITICAL CARE SETTING

ANNE M. GILLIS

KEY POINTS

- *Correct diagnoses and understanding of arrhythmia mechanisms are crucial to successful arrhythmia management.*
- *The hemodynamic effects of an arrhythmia are important in developing an appropriate treatment strategy.*
- *Predisposing conditions and reversible causes should be recognized and corrected.*
- *Knowledge of antiarrhythmic drug therapy, cardiac pacing, electrical cardioversion, and defibrillation are essential to successful arrhythmia management.*
- *The proarrhythmic potential of antiarrhythmic drugs must be recognized and preventive measures taken whenever possible.*
- *Knowledge of antiarrhythmic drug pharmacokinetics and pharmacodynamics and the effect of multisystem organ disease on these parameters are important in preventing drug toxicity.*
- *The intensivist should be skilled in the implantation of temporary pacing systems, external cardioversion, and defibrillation.*
- *The intensivist should recognize when temporary and implantable pacemakers or cardioverter defibrillators are not functioning appropriately.*
- *Not all arrhythmias require long-term prophylactic treatment.*

Cardiac arrhythmias are common in the critical care setting. Many arrhythmias detected are benign, may occur in healthy individuals, and require no investigation or treatment (e.g., sinus tachycardia, sinus bradycardia, Mobitz type I second-degree atrioventricular [AV] block, or premature atrial and ventricular beats). Correct diagnosis and understanding of arrhythmia mechanisms and knowledge of antiarrhythmic drug pharmacology and nonpharmacologic therapies of arrhythmias are crucial for successful arrhythmia management. This chapter focuses on the mechanisms, investigation, and management of the most common, clinically significant arrhythmias encountered.

Tachyarrhythmias

MECHANISMS

Tachycardia mechanisms have been classified as due to abnormalities of impulse formation or impulse conduction.[1–3] Abnormalities of impulse formation may be due to normal automaticity, abnormal automaticity, or triggered activity occurring within atrial or ventricular muscle tissue or the specialized conduction system (Fig. 24-1A).[1,2] Natural pacemaker cells are found in the sinus node, parts of the atria, the atrioventricular node, and the His-Purkinje system. These cells exhibit phasic spontaneous depolarization during diastole, resulting in an action potential when the threshold potential is reached.[1] Although the sinus node is the dominant pacemaker in the normal heart, subsidiary pacemakers may become dominant under certain conditions, such as sympathetic stimulation or digitalis toxicity (see Fig. 24-1). Normal atrial and ventricular muscles maintain a high negative resting potential (−90 mV) and only depolarize when stimulated. Under certain pathophysiologic conditions, including electrolyte abnormalities and ischemia, the resting membrane potential may decrease (−60 mV) and cells may depolarize spontaneously.

Triggered activity is caused by after-depolarizations that occur early in repolarization (early after-depolarizations) or after repolarization is complete (delayed after-depolarizations; see Fig. 24-1B).[1,2] Early after-depolarizations may reach threshold to activate the slow inward current generating a new action potential, and this cycle may repeat, generating a sustained tachycardia. Early after-depolarizations are believed to be the mechanism of torsade de pointes ventricular tachycardia (VT).[2] Delayed after-depolarizations initiate a triggered response only when their amplitude reaches a critical threshold (see Fig. 24-1C). Increasing the heart rate or the prematurity of an extrastimulus increases the amplitude of a delayed after-depolarization, thus increasing the probability of inducing a tachycardia. Delayed after-depolarizations are thought to cause arrhythmias secondary to digitalis toxicity.

Abnormalities of impulse conduction are due primarily to reentry (see Fig. 24-1).[3] Reentry requires an area of fixed or functional unidirectional block in one pathway, slow conduction in an alternate pathway, and return of the impulse along the original path after this tissue has recovered excitability (see Fig. 24-1D). Reentry is the mechanism of many types of supraventricular tachycardias (SVTs; atrioventricular node reentry or in the Wolff-Parkinson-White syndrome) and VT that occur after a myocardial infarction. Table 24-1 summarizes the mechanisms of common tachyarrhythmias.

Antiarrhythmic Drug Therapy

Antiarrhythmic drug therapy may be required for the termination of tachyarrhythmias and prevention of recurrence. Knowledge of the potential mechanisms of an arrhythmia and of the pharmacology of antiarrhythmic drugs are important in selecting appropriate drug therapy. Because the critical care patient often has multisystem disease, special attention to factors that influence drug absorption, protein binding, drug

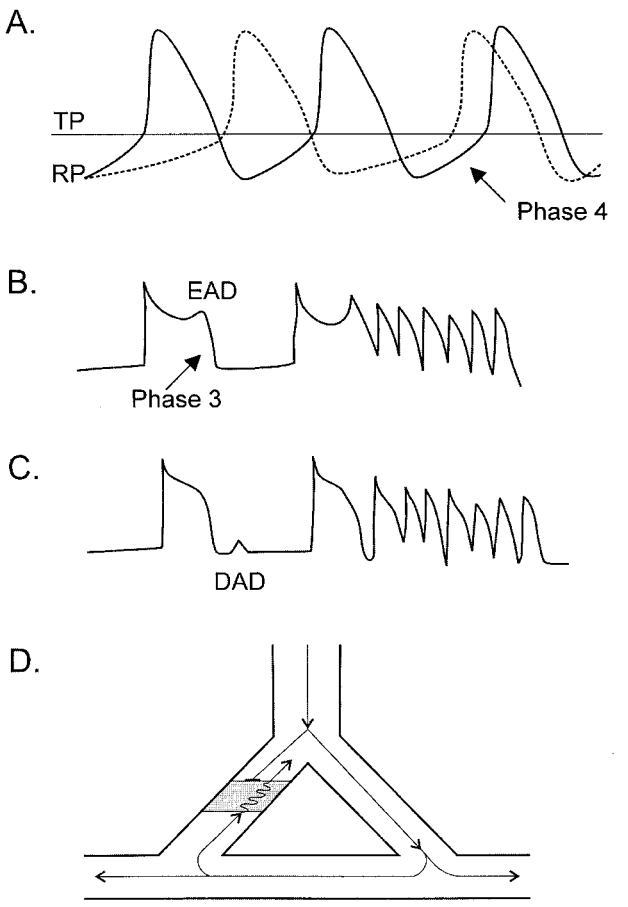

FIGURE 24-1 Mechanisms of cardiac arrhythmias: enhanced or abnormal automaticity and triggered activity or reentry. *A*. The rate of phase 4 depolarization may increase, causing the myocardial cell to reach the threshold potential (TP) sooner and spontaneously depolarize. In diseased tissue, the resting potential (RP) may be elevated and the time to reach TP may then be shortened (not shown). *B*. Early afterdepolarizations (EADs) develop late on phase 3 of repolarization of the action potential and, if they reach threshold, may trigger a depolarization. This is the mechanism of torsade de pointes ventricular tachycardia. *C*. Delayed afterdepolarizations (DADs) occur in diastole after repolarization is complete. If they reach threshold, they may trigger a depolarization. This is the mechanism associated with digitalis toxicity. *D*. Reentry is associated with an area of anatomic or functional unidirectional block (*speckled area*) and a region of slow conduction (*zigzag arrow*). A propagated impulse blocks in one area of tissue, passes through an area of slow conduction, and then conducts retrogradely through the original area of conduction block, which has now repolarized.

metabolism and excretion and knowledge of potential drug interactions are essential (see Chap. 103).[4]

The cardiac action potential varies strikingly in duration and morphology in specific regions of the heart, reflecting differences in ion channel expression or differences in modulators of ion channel function.[4] Antiarrhythmic drugs may therefore exert different effects on these various cardiac cells. Moreover, the effects of antiarrhythmic drugs may be modified in diseased cardiac tissue. For example, the effects of sodium channel blockers may be exaggerated in ischemic myocardium, and the effects of potassium channel blockers may

TABLE 24-1 Mechanisms of Common Tachycardias

Arrhythmia	Mechanism(s)
Supraventricular tachycardia	
AV node	Reentry
Accessory pathway	Reentry
Atrial tachycardia	Enhanced automaticity or reentry
Atrial flutter	Reentry
Atrial fibrillation	Onset: triggered activity
	Maintenance: multiple wavelet reentry
Ventricular tachycardia	
Monomorphic after MI	Reentry
Catecholamine-sensitive	Triggered activity
Torsade de pointes	Triggered activity
Ventricular fibrillation	Multiple wavelet reentry

ABBREVIATIONS: AV, atrioventricular; MI, myocardial infarction.

be exaggerated in the setting of left ventricular hypertrophy.[4] Antiarrhythmic drugs are classified most commonly by their dominant mechanism of action.[4–6] However, this drug classification scheme is imperfect because many of these drugs have effects on multiple ion channels or cell membrane receptors (Table 24-2). Efficacy of one drug does not predict the efficacy of another drug in the same class.

Class I drugs block the inward sodium current, resulting in slowing of conduction in atrial and ventricular muscles.[6] Their subclassification is based on the rate of recovery from sodium channel block. Class Ia antiarrhythmic drugs have an intermediate rate of recovery of sodium channel block and may cause prolongation of the QRS duration at physiologic heart rates. Class Ib drugs have a rapid recovery from sodium channel block and thus slow ventricular conduction only at very rapid heart rates. Class Ic drugs have a slow rate of recovery from sodium channel block and may cause significant prolongation of the QRS duration at resting heart rates. Class Ia and Ic drugs also block different potassium channels that cause prolongation of the atrial and ventricular action potential durations. This may manifest as prolongation of the QT interval. Class II drugs are β-adrenergic receptor blocking drugs.[7] Some of these agents are selective β_1-receptor blockers (see Table 24-2). Class III drugs are predominantly potassium channel blockers and prolong repolarization in atrial and ventricular muscle.[8] They can cause significant prolongation of the QT interval. Class IV drugs are calcium channel blocking drugs that decrease intracellular calcium concentrations.[7]

The mechanisms of action of commonly used antiarrhythmic drugs are listed in Table 24-2. Many of these agents are used to treat supraventricular and ventricular arrhythmias. Perhaps the most serious adverse response to antiarrhythmic drugs is the risk of proarrhythmia.[9,10] Proarrhythmia is defined as provocation of a new arrhythmia or worsening of an existing arrhythmia during therapy with a drug at concentrations not considered to be toxic. Class Ia and Ic drugs may cause excessive slowing of conduction in diseased atrial or ventricular muscle tissue that may exacerbate the clinical arrhythmia (e.g., atrial flutter or VT). These drugs increase the risk of sudden cardiac death in patients after myocardial infarction. Thus, class I antiarrhythmic drugs are contraindicated in patients with ischemic heart disease and a prior myocardial infarction because of the risk of

TABLE 24-2 Pharmacodynamics of Antiarrhythmic Drugs

	Recovery From Sodium Channel Block	K^+ Channels	Receptors
Class I			
Sodium channel blockers			
Class Ia			
Disopyramide	Intermediate	$\downarrow I_{to}$, $\downarrow I_{Kr}$ $\downarrow I_{K(ATP)}$	Inhibits muscarinic receptors
Quinidine	Intermediate	$\downarrow I_{to}$, $\downarrow I_{Kr}$	Inhibits α and muscarinic receptors

Nadolol	—		Nonselective β blocker
Propranolol	Rapid		Nonselective β blocker
Class III			
Drugs that prolong repolarization			
Amiodarone	Rapid	$\downarrow I_{Kr}$	Inhibits α and β receptors, calcium channel blocker
Dofetilide	—	$\downarrow I_{Kr}$	
Sotalol	—	$\downarrow I_{Kr}$	Nonselective β blocker
Class IV			
Calcium channel blockers			
Diltiazem	—	—	—
Verapamil	Rapid	—	—
Digoxin	—	—	Blocks Na^+, K^+ ATPase

ABBREVIATIONS: $I_{K(ATP)}$, ATP-sensitive K^+ channel sensitive to adenosine triphosphate; I_{Kr}, rapidly activating component of delayed rectifying current; I_{Kur}, ultra rapidly activating delayed rectifying current in atrial tissue; I_{to}, transient outward current.

ventricular proarrhythmia. Drugs that cause excessive prolongation of the QT interval may cause torsade de pointes VT.[4,9,10] Torsade de pointes VT may occur in 1% to 8% of patients exposed to QT interval prolonging antiarrhythmic drugs.[4]

The pharmacokinetic characteristics of commonly used antiarrhythmic drugs are summarized in Table 24-3.[6,11–14] Drug dosing, adverse effects, and potential interactions are listed in Table 24-4.[4,6–8,11,15,16] Adverse effects may develop from pharmacokinetic or pharmacodynamic drug interactions. Pharmacokinetic drug interactions develop when one drug modifies the absorption, distribution, metabolism, or elimination of a second drug, such as warfarin with amiodarone or digitalis with quinidine.[4,11] Pharmacodynamic interactions occur when a drug or condition increases or decreases the pharmacologic effect of a drug without changing plasma drug concentrations, such as increased protein binding of propafenone, verapamil, or lidocaine secondary to elevated α_1-acid glycoprotein after myocardial infarction.[11] Several enzymes in the cytochrome P450 family are responsible for drug metabolism. Some drugs may inhibit or induce these enzymes, resulting in important drug interactions (see Table 24-4).[4,11,12]

Ventricular Tachyarrhythmias

VENTRICULAR TACHYARRHYTHMIA CLASSIFICATION AND MECHANISMS

Sustained ventricular arrhythmias including monomorphic VT, polymorphic VT, and ventricular fibrillation (VF) usually occur in the setting of structural heart disease, most frequently in the setting of coronary artery disease, previous myocardial infarction, and poor left ventricular function.[17] However, any form of structural heart disease may be associated with ventricular arrhythmias. In addition, some individuals have primary electrical disease, usually associated with a mutation affecting one or more ion channels or proteins that regulate ion channels, as in the long QT syndrome and Brugada syndrome.[18]

The QRS complexes are uniform in monomorphic VT, whereas the QRS complexes change continuously in polymorphic VT. In VF, the surface electrocardiogram is disorganized without discernible QRS complexes. VT frequently precedes the development of VF, particularly in patients with a prior history of myocardial infarction. These arrhythmias are considered to be sustained if they last longer

TABLE 24-3 Pharmacokinetic Characteristics of Antiarrhythmic Drugs

Drug	Bioavailability (%)	Binding to Plasma Proteins (%)	Renal Elimination of Unchanged Drug (%)	Plasma Half-life (h)	Active Metabolites	Hepatic Metabolism
Class Ia						
Disopyramide	83 ± 11	28–68[a]	55 ± 6	6.0 ± 1.0	Racemic mixture

than 30 seconds or if they require acute intervention for termination.[14,19]

Multiple mechanisms contribute to VT. Monomorphic VT that develops in patients with a prior myocardial infarction is due to reentry near the border of the scar. In patients with dilated cardiomyopathy and an underlying intraventricular conduction delay, monomorphic VT usually with a left bundle branch block pattern may develop due to bundle branch reentry. In patients without structural heart disease, catecholamine-sensitive VT may originate in the right ventricular outflow tract due to triggered activity initiated by cyclic adenosine monophosphate. A verapamil-sensitive monomorphic VT that originates in the region of the left posterior fascicle is thought to be due to triggered activity.[18]

Polymorphic VT in the setting of a normal QT interval usually occurs in the setting of acute ischemia or significant hemodynamic instability,[20] although it may also occur in otherwise healthy individuals due to a mutation of the ryanodine receptor.[21] Torsade de pointes VT is a polymorphic, pause-dependent VT that develops in association with drugs or pathophysiologic conditions that excessively prolong the QT interval (Fig. 24-2 and Table 24-5).[7,8] Torsade de pointes VT is initiated by focal triggered activity and maintained by ventricular reentry. Risk factors for the development of torsade de pointes VT include female sex, baseline QT interval prolongation, excessive QT interval prolongation on drug therapy (>550 ms), bradycardia/pauses, hypokalemia, hypomagnesemia, congestive heart failure, cardiac hypertrophy, prior history of VT or VF, and renal impairment. The drugs and pathophysiologic conditions associated with torsade de pointes VT are listed in Table 24-5.[9] In addition to QT interval prolongation, electrocardiographic features that are harbingers of torsade de pointes VT include QT prolongation and T-wave morphology changes after an extrasystolic pause, T-wave alternans, late-coupled polymorphic ventricular premature beats, and repetitive polymorphic beats.[9]

VF is frequently associated with acute myocardial ischemia, or sustained VT may degenerate into VF. VF may be initiated by a triggered focus or reentrant mechanism and is maintained by multiple reentrant wavelets in the ventricles.

EVALUATION OF THE PATIENT WITH VT/VF

The initial evaluation of the patient with sustained VT or VF should be directed at detecting underlying reversible causes.[22] This evaluation should include a thorough history (if the patient is able to communicate) and physical examination. A 12-lead electrogram of VT is extremely valuable, as is

TABLE 24-4 Antiarrhythmic Drug Dosing and Adverse Effects

Drug	Dosage	Dosage Adjustment	Adverse Effects	Drug Interactions
Class Ia				
Quinidine gluconate (SR)	250 mg PO q 8 h ↑ By 250 mg doses if QTc <460 ms ↓ Dose if QTc ≥500 ms Discontinue if QTc ≥550 ms	↓ Initial dose 50% + ↑ dosing interval to q 12 h in renal failure	Diarrhea, stomach cramps, tinnitus; torsade de pointes VT	↓ Digoxin dose by 50% monitor INR if on warfarin ↓ Dose of β blocker; amiodarone, cimetidine, diltiazem, propranolol, and verapamil may increase quinidine concentrations
Procainamide SR	250 mg PO q 6 h ↑ By 250 mg increments if QTc <460 ms Maximum dose 1 g PO 1 6 h ↓ Dose if QTc ≥500 ms Discontinue if QTc >550 ms	Metabolism depends on rate of acetylation; the active metabolite NAPA accumulates in fast acetylators and in renal failure; monitor procainamide + NAPA levels and keep sum <80 μM: monitor ECG intervals	Agranulocytosis, rash, fever, SLE syndrome, torsade de pointes VT	Amiodarone, cimetidine, propranolol may increase procainamide concentrations
Procainamide IV	750–1000 mg loading 15–17 mg/kg at 20 mg/min; maintenance 1–4 mg/min		Hypotension	
Disopyramide	100 mg PO q 8 h SR 150–250 mg q 12 h ↑ By 100-mg increments if QTc <460 ms Maximum dose 300 mg PO q 8 h dose if QTc ≥500 ms Discontinue if QTc ≥550 ms	↓ Initial dose 50% and ↑ dosing interval q 12 h in renal failure	Urinary retention, blurred vision constipation, dry month, worsening heart failure, torsade de pointes VT	
Class Ib				
Lidocaine IV	1.5 mg/kg loading; 1–4 mg/min maintenance	↓ dose in CHF	Numbness, paresthesia, slurred, speech, altered consciousness.	Propranolol, metoprolol, cimetidine increase lidocaine concentrations
Mexiletine	150 mg–300 mg PO q 8 h		Nausea, stomach cramps, tremor, blurred vision, ataxia, confusion.	Cimetidine, quinidine, increase mexiletine concentrations
Class Ic				
Flecainide	50 mg PO q 12 h ↑ by 25–50-mg increments Maximum dose 200 mg PO q 12 h ↓ Dose if QRS prolonged >20% from baseline	↓ Initial dose 50% in renal failure; titrate dose based on QRS intervals.	Tremor, blurred vision, headache, ataxia, CHF, VT proarrhythmia	Amiodarone, cimetidine, propranolol, quinidine increase flecainide concentrations
Propafenone	150 mg PO q 8–12 h Maximum dose 300 mg PO q 8 h ↓ Dose if QRS prolonged >20% from baseline	↓ Initial dose 50% in renal and hepatic failure and ↑ dosing interval to q 12 h Active metabolites accumulate in rapid metabolizers; monitor QRS duration carefully	Constipation, dizziness, headache, metallic taste, exacerbation of asthma, VT proarrhythmia	↓ Digoxin dose by 25%–50%; cimetidine and quinidine increase propafenone concentrations
Class II				
Atenolol	50–200 mg PO daily	Caution in patients with CHF or bronchiospastic lung disease Monitor carefully in diabetic patients ↓ Dose in moderate to severae renal insufficiency	Bradycardia, hypotension, dyspnea, fatigue, depression	With digoxin, Ca^{2+} channel blockers, amiodarone ↓ Dose 25%–50% Hypoglycemic agents

(continued)

TABLE 24-4 Antiarrhythmic Drug Dosing and Adverse Effects (*continued*)

Drug	Dosage	Dosage Adjustment	Adverse Effects	Drug Interactions
Bisoprolol	2.5–10 mg PO bid	As per atenolol	As per atenolol	As per atenolol
Carvedilol	3.25–50 mg PO bid	As per atenolol Titrate dose every 1–2 wk to achieve maximum tolerated dose	As per atenolol	As per atenolol
Metoprolol	5–15 mg IV 25–400 mg PO bid	As per atenolol	As per atenolol	As per atenolol
Nadolol	20–160 mg PO daily	As per atenolol and ↓ dose in moderate to sever renal insufficiency	As per atenolol	As per atenolol
Propranolol	1–2 mg IV q 2–4 min PRN × 4–5 doses 20–80 mg PO bid/tid	As per atenolol	As per atenolol	As per atenolol
Class III				
Amiodarone	For AF: 200 mg PO tid × 2 wk, then 200 mg/d For VT: accelerated loading dose in hospital 400 mg PO tid × 10–14 d, then 400 mg PO bid × 7 d, then 300–400 mg PO daily	Avoid high loading dose in setting of sinus bradycardia (HR <50 beats/min)	Pulmonary toxicity, CNS effects, hyper-/hypothyroidism, photosensitivity, corneal deposits, hepatic toxicity.	↓ Quinidine/procainamide dose by 50% ↓ Digoxin dose by 50% ↓ β-blocker dose by 50% ↓ Warfarin dose by 50%
Amiodarone IV	150–300 mg IV over 20–30 min, then 0.5–1 mg/min; repeat boluses may be required	May cause hypotension		
Dofetilide	125–500 μg PO bid	↓ Dose if QT interval prolongs after first dose by 15%; discontinue if QTc ≥550 ms	Headache; torsade de pointes VT	Cimetidine, verapamil, ketoconazole, trimethoprim alone or in combination with sulfamethoxazole
Sotalol	80 mg PO q 12 h ↑ By 80-mg increments if QTc <460 ms Maximum dose 240 mg PO q 12 h ↓ Dose if QTc ≥500 ms; discontinue if QTc ≥550 ms	↓ Initial dose in renal failure ↓ Initial dose to 40 mg PO q 12 h in the elderly	Torsade de pointes VT, hypotension, bradycardia, wheezing; caution in CHF and bronchospastic lung disease	Digoxin/verapamil/other β blockers may cause AV block, bradycardia
Class IV				
Diltiazem	0.25–0.35 mg/kg IV 120–480 mg PO daily/bid	Caution in patients with CHF	Bradycardia, hypotension, peripheral edema	β Blockers, digoxin, amiodarone
Verapamil	5–15 mg IV 80 mg PO tid; maximum dose 120 mg qid or 240 mg bid	Caution in patients with CHF	Bradycardia, hypotension, constipation, flushing	β Blockers, digoxin, amiodarone
Digoxin	0.0625–0.25 mg PO daily	↓ Dose in renal failure	Arrhythmias, visual disturbance, nausea, vomiting	β Blockers; calcium channel blockers, quinidine, propafenone, procainamide, amiodarone.
Digoxin IV	0.25–1.0 mg IV over 20–30 min			

ABBREVIATIONS: AF, atrial fibrillation; AV, atrioventricular; bid, twice daily; CHF, congestive heart failure; CNS, central nervous system; ECG, elecrocardiographic; INR, international ratio; IV, intravenous; NAPA, *N*-acetylprocainamide; PO, per os; PRN, as needed; SLE, systemic lupus erythematousus; SR, sustained release; tid, three time daily; VT, ventricular tachycadia.

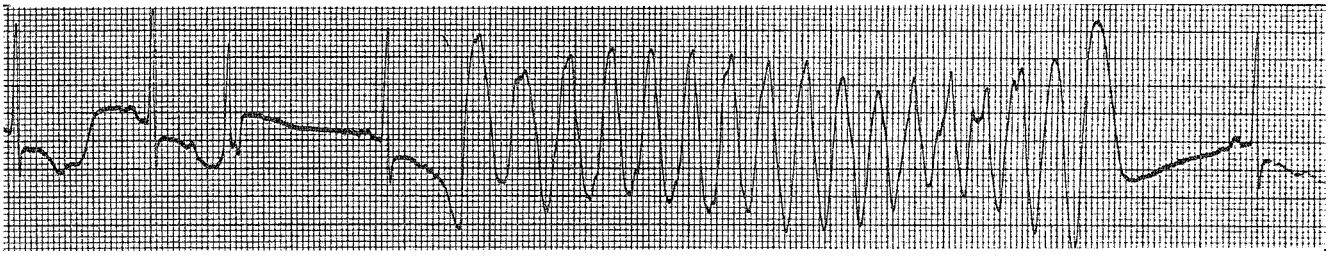

FIGURE 24-2 Example of torsade de pointes ventricular tachycardia (VT). There is significant QT interval prolongation before the onset of polymorphic nonsustained VT.

a review of rhythm strips documenting the onset of VT/VF. Laboratory tests should include cardiac enzymes (creatine kinase or troponin), creatinine, and serum electrolytes including K^+ and Mg^{2+}. An echocardiogram should be performed to determine the presence of structural heart disease and to assess ventricular function. Cardiac hemodynamic data should be reviewed. A drug screen may be required if drug toxicity is suspected (e.g., digitalis or tricyclic antidepressants). Some electrocardiographic features that allow discrimination of VT from SVT with aberrant conduction are summarized in Table 24-6.

TABLE 24-5 Drugs and Conditions Associated with Torsade de Pointes Ventricular Tachycardia

Drug Class	Specific Drugs
Antiarrhythmic drugs	
Class Ia	Disopyramide
	Procainamide
	Quinidine
Class Ic	Propafenone
Class III	Amiodarone
	Dofetilide
	Ibutilide
	d, *l*-Sotalol
Antifungal	Ketoconazole
	Fluconazole
	Itraconazole
Antihistamines	Diphenhydramine
	Terfenadine
	Astemizole
Antimicrobial	Erythromycin
	Clarithromycin
	Trimethoprim-sulfamethoxazole
	Pentamidine
Diuretics	Furosemide
	Hydrochlorothiazide
	Indapamide
	Metolazone
Psychotropic	Haloperidol
	Phenothiazines
	Risperidone
	Tricyclic antidepressants
	Tetracyclic antidepressants
Other conditions	Pathophysiologic condition
Bradycardia	Complete heart block, sinus pauses, or profound sinus bradycardia
Congenital long QT syndrome	Mutations of potassium or sodium channels
Electrolyte abnormalities	Hypokalemia
	Hypomagnesemia
	Hypocalcemia
Nervous system injury	Subarachnoid hemorrhage
Starvation	Anorexia nervosa, liquid protein diets

MANAGEMENT OF VENTRICULAR TACHYARRHYTHMIAS

GENERAL PRINCIPLES OF TREATMENT

Sinus rhythm should be restored as soon as possible in sustained VT or cardiac arrest.[22–24] Treatment of underlying cardiovascular disease should be initiated and any reversible causes should be identified and corrected (Table 24-7).[22–24] Serum potassium should be maintained 4.0 mmol/L or higher, and serum magnesium should be maintained above 0.7 mmol/L. Beta blockers should be prescribed unless contraindicated (see Table 24-4). Management of ischemic heart disease, left ventricular dysfunction, and hypertension must be optimized. If ongoing ischemia is present despite medical therapy, the patient should be considered for urgent coronary artery revascularization.

NONSUSTAINED VT

Beta blockers should be prescribed unless contraindicated, and doses should be titrated to suppress nonsustained VT (see Table 24-4).[16,22,25–27] If frequent, hemodynamically significant nonsustained VT persists, amiodarone may be initiated for suppression.[16,22,24,28] Patients with mild to moderate left ventricular dysfunction (left ventricular ejection fraction [LVEF] >0.30) may be considered for risk stratification electrophysiology study to determine the risk of sudden cardiac death.[16,29] Patients with severe left ventricular dysfunction in the setting of ischemic heart disease (LVEF ≤0.30) should be considered for an implantable cardioverter defibrillator (ICD) for prophylaxis of sudden cardiac death.[19,30]

MONOMORPHIC VENTRICULAR TACHYCARDIA

The acute management algorithm for sustained monomorphic VT is shown in Fig. 24-3. This algorithm is based on

TABLE 24-6 Electrocardiographic Criteria Consistent With Ventricular Tachycardia During Wide QRS Complex Tachycardia

the recommendations of the American Heart Association in collaboration with the International Liaison Committee on Resuscitation.[22–25] Synchronized cardioversion with 50 to 150 J of biphasic shock or 50 to 200 J of monophasic shock is the initial approach for the patient with hemodynamically unstable VT. The higher energy shocks should be used if the patient is unconscious. If the patient is hemodynamically stable and has normal or only mild left ventricular dysfunction, intravenous procainamide or sotalol may promote conversion. Beta-blocker therapy should be initiated to prevent recurrence. The patient with hemodynamically stable VT in the setting of significant left ventricular dysfunction should be treated with intravenous amiodarone (see Table 24-4 and Fig. 24-3).[22–25,28] If VT does not convert with pharmacologic therapy, synchronized electrical cardioversion may be required.

Long-term antiarrhythmic drug therapy in addition to long-term β-blocker therapy may be required to prevent VT recurrence. This decision is made after treatment of underlying

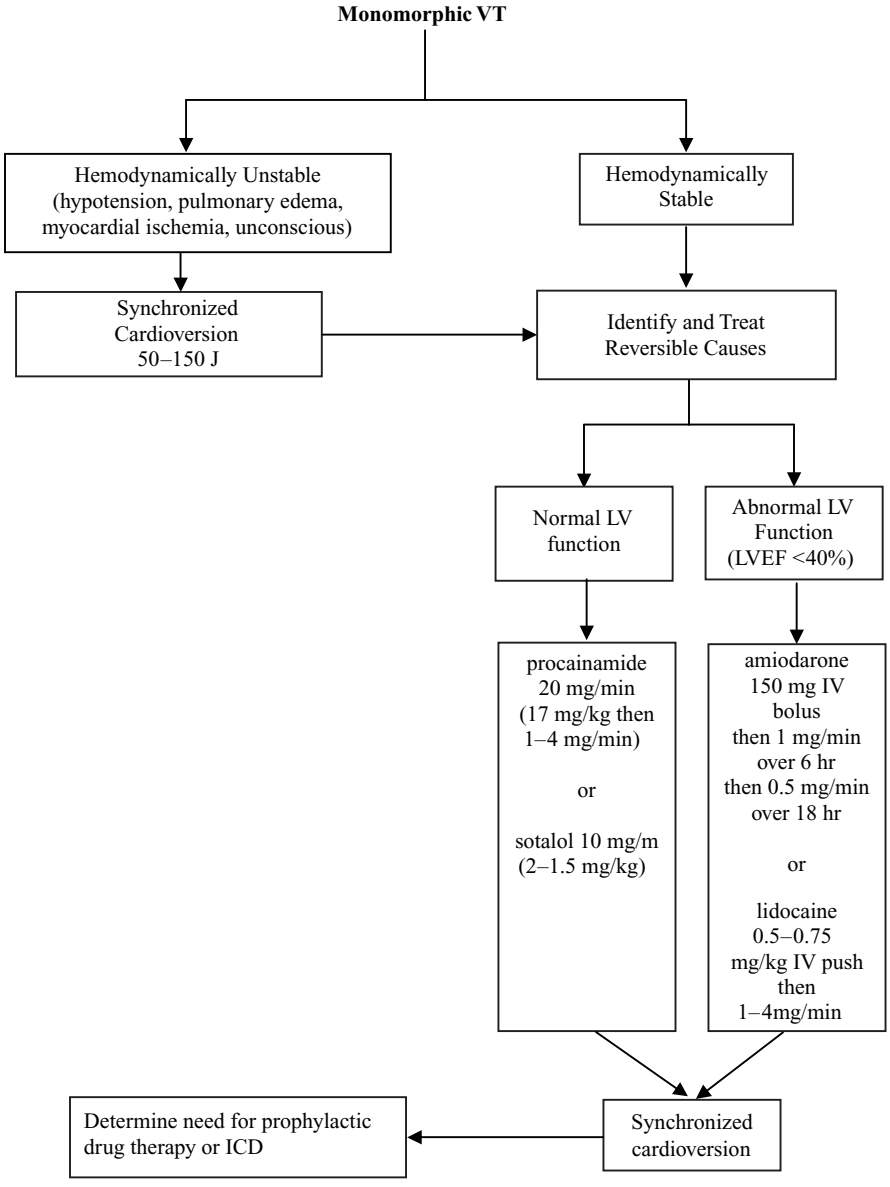

FIGURE 24-3 Management algorithm for sustained monomorphic ventricular tachycardia. ICD, implantable cardioverter defibrillator; LV, left ventricular.

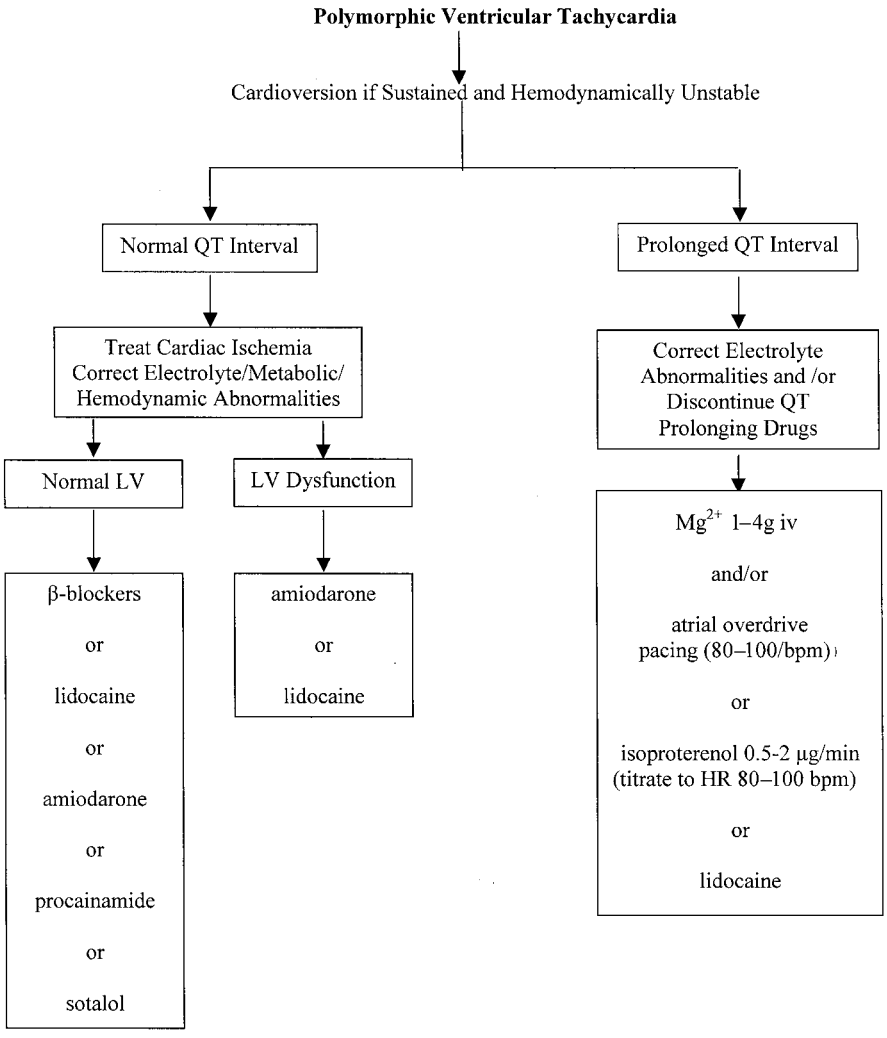

FIGURE 24-4 Management algorithm for sustained polymorphic ventricular tachycardia. LV, left ventricular.

causes has been achieved and coronary artery revascularization, if required, has been accomplished. Class I antiarrhythmic drugs are contraindicated in patients with coronary artery disease and prior myocardial infarction, and class I drugs and sotalol are relatively contraindicated in patients with left ventricular dysfunction because of the risk of ventricular proarrhythmia.[9,10] Patients with sustained VT in the absence of a reversible, correctable cause and in the setting of moderate to severe left ventricular dysfunction (LVEF $\leq$ 0.35) should be considered for an ICD. In this setting, the ICD has been shown to decrease cardiovascular mortality rate as compared with amiodarone therapy.[31–33] In patients with less severe left ventricular dysfunction, amiodarone appears to be as efficacious as the ICD, and long-term therapy with amiodarone or an ICD may be individualized.[33]

POLYMORPHIC VENTRICULAR TACHYCARDIA IN THE SETTING OF A NORMAL QT INTERVAL

The acute management algorithm for sustained polymorphic VT is shown in Fig. 24-4.[22,24] This algorithm is based on the recommendations of the American Heart Association in collaboration with the International Liaison Committee on Resuscitation.[24] Synchronized cardioversion with 50 to 150 J of biphasic shock or 50 to 200 J of monophasic shock is the initial approach for a patient with hemodynamically unstable sustained VT. Polymorphic VT in the absence of QT interval prolongation often is associated with myocardial ischemia.[20] Catecholaminergic polymorphic VT also has been described in patients without structural heart disease who have mutations of cardiac ryanodine receptors.[21] A patient with ischemia should be considered for urgent coronary angiography and revascularization, if required. This arrhythmia is frequently recurrent and intravenous β blockers or amiodarone should be administered to prevent recurrence. If a reversible cause, such as acute ischemia, is identified, long-term prophylactic antiarrhythmic drug therapy may not be required. Patients with significant left ventricular dysfunction should be considered for an ICD in the absence of a reversible, correctable cause.[29–33]

TORSADE DE POINTES VT

This arrhythmia frequently terminates spontaneously. However, cardioversion/defibrillation may be required if the patient develops sustained VT or VF. Magnesium, 1 to 4 g intravenously, is the initial treatment followed by cardiac overdrive pacing at 80 to 100 beats/min, which shortens the QT interval and prevents long pauses after premature beats (see Fig. 24-4).[22,34] Atrial overdrive pacing is preferred to ventricular overdrive pacing. An isoproterenol infusion may be

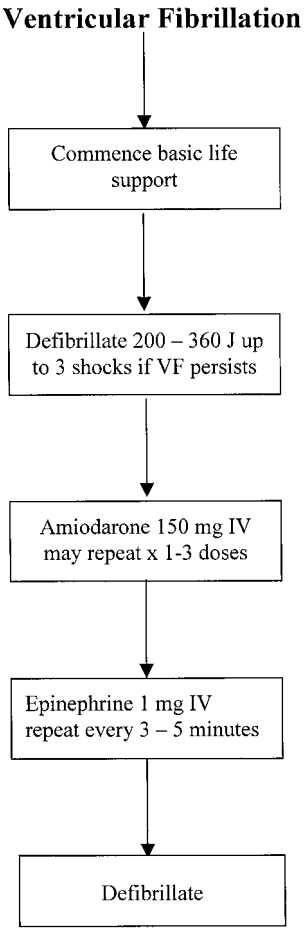

FIGURE 24-5 Management algorithm for ventricular fibrillation.

started until a temporary pacemaker is inserted. Drugs causing QT interval prolongation should be stopped and any electrolyte imbalances corrected. Temporary pacing should be continued until the VT has subsided and the QT interval returns to normal. If the patient has congenital long QT syndrome, long-term prophylactic therapy with β blockers or permanent cardiac pacing will prevent torsade de pointes VT.[18,35] An ICD is the treatment of choice in patients with congenital long QT syndrome who have sustained a cardiac arrest or who have a significant family history of sudden cardiac death.[18]

VENTRICULAR FIBRILLATION

Advanced life support should be initiated for VF, followed by prompt defibrillation (Fig. 24-5).[22–24] If defibrillation is unsuccessful at least three times, amiodarone and adrenaline should be administered before repeat defibrillation.[36] Intravenous amiodarone has been shown to improve resuscitation rates and overall survival rate if initial defibrillation is unsuccessful. If acute myocardial ischemia is the cause of VF, coronary angiography and percutaneous coronary intervention should be considered in the patient with recurrent VF. In the absence of a reversible cause, long-term therapy for prevention of sudden cardiac death should be prescribed. Patients with VF should be considered for an ICD, although in patients with well-preserved left ventricular dysfunction, amiodarone may also be a reasonable treatment option.[29–33]

VT/VF ELECTRICAL STORM

This is defined as multiple recurrent episodes of sustained VT or VF within a 24-hour period. Reversible causes should be identified and treated (see Table 24-7). Beta blockers are effective in suppressing some episodes of VT/VF storm.[22,26] Even in the setting of congestive heart failure (except cardiogenic shock), intravenous β blockers can be administered safely. Amiodarone is very effective in suppressing VT/VF, although multiple boluses may be required in some patients.[28] Combination β-blocker and amiodarone therapy is likely synergistic in suppressing recurrent VT/VF.[22] In the patient with an ICD and VT electrical storm who is receiving frequent, painful shock therapies, the VT cardioversion or defibrillation therapies may need to be temporarily programmed off until pharmacologic therapy suppresses the frequency of VT.

Supraventricular Tachyarrhythmias

SUPRAVENTRICULAR ARRHYTHMIA CLASSIFICATION AND MECHANISMS

Atrial fibrillation (AF) is the most common sustained arrhythmia observed, and its frequency increases with advancing age.[37] AF is believed to be triggered by spontaneous depolarizations that originate most commonly in the pulmonary veins. These often fire repetitively, initiating an atrial tachycardia that degenerates into AF through the development of multiple wavelets of reentry in the atria. AF is characterized by the absence of distinct P waves on the electrogram and an irregular ventricular response. The ventricular response during AF is usually very rapid (120 to 170 beats/min) unless the patient is on AV node blocking drugs or the patient has coexisting AV conduction system disease. Atrial flutter is characterized by atrial rates of approximately 300 beats/min and is usually due to reentry in the atrium, most commonly in the right atrium involving the isthmus between the inferior vena cava and tricuspid annulus. AF and atrial flutter often occur in the same patient. In atrial flutter, distinct P waves are observed on the electrogram; these are often inverted in leads II, III, and aVF. In the absence of AV node blocking drugs or coexisting AV conduction disease, 2:1 AV conduction with ventricular rates of 150 beats/min is the most common pattern observed. Class I antiarrhythmic drugs in the absence of adequate AV node blocking drugs may slow the atrial rate during atrial flutter such that 1:1 AV conduction occurs. This may be misdiagnosed as VT because an intraventricular conduction delay may develop at rapid ventricular rates.[9]

The most common type of SVT is due to AV node reentry.[38] This is characterized by swiftly and slowly conducting pathways in the AV node.[3] The electrogram is characterized by a regular narrow complex tachycardia with a short RP interval; usually P waves, if visible, are observed in the early part of the ST segment. Reciprocating tachycardia is secondary to macro reentry involving an accessory atrioventricular connection, characterized by a narrow complex tachycardia with a longer RP interval. Most patients have overt ventricular preexcitation (Wolff Parkinson White syndrome); however, in some patients, ventricular preexcitation is not manifest on the electrogram and retrograde conduction through the accessory connection is concealed. True atrial tachycardia is most

commonly due to enhanced or abnormal atrial automaticity or triggered activity. P waves usually precede each QRS complex unless there is AV conduction block. Multifocal atrial tachycardia is characterized by variation in P-wave morphology on a beat-to-beat basis.

EVALUATION OF THE PATIENT WITH SUPRAVENTRICULAR TACHYARRHYTHMIA

The initial evaluation of a patient with a sustained supraventricular tachyarrhythmia should include a thorough history (if the patient is able to communicate) and physical examination with special attention to detecting structural heart disease.[15] A 12-lead electrogram of the arrhythmia and during sinus rhythm should be obtained. Rhythm strips documenting onset and termination of the arrhythmia should be reviewed. Laboratory tests should include cardiac enzymes (creatine kinase or troponin), complete blood count, international normalized ratio, and thyroid-stimulating hormone. An echocardiogram should be made to determine the presence of structural heart disease and to assess ventricular function. In some instances, a transesophageal echocardiogram may be required to assess valve function or to determine whether intracardiac thrombus is present. Cardiac hemodynamic data during the arrhythmia, if available, should be reviewed.

MANAGEMENT OF SUPRAVENTRICULAR TACHYARRHYTHMIAS

GENERAL PRINCIPLES OF TREATMENT

Sinus rhythm should be restored as soon as possible if the patient is symptomatic. In the case of AF, therapy aimed at controlling the ventricular rate may be the initial approach. Any reversible causes should be identified and corrected. Underlying structural heart disease should be treated, in particular ischemic heart disease, left ventricular dysfunction, or hypertension. The probability of recurrence and the need for chronic prophylactic therapy should be determined.

ATRIAL FIBRILLATION OR FLUTTER

The therapeutic approach for the management of sustained AF or atrial flutter is illustrated in Fig. 24-6.[15,37] Synchronized electrical cardioversion may be required if the patient is

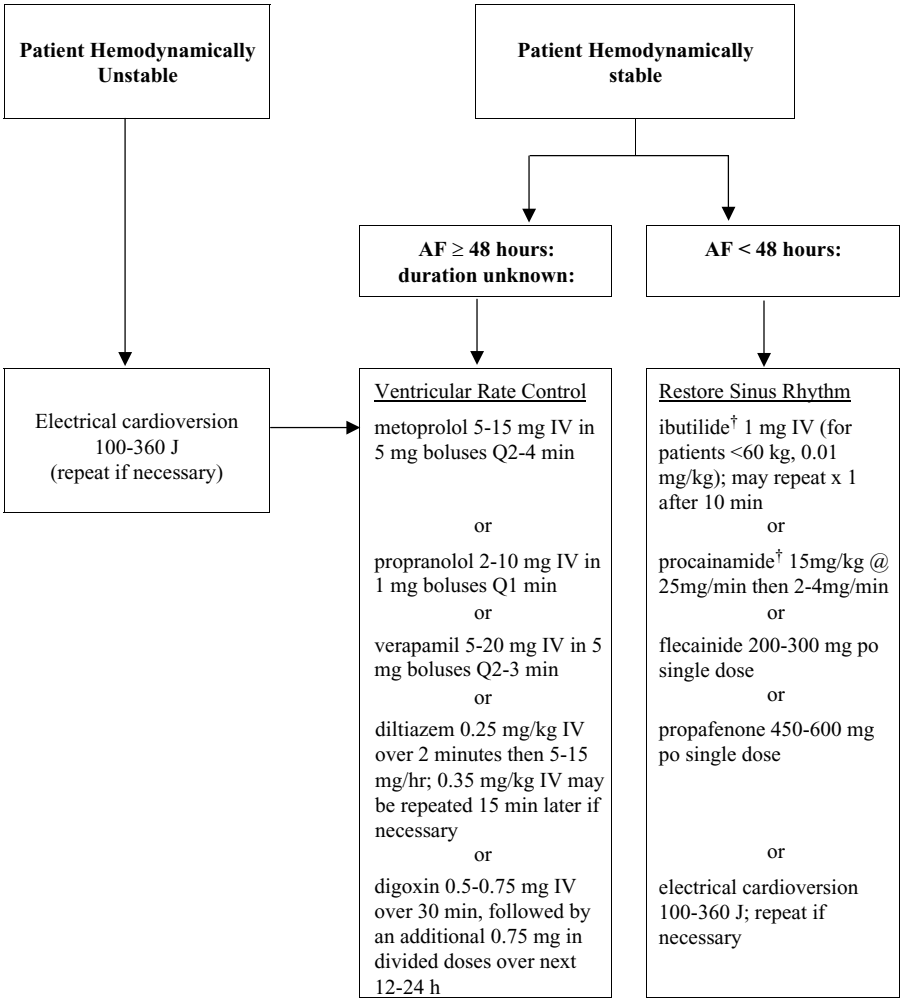

FIGURE 24-6 Management algorithm for atrial fibrillation (AF) or flutter.

† Procainamide or ibutilide is the drug of choice for Wolff-Parkinson-White Syndrome.

hemodynamically unstable. Atrial flutter is frequently terminated with low-energy cardioversion (50 J), whereas higher energies may be required for AF (≥100 J). Since the incorporation of biphasic waveforms into external defibrillators, it is rare for cardioversion to fail to convert recent onset AF. Atrial flutter may be terminated by rapid atrial overdrive pacing. Some dual-chamber pacemakers and implantable defibrillators have atrial antitachycardia pacing therapies for pace termination of atrial flutter.

If AF or flutter has persisted for at least 48 hours in the absence of effective anticoagulation, therapy should be aimed at achieving ventricular rate control (heart rate < 90 beats/min). Pharmacologic cardioversion to sinus rhythm can be considered if the patient has been in AF no longer than 48 hours. Anticoagulant therapy with heparin or low-molecular-weight heparin must be initiated. If cardioversion is performed, anticoagulant therapy should be continued for at least 3–6 weeks after cardioversion.[15,37] Ibutilide or procainamide can be administered intravenously to promote pharmacologic conversion for recent onset AF or flutter or in patients who have been on effective long-term anticoagulation (Table 24-8).[15] The electrogram must be monitored for significant QT interval prolongation because both drugs may cause torsade de pointes VT.[9,15] Intravenous amiodarone is less effective in promoting conversion to sinus rhythm, although it may facilitate improved rate control.[39] One important principle in the management of AF is that each patient deserves at least one attempt at restoration of sinus rhythm.[37]

The decision to initiate class I or III antiarrhythmic drug therapy to maintain sinus rhythm should be based the patient's symptoms and the hemodynamic significance of the arrhythmia. In the relatively asymptomatic patient, rate control is a reasonable first approach.[40,41] Beta blockers, verapamil, or diltiazem should be prescribed in doses to achieve a ventricular rate at rest or with minimal activity at rates slower than 90 beats/min (see Table 24-4).[15,37] Digoxin alone is frequently ineffective in achieving rate control of AF or atrial flutter, although it may be synergistic with class II or IV antiarrhythmic drugs. Rhythm control with class I or III antiarrhythmic drugs may be desirable in the very symptomatic patient or when these arrhythmias cause adverse hemodynamic effects.[40–42] AV node blocking drugs are required in conjunction with class I or III antiarrhythmic drugs because AF or atrial flutter is usually paroxysmal in nature and these drugs are rarely 100% effective at suppression. The dosages, potential side effects, and drug interactions of these drugs are summarized in Table 24-4. Class I drugs are contraindicated for chronic prophylaxis in patients with a prior myocardial infarction, and class I drugs and sotalol are relatively contraindicated in those with significant left ventricular dysfunction because of the risk of ventricular proarrhythmia.[9,10,37,43,44] Long-term antiarrhythmic drug therapy for prevention of AF or atrial flutter may not be required if the episode is thought to be due to a reversible cause, such as pneumonia or perioperative stress.

Catheter ablation for cure of atrial flutter is an effective therapy.[45] Pulmonary vein isolation can be considered for long-term cure of AF in selected patients.[46] AV junction ablation and ventricular pacing is an effective option in patients in whom effective ventricular rate control of AF cannot be achieved pharmacologically.[47]

The patient with AF or atrial flutter is at risk of thromboembolism, particularly if the patient is older or has structural heart disease.[37] Aspirin is indicated for prevention of thromboembolism in low-risk patients, whereas anticoagulation with heparin and then warfarin is required in high-risk patients (see Table 24-8).[37,48] If the patient has not been on anticoagulant therapy, electrical or pharmacologic cardioversion should be deferred for at least 3 weeks if the patient has been in AF or atrial flutter for at least 48 hours or if the duration is unknown. Alternatively, a transesophageal echocardiogram can be performed to demonstrate the absence of intracardiac thrombus if restoration of sinus rhythm is desired urgently. Patients should be maintained on oral anticoagulation for at least 6 weeks after electrical cardioversion.

TABLE 24-8 Antithrombotic Treatment for Paroxysmal and Chronic Atrial Fibrillation

Medical Condition	Drug
Patient with no risk factors and age <65 ys	ASA 325 mg/d
Age 65–75 y with any one of the following risk factors	
Congestive heart failure	Warfarin (INR 2.0–3.0)
Left ventricular dysfunction	
Mitral valve disease	
Hypertension	
Diabetes mellitus	
Previous stroke or embolism	
Left atrial enlargement	
Age ≥75 y	Warfarin (INR 2.0–2.5) unless high risk of hemorrhage

ABBREVIATIONS: ASA, aspirin; INR, international ratio.

SUPRAVENTRICULAR TACHYCARDIA

The therapeutic approach to the management of SVT is illustrated in Fig. 24-7.[15,24] Vagal maneuvers (carotid sinus massage or Valsalva maneuver) may terminate AV node reentry or reciprocating tachycardia involving a bypass tract. Adenosine is the initial drug of choice for regular narrow complex SVT, although β blockers, verapamil, and diltiazem are also effective. Oral antiarrhythmic drug therapy may be required to prevent recurrent SVT (see Table 24-4). Infrequently, synchronized electrical cardioversion may be required; 25 to 50 J is usually sufficient. Catheter ablation is an effective cure for AV node reentrant tachycardias secondary to accessory pathways or atrial tachycardias.[49] Multifocal atrial tachycardias may be difficult to suppress or to achieve rate control pharmacologically. In this case, implantation of a ventricular pacemaker followed by a total AV junction ablation is an effective treatment option.[47]

Bradyarrhythmias

Disorders of impulse formation or conduction may cause bradyarrhythmias. Sinus node dysfunction characterized by sinus bradycardia, sinoatrial exit block, or sinus arrest causing symptomatic bradycardia is the most common indication for permanent cardiac pacing.[50] AV block, permanent or

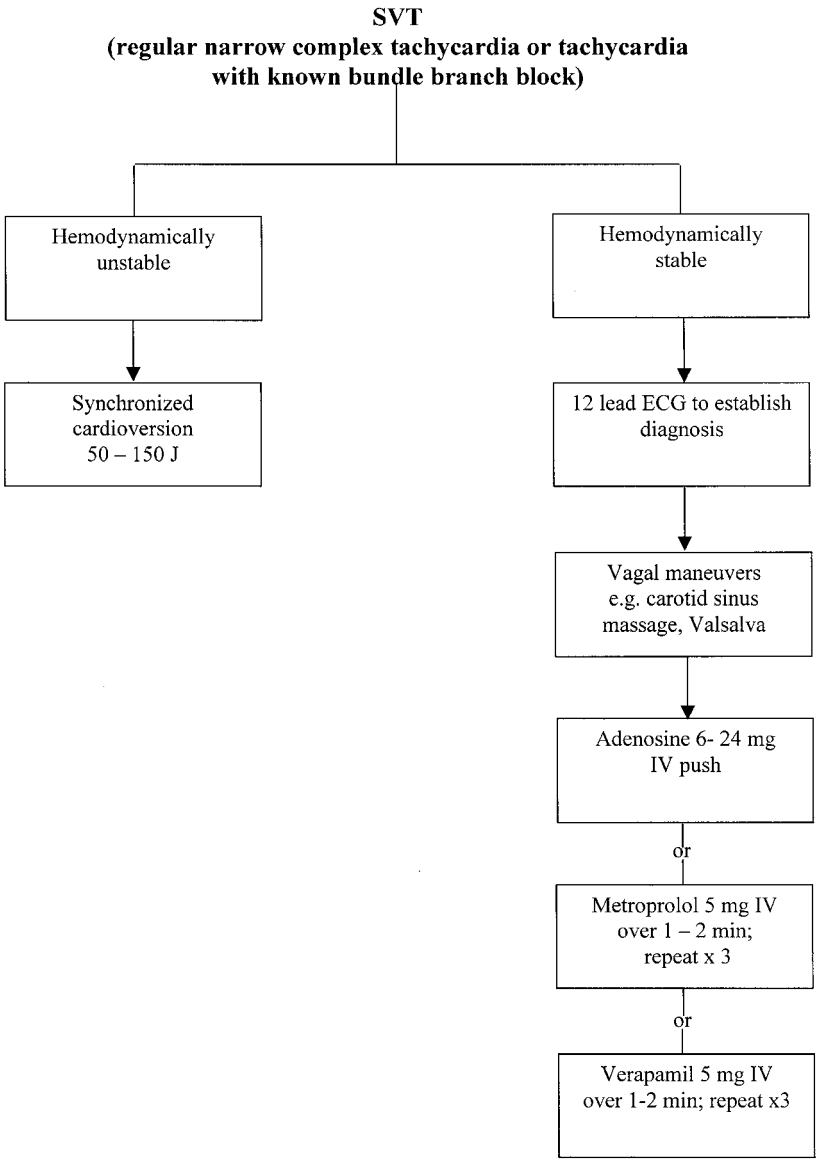

FIGURE 24-7 Management algorithm for regular narrow complex supraventricular tachycardia (SVT).

intermittent, is the second most common cause for permanent cardiac pacing.

EVALUATION OF THE PATIENT WITH BRADYARRHYTHMIAS

The initial evaluation of the patient with a documented bradyarrhythmia should include a thorough history (if the patient is able to communicate) and physical examination with a focus on detecting structural heart disease. A 12-lead electrogram and rhythm strips documenting the bradyarrhythmia should be reviewed. Carotid sinus massage should be performed to look for carotid sinus hypersensitivity unless contraindicated (carotid bruits or prior stroke). Cardiac hemodynamic data during the arrhythmia should be reviewed. Any drugs likely to contribute to the bradyarrhythmia should be identified and drug levels should be determined, if appropriate. Laboratory tests should include cardiac enzymes (creatine kinase or troponin). Echocardiography should be performed to determine the presence of structural heart disease and to assess ventricular function.

GENERAL PRINCIPLES OF TREATMENT

In a patient in the intensive care unit (ICU) with hemodynamically significant persistent bradycardia, transcutaneous pacing should be commenced until a temporary pacemaker can be inserted. A transvenous electrode catheter usually can be placed at the bedside and inserted through the internal jugular or subclavian route by using a flotation pacing catheter. Fluoroscopy may be required for positioning the pacing electrode if adequate pacing thresholds cannot be achieved. If the bradyarrhythmia is transient, temporary pacing may not be required and the risk/benefit of this intervention needs to be considered. Any reversible causes should be identified and corrected. Drugs contributing to bradycardia should be discontinued. Second-degree AV block or complete heart block after an inferior myocardial infarction may not be persistent.

TABLE 24-9 Indications for Cardiac Pacing

Acquired AV block
Class I
Symptomatic permanent or intermittent AV block
Symptomatic second-degree AV block
Atrial flutter or fibrillation with advanced symptomatic AV block
Class II
Asymptomatic complete AV block with ventricular rate >40 beats/min
Asymptomatic type II second-degree AV block
After myocardial infarction
Class I
Persistent complete heart block
Persistent type II second-degree AV block
Class II
Newly acquires bundle branch block with transient high-grade AV or complete heart block
Newly acquired bundle branch block with first-degree AV block
Newly acquired bifascicular bundle branch block
Chronic bifascicular block
Class I
Symptomatic patients with fascicular block and intermittent high-grade AV or complete heart block
Symptomatic patients with bifascicular block and HV interval prolongation (>100 ms) or block distal to the His bundle at rates <100 beats/min
Class II
Symptomatic patients with bifascicular block and no identifiable cause of syncope
Asymptomatic patients with bifascicular block and intermittent type II second-degree AV block.
Sinus node dysfunction
Class I
Sinus node dysfunction with symptoms of bradycardia with or without required drug therapy
Symptomatic sinus bradycardia
Symptomatic chronotropic incompetence
Class II
Sinus bradycardia <40–50 beats/min or asystole >3 s and suggested symptoms not documented to be due to bradycardia
Hypersensitive carotid sinus
Class I
Recurrent syncope and asystole or heart block >3 s during carotid sinus massage or clearcut clinical situation suggestive of a vasoinhibitory response
Class II
Recurrent syncope without clear clinical setting but abnormal response to carotid sinus massage

ABBREVIATIONS: AV, atrioventricular; class I, general consensus that a pacing system is indicated; class II, consensus that a pacing system might be beneficial.
SOURCE: Printed with permission from Yee et al.[49]

If the bradyarrhythmia does not resolve, permanent cardiac pacing may be required. The indications for permanent cardiac pacing are summarized in Table 24-9.[50]

TEMPORARY PACING

Transcutaneous pacing may be achieved by delivering a high current (40 to 100 mA) through defibrillation pads on most external cardioverters. Because this is painful for the conscious patient, the current should be decreased to the lowest setting that achieves continuous pacing. The rate programmed should be 60 to 70 beats/min and may need to be adjusted based on the patient's hemodynamic status. A temporary transvenous pacing lead should be inserted as quickly as possible. The initial current should be 3 to 5 mA. The current should then be reduced every five beats until there is failure to capture. The selected current for pacing should be twice the lowest current that effectively captured the atrium or ventricle.

TABLE 24-10 Pacing System Code

Chamber Paced	Chamber Sensed	Response
A	A	O/I/T
V	V	O/I/T
D	D	O/I/T/D

ABBREVIATIONS: A, atrium; D, dual chamber; I, inhibited; O, off; T, triggered; V, ventricle.

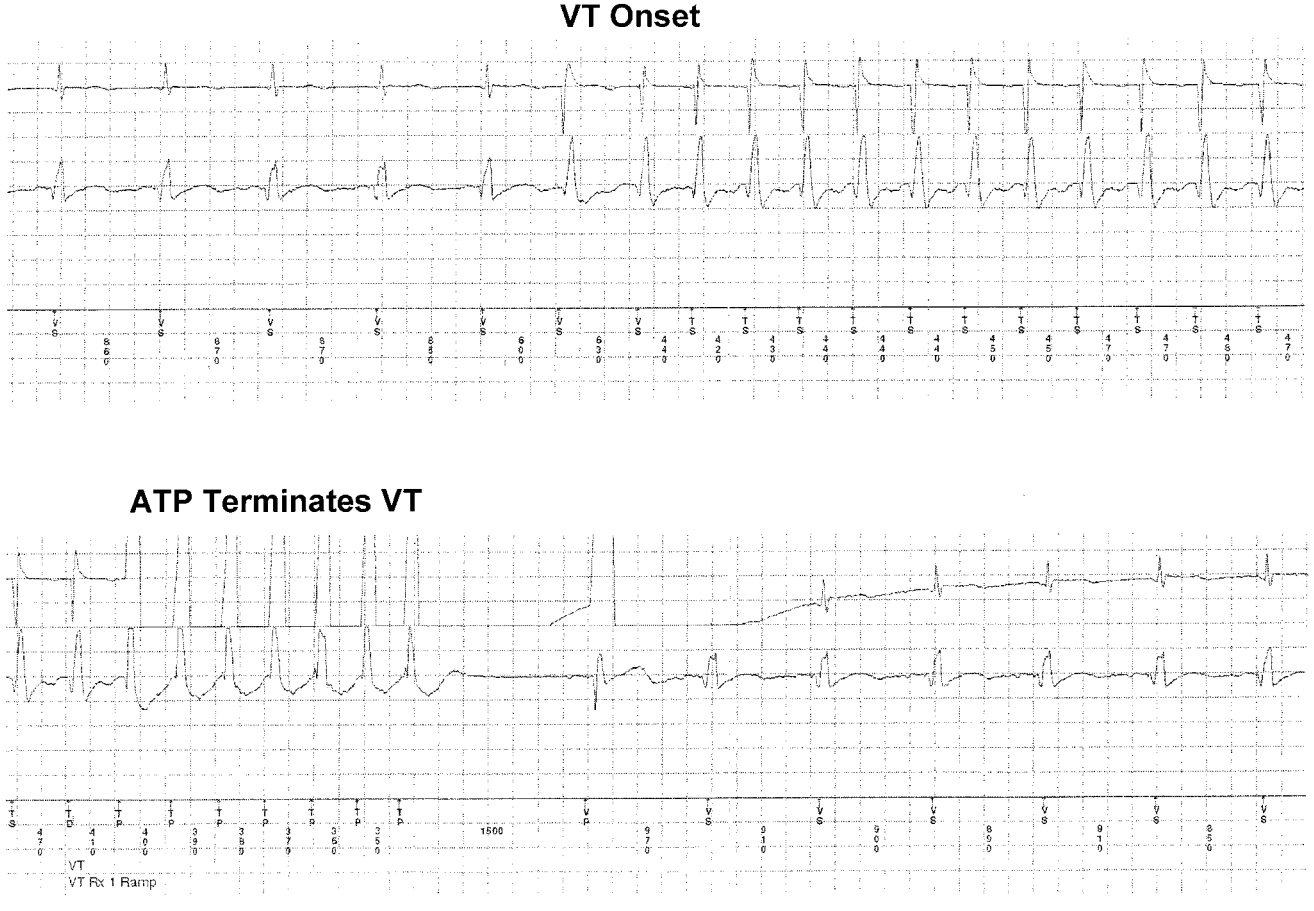
PACING MODALITIES

The codes that are frequently used to describe the functions of a pacing system are summarized in Table 24-10.[51] The first letter describes the chamber paced, the second describes the chamber sensed, and the third describes how the chamber responds to a paced or intrinsic event. AAI indicates that the pacemaker paces and senses in the atrium and inhibits when an intrinsic cardiac signal is sensed in the atrium. DDD indicates that the pacemaker paces and senses in the atrium and ventricle and that there are dual responses to sensed events (e.g., the system inhibits in response to sensed events in both chambers, but a sensed or paced event in the atrium triggers a paced event in the ventricle after a programmed delay). The code R denotes a rate adaptive feature. VVIR indicates that the pacemaker paces and senses in the ventricle, inhibits when an intrinsic cardiac signal is sensed in the ventricle, and has the ability to change the pacing rate within a programmed range, for example, 60 to 130 beats/min, based on the programmable rate sensor settings.

CHOICE OF PACING MODALITY

Atrially based pacing (AAI/R or DDD/R systems) has been shown to prevent the development of paroxysmal and permanent AF as compared with ventricular pacing systems.[52–54] In patients with sinus node dysfunction, atrially based pacing has been reported to reduce symptomatic heart failure in comparison with ventricular pacing.[54] Atrially based pacing optimizes cardiac hemodynamics by preserving the atrial contribution to cardiac output, which is particularly important in patients with heart failure and patients with diastolic dysfunction. However, atrially based pacing therapies have not been shown to be associated with substantial improvements in quality of life, exercise tolerance, or overall survival rate when compared with ventricular pacing in several large, prospective, randomized, clinical trials.[52–54] Thus, the choice of pacing modality should be individualized based on the patient's long-term prognosis, associated comorbidities, and expected functional status.

CARDIAC PACING ISSUES IN THE ICU



The pacing system consists of an implantable pulse generator, which contains the battery and integrated circuits that control pacing function, and one or more leads. The programming of a pacemaker is determined by the patient's underlying intrinsic rhythm. If the patient has only transient episodes of bradycardia, the pacemaker may be programmed to VVI at a low backup rate of 40 beats/min. If the patient has complete heart block, the pacemaker is usually programmed to a lower physiologic rate of 60 to 70 beats/min and an upper rate of 120 to 150 beats/min depending on age, type of heart disease, and activity level.

The most common problems related to a pacing system are capture failure, undersensing, oversensing, and triggered pacing. Capture failure may be due to pacing lead dislodgement, lead perforation, lead fracture, disconnection of the pacing lead from the power source, power source failure, or pacing thresholds higher than programmed. Pacing threshold may increase secondary to myocardial infarction, fibrosis, antiarrhythmic drug use, electrolyte abnormalities (hyperkalemia), and acidosis. Failure to sense may occur due to lead dislodgment or perforation, changes in intracardiac electrograms due to underlying disease state, electromagnetic interference causing reversion to asynchronous pacing, or spontaneous occurrence of a spontaneous ventricular event in the pacemaker blanking period. Oversensing may occur due to myopotential inhibition (more common with unipolar leads), sensing extraneous signals (usually due to lead insulation failure), or P- or T-wave oversensing. Triggered pacing may occur inappropriately when the patient with a dual-chamber pacemaker develops AF or atrial flutter or the pacemaker senses retrograde P waves causing pacemaker-mediated tachycardia. Most of these problems can be identified by interrogation and evaluation of the pacing system by using the pacemaker programmer. Many of these problems can be solved by reprogramming the pacemaker.[55]

Cardioversion and Defibrillation

Electrical shocks delivered transcutaneously, transvenously, or epicardially induce changes in the transmembrane potential of myocardial cells.[56] These stimuli may interrupt reentrant circuits by prolonging tissue refractoriness or by producing new excitation waves. Synchronized cardioversion effectively terminates most supraventricular tachyarrhythmias and monomorphically sustained VT. Biphasic waveforms have been incorporated into ICDs and the most recent generations of external defibrillators. These biphasic

FIGURE 24-8 Example of ventricular antitachycardia pacing (ATP) for ventricular tachycardia (VT). The *upper trace* is an intracardiac ventricular electrogram; the *middle trace* is the electrographic signal recorded from the intracardiac lead and the ICD can; and the *lower trace* indicates the marker channel annotations (how the device classifies each beat) and the interval between successive beats (in milliseconds).

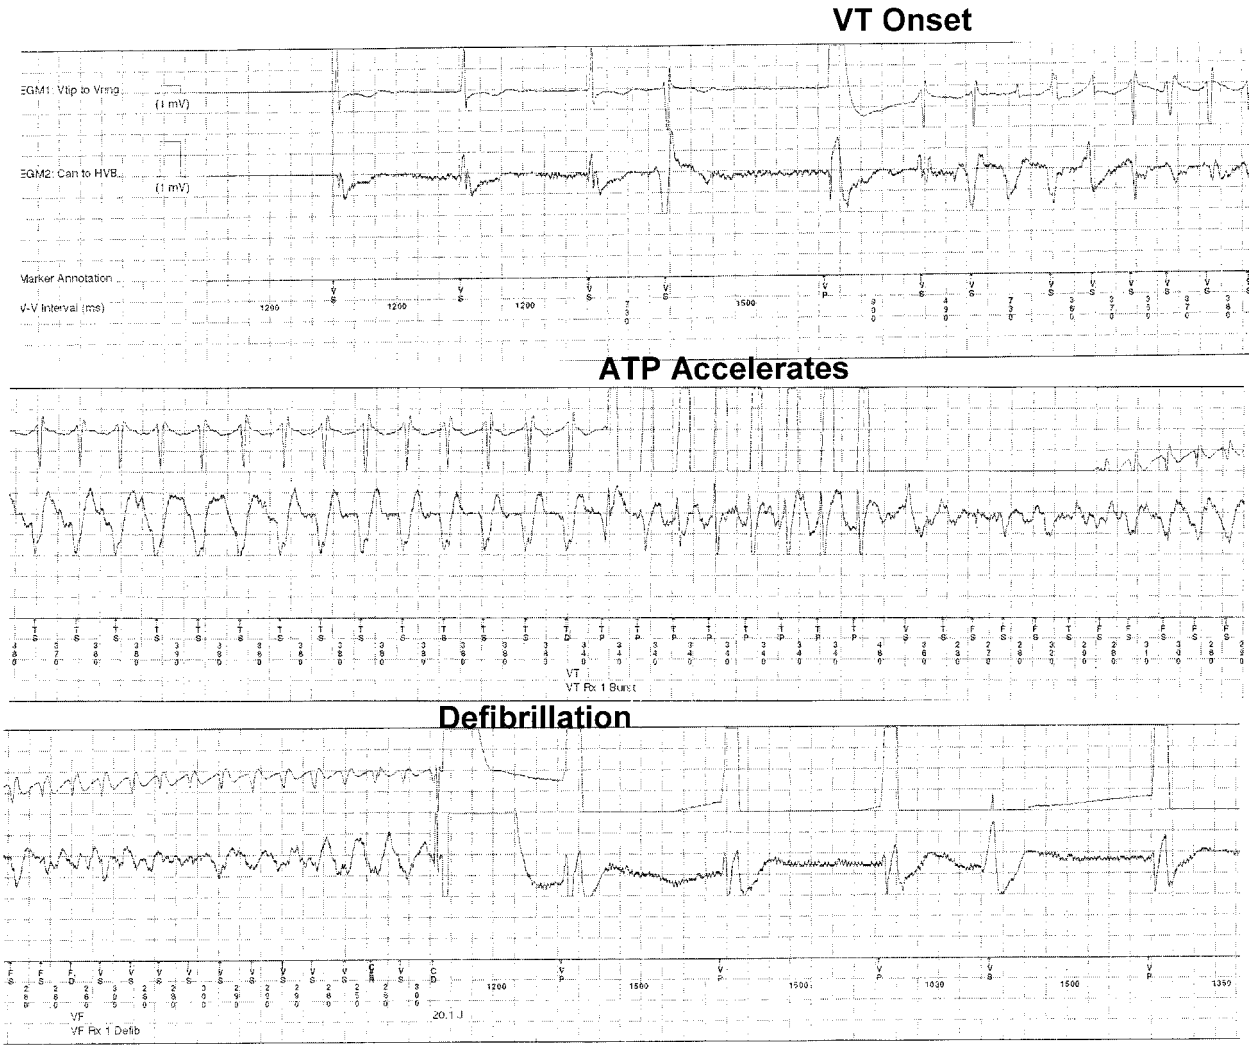


FIGURE 24-9 Example of ventricular antitachycardia pacing therapy that accelerates the ventricular tachycardia. A 20-J shock converts the arrhythmia to sinus rhythm. The format is similar to that shown in Fig. 24-8.

waveforms have been demonstrated to reduce cardioversion and defibrillation energy requirements.[57] If an electrical shock is not synchronized to the QRS complex, the shock may be delivered during the vulnerable repolarization phase and initiate VF. External pads rather than handheld paddles improve tissue contact, decrease overall system impedance, and reduce the energy required for cardioversion or defibrillation.

Implantable Cardioverter Defibrillators

Three major secondary prevention trials have demonstrated the superiority of the ICD over pharmacologic therapy for the prevention of sudden cardiac death in patients presenting with a life-threatening episode of VT or VF in the absence of a reversible cause.[31–33] In several clinical trials, the ICD also has been shown to prevent sudden cardiac death in patients with coronary heart disease and no history of spontaneous, sustained VT/VF.[29,30,58] As a consequence, more and more patients will receive ICDs, and knowledge of their functioning is important to the critical care physician.

ICD THERAPIES

ICDs provide antitachycardia pacing therapies for termination of sustained VT, internal cardioversion therapies for VT if pacing therapies are ineffective, and defibrillation therapies for VF and very rapid VT.[59] In addition, pacing therapy for bradycardia may be programmed. The ICD is usually programmed to back up VVI pacing at 40 beats/min unless the patient has significant bradycardia at baseline. VT detection is based on rate and sometimes on onset characteristics, regularity of rhythm, or duration of the intracardiac electrogram. An example of effective antitachycardia pacing therapy for sustained VT is shown in Fig. 24-8. Occasionally, the antitachycardia pacing therapy accelerates the VT to a more rapid VT or VF for which a shock is delivered (Fig. 24-9). One of the most frequent complications associated with the ICD is the delivery of an inappropriate shock for sinus tachycardia or a rapid atrial tachyarrhythmia. This can be minimized by programming a high tachycardia-detection interval (the rate that the device classifies as VT), programming a sudden rate onset feature to eliminate detection of sinus tachycardia that is rarely abrupt in onset, or programming a rate regularity feature to prevent AF being detected as VT. Newer ICDs

may discriminate between VT and atrial tachyarrhythmias by using ventricular electrographic morphologic changes. Dual-chamber ICDs enhance discrimination of AF or SVT from VT by comparing atrial activity relations with ventricular activity.

ICD ISSUES IN THE ICU SETTING

Device malfunctions similar to those described in the section on cardiac pacing may occur in the ICD patient. If the patient experiences AF or atrial flutter or other SVT, this may be classified by the ICD as VT resulting in inappropriate ICD therapies. Transthoracic cardioversion or defibrillation in the region of, or over, an ICD or pacemaker may damage the electronic circuits. If performed, the device should be interrogated after the procedure to ensure that the device is functioning appropriately. If a patient is experiencing frequent incessant VT, cardioversion and defibrillation therapies may need to be programmed "off" until pharmacologic therapy has been initiated to suppress the frequency of episodes. If surgery is urgently required, precautions must be implemented to minimize the likelihood that electrocautery signals will be detected by the ICD.[60]

Chapter 25
MYOCARDIAL ISCHEMIA

STEVEN M. HOLLENBERG
JOSEPH E. PARRILLO

KEY POINTS

- *Myocardial ischemia results from an imbalance between myocardial oxygen demand and supply.*
- *The major determinants of myocardial oxygen requirements are heart rate, contractility, and wall stress (afterload).*
- *Patients with myocardial ischemia are categorized by presentation with or without ST elevation, in accordance with treatment strategies. Patients with ST elevation benefit from immediate reperfusion with thrombolytic agents or direct angioplasty.*
- *All patients with suspected myocardial ischemia should be given aspirin at presentation.*
- *Myocardial infarction is diagnosed by a compatible clinical history, evolution of characteristic electrocardiographic changes, and an increase and subsequent decrease in cardiac enzymes.*
- *Acute reperfusion of the occluded coronary artery is the key to achieving a good outcome. The promptness of reperfusion is more important than the mode by which it is accomplished.*
- *Prognosis after myocardial infarction is most closely related to the degree of left ventricular impairment.*
- *Risk stratification is the key to initial management of patients with non–ST-elevation acute coronary syndromes.*
- *In patients with high-risk non–ST-elevation acute coronary syndromes, use of low-molecular-weight heparin, glycoprotein IIb/IIIa inhibition, and an early invasive approach is preferred.*
- *Aspirin, β blockers, angiotensin-converting enzyme inhibitors, and statins have been shown to decrease mortality rate after myocardial infarction.*
- *Echocardiography is extremely useful for the diagnosis of complications after myocardial infarction.*
- *Patients with cardiogenic shock should be stabilized with an intra-aortic balloon pump and promptly revascularized, if possible, by angioplasty or bypass surgery.*

Myocardial ischemia can go unrecognized in an intensive care unit (ICU). Signs of myocardial ischemia may be obscured by other illnesses in the critically ill patient. Physical examination in these patients often is limited, or its results altered, by the presence of other disease processes.

Myocardial ischemia and attendant left ventricular dysfunction may complicate the course and treatment of a particular illness. Conversely, multisystem illness may set the conditions for increased oxygen demand, often accompanied by diminished delivery of oxygen to the heart. For these reasons, the critical care physician must maintain a high index of suspicion for myocardial ischemia in the ICU setting, especially in the patient with a history of or multiple risk factors for coronary artery disease (CAD).

Terminology

Myocardial ischemia results from an imbalance of oxygen supply and oxygen demand. The heart is an aerobic organ with only a limited capacity for anaerobic glycolysis, and it makes use of oxygen avidly and efficiently, extracting 70% to 80% of the oxygen from coronary arterial blood.[1] Because the heart extracts oxygen nearly maximally, independent of demand, increases in demand must be met by commensurate increases in coronary blood flow.

Classically, myocardial ischemia has been divided into categories such as stable angina, unstable angina, and myocardial infarction (MI). Typical angina is exertional and is relieved promptly by rest or nitroglycerin. Stable angina occurs reproducibly with a similar level of exertion, in a pattern that is unchanged over the previous 6 months. Acute coronary syndromes comprise unstable angina and MI. Unstable angina consists of ischemic symptoms that are more frequent, severe, or prolonged than the patient's usual angina, are more difficult to control with drugs, or are occurring at rest or with minimal exertion. Cardiac biomarkers are not elevated. MI has been classified as "transmural" and "nontransmural," but this division has been largely abandoned due to the recognition that electrocardiographic (ECG) criteria are neither sensitive nor specific enough to make this distinction.

Acute coronary syndromes have traditionally been classified into Q-wave MI, non–Q-wave MI, and unstable angina. More recently, classification has shifted and has become based on the initial electrocardiogram: patients are categorized into three groups: those with ST-elevation MI (STEMI), those without ST elevation but with enzyme evidence of myocardial damage (non–ST-elevation MI, or NSTEMI), and those with unstable angina. Classification according to the presenting electrocardiogram coincides with current treatment strategies because patients presenting with ST elevation benefit from immediate reperfusion and should be treated with thrombolytic therapy or urgent revascularization, whereas fibrinolytic agents are not effective in other patients with acute coronary syndromes. The discussion of MI in this chapter follows this schematization.

Pathophysiology

Myocardial ischemia results from an imbalance between oxygen supply and demand. The myocardial requirement for oxygen and, hence, for oxygenated blood is affected by three major variables: heart rate, myocardial wall stress, and contractility. Myocardial wall stress is a function of the radius and the transmural ventricular pressure, which is highly dependent on ventricular afterload (Fig. 25-1).

Coronary blood flow depends on coronary perfusion pressure and filling time. Because coronary perfusion occurs primarily in diastole, the relevant pressure gradient is aortic diastolic pressure minus left ventricular diastolic pressure. Filling time is directly related to heart rate.

Myocardial ischemia usually develops in the setting of an obstructive atherosclerotic left ventricle, which limits blood supply. The pathophysiology of unstable coronary syndromes and MI usually involves dynamic partial or complete occlusion of an epicardial coronary artery because of acute intracoronary thrombus formation.[2]

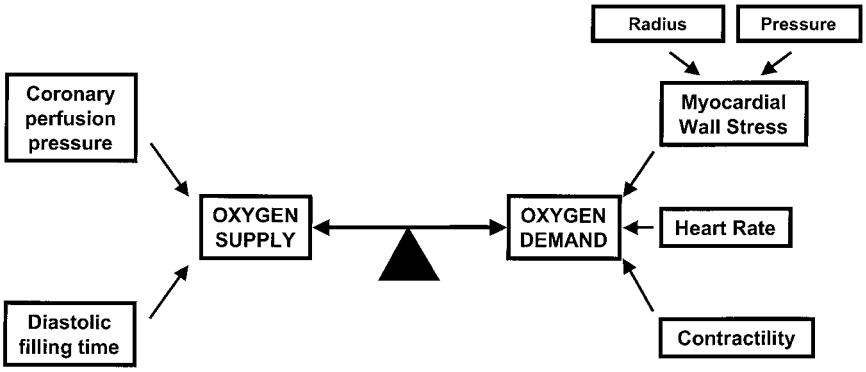

FIGURE 25-1 Determinants of myocardial oxygen supply and demand.

Different factors in critically ill patients can increase myocardial oxygen demand, including tachycardia, hypertension, and increased catecholamines. Similarly, many factors may contribute to limitation of oxygen supply, particularly in the setting of hemodynamic instability. These factors include hypotension (decreasing coronary perfusion pressure) and tachycardia (limiting diastolic filling time). In addition, anemia and hypoxemia can limit the amount of oxygen delivered to the heart. Coronary vasospasm may also play a role in some patients. Elevation of left ventricular pressures by heart failure can increase demand and decrease coronary perfusion pressure.

Thus, critically ill patients, usually those with at least some component of obstructive coronary artery disease, may develop myocardial ischemia on a hemodynamic basis, with variable contributions of increased demand and decreased supply. On the other hand, catecholamine surges, hemodynamic changes, and inflammatory processes may predispose to rupture of preexisting atherosclerotic plaques. Making the distinction is vital because the treatment is completely different. In the former case, treatment is aimed at decreasing the oxygen requirement of the myocardium by eliminating provocative stimuli and controlling heart rate and blood pressure and on optimizing oxygenation and hemoglobin concentration. Relief of myocardial ischemia by these measures usually results in prompt restoration of left ventricular function without significant cellular damage because the obstruction to flow is ordinarily fixed and not total. If plaque rupture is playing a role, then simply removing or lessening stimuli that increase myocardial oxygen requirements may not be sufficient to increase the ratio of myocardial oxygen supply to demand, and, unless attempts are made to reestablish coronary blood flow, significant myocardial damage may ensue. Antithrombotic and anticoagulant strategies should be instituted, and consideration of coronary revascularization may be indicated.

RECOGNITION OF MYOCARDIAL ISCHEMIA

SIGNS AND SYMPTOMS

Myocardial ischemia is most commonly manifested as constant substernal chest tightness or pressure. The pain typically is on the left side and may radiate to the throat and jaw or to the left shoulder and left arm and is often accompanied by acute onset of dyspnea and diaphoresis. Angina occasionally may be right-sided, interscapular, or perceived in the epigastrium.

Because other syndromes may mimic angina, it is important to consider them in the differential diagnosis. These include dissecting aortic aneurysm; pericarditis; pleuritis; pulmonary processes such as pulmonary embolism, pneumonia, and pneumothorax; gastrointestinal processes such as esophageal or peptic ulcer disease and cholecystitis; musculoskeletal pain; and costochondritis. Other heart diseases (valvular heart disease, cardiomyopathies, and myocarditis) not attributable to coronary artery stenosis may also cause substernal chest tightness and should be included in the differential diagnosis. The presentation of ischemia in postsurgical patients may be subtle. Aftereffects of surgery and medication can mimic or mask the classic features of MI such as substernal chest pain radiating to the arm, neck, or jaw, and dyspnea, nausea, and diaphoresis. The vigilant clinician must therefore maintain a high index of suspicion and a low threshold for obtaining a 12-lead electrocardiogram.

The physical examination, although sometimes insensitive and nonspecific, especially in the patient with multisystem illness or preexisting left ventricular dysfunction, may be helpful in confirming the diagnosis. Elevated jugular veins signal right ventricular diastolic pressure elevation, and the appearance of pulmonary crackles (in the absence of pulmonary disease) indicates elevated left ventricular filling pressures secondary to depressed left ventricular function. A systolic bulge occasionally can be palpated on the precordium in the area of the apex of the heart, representing contact of an ischemic dyskinetic segment of the left ventricle with the chest wall. During the ischemic episode, auscultation of the precordium may demonstrate the presence of a fourth heart sound, indicative of a noncompliant left ventricle. With extensive myocardial dysfunction, a third heart sound may be present. A murmur of mitral regurgitation attributable to papillary muscle dysfunction may also emerge.

THE ELECTROCARDIOGRAM

The ECG abnormalities in myocardial ischemia vary widely and depend in large part on the extent and nature of coronary stenosis and the presence of collateral blood flow to ischemic zones. With acute total occlusion of a coronary artery, the first demonstrable ECG changes are peaked T-wave changes in the leads reflecting the anatomic area of myocardium in jeopardy. As total occlusion continues, there is elevation of the ST segments in the same leads. With continued occlusion, there is an evolution of ECG abnormalities, with biphasic and then inverted T waves. If enough myocardium is infarcted, q waves may appear, representing unopposed initial depolarization

forces away from the mass of infarcted myocardium, which has lost electrical activity and no longer contributes to the mean QRS voltage vector. The formation of q waves is accompanied by a decrease in the magnitude of the R waves in the same leads, representing diminution of voltage in the mass of infarcted myocardium. Loss of R-wave voltage, visualized by comparison with previous ECG tracings, may be the only ECG evidence for the presence of permanent myocardial damage. It is important to note that QRS voltage can be affected by multiple factors, such as lead placement, body position, QRS axis shifts, and pericardial and thoracic abnormalities that may shield the electrical activity of the heart. These conditions are frequently encountered in patients in the ICU and should be taken into consideration in interpretation of q and R waves.

Extension of an inferior MI to the posterior segment can be detected by enhancement of R waves in the anterior chest leads because these forces are now less opposed by posterior forces. True posterior infarction can be subtle because the only signs may be prominent R waves, tall upright T waves, and depressed ST segments in leads V_1 and V_2. Involvement of the right ventricle in inferior MI also is not readily detected on the standard 12-lead electrocardiogram because of the small mass of the right ventricle relative to the left ventricle and because of the positioning of the standard precordial leads away from the right ventricle. Right ventricular infarction may be detected by ST elevation in recordings from right precordial leads, in particular V_{4R}.[3]

Subtotal occlusion of an epicardial coronary artery may not result in ST elevation but in T-wave changes or ST depression in the leads reflecting the involved myocardium. These findings are less specific than ST elevation for myocardial ischemia because they may also be caused by a myriad of factors other than ischemia, including cardioactive drugs, in particular digoxin, and electrolyte disorders, in particular hypokalemia. Left ventricular hypertrophy and acute left ventricular pressure overload, as might occur in hypertensive crisis, may also result in ST depression—the so-called strain pattern. Supraventricular tachycardias have also been shown to cause ST depression, even in the absence of left ventricular pressure. In the presence of preexisting T-wave abnormalities, ST-segment or T-wave changes are even less specific for ischemia. Ischemia may also be indicated by previously flattened or inverted T waves that revert to upright—the so-called pseudonormalization of T waves.

The clinician also must be careful not to be fooled by ECG "imposters" of acute infarction, which include pericarditis, J-point elevation, Wolff-Parkinson-White syndrome, and hypertrophic cardiomyopathy. In pericarditis, ST segments may be elevated, but the elevation is diffuse and the morphology of the ST segments tends to be concave upward, whereas that of ischemia is convex. Pericarditis also may be distinguished from infarction by the presence of PR-segment depression in the inferior leads (and also by the PR segment in lead aVR).[4]

SILENT ISCHEMIA

Recent interest has focused on "silent" myocardial ischemia, that is, objective ECG evidence of myocardial ischemia that is not associated with angina or with anginal equivalents.[5] Silent myocardial ischemia may be an incidental observation on a cardiac monitor or on a routine electrocardiogram and consists of transient ST-segment depression that may last several minutes or even hours. The frequency of episodes of ST-segment depression correlates with the severity of coronary artery disease in patients with known left ventricular pressure or a history of angina.

Decreased left ventricular function is associated with episodes of silent ST depression.[6,7] In patients monitored with pulmonary artery catheters (PACs), silent ischemia may be manifested by increased pulmonary artery occlusion pressures, reflecting increased left ventricular end-diastolic pressure. Echocardiography may demonstrate transient wall motion abnormalities and diminished diastolic compliance. These signs of left ventricular dysfunction may precede ST-segment changes.[6,7]

Not all episodes of transient ST-segment depression are attributable to silent ischemia. Nevertheless, should this finding be observed on the cardiac monitor, especially in association with transient elevation of left ventricular filling pressures, it is prudent to consider the possibility of myocardial ischemia as a potential factor complicating the course of the critically ill patient.

CARDIAC BIOMARKERS

Measurement of enzymes released into the serum from necrotic myocardial cells after infarction can aid in the diagnosis of MI.[8,9] The classic biochemical marker of acute MI is elevation of creatine phosphokinase (CPK) levels. The CPK-MB isoenzyme is found primarily in cardiac muscle, and only small amounts are present in skeletal muscle and brain. CK released from the myocardium begins to appear in the plasma 4 to 8 hours after onset of infarction, and its level peaks at 12 to 24 hours and returns to baseline at 2 to 4 days. The magnitude of the increase in serum CK level and the rate at which it rises and falls are a function of the total mass of myocardium affected, the extent and nature of coronary occlusion (e.g., total or subtotal occlusion), the rate of washout from the infarcted myocardium, and the clearance from the body. To be diagnostic for MI, the total plasma CK value must exceed the upper limit of normal, and the fraction consisting of the MB isoenzyme must exceed a certain value (which depends on the CK-MB assay used, usually >5%).

A newer serologic test for the detection of myocardial damage uses measurement of cardiac troponins.[10] Troponins T and I are constituents of the contractile protein apparatus of cardiac muscle. Whereas CPK-MB may arise from other tissues, troponins originate only from cardiac muscle, rendering them more specific than the conventional CPK-MB assays for the detection of myocardial damage. Their use is becoming more widespread and has superseded the use of CPK-MB in many settings.[11] Troponins are also more sensitive for the detection of myocardial damage, and troponin elevation in patients without ST elevation (or without elevation of CPK-MB) identifies a subpopulation at increased risk for complications. Rapid point-of-care troponin assays, which have become available in the past few years, have extended the clinical utility of this marker. Troponins may not be elevated until 6 hours after an acute event, so critical therapeutic interventions should not be delayed pending assay results. Once elevated, troponin levels can remain high for days to weeks, thereby limiting their utility to detect late reinfarction.

Lactate dehydrogenase (LDH) is also released from necrotic myocardial tissue after infarction, although elevation of this enzyme is relatively nonspecific for MI because LDH

is present in many other tissues. LDH levels peak at 72 to 96 hours and may be used to detect recent infarction, which is associated with an increase in the LDH_1 isoenzyme.

ECHOCARDIOGRAPHY

To the physician confronted with a critically ill patient, echocardiography can be a key element in successful differential diagnosis.[12] Echocardiography is simple, safe, and permits systemic interrogation of cardiac chamber size, left and right ventricular functions, valvular structure and motion, atrial size, and the anatomy of the pericardial space. The presence of segmental left ventricular wall motion abnormalities suggests compromise of blood flow to those segments.[13] Doppler interrogation can be used for noninvasive assessment of right and left ventricular filling pressures, pulmonary artery pressures, stroke volume, and cardiac output.

Echocardiography is particularly useful in the evaluation of patients with acute heart failure or suspected cardiogenic shock, and early echocardiography should be performed routinely.[14] Expeditious evaluation of global and regional left ventricular performance is crucial for management of congestive heart failure, with or without suspected myocardial ischemia.

Echocardiography is also extremely valuable for the rapid diagnosis of mechanical causes of shock after MI such as papillary muscle rupture and acute mitral regurgitation, acute ventricular septal defect, and free wall rupture and tamponade.[14] In some cases, echocardiography may demonstrate findings compatible with right ventricular infarction. Echocardiography can also show alternative diagnoses, such as valvular abnormalities, pericardial tamponade, or hypertrophic cardiomyopathy. Acute right heart failure, manifested by a dilated and hypokinetic right ventricle without hypertrophy suggestive of chronic pulmonary hypertension, can suggest pulmonary embolism (see Chap. 26).[15]

Transthoracic echocardiographic images may be suboptimal due to a poor acoustic window in critically ill patients, in particular those who are obese, have chronic lung disease, or are on positive pressure ventilation. Contrast echocardiography may be used to improve image quality.[16] Transesophageal echocardiography also can provide better visualization, particularly of valvular structures, and can be performed safely at the bedside.

RADIONUCLIDE STUDIES

Technetium pyrophosphate is deposited in irreversibly damaged regions of myocardium.[17] The regions of radioactivity are detected by scintigraphy and appear as "hot spots" on imaging. The period during which technetium pyrophosphate scanning is most sensitive for the detection of infarcted myocardium is approximately 1 to 3 days after MI; if a scan performed then is positive, scans may remain positive for weeks to months thereafter. Whereas the sensitivity and specificity for detection of a transmural infarct are high with this technique, they are low to moderate for a non–Q-wave or subendocardial infarct. Therefore, the usefulness of this test is limited for the diagnosis of MIs, especially non–Q-wave infarcts, because it offers little information unavailable by other means.[18]

Thallium 201 is transported into viable myocardial tissue by processes dependent on adenosine triphosphate via Na/K-ATPase. It is distributed to the myocardium on the basis of blood flow. Necrotic or scarred myocardial tissue from a new or previous MI will appear as a "cold spot" on scintigraphy. Technetium 99 sestamibi is a newer isotope preparation widely used to assess myocardial perfusion. Sestamibi also distributes to the myocardium on the basis of blood flow. The major advantage of using sestamibi instead of thallium is that the photons produced by the technetium 99 radionuclide have higher energy and therefore more readily penetrate the fat and other tissues that overlie the heart, resulting in fewer attenuation artifacts than seen with thallium 201. In addition, unlike thallium, sestamibi does not undergo significant redistribution, so perfusion defects seen on scintigraphic images do not reverse over time. Sestamibi scans at rest can be used in patients presenting to the emergency department with chest pain of unclear cause. Patients without perfusion defects do not have evidence of ongoing myocardial underperfusion and can be safely discharged, with follow-up stress testing as needed.[19] A positive scan does not differentiate between new and old perfusion defects, so hospital admission and further evaluation are necessary.

HEMODYNAMIC MONITORING

In patients with hemodynamic instability that does not improve relatively quickly with simple therapeutic maneuvers, pulmonary artery catheterization should be considered (see Chap. 13). Pulmonary artery catheterization provides simultaneous assessment of filling pressures and cardiac output and can be quite useful for differential diagnosis in critically ill patients. In patients with hypoxemia and pulmonary infiltrates on chest radiogram, a frequent dilemma in ICU patients, pulmonary artery catheterization may be used to differentiate cardiac from pulmonary causes. Right heart catheterization is also quite useful in the differential diagnosis of shock. Hemodynamic profiles of patients with different forms of shock are presented in Table 25-1. It is important to recognize the possibility of mixed forms of shock in the critically ill patient (see Chap. 21). For example, even in the presence of significant left ventricular dysfunction and suspected cardiogenic shock, patients with cardiogenic shock can be relatively depleted of volume, perhaps due to diaphoresis or vomiting.[20,21]

Hemodynamic monitoring also can be useful in the diagnosis of mechanical complications of infarction. Right heart catheterization may show a step up in hemoglobin oxygen saturation diagnostic of ventricular septal rupture. The waveform of the pulmonary artery occlusion pressure tracing may show a prominent V wave (10 mm Hg above the mean pulmonary artery occlusion pressure is regarded as significant), suggesting severe mitral regurgitation, although V waves also may be present in acute ventricular septal rupture. Equalization of diastolic filling pressures may suggest pericardial tamponade. The hemodynamic profile of right ventricular infarction includes high right-side filling pressures in the presence of normal or low occlusion pressures.[22]

Perhaps more importantly, pulmonary artery catheterization may be used to guide therapy in hemodynamically unstable patients. Infusions of vasoactive agents need to be titrated carefully in patients with myocardial ischemia to maximize coronary perfusion pressure with the least possible increase in myocardial oxygen demand. Invasive hemodynamic monitoring is often considered useful in guiding therapy in these unstable patients because clinical estimates of filling pressure can be unreliable;[23] in addition, changes in myocardial performance and compliance and therapeutic interventions can

TABLE 25-1 Use of Right Heart Catheterization to Diagnose the Etiology of Shock

Diagnosis	PAOP	$\dot{Q}_T$	SVR	Miscellaneous Comments
Cardiogenic shock				
Cardiogenic shock due to myocardial dysfunction	↑↑	↓↓	↑↑	Usually extensive infarction (>40% of left ventricle), severe cardiomyopathy, or myocarditis
Cardiogenic shock due to mechanical defects				
Acute ventricular septal defect	↑	↓↓	↑↑	Oxygen "step-up" at RV level
Acute mitral regurgitation	↑↑	Forward $\dot{Q}_T$ ↓↓	↑	V waves in Paop tracing
RV infarction	Normal or ↓	↓↓	↑↑	Elevated RA and RV filling pressures with low or normal Paop
Extracardiac obstructive forms of shock				
Pericardial tamponade	↑	↓ Or ↓↓	↑↑	RA mean, RV end-distolic pulmonary capillary wedge mean pressures are elevated and within 5 mm Hg of one another
Massive pulmonary embolism	Normal or ↓	↓↓	↑↑	Usual finding is elevated right-side pressures
Hypovolemic shock	↓↓	↓↓	↑↑	
Distributive forms of shock				
Septic shock	↓ Or normal	↑ Or normal, rarely ↓	↓↓	
Anaphylactic shock	↓ Or normal	↑ Or normal	↓↓	

ABBREVIATIONS: ↑↑ or ↓↓, moderate to severe increase or decrease; ↑ or ↓, mild to moderate increase or decrease; $\dot{Q}_T$, cardiac output; PAOP, pulmonary artery occlusion pressure; RA, right atrial; RV, right ventricular; SVR, systemic vascular resistance.

change cardiac output and filling pressures precipitously. Optimization of filling pressures and serial measurements of cardiac output (and other parameters such as mixed venous oxygen saturation) allow for titration of the dosage of inotropic agents and vasopressors to the minimum dosage required to achieve the chosen therapeutic goals. This minimizes the increases in myocardial oxygen demand and arrhythmogenic potential.[24]

The PAC provides hemodynamic data not easily inferred from physical examination or laboratory evaluation, but whether its use translates into definable benefits for patients has long been questioned.[25] Despite the many theoretical advantages to the PAC, retrospective analyses in patients with acute myocardial ischemia have found no benefit,[26] and some have found associations between catheter use and adverse outcomes. Prospective trials have shown PAC to be practical in high-risk surgical patients and in patients with septic shock and acute respiratory distress syndrome; such a trial would be interesting in patients with cardiac ischemia. Lacking prospective trials to answer the question of efficacy, we nevertheless believe the benefits of more rapid diagnosis are clear and find the catheter essential to guide supportive therapy.[21] Prudence should be exercised in choosing a site for central venipuncture because many will have received or are candidates for thrombolytic and intravenous heparin therapy. Insertion sites that can be compressed easily should significant bleeding occur are preferred.

MANAGEMENT OF ANGINA

Patients with a history of stable angina who develop chest pain while in the critical care setting are best treated by removal of provocative stimuli that increase myocardial oxygen consumption or lead to compromised coronary blood flow, if these factors can be identified. For example, correction of hypoxia, anemia, hypovolemia, tachycardia, or labile hypertension may be sufficient to control anginal episodes. Often overlooked are fever, infection, anxiety, stress, activity, and the work of breathing. Antianginal medications the patient was receiving before hospitalization should be continued, and the doses may have to be increased.

In instances of refractory angina or when provocative stimuli cannot be ameliorated, it may be necessary to perform coronary angiography and revascularization of the culprit vessels (preferably percutaneously), especially if the myocardial ischemia is complicating further management of the patient.

ASPIRIN

Aspirin is the best known and most widely used of the antiplatelet agents because of its low cost and relatively low toxicity. Use of salicylates to treat coronary artery disease in the United States was first reported in 1953.[27] Aspirin inhibits the production of thromboxane A_2 by irreversibly acetylating the serine residue of the enzyme prostaglandin H_2 synthetase.

Reduction of death or nonfatal MI in patients with unstable angina and NSTEMI has been well established in several large randomized clinical trials.[28,29] In addition to its use in acute clinical settings, aspirin has been shown to be beneficial in preventing cardiovascular events when administered as secondary prevention in patients after acute MI and as primary prevention in subjects with no prior history of vascular disease.[30]

The most widely used and effective dose of aspirin in cardiovascular disease is 81 to 325 mg/d. Despite the fact that small-dose aspirin preferentially blocks the conversion of thromboxane to prostacyclin and thus has a more profound antiplatelet effect, large-dose aspirin has been found

to be as effective as small-dose aspirin in prevention of cardiovascular death, MI and stroke,[31] which suggests that anti-inflammatory effects of aspirin also play a role.[32] Once begun, aspirin likely should be continued indefinitely. Toxicity with aspirin is mostly gastrointestinal; enteric-coated preparations may minimize these side effects.

NITRATES

Nitroglycerin is a mainstay of therapy for angina because of its efficacy and rapid onset of action. The most important antianginal effect of nitroglycerin is preferential dilation of venous capacitance vessels. Myocardial oxygen consumption is reduced as left ventricular volume and arterial pressure decrease.[33] At larger doses, nitroglycerin also may relax arterial smooth muscle, causing a modest decrease in afterload.[33] In addition, nitroglycerin can dilate epicardial coronary arteries and redistribute coronary blood flow to ischemic regions by dilating collateral vessels. Nitroglycerin also has antithrombotic and antiplatelet effects.

The quickest route of administration of nitroglycerin is sublingual. Sublingual doses of 0.4 mg may be administered every 5 to 10 minutes to a total of three doses, if required to control pain. Topical or oral nitrates may be used for long-term therapy.

In patients with unstable angina, if sublingual nitroglycerin does not cause chest pain to resolve completely, intravenous nitroglycerin should be administered, starting at a dose of 10 to 20 μg/min. This dose may be titrated upward as tolerated in increments of 10 to 20 μg/min every 5 to 10 minutes until pain resolves. An upper limit of 400 μg/min is usually accepted as maximal; above this dose, usually there is no further clinical response. Excessive lowering of blood pressure can compromise perfusion of the coronary vascular bed.

Because of its hemodynamic actions, systemic blood pressure may fall after nitroglycerin administration, so frequent blood pressure checks are required. Hypotension typically responds to the Trendelenburg-position and to fluid boluses.

β BLOCKERS

The rationale for administering β blockers during ischemic episodes derives from their negative chronotropic and inotropic properties. Heart rate and contractility are two of the three major determinants of myocardial oxygen consumption. By altering these variables, myocardial ischemia can be attenuated significantly.[34] These agents are particularly effective in patients with angina who remain tachycardic or hypertensive (or both) and in patients with supraventricular tachycardia complicating myocardial ischemia. Rapid control can be achieved by intravenous administration of metoprolol, a β_1-selective blocker, in 5-mg increments every 5 minutes up to 15 mg. Thereafter, 25 to 50 mg every 6 hours can be given orally.

Beta blockers should be used with caution in patients with marginal blood pressure, preexisting bradycardia, atrioventricular nodal conduction disturbances, or evidence for left ventricular failure and in those with bronchospastic disease. A short-acting intravenous β blocker, such as esmolol, may be the preferred agent in patients who have the potential for hemodynamic instability or who have relative contraindications.

CALCIUM CHANNEL BLOCKERS

Nondihydropyridine calcium channel blockers (verapamil and diltiazem) also have negative chronotropic and inotropic effects and can be used to control myocardial oxygen demand in patients with ischemia. Both can be given as intravenous boluses, starting with small doses (diltiazem 10 to 20 mg, verapamil 2.5 mg), and then infused continuously.

Calcium channel blockers are particularly useful in the setting of coronary vasospasm because they cause direct dilation of coronary vascular smooth muscle. Vasospasm can produce variant angina in patients with mild or no coronary artery disease (Prinzmetal's angina) or aggravate ischemia in patients with atherosclerotic coronary stenoses that are subcritical but serve as sites of vasospasm, possibly as a consequence of abnormalities of the underlying smooth muscle or derangements in endothelial physiology.[35] The illicit use of cocaine is increasingly being recognized as a cause of coronary vasospasm leading to angina and myocardial ischemia. Coronary vasospasm usually presents with ST elevation associated with chest pain and can be difficult to differentiate from vessel closure due to coronary thrombosis. Consideration of the clinical setting, rapid fluctuation of ST segments, and prompt resolution with nitrates can provide useful clues. Variant angina attributable to vasospasm responds well to treatment with calcium channel blockers.

ANGIOTENSIN-CONVERTING ENZYME INHIBITORS

Angiotensin-converting enzyme (ACE) generates angiotensin II from angiotensin I and catalyzes the breakdown of bradykinin. Thus ACE inhibitors can decrease circulating levels of angiotensin II and increase levels of bradykinin, which in turn stimulates production of nitric oxide by endothelial nitric oxide synthase. In the vasculature, ACE inhibition promotes vasodilation and tends to inhibit smooth muscle proliferation, platelet aggregation, and thrombosis.

The major hemodynamic effect of ACE inhibition is afterload reduction, which is most important as an influence of myocardial oxygen demand in patients with impaired left ventricular function. A recent study, however, has demonstrated that ACE inhibition may be beneficial to prevent recurrent events in high-risk patients. The HOPE trial randomized 9297 patients with documented vascular disease or at high risk for atherosclerosis (diabetes plus at least one other risk factor) in the absence of heart failure to treatment with the tissue-selective ACE inhibitor ramipril (target dose 10 mg/d) or placebo.[36] An impressive 22% reduction in the combined end point of cardiovascular death, MI, and stroke was observed, and the number of patients and effect size were sufficient so that the reduction in individual end points was significant.[36] Patients were normotensive at the start of the trial, and the magnitude of benefit observed was not explained by the modest reduction in blood pressure (2 to 3 mm Hg).[36] On the basis of this study, the latest American College of Cardiology/American Heart Association guidelines recommend the use of ACE inhibitors in most cases as routine secondary prevention for patients with known CAD, particularly in diabetics without severe renal disease.[37]

LIPID-LOWERING AGENTS

There is extensive epidemiologic, laboratory, and clinical evidence linking cholesterol and coronary artery disease. Total cholesterol level has been linked to the development of

CAD events with a continuous and graded relation.[38] Most of this risk is due to low-density lipoprotein (LDL) cholesterol. Different large primary and secondary prevention trials have associated decreasing LDL cholesterol with a decreased risk of coronary disease events. Earlier lipid-lowering trials used bile-acid sequestrants (cholestyramine), fibric acid derivatives (gemfibrozil and clofibrate), or niacin in addition to diet. The reduction in total cholesterol in these early trials was 6% to 15% and was accompanied by a consistent trend toward a reduction in fatal and nonfatal coronary events.[39]

More impressive results have been achieved by using 3-hydroxy-3-methylglutaryl coenzyme A reductase inhibitors (statins). Statins have been demonstrated in several trials to decrease the rate of adverse ischemic events in patients with documented CAD.[40–42] The goal of treatment has conventionally been an LDL cholesterol level below 100 mg/dL,[37] but a recent study has shown that more aggressive LDL lowering has significantly greater protective effects. Patients were randomized within 10 days of an acute coronary syndrome to pravastatin (40 mg/d, standard therapy) or atorvastatin (80 mg/d, intensive therapy). Atorvastatin lowered LDL cholesterol more (to 62 mg/dL compared with 95 mg/dL) and significantly reduced the composite end point of death, MI, unstable angina, revascularization, and stroke.[42] Maximum benefit may require management of other lipid abnormalities (elevated triglycerides and low high-density lipoprotein cholesterol) and treatment of other atherogenic risk factors.

REFRACTORY ANGINA

Intraaortic Balloon Pump Counterpulsation

When angina remains refractory to maximal medical therapy, intraaortic balloon pump (IABP) counterpulsation may be considered. The IABP is a device that is inserted through the femoral artery into the descending thoracic aorta just distal to the aortic arch. A 40-mL balloon at the tip of the catheter is inflated in diastole by a pneumatic pump in synchrony with closure of the aortic valve and is deflated on opening of the aortic valve. Inflation and deflation are gated to the R and T waves on the electrocardiogram or to the arterial pressure recording. By deflating during ventricular systole, ventricular afterload is reduced, resulting in significant decreases in myocardial wall stress and significant decreases in myocardial oxygen requirements.[43] Further, inflation during diastole augments coronary blood flow by increasing coronary perfusion pressure. The main way in which an IABP relieves myocardial ischemia is by decreasing oxygen demand through afterload reduction.[44]

Use of an IABP is indicated in unstable angina when the angina and attendant ECG abnormalities are persistent and refractory to maximal pharmacologic therapy. Insertion of an IABP may improve hemodynamics and control symptoms so that coronary angiography can be performed safely. An IABP also may be inserted in patients who are stable and have undergone angiography but in whom precarious coronary lesions (e.g., left main coronary artery stenosis) have been identified. Typically, these patients are maintained on the device while awaiting surgery or angioplasty.

Although insertion of an IABP can result in immediate and dramatic relief of myocardial ischemia, placement of this device can be associated with significant complications.[43] These include aortic dissection, femoral artery lacerations, hematomas, femoral neuropathies, renal failure from renal artery occlusion, arterial thrombi and emboli, limb ischemia, and line sepsis. These potential complications must be weighed in determining whether an IABP should be inserted. Once one is inserted, the patient should be maintained on full anticoagulating doses of intravenous heparin by constant infusion. Frequent checks of peripheral pulses and surveillance for other complications should be performed routinely.

Coronary Angiography

If anginal symptoms persist despite maximal medical therapy, coronary angiography with an aim toward possible revascularization should be considered. One must keep in mind that coronary angiography is not a therapeutic intervention but a diagnostic test. Angiography is of little tangible value if there are no viable revascularization options.

Recommendations for the timing of angiography in patients with unstable ischemic syndromes are controversial. Early angiography can identify patients with left main or severe three-vessel disease, in whom early coronary artery bypass surgery can be lifesaving. The decision to perform angiography early should be based on the frequency and severity of angina episodes and the nature and extent of ECG changes. For example, extensive ST depression in the anterior chest leads suggests stenosis of the proximal left anterior descending artery or left main coronary artery, total occlusion of which might result in sudden death. Frequent anginal episodes or episodes that are difficult to control with conventional antianginal medications also point to impending infarction. Under these circumstances, early angiography is indicated. Otherwise, in cases in which the patient is stabilized readily with pharmacologic agents, including aspirin and heparin, there is no need for early angiography. Under these circumstances, one option is to forego coronary angiography altogether and then to evaluate patients several days to weeks later when they are completely stabilized and ambulatory. That can be accomplished by exercise stress testing, which can stratify patients according to their risk for subsequent cardiac events. Our usual approach, however, is to perform coronary angiography in all patients who are appropriate candidates after they have been stabilized but before hospital discharge.

ST-ELEVATION MYOCARDIAL INFARCTION

Symptoms suggestive of MI are usually similar to those of ordinary angina but are greater in intensity and duration. Nausea, vomiting, and diaphoresis may be prominent features, and stupor and malaise attributable to low cardiac output may occur. Compromised left ventricular function may result in pulmonary edema with development of pulmonary bibasilar crackles and jugular venous distention; a fourth heart sound can be present with small infarcts or even mild ischemia, but a third heart sound is usually indicative of more extensive damage.

Patients presenting with suspected myocardial ischemia should undergo a rapid evaluation and should be treated with oxygen, sublingual nitroglycerin (unless systolic pressure < 90 mm Hg), adequate analgesia, and aspirin (160 to 325 mg orally).[45] Narcotics should be used to relieve pain and anxiety, the salutary effects of which have been known for decades and must not be underestimated. It is also important to

provide reassurance to the patient. A 12-lead electrocardiogram should be made and interpreted expeditiously.

ST-segment elevation of at least 1 mV in two or more contiguous leads provides strong evidence of thrombotic coronary occlusion: the patient should be considered for immediate reperfusion therapy. The diagnosis of STEMI can be limited in the presence of preexisting left bundle branch block or permanent pacemaker. Nonetheless, new left bundle branch block with a compatible clinical presentation should be treated as acute MI and treated accordingly. Recent data have suggested that patients with STEMI and new left bundle branch block may gain greater benefit from reperfusion strategies than those with ST elevation and preserved ventricular conduction.[46]

THROMBOLYTIC THERAPY

Early reperfusion of an occluded coronary artery is indicated for all eligible candidates. Overwhelming evidence from multiple clinical trials has demonstrated the ability of thrombolytic agents administered early in the course of an acute MI to reduce infarct size, preserve left ventricular function, and decrease short-term and long-term mortality rates.[47,48] Patients treated early derive the most benefit. Indications and contraindications for thrombolytic therapy are listed in Table 25-2. Because of the small, but nonetheless significant, risk of a bleeding complication, most notably intracranial hemorrhage, the decision to give a thrombolytic agent should be undertaken with prudence and caution. That is of special importance in ICU patients who may have a predisposition to bleeding complications because of multiple factors. Contraindications can be regarded as absolute or relative. In the surgical patient, thrombolysis may pose a prohibitive risk and emergent coronary angiography (with percutaneous coronary intervention as clinically indicated) may be preferable.

In contrast to the treatment of STEMI, thrombolytics have shown no benefit or even increased risk of adverse events when used for the treatment of unstable angina or NSTEMI.[49] Based on these findings, there is currently no role for thrombolytic agents in these latter syndromes.

TABLE 25-2 Indications for and Contraindications to Thrombolytic Therapy in Acute Myocardial Infarction

Indications
Symptoms consistent with acute myocardial infarction
Electrocardiogram showing 1-mm (0.1-mV) ST elevation in ≥2 contiguous leads or new left bundle branch block
Presentation within 12 h of symptom onset
Absence of contraindications
Contraindications
Absolute
Active internal bleeding
Intracranial neoplasm, aneurysm, or AV malformation
Stroke or neurosurgery within 6 wk
Trauma or major surgery within 2 wk, which may be a potential source of serious rebleeding
Aortic dissection
Relative
Prolonged (>10 min) or clearly traumatic cardiopulmonary resuscitation[a]
Noncompressible vascular punctures
Severe uncontrolled hypertension (>200/110 mm Hg)[a]
Trauma or major surgery within 6 wk (but >2 wk)
Preexisting coagulopathy or current use of anticoagulants with INR >2–3
Active peptic ulcer
Infective endocarditis
Pregnancy
Chronic severe hypertension

[a] May be an absolute contraindication in low-risk patients with myocardial infarction.

ABBREVIATIONS: AV, atrioventricular; INR, international normalized ratio.

Thrombolytic Agents

Streptokinase (SK) is a single-chain protein produced by α-hemolytic streptococci. SK is given as a 1.5 million U intravenous infusion over 1 hour, which produces a systemic lytic state for approximately 24 hours. Hypotension with infusion usually responds to fluids and a decreased infusion rate, but allergic reactions are possible. Hemorrhagic complications are the most feared side effect, with a rate of intracranial hemorrhage of approximately 0.5%. SK produces coronary arterial patency approximately 50% to 60% of the time and has been shown to decrease mortality rate by 18% compared with placebo.[47]

Tissue plasminogen activator (t-PA) is a recombinant protein that is more fibrin selective than SK and produces a higher early coronary patency rate (70% to 80%). The Global Utilization of Streptokinase and Tissue Plasminogen Activator for Occluded Coronary Arteries (GUSTO) was a large (41,021 patients) clinical trial comparing SK with t-PA in patients with STEMI and demonstrated a small but significant survival benefit for t-PA (1.1% absolute, 15% relative reduction).[50] The GUSTO angiographic substudy showed that the difference in patency rates explains the difference in clinical efficacy between these two agents.[51] t-PA is usually given in an accelerated regimen consisting of a 15-mg bolus, with 0.75 mg/kg (up to 50 mg) intravenously over the initial 30 minutes and 0.5 mg/kg (up to 35 mg) over the next 60 minutes. Allergic reactions do not occur because t-PA is not antigenic, but the rate of intracranial hemorrhage may be slightly higher ($\sim$0.7%) than that with SK.

Reteplase is a deletion mutant of t-PA with an extended half-life and is given as two 10-mg boluses 30 minutes apart. Reteplase was originally evaluated in angiographic trials that demonstrated improved coronary flow at 90 minutes compared with t-PA, but subsequent trials showed similar 30-day mortality rates.[52] Why enhanced patency with reteplase did not translate into lower mortality is uncertain.

Tenecteplase (TNK-tPA) is a genetically engineered t-PA mutant with amino acid substitutions that result in prolonged half-life, resistance to plasminogen-activator inhibitor 1, and increased fibrin specificity. TNK-tPA is given as a single bolus adjusted for weight. A single bolus of TNK-tPA has been shown to produce coronary flow rates identical to those seen with accelerated t-PA, with equivalent 30-day mortality and bleeding rates.[53] Based on these results, single-bolus TNK-tPA is an acceptable alternative to t-PA.

Because these newer agents have equivalent efficacy and side effect profiles at no additional cost compared with t-PA, and because they are simpler to administer, they have gained popularity. The ideal thrombolytic agent has not been developed. Newer recombinant agents with greater fibrin specificity, slower clearance from the circulation, and more resistance to plasma protease inhibitors are being studied.

PRIMARY PERCUTANEOUS CORONARY INTERVENTION IN ACUTE MI

As many as 50% to 66% of patients presenting with acute MI may be ineligible for thrombolytic therapy, and these patients should be considered for primary percutaneous coronary intervention (PCI). The major advantages of primary PCI over thrombolytic therapy include a higher rate of normal (Thrombolysis In Myocardial Infarction [TIMI] grade 3) flow,[48] lower risk of intracranial hemorrhage, and the ability to stratify risk based on the severity and distribution of coronary artery disease. Data from several randomized trials have suggested that PCI is preferable to thrombolytic therapy for patients with acute MI at higher risk, including those older than 75 years, those with anterior infarctions, and those with hemodynamic instability.[54] The largest of these trials is the GUSTO-IIb angioplasty substudy, which randomized 1138 patients. At 30 days, there was a clinical benefit in the combined primary end points of death, nonfatal reinfarction, and nonfatal disabling stroke in the patients treated with percutaneous transluminal coronary angioplasty (PTCA) as opposed to t-PA, but there was no difference in the "hard" end points of death and MI at 30 days.[55]

These trials were performed in institutions in which a team skilled in primary angioplasty for acute MI was immediately available, with standby surgical backup, allowing for prompt reperfusion of the infarct-related artery. More important than the method of revascularization is the time to revascularization.[56] Procedural volume also is important.[57] A recent meta-analysis comparing direct PTCA with thrombolytic therapy found lower rates of mortality and reinfarction among those receiving direct PTCA.[58,59] Thus, direct angioplasty, if performed in a timely manner (ideally within 60 minutes) by highly experienced personnel, may be the preferred method of revascularization because it offers more complete revascularization with improved restoration of normal coronary blood flow and detailed information about coronary anatomy. There are certain subpopulations in which primary PCI is preferred. These subsets are listed in Table 25-3.

Coronary Stenting and Glycoprotein IIb/IIIa Antagonists

Primary angioplasty for acute MI results in a significant decrease in mortality rate but is limited by the possibility of abrupt vessel closure, recurrent in-hospital ischemia, reocclusion of the infarct-related artery, and restenosis. The use of coronary stents has been shown to decrease restenosis and adverse cardiac outcomes in routine and high-risk PCI.[60]

TABLE 25-3 Situations in Which Primary Angioplasty Is Preferred in Acute Myocardial Infarction

Situations in which PTCA is clearly preferable to thrombolytics
Contraindications to thrombolytic therapy
Cardiogenic shock
Patients in whom uncertain diagnosis prompted cardiac catherization which revealed coronary occlusion
Situations in which PTCA *may be* preferable to thrombolytics
Elderly patients (>75 y)
Hemodynamic instability
Patients with prior coronary artery bypass grafting
Large anterior infarction
Patients with a prior myocardial infarction

ABBREVIATION: PTCA, percutaneous transluminal coronary angioplasty.

The Primary Angioplasty in Myocardial Infarction Stent Trial tested the hypothesis that routine implantation of an intracoronary stent in the setting of MI would reduce angiographic restenosis and improve clinical outcomes compared with primary balloon angioplasty alone. This large, randomized, multicenter trial involving 900 patients did not show a difference in mortality rate at 6 months but did show improvement in ischemia-driven target vessel revascularization and less angina in the stented patients compared to PTCA alone.[61]

Glycoprotein (GP) IIb/IIIa receptor antagonists inhibit the final common pathway of platelet aggregation by blocking cross linking of activated platelets, and their use in percutaneous intervention has become routine.[62] The benefits of GP IIb/IIIa inhibition and coronary stenting appear to be additive.[63,64] Thus, combining GP IIb/IIIa antagonism and stenting in acute MI makes theoretical sense and has been tested in two large clinical trials. The ADMIRAL trial evaluated abciximab as an adjunct to primary PTCA and stenting in 300 patients with acute MI. Abciximab used in conjunction with stenting improved coronary patency before stenting and resulted in a nearly 50% relative risk reduction in the incidence of death, recurrent MI, and urgent revascularization at 30 days, although this was associated with an increased incidence of minor bleeding.[65] The CADILLAC trial randomized 2082 patients to angioplasty alone, angioplasty plus abciximab, stenting alone, or stenting plus abciximab. The composite end point of death, reinfarction, disabling stroke, and repeat revascularization was reduced with addition of abciximab to angioplasty, and outcomes were better with stenting (but abciximab added to stenting alone did not improve outcomes, although the event rate was low).[66] Based on the results of these trials, stenting has become routine for patients with PCI in the setting of acute MI, usually with the addition of GP IIb/IIIa inhibition.

In patients who fail thrombolytic therapy, salvage PTCA is indicated, although the initial success rate is lower than that of primary angioplasty, reocclusion is more common, and mortality is higher. The RESCUE trial focused on a subset of patients with acute MI and anterior infarction and showed a reduction in the combined end point of death and congestive heart failure at 30 days in the group receiving salvage PTCA.[67]

There is no convincing evidence to support empirical delayed PTCA in patients without evidence of recurrent or provocable ischemia after thrombolytic therapy. The TIMI IIB trial and other studies have suggested that a strategy of "watchful waiting" allows for identification of patients who will benefit from revascularization.[68]

ADJUNCTIVE THERAPIES IN STEMI

Aspirin

Aspirin has been shown to decrease mortality rate in acute infarction to the same degree as thrombolytic therapy, and its effects are additive to thrombolytics.[69] In addition, aspirin reduces the risk of reinfarction. Unless contraindicated, all patients with a suspected acute coronary syndrome (STEMI, NSTEMI, or unstable angina) should be given aspirin as soon as possible.

Heparin

Administration of full-dose heparin after thrombolytic therapy with t-PA is essential to diminish reocclusion after successful reperfusion.[47,69] Dosing should be adjusted to weight,

with a bolus of 60 U/kg up to a maximum of 4000 U and an initial infusion rate of 12 U/kg per hour up to a maximum of 1000 U/hr, with adjustment to keep the partial thromboplastin time between 50 and 70 seconds. Heparin should be continued for 24 to 48 hours.

Nitrates

Nitrates have several beneficial effects in acute MI. They reduce myocardial oxygen demand by decreasing preload and afterload and may improve myocardial oxygen supply by increasing subendocardial perfusion and collateral blood flow to the ischemic region. Occasional patients with ST elevation due to occlusive coronary artery spasm may have dramatic resolution of ischemia with nitrates. In addition to their hemodynamic effects, nitrates also reduce platelet aggregation. Despite these benefits, the Third Gruppo Italiano per lo Studio della Streptochinasi nell'Infarto Miocardico (GISSI-3) and Fourth International Study of Infarct Survival (ISIS-4) trials found no significant decrease in mortality rate from routine short- and long-term nitrate therapies.[70,71] Nonetheless, nitrates remain first-line agents for the symptomatic relief of angina pectoris and when MI is complicated by congestive heart failure.

β Blockers

Beta blockers are beneficial in the early management of MI and as long-term therapy. In the era before thrombolysis, early intravenous atenolol was shown to significantly decrease reinfarction, cardiac arrest, cardiac rupture, and death.[72] In conjunction with thrombolytic therapy with t-PA, immediate β blockade with metoprolol resulted in a significant reduction in recurrent ischemia and reinfarction, although mortality rate was not decreased.[68]

Intravenous β blockade should be considered for all patients presenting with acute MI, especially those with continued ischemic discomfort and sympathetic hyperactivity manifested by hypertension or tachycardia. Therapy should be avoided in patients with moderate or severe heart failure, hypotension, severe bradycardia or heart block, and severe bronchospastic disease. Metoprolol can be given intravenously as a 5-mg bolus, repeated every 5 minutes for a total of three doses. Because of its brief half-life, esmolol may be advantageous in situations in which precise control of heart rate is necessary or rapid drug withdrawal may be needed if adverse effects occur.

Oral β blockade has been clearly demonstrated to decrease mortality rate after acute MI[73,74] and should be initiated in all patients who can tolerate it, even if they have not been treated with intravenous β blockers. Diabetes mellitus is not a contraindication.

Angiotensin-Converting Enzyme Inhibitors

ACE inhibitors have been shown unequivocally to improve hemodynamics, functional capacity and symptoms, and survival in patients with chronic congestive heart failure.[75,76] Moreover, ACE inhibitors prevent the development of congestive heart failure in patients with asymptomatic left ventricular dysfunction.[77] This information was the spur for trials evaluating the benefit of prophylactic administration of ACE inhibitors in the period after MI. The Survival and Ventricular Enlargement trial showed that patients with left ventricular dysfunction (ejection fraction < 40%) after MI had a 21% improvement in survival rate after treatment with the ACE inhibitor captopril.[78] A smaller but still significant reduction in mortality rate was seen when all patients were treated with captopril in the ISIS-4 study.[71] The HOPE study demonstrated that the ACE inhibitor ramipril improves survival rate when added to aspirin and β blockers.[36] The mechanisms responsible for the benefits of ACE inhibitors probably include limitation in the progressive left ventricular dysfunction and enlargement (remodeling) after infarction, but a reduction in ischemic events also is seen.

ACE inhibition should be started early, preferably within the first 24 hours after infarction. Immediate intravenous ACE inhibition with enalaprilat has not been shown to be beneficial.[79] Patients should be started on small doses of oral agents (captopril 6.25 mg three times daily) and rapidly increased to the range demonstrated to be beneficial in clinical trials (captopril 50 mg three times daily, enalapril 10 to 20 mg twice daily, lisinopril 10 to 20 mg once daily, or ramipril 10 mg once daily).

Calcium Channel Blockers

Randomized clinical trials have not demonstrated that routine use of calcium channel blockers improves survival rate after MI. Meta-analyses have suggested that large doses of the short-acting dihydropyridine nifedipine increase mortality rate in MI. Adverse effects of calcium channel blockers include bradycardia, atrioventricular block, and exacerbation of heart failure. The relative vasodilating, negative inotropic effects, and conduction system effects of the various agents must be considered when they are used in this setting. Diltiazem is the only calcium channel blocker that has been proven to have tangible benefits by reducing reinfarction and recurrent ischemia in patients with non–Q-wave infarctions who do not have evidence of congestive heart failure.[80]

Calcium channel blockers may be useful for patients whose postinfarction course is complicated by recurrent angina because these agents not only reduce myocardial oxygen demand but also inhibit coronary vasoconstriction. For hemodynamically stable patients, diltiazem can be given starting at 60 to 90 mg orally every 6 to 8 hours. In patients with severe left ventricular dysfunction, a long-acting dihydropyridine without prominent negative inotropic effects such as amlodipine, nicardipine, or the long-acting preparation of nifedipine may be preferable; increased mortality rate with these agents has not been demonstrated.

Antiarrhythmic Therapy

A major purpose for admitting patients with MI to the ICU is to monitor for and prevent malignant arrhythmias. Ventricular extrasystoles are common after MI and are a manifestation of electrical instability of peri-infarct areas. The incidence of sustained ventricular tachycardia or fibrillation is highest in the first 3 to 4 hours, but these arrhythmias may occur at any time. Malignant ventricular arrhythmias may be heralded by frequent premature ventricular contractions (more than five or six per minute), closely coupled premature ventricular contractions, complex ectopy (couplets, multiform premature ventricular contractions), and salvos of nonsustained ventricular tachycardia. However, malignant arrhythmia may occur suddenly without these "warning" arrhythmias.

Based on these pathophysiologic considerations, prophylactic use of intravenous lidocaine has been advocated, even

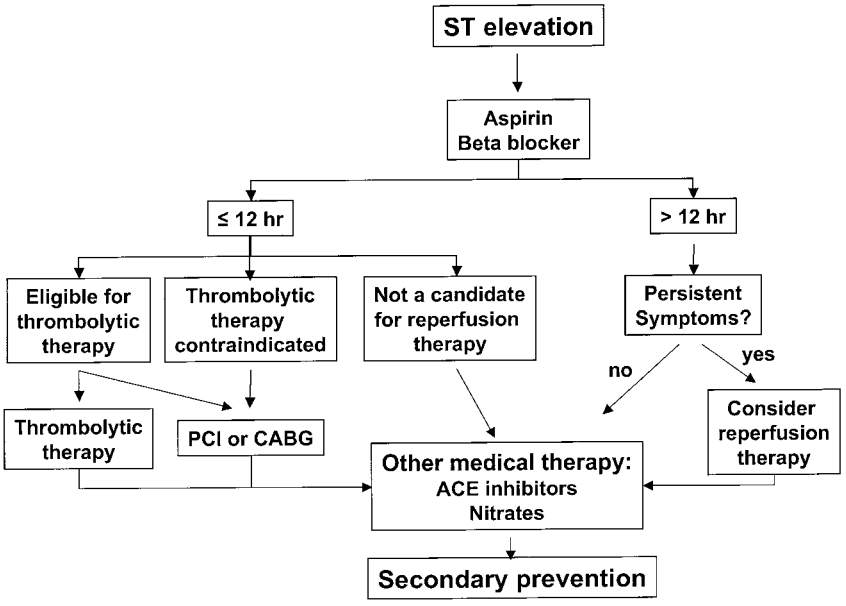

FIGURE 25-2 Possible treatment algorithm for patients presenting with ST-elevation myocardial infarction. ACE, angiotensin-converting enzyme; CABG, coronary artery bypass grafting; PCI, percutaneous coronary intervention.

in the absence of ectopy. Even though lidocaine decreases the frequency of premature ventricular contractions and of early ventricular fibrillation, overall mortality rate is not decreased. Meta-analyses of pooled data have demonstrated increased mortality rate from the routine use of lidocaine.[81] Therefore, routine prophylactic administration of lidocaine is no longer recommended.

Nonetheless, lidocaine infusion is clearly indicated after an episode of sustained ventricular tachycardia or ventricular fibrillation and should be considered in patients with nonsustained ventricular tachycardia. Lidocaine is administered as a bolus of 1 mg/kg (not to exceed 100 mg), followed by a second bolus of 0.5 mg/kg 10 minutes later, and an infusion at 1 to 3 mg/min. Lidocaine is metabolized by the liver, so smaller doses should be given in the presence of liver disease, in the elderly, and in patients who have congestive heart failure severe enough to compromise hepatic perfusion. Toxic manifestations primarily involve the central nervous system and can include confusion, lethargy, slurred speech, and seizures. Because the risk of malignant ventricular arrhythmias decreases after 24 hours, lidocaine is usually discontinued after this point. For prolonged infusions, monitoring of lidocaine levels (therapeutic between 1.5 and 5 μg/mL) is sometimes useful.

Intravenous amiodarone is an alternative to lidocaine for ventricular arrhythmias. Amiodarone is given as a 150-mg intravenous bolus over 10 minutes, followed by 1 mg/min for 6 hours, and then 0.5 mg/min for 18 hours.

Perhaps the most important points in the prevention and management of arrhythmias after acute MI are correcting hypoxemia and maintaining normal serum potassium and magnesium levels. Serum electrolytes should be followed closely, particularly after diuretic therapy. Magnesium depletion is another frequently overlooked cause of persistent ectopy.[82] The serum magnesium level may not reflect myocardial concentrations. Routine administration of magnesium has not been shown to decrease mortality rate after acute MI,[71] but empiric administration of 2 g of intravenous magnesium in patients with early ventricular ectopy is probably a good idea.

One possible treatment algorithm for treating patients with STEMI is shown in Fig. 25-2.

NON–ST-ELEVATION MYOCARDIAL INFARCTION

The key to initial management of patients with acute coronary syndromes who present without ST elevation is risk stratification. The overall risk of a patient is related to the severity of preexisting heart disease and the degree of plaque instability. Risk stratification is an ongoing process, which begins with hospital admission and continues through discharge.

Braunwald proposed a classification for unstable angina based on severity of symptoms and clinical circumstances for risk stratification.[83] The risk of progression to acute MI or death in acute coronary syndromes increases with age. ST-segment depression on the electrocardiogram identifies patients at higher risk for clinical events.[83] Conversely, a normal electrocardiogram confers an excellent short-term prognosis. Biochemical markers of cardiac injury are also predictive of outcome. Elevated levels of troponin T are associated with an increased risk of cardiac events and a higher 30-day mortality rate and are more strongly correlated with 30-day survival rate than is ECG category or CPK-MB level.[84] Conversely, low levels are associated with low event rates, although the absence of troponin elevation does not guarantee a good prognosis and is not a substitute for good clinical judgment.

ANTIPLATELET THERAPY

Aspirin is a mainstay of therapy for acute coronary syndromes. The Veterans Administration Cooperative Study Group[28] and the Canadian Multicenter Trial[85] showed that aspirin reduces the risk of death or MI by approximately 50% in patients with unstable angina or non–Q-wave MI. Aspirin also reduces events after resolution of an acute coronary syndrome and should be continued indefinitely.

Clopidogrel or ticlopidine, thienopyridines that inhibit platelet activation induced by adenosine diphosphate and are more potent than aspirin, can be used in place of aspirin, if necessary. They are used in combination with aspirin when intracoronary stents are placed. Clopidogrel is generally better

tolerated than ticlopidine because the risk of neutropenia is much lower.

In the CURE trial, 12,562 patients were randomized to receive clopidogrel or placebo in addition to standard therapy with aspirin within 24 hours of unstable angina symptoms.[86] Clopidogrel significantly reduced the risk of MI, stroke, or cardiovascular death from 11.4% to 9.3% ($p < 0.001$).[86] It should be noted that this benefit included a 1% absolute increase in major, non–life-threatening bleeds ($p = 0.001$) and a 2.8% absolute increase in major or life-threatening bleeds associated with coronary artery bypass graft (CABG) within 5 days ($p = 0.07$).[86] These data have raised concerns about giving clopidogrel before obtaining information about the coronary anatomy.

Clopidogrel has also been tested for secondary prevention of events. The Clopidogrel Versus Aspirin in Patients at Risk of Ischaemic Events trial, a multicenter trial of 19,185 patients with known vascular disease (prior stroke, MI, or peripheral vascular disease), randomized patients to 75 mg/d of clopidogrel or 325 mg/d aspirin.[87] After an average follow-up period of 1.6 years, patients treated with clopidogrel had significantly fewer cardiovascular events than did patients treated with aspirin (5.8% vs. 5.3%, a relative risk reduction of 8.7%).[87]

ANTICOAGULANT THERAPY

Heparin is an important component of primary therapy for patients with unstable coronary syndromes without ST elevation. When added to aspirin, heparin has been shown to reduce refractory angina and the development of MI,[29] and a meta-analysis of the available data has indicated that addition of heparin reduces the composite end point of death or MI.[88]

Heparin can be difficult to administer because the anticoagulant effect is unpredictable in individual patients; this is due to heparin binding to heparin-binding proteins, endothelial and other cells, and heparin inhibition by several factors released by activated platelets. Therefore, the activated partial thromboplastin time must be monitored closely. The potential for heparin-associated thrombocytopenia is another safety concern.

Low-molecular-weight heparins (LMWHs), which are obtained by depolymerization of standard heparin and selection of fractions with lower molecular weights, have several advantages. Because they bind less avidly to heparin-binding proteins, there is less variability in the anticoagulant response and a more predictable dose-response curve, so the need to monitor activated partial thromboplastin time is eliminated. The incidence of thrombocytopenia is lower (but not absent, and patients with heparin-induced thrombocytopenia with anti-heparin antibodies cannot be switched to LMWH). Moreover, LMWHs have longer half-lives and can be given by subcutaneous injection. These properties make treatment with LMWH at home after hospital discharge feasible. Because evidence suggests that patients with unstable coronary syndromes may remain in a hypercoagulable state for weeks or months, the longer duration of anticoagulation possible with LMWH may be desirable.

Several trials have documented beneficial effects of LMWH therapy in unstable coronary syndromes. The Efficacy and Safety of Subcutaneous Enoxaparin in Non-Q-Wave Coronary Events trial showed that the LMWH enoxaparin reduces the combined end point of death, MI, or recurrent ischemia at 14 days and at 30 days when compared with heparin.[89] Similar results were found in the TIMI 11B trial comparing enoxaparin with heparin.[90] A meta-analysis of these two very similar trials demonstrated a 23% 7-day and an 18% 42-day reduction in death or MI.[91] Dalteparin, another LMWH, is also available, but the evidence for its efficacy is not nearly as compelling as that for enoxaparin.

Although LMWHs are substantially easier to administer than standard heparin and long-term administration can be contemplated, they are more expensive. Specific considerations with the use of LMWHs include decreased clearance in renal insufficiency and the lack of a commercially available test to measure the anticoagulant effect. LMWH should be given strong consideration in high-risk patients, but whether substitution of LMWH for heparin in all patients is cost effective is uncertain.

GLYCOPROTEIN IIB/IIIA ANTAGONISTS

Given the central role of platelet activation and aggregation in the pathophysiology of unstable coronary syndromes, attention has focused on platelet GP IIb/IIIa antagonists, which inhibit the final common pathway of platelet aggregation. Three agents are currently available. Abciximab is a chimeric murine-human monoclonal antibody Fab fragment that binds with relatively high affinity to platelet receptors, giving it a short plasma half-life (10 to 30 minutes) but a long duration of biologic action by virtue of the strength of the bond formed with the surface of the activated platelet. Because there is a relatively low ratio of abciximab molecules to platelets (i.e., limited plasma pool of unbound drug), platelet transfusions may be helpful in the event of a major bleeding complication. Abciximab is currently approved for elective PCI or unstable coronary syndromes with planned PCI. Tirofiban is a synthetic nonpeptide agent with a half-life of approximately 2.5 hours and a lower receptor affinity than abciximab. This drug is approved for the medical management of unstable angina or NSTEMI with or without planned PCI. Given the large ratio of drug to platelet (i.e., large plasma pool of free drug) seen with this agent and with eptifibatide, platelet transfusions are generally not regarded as helpful in the event of a major bleed. It is recommended that the drug simply be stopped and supportive therapy instituted during the relatively short biologic activity period. Eptifibatide is a cyclic heptapeptide with a 2-hour half-life. Like tirofiban, it is approved for the medical management of unstable angina with or without subsequent PCI; however, it may also be used as adjunctive therapy in elective PCI.

The benefits of GP IIb/IIIa inhibitors as adjunctive treatment in patients undergoing percutaneous intervention have been substantial and consistently observed. Abciximab has been most extensively studied, but a benefit for eptifibatide has also been demonstrated. In acute coronary syndromes, the evidence supporting the efficacy of GP IIb/IIIa inhibitors is somewhat less impressive. Five major trials have been completed (the "4 P's" and GUSTO-IV). In the Platelet Receptor Inhibition in Ischemic Syndrome Management trial, tirofiban decreased death rate, MI, or refractory ischemia when compared with heparin, from 5.6% to 3.8% ($p < 0.01$) at 48 hours, but there was no difference at 30 days (7.1% vs. 5.8%, $p = 0.11$).[92] In the subsequent Platelet Receptor Inhibition in Ischemic Syndrome Management in Patients Limited by Unstable Signs and Symptoms trial, tirofiban added to

heparin decreased death rate, MI, or refractory ischemia at 30 days, from 11.9% to 8.7% ($p = 0.03$).[31] In the PURSUIT trial, eptifibatide decreased the rate of death or MI, from 15.7% to 14.2% ($p = 0.04$) at 30 days.[93] The PARAGON trial with lamifiban did not show a significant benefit with GP IIb/IIIa inhibition.[94] In the GUSTO-IV ACS trial, however, abciximab did not produce an improvement; death rate or MI was slightly higher in the treatment group.[95] This trial included patients for whom percutaneous intervention was not planned; when patients with refractory angina and planned angioplasty were randomized to receive abciximab or placebo from 24 hours before the procedure through 1 hour after PTCA in the CAPTURE trial, the primary end point—death, MI, or urgent revascularization at 30 days—was decreased by GP IIb/IIIa inhibition, and the rate of MI before PTCA also was decreased.[96] When patients were categorized as those with or without increased troponin, the benefit was confined to the positive troponin group.[96]

Recent meta-analyses have found a relative risk reduction of 40% for GP IIb/IIIa therapy adjunctive to PCI, and a reduction of 11% for GP IIb/IIIa inhibitors in NSTEMI acute coronary syndromes.[62] Additional analysis has suggested that GP IIb/IIIa inhibition is most effective in high-risk patients (those with ECG changes or elevated troponin).[62] The benefits appear to be restricted to patients undergoing percutaneous intervention.

INTERVENTIONAL MANAGEMENT

Cardiac catheterization may be undertaken in patients presenting with symptoms suggestive of unstable coronary syndromes for one of several reasons: to assist with risk stratification, as a prelude to revascularization, and to exclude significant epicardial coronary stenosis as a cause of symptoms when the diagnosis is uncertain.

An early invasive approach has been compared with a conservative approach in several prospective studies. Two earlier trials were negative. The TIMI IIIb study randomized 1473 patients to early angiography or conservative management with angiography and revascularization only for recurrent chest pain or provocable ischemia.[49] No significant difference was found in the combined end point of death, MI, or positive treadmill test at 6 weeks. However, there was a high (64%) cross-over rate from the conservative to the invasive arm, and hospital stays were shorter with the early invasive approach.[49] The VANQWISH trial of 920 patients with non–Q wave MI showed an increase in the primary end point of death rate or MI with an invasive strategy, although overall mortality was not significantly different.[97] Difficulties with this trial included the fact that only 44% of patients randomized to the invasive arm actually underwent revascularization, compared with 33% in the conservative arm, and the entire trial had a very high surgical mortality rate (11.6%).[97] It is important to realize that these trials were performed before widespread use of coronary stenting and platelet GP IIb/IIIa inhibitors, both of which have been shown to improve outcomes after angioplasty.

More recently, a substudy of the Second Fragmin and Fast Revascularisation during Instability in Coronary Artery Disease study, which used the LMWH dalteparin, randomized 2457 patients to an early invasive or a noninvasive strategy and found a significantly lower mortality rate in the invasive group at 30 days, which was maintained at 1 year.[98] The TACTICS TIMI-18 trial used aspirin, heparin, and tirofiban in 2220 patients and found a significant reduction in the combined end point of death rate, MI, or readmission for acute coronary syndrome with invasive management.[99] It is important to recognize that these trials selected high-risk patients (identified on the basis of ECG changes or enzyme elevations) for inclusion. Addition of antiplatelet therapy (beyond the use of aspirin alone) to reperfusion also may have contributed to the improved outcomes with invasive strategies in these more recent trials.

Risk stratification is the key to managing patients with NSTEMI acute coronary syndromes. One possible algorithm for managing patients with NSTEMI is shown in Fig. 25-3. An initial strategy of medical management with attempts at stabilization is warranted in patients with lower risk, but patients at higher risk should be considered for cardiac catheterization. Pharmacologic and mechanical strategies are intertwined in the sense that selection of patients for early revascularization will influence the choice of antiplatelet and anticoagulant medication. When good clinical judgment is used, early coronary angiography in selected patients with acute coronary syndromes can lead to better management and lower morbidity and mortality rates.

COMPLICATIONS OF ACUTE MYOCARDIAL INFARCTION

POSTINFARCTION ISCHEMIA

Causes of ischemia after infarction include decreased myocardial oxygen supply due to coronary reocclusion or spasm, mechanical problems that increase myocardial oxygen demand, and extracardiac factors such as hypertension, anemia, hypotension, or hypermetabolic states. Nonischemic causes of chest pain, such as postinfarction pericarditis and acute pulmonary embolism, should also be considered.

Immediate management includes aspirin, β blockade, intravenous nitroglycerin, heparin, consideration of calcium channel blockers, and diagnostic coronary angiography. Postinfarction angina is an indication for revascularization. PTCA can be performed if the culprit lesion is suitable. CABG should be considered for patients with left main disease, three-vessel disease, or unsuitable for PTCA. If the angina cannot be controlled medically or is accompanied by hemodynamic instability, an IABP should be inserted.

VENTRICULAR FREE WALL RUPTURE

Ventricular free wall rupture typically occurs during the first week after infarction. The classic patient is elderly, female, and hypertensive. Early use of thrombolytic therapy decreases the incidence of cardiac rupture, but late use may actually increase the risk. Free wall rupture presents as a catastrophic event with shock and electromechanical dissociation. Salvage is possible with prompt recognition, pericardiocentesis to relieve acute tamponade, and thoracotomy with repair.[100] Emergent echocardiography or pulmonary artery catheterization can help make the diagnosis.

VENTRICULAR SEPTAL RUPTURE

Septal rupture presents as severe heart failure or cardiogenic shock, with a pansystolic murmur and parasternal thrill. The hallmark finding is a left-to-right intracardiac shunt ("step up" in oxygen saturation from the right atrium to the right

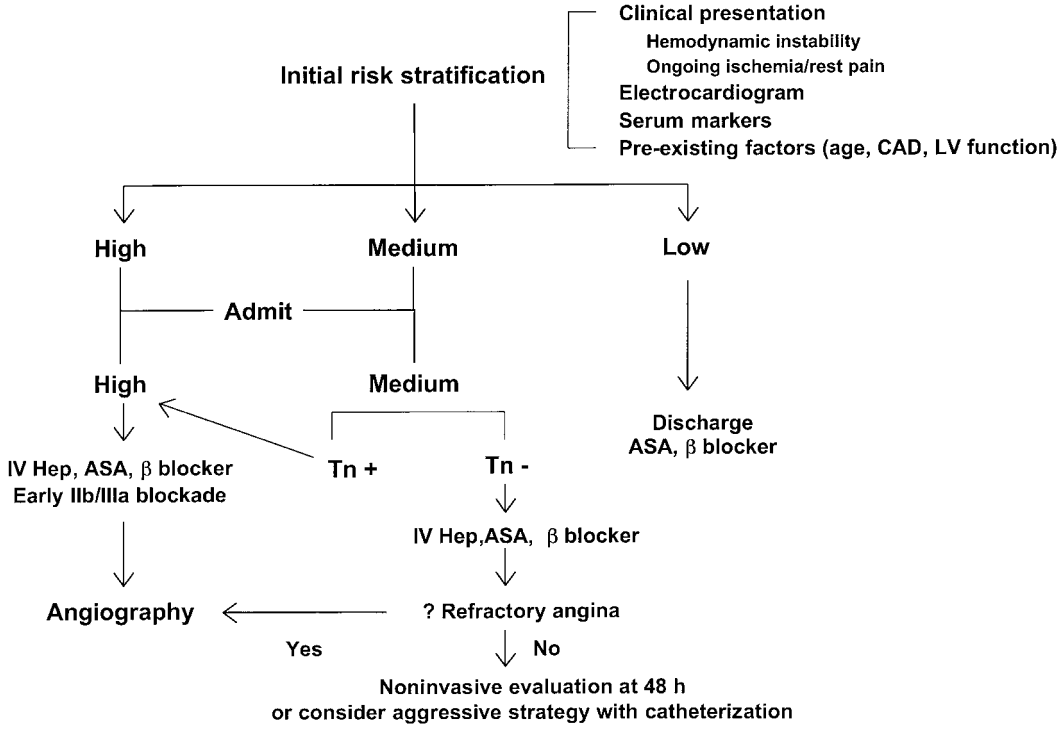

FIGURE 25-3 Possible treatment algorithm for patients with non–ST-elevation acute coronary syndromes. ASA, aspirin; Hep, heparin; IV, intravenous; Tn, troponin.

ventricle), but the diagnosis is most easily made with echocardiography.

Rapid institution of an IABP and supportive pharmacologic measures is necessary. Operative repair is the only viable option for long-term survival. The timing of surgery has been controversial, but most authorities currently suggest that repair should be undertaken early, within 48 hours of the rupture.[101]

ACUTE MITRAL REGURGITATION

Ischemic mitral regurgitation is usually associated with inferior MI and ischemia or infarction of the posterior papillary muscle, although anterior papillary muscle rupture can also occur. Papillary muscle rupture typically occurs 2 to 7 days after acute MI and presents dramatically with pulmonary edema, hypotension, and cardiogenic shock. When a papillary muscle ruptures, the murmur of acute mitral regurgitation may be limited to early systole because of rapid equalization of pressures in the left atrium and left ventricle. More importantly, the murmur may be soft or inaudible, especially when cardiac output is low.[102]

Echocardiography is extremely useful in the differential diagnosis, which includes free wall rupture, ventricular septal rupture, and infarct extension with pump failure. Hemodynamic monitoring with pulmonary artery catheterization may also be helpful. Management includes afterload reduction with nitroprusside and an IABP as temporizing measures. Inotropic or vasopressor therapy also may be needed to support cardiac output and blood pressure. Definitive therapy is surgical valve repair or replacement, which should be undertaken as soon as possible because clinical deterioration can be sudden.[102,103]

RIGHT VENTRICULAR INFARCTION

Right ventricular infarction occurs in up to 30% of patients with inferior infarction and is clinically significant in 10%.[104] The combination of a clear chest radiogram with jugular venous distention in a patient with an inferior wall MI should lead to the suspicion of a coexisting right ventricular infarct. The diagnosis is substantiated by demonstration of ST-segment elevation in the right precordial leads (V_{3R} to V_{5R}) or by characteristic hemodynamic findings on right heart catheterization (elevated right atrial and right ventricular end-diastolic pressures with normal to low pulmonary artery occlusion pressure and low cardiac output). Echocardiography can demonstrate depressed right ventricular contractility.[22] Patients with cardiogenic shock on the basis of right ventricular infarction have a better prognosis than do those with left-side pump failure.[104] This may be due in part to the fact that right ventricular function tends to return to normal over time with supportive therapy.[105]

In patients with right ventricular infarction, hypovolemia should be avoided because it can seriously compromise perfusion. However, most patients have elevated central venous pressures after initial resuscitation, and fluid loading is ineffective in raising perfusion further. Continued fluid loading can compromise left ventricular filling and cardiac output.[105] Inotropic therapy with dobutamine is often more effective in increasing cardiac output. Serial echocardiograms may be useful to detect right ventricular overdistention.[105] Maintenance of atrioventricular synchrony is also important in these patients to optimize right ventricular filling.[22] For patients with continued hemodynamic instability, using an IABP may be useful, particularly because elevated right ventricular pressures and volumes increase wall stress and oxygen

consumption and decrease right coronary perfusion pressure, exacerbating right ventricular ischemia.

Reperfusion of the occluded coronary artery is also crucial. A study using direct angioplasty found that restoration of normal flow can result in dramatic recovery of right ventricular function and a mortality rate of only 2%, whereas unsuccessful reperfusion was associated with persistent hemodynamic compromise and a mortality rate of 58%.[106]

CARDIOGENIC SHOCK

Epidemiology and Pathophysiology

Cardiogenic shock, resulting from left ventricular pump failure or from mechanical complications, represents the leading cause of in-hospital death after MI.[20] Despite advances in the management of heart failure and acute MI, clinical outcomes in patients with cardiogenic shock have been frustratingly poor, with reported mortality rates ranging from 50% to 80%.[107] Patients may have cardiogenic shock at initial presentation, but shock often evolves over several hours.[108,109] This is important because it suggests that early treatment may potentially prevent shock.

Cardiac dysfunction in patients with cardiogenic shock is usually initiated by MI or ischemia. The myocardial dysfunction resulting from ischemia worsens that ischemia, creating a downward spiral (Fig. 25-4). Once a critical mass of ischemic or necrotic left ventricular myocardium (usually about 40%)[110] fails to pump, stroke volume and cardiac output begin to diminish significantly. Systolic dysfunction leads to decreased systemic perfusion and hypotension, which reduces coronary perfusion pressure and induces compensatory peripheral vasoconstriction and fluid retention. These compensatory mechanisms create a vicious cycle that further worsens the systolic dysfunction. Likewise, myocardial ischemia increases myocardial stiffness, thus increasing left ventricular end-diastolic pressure and myocardial wall stress at a given end-diastolic volume. Increased left ventricular stiffness limits diastolic filling and may result in pulmonary congestion, causing hypoxemia and worsening the imbalance of oxygen delivery and oxygen demand in the myocardium, resulting in further ischemia and myocardial dysfunction. The compensatory mechanisms that retain fluid to maintain cardiac output may add to the vicious cycle and further increase diastolic filling pressures. The interruption of this cycle of myocardial dysfunction and ischemia forms the basis for the therapeutic regimens for cardiogenic shock.

Initial Management

Maintenance of adequate oxygenation and ventilation is critical. Many patients require intubation and mechanical ventilation, if only to reduce the work of breathing and facilitate sedation and stabilization before cardiac catheterization. Electrolyte abnormalities should be corrected, and morphine (or fentanyl, if systolic pressure is compromised) should be used to relieve pain and anxiety, thus decreasing excessive sympathetic activity and oxygen demand, preload, and afterload. Arrhythmias and heart block may have major effects on cardiac output and should be corrected promptly with antiarrhythmic drugs, cardioversion, or pacing.

The initial approach to the hypotensive patient should include fluid resuscitation unless frank pulmonary edema is present. Patients are commonly diaphoretic and relative hypovolemia may be present in as many as 20% of patients with cardiogenic shock. Fluid infusion is best initiated with predetermined boluses titrated to clinical end points of heart rate, urine output, and blood pressure. Ischemia produces diastolic and systolic dysfunctions; hence, elevated filling pressures may be necessary to maintain stroke volume in patients with cardiogenic shock. Patients who do not respond rapidly to initial fluid boluses or those with poor physiologic reserve should be considered for invasive hemodynamic monitoring. Optimal filling pressures differ from patient to patient; hemodynamic monitoring can be used to construct a Starling curve at the bedside to identify the filling pressure at which cardiac output is maximized. Maintenance of adequate preload is particularly important in patients with right ventricular infarction.

When arterial pressure remains inadequate, therapy with vasopressor agents may be required to maintain coronary perfusion pressure. Dopamine increases blood pressure and

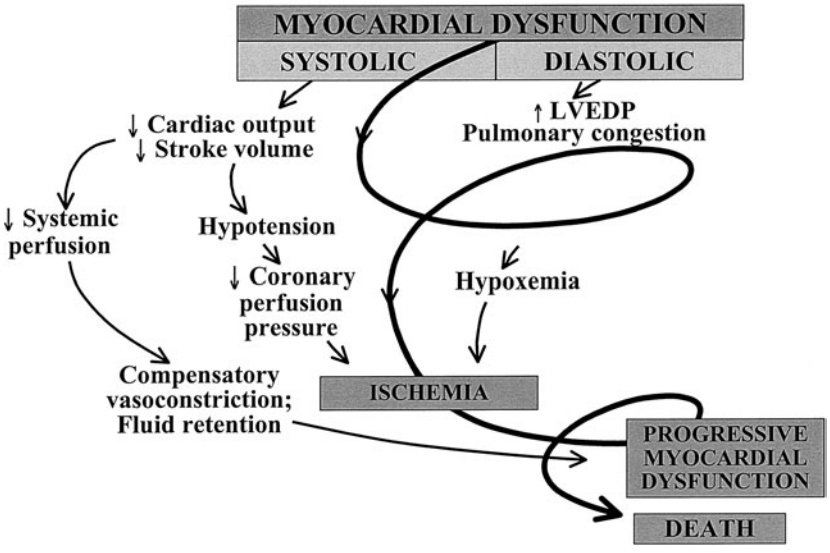

FIGURE 25-4 The 'downward spiral' in cardiogenic shock. Stroke volume and cardiac output fall with left ventricular (LV) dysfunction, producing hypotension and tachycardia that reduce coronary blood flow. Increasing ventricular diastolic pressure reduces coronary blood flow, and increased wall stress elevates myocardial oxygen requirements. All of these factors combine to worsen ischemia. The falling cardiac output also compromises systemic perfusion. Compensatory mechanisms include sympathetic stimulation and fluid retention to increase preload. These mechanisms can actually worsen cardiogenic shock by increasing myocardial oxygen demand and afterload. Thus, a vicious circle can be established. LVEDP, left ventricular enddiastolic pressure. ***(Adapted with permission from Hollenberg and colleagues.[20])***

cardiac output and is usually the initial choice in patients with systolic pressures below 80 mm Hg. When hypotension remains refractory, norepinephrine may be necessary to maintain organ perfusion pressure. Phenylephrine, a selective α_1-adrenergic agonist, may be useful when tachyarrhythmias limit therapy with other vasopressors. Vasopressor infusions need to be titrated carefully in patients with cardiogenic shock to maximize coronary perfusion pressure with the least possible increase in myocardial oxygen demand. Hemodynamic monitoring, with serial measurements of cardiac output and filling pressures (and other parameters such as mixed venous oxygen saturation), allows for titration of the dosage of vasoactive agents to the minimum dosage required to achieve the chosen therapeutic goals.[24]

After initial stabilization and restoration of adequate blood pressure, tissue perfusion should be assessed. If tissue perfusion remains inadequate, inotropic support or use of an IABP should be initiated. If tissue perfusion is adequate but significant pulmonary congestion remains, diuretics may be used. Vasodilators also can be considered, depending on the blood pressure.

In patients with inadequate tissue perfusion and adequate intravascular volume, the circulation should be supported with inotropic agents. Dobutamine, a selective β_1-adrenergic receptor agonist, can improve myocardial contractility and increase cardiac output and is the initial agent of choice in patients with systolic pressures above 80 mm Hg. Dobutamine may exacerbate hypotension in some patients, especially when hypovolemia has not been corrected, and can precipitate tachyarrhythmias. Dopamine may be preferable if systolic pressure is below 80 mm Hg, although tachycardia and increased peripheral resistance may worsen myocardial ischemia. In some situations, a combination of dopamine and dobutamine can be more effective than either agent used alone. Phosphodiesterase inhibitors such as milrinone increase intracellular cyclic adenosine monophosphate by mechanisms not involving adrenergic receptors, have positive inotropic and vasodilatory actions, and are less arrhythmogenic than catecholamines. Milrinone, however, has the potential to cause hypotension and has a long half-life; in patients with tenuous clinical status, its use is often reserved for situations in which other agents have proven ineffective. Standard administration of milrinone calls for a bolus loading dose followed by an infusion, but many clinicians eschew the loading dose (or halve it) in patients with marginal blood pressure.

Counterpulsation with an IABP reduces afterload and augments diastolic perfusion pressure, thereby increasing cardiac output and improving coronary blood flow.[111] These beneficial effects, in contrast to those of inotropic or vasopressor agents, occur without an increase in oxygen demand. However, IABP does not produce a significant improvement in blood flow distal to a critical coronary stenosis and has not been shown to improve mortality when used alone, that is, without reperfusion therapy or revascularization. In patients with cardiogenic shock and compromised tissue perfusion, IABP can be an essential support mechanism to stabilize patients and allow time for definitive therapeutic measures.[111,112] In appropriate settings, more intensive support with mechanical assist devices may also be implemented.

Reperfusion Therapy

Although thrombolytic therapy reduces the likelihood of subsequent development of shock after initial presentation,[109] its role in the management of patients who have already developed shock is less certain. The number of patients in randomized trials is small because most fibrinolytic trials have excluded patients with cardiogenic shock at presentation, but the available trials (GISSI, ISIS-2, and GUSTO-1)[47,50,69,113] have not demonstrated that fibrinolytic therapy decreases mortality rate in patients with established cardiogenic shock. In contrast, in the Should We Emergently Revascularize Occluded Coronaries for Cardiogenic Shock? (SHOCK) Registry,[114] patients treated with fibrinolytic therapy had a lower in-hospital mortality rate than did those who were not (54% vs. 64%, $p = 0.005$), even after adjustment for age and revascularization status (odds ratio, 0.70; $p = 0.027$).

Fibrinolytic therapy is clearly less effective in patients with cardiogenic shock than in those without. The explanation for this lack of efficacy appears to be the low reperfusion rate achieved in this subset of patients. The reasons for decreased thrombolytic efficacy in patients with cardiogenic shock likely include hemodynamic, mechanical, and metabolic factors that prevent achievement and maintenance of infarct-related artery patency.[115] Attempts to increase reperfusion rates by increasing blood pressure with aggressive inotropic and pressor therapies and counterpulsation with an IABP make theoretical sense, and two small studies have supported the notion that vasopressor therapy improves thrombolytic efficacy.[115,116] The use of an IABP to augment aortic diastolic pressure also may increase the effectiveness of thrombolytics.

To date, emergency percutaneous revascularization is the only intervention that has been shown to reduce mortality rates consistently in patients with cardiogenic shock. Use of angioplasty in patients with cardiogenic shock grew out of its use as primary therapy in patients with MI. An analysis of the first 1000 patients treated with primary angioplasty at the Mid America Heart Institute showed a mortality rate of 44% in the subgroup of 79 patients presenting with cardiogenic shock, which was substantially lower than the 80% to 90% mortality rate in historical controls.[117] Most other reported case series also showed results with percutaneous intervention that were superior to those with fibrinolytic therapy or conservative medical management (mortality rates of approximately 40% to 50%).[20] Observational studies from registries of randomized trials have also reported improved outcomes in patients with cardiogenic shock selected for revascularization. Notable among these are the GUSTO-1 trial, in which patients treated with an "aggressive" strategy (coronary angiography performed within 24 hours of shock onset with revascularization by PTCA or CABG) had a significantly lower mortality rate (38% vs. 62%).[118] This benefit was present even after adjustment for baseline characteristics[118] and persisted to 1 year.[119]

The National Registry of Myocardial Infarction 2 (NRMI-2), which collected 26,280 patients with cardiogenic shock in the setting of MI between 1994 and 1997, similarly supported the association between revascularization and survival.[120] Improved short-term mortality rate was noted in those who underwent revascularization during the reference hospitalization by PTCA (12.8% vs. 43.9% mortality rate) or CABG (6.5%

vs. 23.9%).[120] These data complement the GUSTO-1 substudy data and are important, not only because of the sheer number of patients from whom these values are derived but also because NRMI-2 was a national cross-sectional study that more closely represents general clinical practice than carefully selected trial populations.

This extensive body of observational and registry studies showed consistent benefits from revascularization but could not be regarded as definitive due to their retrospective design. Two randomized controlled trials have evaluated revascularization for patients with MI.

The SHOCK study was a randomized, multicenter international trial that assigned patients with cardiogenic shock to receive optimal medical management, including IABP and thrombolytic therapy, or cardiac catheterization with revascularization using PTCA or CABG.[121,122] The trial enrolled 302 patients and was powered to detect a 20% absolute decrease in 30-day all-cause mortality rates. Mortality rates at 30 days were 46.7% in patients treated with early intervention and 56% in patients treated with initial medical stabilization, but this difference did not quite reach statistical significance ($p = 0.11$).[121] It is important to note that the control group (patients who received medical management) had a lower mortality rate than that reported in previous studies; this may reflect the aggressive use of thrombolytic therapy (64%) and IABP (86%) in these controls. These data provide indirect evidence that the combination of thrombolysis and IABP may produce the best outcomes when cardiac catheterization is not immediately available. At 6 months, the absolute risk reduction with early invasive therapy in the SHOCK trial was 13% (50.3% vs. 63.1%, $p = 0.027$),[121] and this risk reduction was maintained at 12 months (53.3% vs. 66.4% mortality rate, $p < 0.03$).[122] Subgroup analysis showed a substantial improvement in mortality rates in patients younger than 75 years at 30 days (41.4% vs. 56.8%, $p = 0.01$) and 6 months (44.9% vs. 65.0%, $p = 0.003$).[121]

The Swiss Multicenter Trial of Angioplasty for Shock (SMASH trial) was independently conceived and had a very similar design, although a more rigid definition of cardiogenic shock resulted in enrollment of sicker patients and a higher mortality rate.[123] The trial was terminated early due to difficulties in patient recruitment and enrolled only 55 patients. In the SMASH trial, a similar trend in 30-day absolute decrease in mortality rate similar to that in the SHOCK trial was observed (69% mortality rate in the invasive group vs. 78% in the medically managed group; relative risk, 0.88; 95% confidence interval, 0.6 to 1.2; p = NS).[123] This benefit was also maintained at 1 year.

When the results of the SHOCK and SMASH trials are put into perspective with results from other randomized, controlled trials of patients with acute MI, an important point emerges: despite the moderate decrease in *relative* risk (0.72 for the SHOCK trial, with a 95% confidence interval of 0.54 to 0.95; and 0.88 for the SMASH trial, with a 95% confidence interval of 0.60 to 1.20), the *absolute* benefit is important, with nine lives saved for 100 patients treated at 30 days in both trials, and 13.2 lives saved for 100 patients treated at 1 year in the SHOCK trial. This latter figure corresponds to a number needed to treat of 7.6, one of the lowest figures ever observed in a randomized, controlled trial of cardiovascular disease.

On the basis of these randomized trials, the presence of cardiogenic shock in the setting of acute MI is a class I indication for emergency revascularization by PCI or CABG.[45]

INDICATIONS FOR TEMPORARY PACING IN ACUTE MYOCARDIAL INFARCTION

Damage to the impulse formation and conduction system of the heart from MI can result in bradyarrhythmias and conduction disturbances that do not respond reliably to conventional pharmacologic agents such as atropine or isoproterenol. These disturbances may lead to further hemodynamic compromise and coronary hypoperfusion. Disturbances of conduction distal to the atrioventricular node and the bundle of His are particularly worrisome, even if they are tolerated well hemodynamically. Ventricular escape rhythms in the setting of acute MI are unstable and unreliable; their discharge rate may vary widely, with abrupt acceleration to ventricular tachycardia or deceleration to asystole. It is this characteristic of subsidiary ventricular pacemakers that guides the indication for prophylactic placement of temporary transvenous pacing in acute MI (see Chap. 24). Table 25-4 lists these indications, which are based on studies documenting the progression to high-grade atrioventricular block when the indicated conduction disturbances are present. Any bradyarrhythmia unresponsive to atropine that results in hemodynamic compromises requires pacing.

TABLE 25-4 Indications for Temporary Transvenous Pacing in Acute Myocardial Infarction[a]

Class I
Asystole
Complete heart block
Mobitz type II second-degree heart block
Bilateral BBB (alternating BBB or RBBB with alternating LAFB/LPHB)
New bifascicular block (RBBB with LAFB or LPHB or with LBBB) with first-degree AV block
Symptomatic bradycardia
Class IIa
New bifascicular block
RBBB with first-degree AV block
Incessant VT, for atrial or ventricular overdrive pacing
Recurrent sinus pauses (>3 s) not responsive to atropine
New LBBB[b]
Class IIb
Bifascicular block of indeterminate age
New isolated RBBB
Class III
First-degree AV block
Type I second-degree AV block
Accelerated idioventricular rhythm

[a] Class I, general agreement that treatment is effective; class IIa, weight of evidence favors efficacy; class IIb, efficacy less well established by evidence or opinion; class III, general agreement treatment is not useful and in some cases may be harmful.

[b] Controversial.

ABBREVIATIONS: AV, atrioventricular; BBB, bundle branch block; LAFB, left anterior fascicular block; LPFB, left posterior fascicular block; LBBB, left bundle branch block; RBBB, right bundle branch block; VT, ventricular tachycardia.

Chapter 26

ACUTE RIGHT HEART SYNDROMES

IVOR S. DOUGLAS
GREGORY A. SCHMIDT

KEY POINTS

- *Right heart syndromes (RHS) as a cause of shock are less common than left heart dysfunction, but recognizing them requires a high level of vigilance.*
- *Clues to recognizing RHS as a cause of shock include a history of a condition that is associated with pulmonary hypertension, elevated neck veins, peripheral edema greater than pulmonary edema, or a right-sided third heart sound, in addition to electrocardiographic, radiographic, and echocardiographic findings.*
- *Echocardiography is extremely valuable, not only for demonstrating the presence of RHS, but also for guiding hemodynamic management.*
- *Progressive right heart shock can be worsened by excessive fluid infusion, concomitant left ventricular failure, inappropriate application of extrinsic positive end-expiratory pressure (PEEP) and hypoxia.*
- *The drug of choice for resuscitation of patients with acute RHS is dobutamine, initially infused at 5 μg/kg per minute. Systemically-active vasoconstrictors may provide additional benefit.*
- *Prostacyclin and nitric oxide are often beneficial in improving pulmonary hemodynamics and oxygenation, but may not improve survival.*

In the majority of patients with shock due to "pump failure," assessment is focused appropriately on the left ventricle. However, in a substantial minority of patients, right heart dysfunction is the cause of shock. Examples include acute pulmonary embolism (PE), other causes of acute right heart pressure overload (e.g., acute respiratory distress syndrome [ARDS] treated with positive pressure ventilation), acute deterioration in patients with chronic pulmonary hypertension, and right ventricular infarction. Although right ventricular infarction differs from the other right heart syndromes (RHS) in that the pulmonary artery pressure is not high, in many other regards right ventricular infarction resembles the other syndromes, so we will consider them together. Failure to consider the right heart in the differential diagnosis of shock risks incomplete or inappropriate treatment of the shock. It would be hard to overemphasize the importance of echocardiography, both in aiding the recognition of the right heart syndromes and in guiding management. In this chapter we review the notable features that distinguish the right heart from the left, describe the themes that unify the acute RHS and allow their recognition, discuss the pathophysiology and differential diagnosis of RHS, and review their management.

Right Ventricular Physiology

The right ventricle (RV) has long been considered the "forgotten ventricle," because under normal pressure and volume loading conditions the RV is thought to function as a passive conduit for systemic venous return. When the pulmonary vasculature is normal, right ventricular performance has little impact on the maintenance of cardiac output. In animal models, complete ablation of the right ventricular free wall has little effect on venous pressures.

Despite the requirement for an equal, average cardiac output between the left and right ventricles, the bioenergetic requirement for RV ejection is approximately one fifth of the left ventricle (LV). This is in large part accounted for by the significant difference in downstream vascular resistance between the systemic and pulmonary circulations. In comparison with the LV, the RV ejects into a low-resistance circuit (normally only one tenth the resistance of the systemic arteries).

The pressure-volume relationship of the normal RV differs significantly from that of the LV. In contrast to the LV ejection, the RV ejects into the pulmonary outflow tract early during systole, continuing even after the maximal development of RV systolic pressure.[1] This exaggerated "hang out" period (ventricular outflow between the onset of right ventricular pressure decline and pulmonary valve closure) optimizes pump efficiency and results in a triangular pressure-volume relationship compared with the square wave pump of the LV.

Under conditions of increased RV impedance (e.g., pulmonary stenosis or pulmonary embolism) the RV pressure-volume relationship assumes a square wave appearance similar to that of the LV.[2] Unlike the LV, however, even modest acute increases in RV afterload may precipitate ventricular failure. This is not the case if volume and pressure loading develop more chronically. Significant contractile reserve is supported by RV myocyte hypertrophy and is regulated in part by increased expression of angiotensin II, insulin-like growth factor-I, and endothelin-1.[3] Ventricular hypertrophy is not uniform and is frequently associated with regional diastolic and systolic dysfunction.[4] Increased cardiac output is accommodated by recruitment of previously unperfused pulmonary vessels and by distention of vessels.

However, when pulmonary vascular resistance and pulmonary artery (PA) pressure rise, right ventricular systolic function deteriorates more readily than that of the left ventricle. Right ventricular ejection fraction falls as mean PA pressure rises and RV end-systolic and end-diastolic pressures rise. During acute PA hypertension, RV preload, afterload, and contractile state rise at the same time that heart rate rises. These features join to raise the RV myocardial oxygen consumption. At the same time, when an acute RHS is sufficiently severe to cause systemic hypotension, coronary perfusion of the RV may fall. The combination of rising oxygen demand and falling coronary oxygen supply subjects the RV to ischemia sufficient to reduce RV contractility and reduce systolic ejection against the increased PA pressure afterload (Fig. 26-1). The close anatomic approximation between the right and left ventricles confers a mechanical and functional interdependence in the face of right ventricular dysfunction.

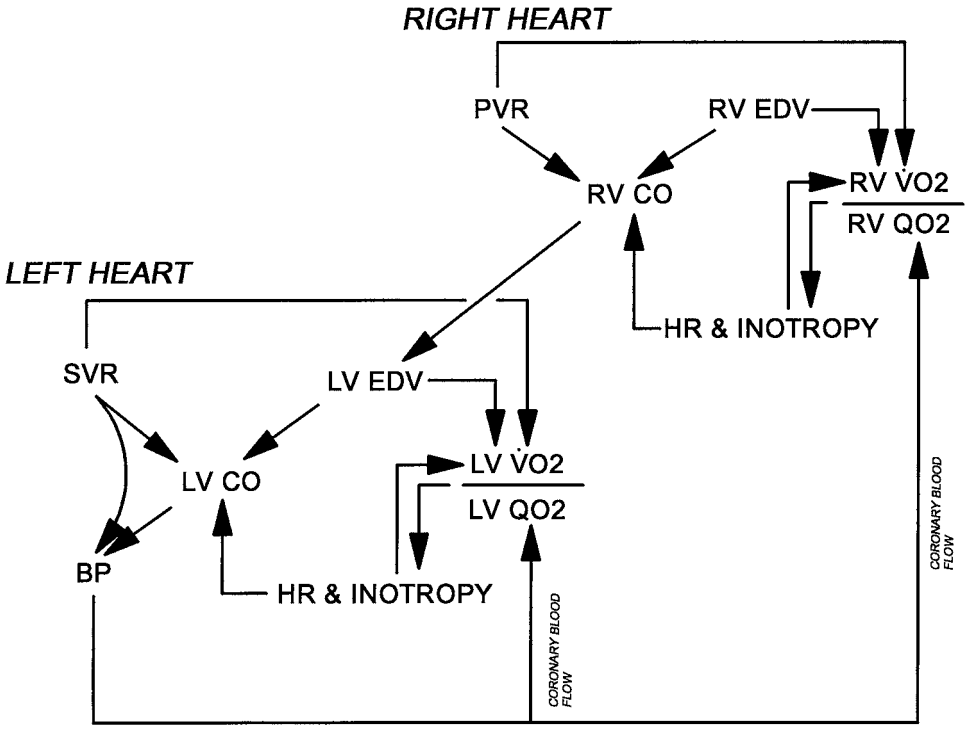

FIGURE 26-1 This figure illustrates the theory of right ventricular infarction in the right heart syndromes. A sudden rise in pulmonary artery pressure impedes right ventricular ejection. Right ventricular stroke volume falls, and end-diastolic and end-systolic volumes rise. Heart rate increases as the baroreceptors sense the fall in systemic blood pressure. These features of increased preload, afterload, and rate raise the right ventricular oxygen consumption. At the same time, the fall in aortic pressure lessens the driving gradient (roughly aortic pressure – right atrial pressure) for right coronary flow, reducing oxygen delivery to the right ventricle. If the rise in pulmonary artery pressure is sufficient, the right ventricle will fail. Vasoconstrictors have the potential to partially restore right ventricular function. Constriction of the systemic arteries raises left ventricular oxygen demands, but the normal left ventricle is operating with a margin of safety before the increased aortic pressure would be a problem. The higher aortic pressure drives more blood flow to the right ventricle without augmenting any of the components of right ventricular oxygen demand, thereby relieving ischemia and improving function.

Interdependence is influenced by (1) the cardiac fibroskeleton that limits acute annular distension, (2) the interventricular septum, and (3) the pericardium. As right heart pressures rise, the interventricular septum shifts progressively to the left, causing left ventricular diastolic dysfunction, further reducing systemic cardiac output and coronary perfusion pressure. Additionally, the pericardium restricts excessive acute ventricular distension while impairing diastolic filling of both the left and right heart. A vicious cycle ensues in which RV ischemia impairs right ventricular ejection, which leads to progressive dilation of the RV and septal displacement that causes more LV diastolic dysfunction, progressive systemic hypotension, and further impairment of RV perfusion.

This cycle has long been recognized in the acute inability of the RV to sustain a mean pulmonary artery pressure greater than about 40 mm Hg, based on studies of pulmonary hemodynamics in patients with acute PE without prior cardiopulmonary disease.[1,5]

There is significant evidence that RV ischemia underlies acute RV failure in settings of acute pulmonary hypertension. Indirect indications include the significantly increased load tolerance of the right ventricle when aortic pressure is raised,[6] and a beneficial hemodynamic response to infusion of norepinephrine.[7] These findings suggest, but do not establish, that greater coronary flow driven by the higher aortic pressure enhances RV function by relieving ischemia. More direct evidence comes from a biochemical analysis of the RV during PA constriction[8] (Table 26-1). In this experiment, constriction of the pulmonary artery led to both hemodynamic failure and to biochemical evidence of ischemia. Moreover, the infusion of a vasoconstrictor reversed the hemodynamic deterioration and reversed the biochemical evidence of ischemia. Additional support for the role of RV ischemia comes from the occasional patient with electrocardiographic evidence of RV infarction or elevated myocardium-derived enzymes (MB fractions of serum creatine phosphokinase and troponins). Significant troponin elevation may be an early and reliable marker of right ventricular dysfunction in acute pulmonary embolism, and has been shown to predict an adverse outcome.[9] Significant elevations of serum cardiac troponins T and I are thought to result from RV microinfarction.[10]

RECOGNIZING THE RIGHT HEART SYNDROMES: CLINICAL CLUES

In the hypoperfused patient, several clinical features should suggest the possibility of an acute right heart syndrome (Table 26-2). First, any history of pulmonary hypertension raises the possibility that the new shock state represents a (potentially minor) precipitant on top of preexisting right heart compromise (acute-on-chronic pulmonary hypertension; Table 26-3). When there is no antecedent history of pulmonary

TABLE 26-1 Right Ventricular Ischemia Due to Pulmonary Hypertension

Assay	Control	RV HTN	RV Failure	Phenylephrine
Creatine phosphate (mmol/g)	8.4	8.2	3.7	7.5
Lactate:pyruvate ratio	18	14	57	19

Simultaneous biopsies of the LV showed no change in creatine phosphate or lactate:pyruvate ratios at any stage of the experiment.
RV HTN, Right ventricular hypertension caused by pulmonary artery constriction; Phenylephrine, infusion at 1–3μg/kg per minute.

hypertension, elevated neck veins, a pulsatile liver, peripheral edema out of proportion to pulmonary edema, a right-sided third heart sound, or tricuspid regurgitation, these factors should alert the intensivist that she or he may be dealing with an RHS. The pulmonic component of the second heart sound may be loud, and the time interval between the aortic (A_2) and the pulmonary (P_2) components of the second heart sound (A_2-P_2 splitting) is increased in the presence of pulmonary hypertension. However, these findings are appreciable with a binaural stethoscope in only a minority of patients with acute pulmonary embolism,[11] and are probably too subjective to be useful. More sophisticated acoustic processing of digitally acquired heart sounds may provide an accurate estimation of pulmonary arterial pressures.[12]

Despite the insensitivity of individual clinical signs to detect and diagnose acute right heart syndromes, a combination of clinical features (symptoms of deep venous thrombosis [DVT]; an alternative diagnosis is less likely than PE; heart rate >100 bpm; immobilization or surgery in the previous 4 weeks; previous DVT or PE; hemoptysis; and cancer, being treated currently or within the previous 6 months) and laboratory results, especially serum D-dimer level, can be useful in excluding pulmonary embolism as a likely cause.[13]

Electrocardiographic (ECG) evidence of pulmonary hypertension includes right axis deviation or a rightward shift in axis, right atrial enlargement, right ventricular hypertrophy, right bundle-branch block (RBBB), right precordial T-wave inversions, and the $S_1Q_3T_3$ pattern. In the Prospective Investigation of Pulmonary Embolism Diagnosis (PIOPED) trial, fewer than 1 patient in 17 with proven pulmonary embolism had any of the patterns of acute right heart strain.[11] By contrast, the experience at a single Italian center of 160 cases of proven PE resulted in a higher rate of electrocardiographic abnormalities. Of all patients, 76% had at least one abnormality; RBBB in 47%, $S_1Q_3T_3$ in 37%, T-wave inversion in 32%, and an inferior distribution "pseudonecrosis pattern" in 11%.[14] This variation in detection between studies suggests relative insensitivity in the performance characteristics of the 12-lead ECG in broad groups of mixed severity right heart syndrome patients. However, in patients with hemodynamically significant pulmonary embolism, the likelihood of suggestive electrocardiographic findings is probably much higher. For example, among 49 patients with PE (all of whom had RV dilation and tricuspid regurgitation by echocardiography), 37 (76%) had electrocardiographic abnormalities strongly suggestive of PE, including at least three of the following: incomplete or complete RBBB; S waves greater than 1.5 mm in leads I and aVL; shift of the precordial transition zone to V_5; Q waves in leads III and aVF, but not lead II; right axis deviation or an indeterminate axis; low QRS voltage in the limb leads; or T-wave inversion in leads III and aVR or in leads V_1 to V_4.[15] The electrocardiographic signs of right ventricular infarction are described below in the section on right ventricular infarction.

TABLE 26-3 Causes of the Acute Right Heart Syndrome

Acute pressure overload
Pulmonary embolism
ARDS
Excessive PEEP, tidal volume, and alveolar pressure
Air, amniotic, fat, or tumor microembolism
Sepsis (rarely)
Pulmonary leukostasis, leukoagglutination
Extensive lung resection
Drugs (e.g., heparin-protamine reaction)
Hypoxia
Acute-on-chronic PA hypertension
Chronic lung diseases
Emphysema, chronic bronchitis, bronchiectasis, cystic fibrosis
Restrictive diseases of the lung
Collagen vascular diseases of the lung
Thoracic cage deformities
Kyphoscoliosis, thoracoplasty
Cardiovascular disorders
Chronic thromboembolism
Primary pulmonary hypertension
Congenital heart diseases
Pulmonary venoocclusive disease
Miscellaneous disorders
Sleep disordered breathing
Hyperviscosity syndromes
Toxins and drugs
Parasites
End-stage liver disease
HIV infection
Right ventricular systolic dysfunction
RV infarction
Sepsis
Toxins

ABBREVIATIONS: ARDS, acute respiratory distress syndrome; HIV, human immunodeficiency virus; PA, pulmonary artery; PEEP, positive end-expiratory pressure; RV, right ventricular.

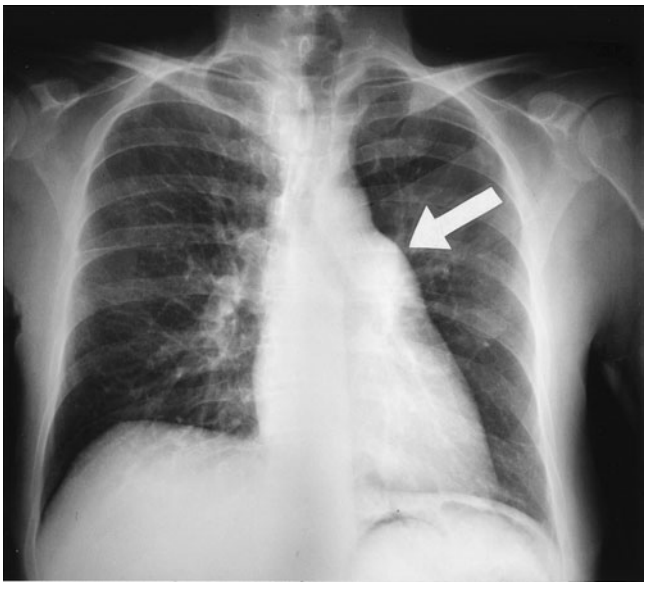

FIGURE 26-2 Chest radiograph demonstrating significant enlargement of the main pulmonary artery (*arrow*) in a young woman with chronic pulmonary hypertension due to recurrent pulmonary emboli.

Radiographic signs include an enlarged pulmonary artery or right ventricle, oligemia of a lobe or lung (Westermark's sign), and a distended azygos (or other central) vein (Figs. 26-2 and 26-3). Contrast-enhanced computed tomography of the pulmonary vasculature (helical CT angiography) has evolved as a central diagnostic tool in the evaluation of acute right heart syndromes, particularly pulmonary thromboembolism, as discussed in Chap. 27.[16–19] The sensitivities range from 53% to 89%, and specificities from 78% to 100% for single-slice helical CT diagnosis of acute PE.[20] Newer multi-row detector scanners should increase sensitivity to more than 90%.[21] In addition to detecting the presence of a pulmonary vascular clot, CT is able to detect RV dilatation and septal shift. In a small series of patients with acute PE, CT sensitivity was 78% for detecting RV dysfunction when compared with transthoracic echocardiography (TTE).[22]

Furthermore, TTE can be used to quantify pulmonary artery pressures and assess right ventricular function, thereby allowing for rapid initiation of appropriate therapeutic interventions. Echocardiography may also provide indirect evidence of pulmonary embolism by demonstrating a specific pattern of right ventricular dysfunction characterized by free-wall hypokinesis with apical sparing, a finding possibly useful in differentiating pulmonary embolism from other causes of right ventricular dysfunction.[23–25] Finally, echocardiography can be used to visualize massive pulmonary embolism directly in many patients.[26] Therefore we believe that echocardiography is a practical and readily available diagnostic tool that should be considered in the evaluation of patients with suspected pulmonary embolism.

The typical echocardiographic findings include a normally contracting left ventricle, often with end-systolic obliteration of the LV cavity; a thin-walled, dilated, poorly contracting RV; right atrial enlargement; tricuspid insufficiency with a high-velocity regurgitant jet; increased estimated PA pressures; leftward shift of the interventricular septum causing the typical "D" shape of the LV on the short-axis view (Fig. 26-4); right PA dilation; or loss of respirophasic variation in the inferior vena cava.[27] RV infarction can usually be readily distinguished from acute pulmonary hypertension in that high PA pressures are lacking. Right ventricular diastolic dimensions can be obtained by measuring right ventricular end-diastolic area in the long axis, from an apical four-chamber view, or by a transesophageal approach in the volume-repleted patient.[28]

FIGURE 26-3 Chest radiograph showing a huge azygos vein (*arrow*) in an elderly man with shock due to acute massive pulmonary embolism. The normal vein measures less than 10 mm in transverse diameter, whereas this patient's azygos vein measures more than 22 mm. This film also demonstrates Westermark's sign (oligemia, here of all lung fields).

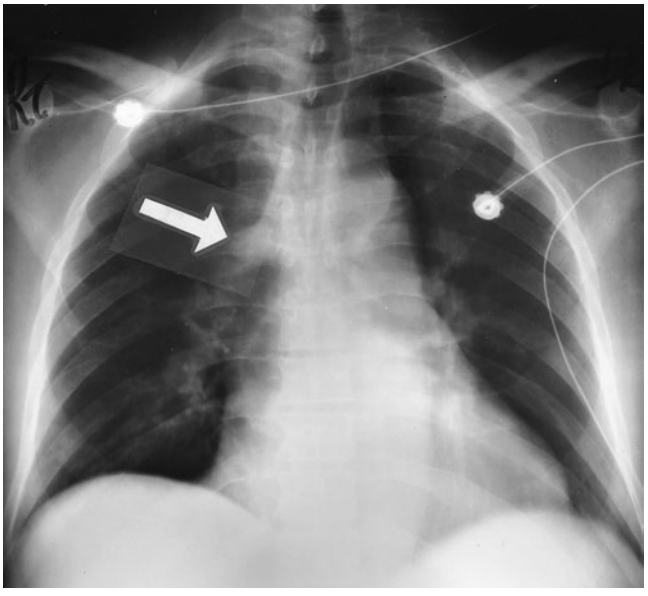

FIGURE 26-4 Echocardiographic short-axis view showing the obvious shift of the interventricular septum toward the left ventricle, changing the shape of the left ventricle from its normal circular cross-section to a "D" shape.

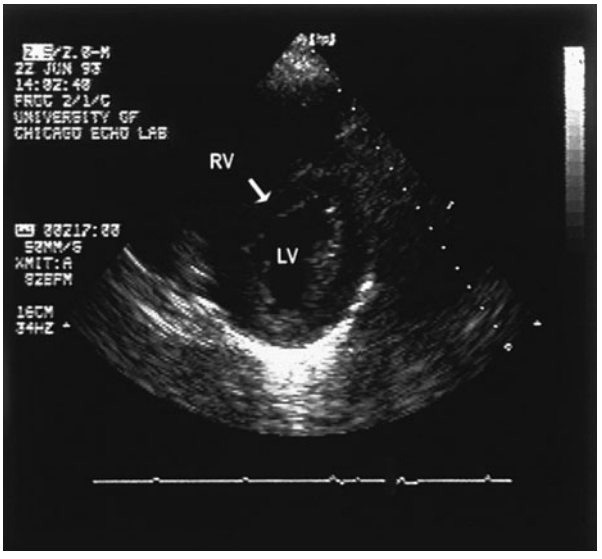

TABLE 26-4 Features of Right Heart Syndromes

Diagnosis not readily apparent: A high index of suspicion aids recognition
Routine therapy for congestive heart failure may be detrimental
Fluid loading may lower cardiac output
Vasodilators may cause abrupt deterioration
Vasoconstrictors may have a role in some patients
Echocardiography is extremely valuable

Echocardiography is of great utility in the detection of RHS and should be obtained early in the hypoperfused patient whenever one of the previously mentioned clinical indicators is present.[24] Of course, most of these signs are not specific for RHS, but their recognition is important because the treatment of RHS is unique in several regards (Table 26-4). TTE is particularly useful in differentiating at the bedside right ventricular pressure overload from myocardial infarction, aortic dissection, or pericardial tamponade, all of which may be clinically indistinguishable from PE.[29] Identification of a patent foramen ovale and free-floating right-heart thrombus are echocardiographic markers of particularly grave prognosis, including recurrent PE and death.[26,29,30]

Pulmonary artery catheterization can estimate pulmonary arterial pressures more accurately than echocardiography. However, interpretation of mean pulmonary pressures and measurement of tricuspid regurgitation by thermodilution are confounded by technical limitations. A pulmonary artery catheter (PAC) with a fast-response thermistor has been advocated for accurate measurement of right ventricular volume and hemodynamic parameters by thermodilution in the presence of tricuspid regurgitation. However, as is the case for PAC use in the management of ARDS and left heart shock, the fast-response thermistor PAC has not been demonstrated to confer an improvement in survival.

Severity of RV systolic failure is an independent determinant of serum levels of brain natriuretic peptide (BNP) in patients with severe heart failure.[31] Furthermore, BNP elevations have been demonstrated to predict RV dysfunction in patients with acute PE. In one study, the relative risk ratio for RV dysfunction was 28.4 (95% CI, 3.22 to 251.12) if the serum BNP >90 pg/mL.[32] A lower cut-off of 50 pg/mL might improve the specificity of BNP as a predictor of favorable outcome, but it remains unclear whether measurement of BNP has any role in these patients.[10,33]

Specific Right Heart Syndromes

ACUTE PULMONARY HYPERTENSION

Acute pulmonary hypertension is caused by an abrupt increase in pulmonary vascular resistance due to vascular obstruction or surgical resection. The prototype of acute pulmonary hypertension is acute pulmonary embolism (PE; see Chap. 27), but other forms of embolism (e.g., air or fat), microvascular injury (e.g., ARDS), drug effect, and inflammation can acutely raise pulmonary vascular resistance (see Table 26-3). For example, Zapol and Snider described the pulmonary hemodynamics in 30 patients with severe ARDS (20% survival; 8 had received extracorporeal membrane oxygenation).[34] Following correction of hypoxemia, the mean pulmonary artery pressure was about 30 mm Hg and was abnormally elevated in all patients. Similar levels of pulmonary artery pressure were seen in a group of postsurgical patients with ARDS who were treated with nitric oxide (NO).[35] Mean pulmonary artery pressure fell from 33 $\pm$ 2 mm Hg to 28 $\pm$ 1 mm Hg when NO was inhaled at 18 ppm. Contributors to PA hypertension in ARDS include hypoxic pulmonary vasoconstriction, mediator release, high alveolar pressure during mechanical ventilation, and microthrombi.

The frequency of significant pulmonary hypertension in ARDS has not been clearly defined. In the patients studied by Zapol and Snider, right heart dysfunction was clinically significant, even when the change in PA pressures and pulmonary vascular resistance was small.[34] The large prospective European ARDS Collaborative Study evaluated pulmonary hemodynamic variables in 424 of 586 ARDS patients.[36] In most patients, PA pressure was modestly elevated on admission (26.1 $\pm$ 8.5 mm Hg) and was persistently elevated at 48 hours in nonsurvivors compared with survivors (28.4 $\pm$ 8.5 mm Hg versus 24.1 $\pm$ 6.7 mm Hg). The ratio of RV to LV stroke work was also significantly elevated in all patients, and along with the ratio of partial oxygen pressure to the fraction of inspired oxygen (OR 0.96 to 0.98), was identified as an independent predictor of survival (OR 20 to 85; $p = 0.0001$).

These findings would suggest an aggressive approach to lowering RV afterload in patients with ARDS by reducing alveolar pressures and administering inhaled nitric oxide or prostacyclin. However, despite reproducible reductions in PA pressure and improvements in oxygenation indices, randomized controlled studies using this approach have repeatedly failed to demonstrate a survival benefit, as discussed below.

Sepsis itself is probably capable of causing pulmonary hypertension, even in the absence of acute lung injury, based on animal models[37] and limited human studies.[38,39] Although common in patients with severe sepsis, it is our experience that acute pulmonary hypertension is only of clinical importance when ARDS (or another clear precipitant) is present. It seems likely that the systemic hypotension of septic shock makes the RV more vulnerable to ischemic systolic dysfunction when combined with modest increases in afterload.[40] It has been argued that this right ventricular perfusion gradient accounts for the differentially impaired perfusion and contractility of the RV compared with the LV in sepsis.[39] The sepsis-associated proinflammatory cytokines tumor necrosis factor-α and interleukin-1β have been demonstrated to have negative inotropic effects on the ventricular myocardium.

A notable insight into the complex role of endogenous nitric oxide in regulating pulmonary vascular tone in septic shock patients was derived from a randomized, placebo-controlled, double-blind study of the nitric oxide synthase inhibitor 546C88.[41] Patients who were randomized to the treatment arm had a 10% absolute higher mortality rate at 28 days than patients in the placebo arm. 546C88-treated patients had a greater incidence of pulmonary hypertension, with an initial increase in the pulmonary vascular resistance and a sustained reduction in the pulmonary venous admixture, possibly through augmented hypoxic pulmonary vasoconstriction. Three patients in the treatment arm developed right heart failure. It has been suggested that sepsis-associated NO production may have a partially protective effect on the pulmonary vasculature by optimizing pulmonary ventilation-perfusion relationships.

Acute pulmonary hypertension in sickle chest syndrome results from pulmonary microvascular in-situ thrombosis, pulmonary fat embolism from infarcted long bone marrow, and hypoxic vasoconstriction. Recurrent episodes result in secondary chronic pulmonary hypertension and cor pulmonale. Inhaled NO, in addition to supplemental oxygen, blood transfusions, and bronchodilators, may provide some additional benefit for generalized vasoocclusive crises,[42] but has not been systematically studied for sickle-associated pulmonary hypertension.[43]

Acute right heart failure following cardiac surgery, especially in patients operated on for severe mitral valve disease, some congenital cardiac defects, acute pulmonary embolism, or following heart transplantation or institution of left ventricular mechanical assistance, continues to vex cardiac surgeons and surgical intensivists. The mechanisms underlying this are multifactorial[44] and include cardiopulmonary bypass–induced activation of pulmonary inflammatory pathways,[45] and impairment of nitric oxide production by pulmonary endothelial cells. A favorable response to inhaled NO has been demonstrated when used postoperatively[46,47] or perioperatively.[48] More recently, inhaled prostacyclin has been shown to improve PA hypertension and RV dysfunction.[49]

In about 1.5% of CPB patients, reversal of heparin anticoagulation with protamine is accompanied by transient, at times intense, pulmonary vasoconstriction.[50] This phenomenon is thought to result from thromboxane B_2 generation.[50] Effective prophylaxis for this syndrome has not yet been reported. Inhibition of poly(ADP-ribose) polymerase, a terminal effector of oxidative stress injury, may offer future therapeutic opportunities for this syndrome.[51]

ACUTE-ON-CHRONIC PULMONARY HYPERTENSION

Many patients with acute RHS have preexisting pulmonary vascular disease, at times with clinically recognized pulmonary hypertension, but often without (see Table 26-3). In such patients, intercurrent critical illness may unmask pulmonary vascular disease when a higher-than-normal cardiac output is needed. For example, in 12 men with moderate to severe but stable chronic obstructive pulmonary disease (COPD), mean PA pressure was normal at rest (17 ± 6 mm Hg), and the systolic PA pressure ranged from 21 to 27 mm Hg.[52] During exercise (25 to 50 Watts), mean PA pressure rose significantly to 31 ± 11 mm Hg and systolic PA pressure to 20 to 55 mm Hg. At the same time, right ventricular end-diastolic volume increased, and right ventricular ejection fraction failed to rise.

When pulmonary hypertension is diagnosed during the course of critical illness, the potential for underlying chronic pulmonary vascular disease should be considered, especially when the history suggests chronic disease, the mean PA pressure is higher than 40 mm Hg, or echocardiography shows evidence of RV hypertrophy.

RIGHT VENTRICULAR INFARCTION

Right ventricular infarction is a well-recognized and fatal feature of inferior myocardial infarction.[53,54] It is also seen in anterior infarcts. Meta-analysis of six studies involving 1198 patients with RV myocardial involvement suggested an increased probability of death (OR 3.2; 95% CI 2.4 to 4.1) compared with non RV MI.[55] In most cases RV free wall infarction or ischemia is accompanied by varying degrees of septal and posteroinferior left ventricular injury, but relatively isolated RV injury is occasionally seen. RV myocardial injury and dysfunction representing noninfarcted hibernating myocardium may be able to sustain long periods of low coronary oxygen delivery and ultimately recover substantial contractile function.[56]

RV dilation accompanies significant myocardial injury. Concomitant LV infarction involving the interventricular septum may lead to further hemodynamic deterioration in patients with RV infarction because of the loss of LV septal contraction which can assist RV ejection. Elevation of right atrial pressure on physical examination or direct measurement in a patient with an inferior myocardial infarction and clear lungs by exam and chest x-ray should lead to suspicion of RV infarction. When these features occur in a critically ill patient, the essential distinction is between RHS resulting from acute PA hypertension and RHS resulting from RV infarction. Confirmatory evidence includes a right precordial electrocardiogram or echocardiographic evidence of RV injury (see Chap. 25). The focus of management in RV infarction is on maintenance of optimal RV preloading to avoid worsened RV distension, preservation of RV synchrony, reduction in RV afterload (particularly when LV dysfunction is present), and inotropic and mechanical support of the RV.[57]

Early reperfusion with fibrinolytics or direct coronary intervention may have a role in many patients. Echocardiography can be highly useful in confirming RV infarction and in determining the response to therapeutic interventions.

Treatment

Some patients with acute RHS may benefit from specific therapies, such as thrombolysis for acute pulmonary embolism (see Chap. 27). In most patients, however, the two basic aims of treatment are supportive: to reduce systemic oxygen demand while improving oxygen delivery (Table 26-5). Oxygen demand can be lowered by treating fever, sedating the patient, instituting mechanical ventilation, and in severe cases, using therapeutic muscle relaxation. Oxygen delivery can be enhanced by correcting hypovolemia, transfusing red blood cells, relieving alveolar hypoxia, infusing vasoactive drugs, and avoiding detrimental ventilator settings. The goals of oxygen therapy in RHS are to enhance arterial saturation (Sa_{O_2}) and to block alveolar hypoxic vasoconstriction (AHV). Using a sufficient oxygen concentration to achieve 88% Sa_{O_2} is advocated in ARDS and other alveolar flooding diseases (see Chap. 38), but in RHS not associated with intrapulmonary

TABLE 26-5 Goals of Therapy in the Right Heart Syndromes

Correct hypoxemia
Find optimal volume
Exclude or treat concomitant left ventricular dysfunction
Minimize volume of oxygen utilization
Reduce intrinsic positive end-expiratory pressure and other causes of elevated alveolar pressure
Dobutamine, begin at 5μg/kg per minute
Norepinephrine, begin at 0.4μg/kg per minute
Nitric oxide, begin at 18 ppm

shunt, we target Sa_{O_2} to >96% to ensure alveolar oxygen values sufficient to block AHV (PA_{O_2} >55 mm Hg). It may be useful to correct anemia with red blood cell transfusion, raising the arterial oxygen content, and reducing the necessary cardiac output. The resulting increased blood viscosity (and its tendency to raise pulmonary vascular resistance) probably does not outweigh the reduced demand for forward flow.

Fluid therapy, ventilator management, and vasoactive drug infusion are discussed below and have been the subject of a recent review.[58]

FLUID THERAPY

In most patients with shock it is appropriate to administer fluid, often in massive quantities, to restore left ventricular diastolic filling and boost cardiac output. Despite the recognition that the right heart becomes extremely preload dependent during ischemia and infarction,[56] excessive fluid administration is likely to worsen hemodynamic stability. In many of these patients the right-sided pressures are already well above normal, signaled by neck vein distention. Data from animal models of pulmonary embolism, as well as from studies of patients with right ventricular infarction, demonstrate that fluid therapy may be unhelpful or even detrimental.

In a canine autologous clot model of pulmonary embolism, the effects of fluid loading were studied before embolism, then following embolism.[59] Before embolism, fluid loading significantly raised the right atrial pressure, the transmural left ventricular end-diastolic pressure (LVEDP), and the left ventricular end-diastolic area index (a measure of left ventricular volume using sonomicrometry). Following multiple emboli, fluid loading raised right atrial pressure, but transmural LVEDP fell significantly as did the left ventricular end-diastolic area index. These findings indicate that fluid loading following embolism causes further leftward displacement of the interventricular septum, further compounding LV diastolic dysfunction. In a canine glass bead embolization model, fluid loading was found to precipitate right ventricular failure, even when relatively small volumes were infused.[60]

Similar results have been shown in human right ventricular infarction.[61,62] Despite raising the right atrial and wedge pressures, fluid loading failed to increase the cardiac index, blood pressure, or left and right ventricular stroke work. These findings should serve as a caution regarding fluid administration to patients with shock due to acute RHS. Since some patients may be volume depleted at presentation, a fluid challenge is reasonable, especially if the neck veins are flat or right heart filling pressures are low. Nevertheless, fluid should be given with a healthy degree of skepticism and careful attention to the consequences. We recommend that a discrete crystalloid fluid bolus of no more than 250 mL be administered while assessing relevant indicators of perfusion such as blood pressure, heart rate, pulsus paradoxus, cardiac output, central venous oxyhemoglobin saturation, or urine output. If no benefit can be detected, further fluids should not be given, and attention should shift to vasoactive drugs.

VASOACTIVE DRUG THERAPY

A wide variety of vasoactive drugs has been tried in patients or animal models for the treatment of acute RHS due to pulmonary embolism, ARDS, or right ventricular infarction, with variable success. These include nonspecific vasodilators (hydralazine[63] and nitroprusside[61,64,65]), vasoconstrictors (norepinephrine,[7,60,66] epinephrine,[67] phenylephrine,[8,68] dopamine,[69] and vasopressin[70,71]), inotropes (dobutamine,[61,62,72–74] amrinone,[75] milrinone,[76] isoproterenol,[7] epinephrine,[67] and levosimendan[77]), and pulmonary vasodilators (prostaglandin E_1,[78,79] prostaglandin I_2,[35] and nitric oxide[35,65,70,80–86]). Predicting the response to any of these drugs a priori is complicated by their tendency toward opposing effects. Conflicting data from studies of an agent in different animal models suggest that the interspecies variation and prevailing pulmonary vascular tone are important in determining if a particular agent has a predominantly pulmonary vasodilatory or vasoconstricting effect.[73,74] Thus the choice of vasoactive drugs cannot be based solely on the presumed pathophysiology, but also must be based on the results of human and animal studies summarized below. We contend that a vasoactive drug is effective in RHS when it significantly raises cardiac output without significantly worsening systemic hypotension, Sa_{O_2}, or RV ischemia. Dobutamine is our preferred positive inotrope, inhaled NO (and perhaps aerosolized prostacyclin) have salutary short-term physiologic effects as pulmonary vasodilators, and norepinephrine may provide added benefit as a systemic vasoconstrictor and positive inotrope by raising coronary perfusion pressure to an ischemic RV.

CATECHOLAMINES

In massive pulmonary embolism, dobutamine and norepinephrine appear superior to other vasoactive drugs.[7,72] In human PE, dobutamine has been most intensively studied. For example, of 10 patients with shock due to massive PE treated with dobutamine, 1 rapidly died, but 9 showed impressive hemodynamic improvement (Table 26-6). These results show that dobutamine improves cardiac output by improving right ventricular function or reducing pulmonary vascular resistance. Although fewer data are available regarding norepinephrine in human embolism, animal studies and limited human data support its use.[7,66,72] In a canine model of pulmonary embolism, dobutamine and dopamine had essentially identical hemodynamic effects.[69] Data from a separate canine study suggest that at doses less than 10 μg/kg per minute, dobutamine-induced pulmonary circulatory changes are exclusively flow dependent.[74] At higher doses, changes in pulmonary vascular resistance are variable and may depend on the prevailing pulmonary vascular tone. These drugs

TABLE 26-6 Dobutamine for Shock Due to Massive Pulmonary Embolism in 10 Patients

	Preinfusion	Dobutamine
Pao (mm Hg)	81	86
Ppa (mm Hg)	32	31
Pra (mm Hg)	13	11
Ppw (mm Hg)	12	11
CI (L/min per m^2)	1.7	2.3
HR (beats/min)	108	86
$P\bar{v}_{O_2}$ (torr)	24	29

[a] Mean dobutamine dose 8.3 μg/kg per minute; values after 30 minutes.
CI, cardiac index; HR, heart rate; Pao, mean aortic pressure; Ppa, mean pulmonary artery pressure; Ppw, pulmonary artery wedge pressure; Pra, right atrial pressure; $P\bar{v}_{O_2}$, mixed venous oxygen pressure.
SOURCE: Data taken from Jardin et al.[72]

should be titrated according to clinical measures of the adequacy of perfusion, such as renal function, mentation, thermodilution cardiac output, or central venous oxyhemoglobin saturation, rather than to blood pressure alone. We begin dobutamine at 5 μg/kg per minute, raising the dose in increments of 5 μg/kg per minute every 10 minutes. If the patient fails to respond to dobutamine (or the response is incomplete), we substitute (or add) norepinephrine infused at 0.4 to 4 μg/kg per minute. In patients with hypoperfusion due to right ventricular infarction, dobutamine is superior to nitroprusside[61] (and to fluid infusion[61,62]), significantly improving right ventricular ejection fraction and cardiac output. Therefore dobutamine is the drug of first choice in all cases of RHS. We avoid the use of dopamine because of its highly variable pharmacokinetics and concern for disproportionate splanchnic vasoconstriction, even in relatively low doses.

VASOPRESSIN

The role of vasopressin (and its longer acting congener, terlipressin) remains controversial and incompletely evaluated. Vasopressin clearly functions as a systemic vasoconstrictor at high doses. In patients with septic shock, replacement of acutely depleted endogenous vasopressin with a low-dose infusion (0.04 U/min) is thought to improve catecholamine sensitivity via the functionally vasoconstricting V_1 receptor. The pulmonary vasculature has been shown by some investigators to express V_1 receptors, but that vasopressinergic stimuli may paradoxically mediate pulmonary vasodilation.[87,88] This might suggest a salutary potential for vasopressin therapy in acute right heart syndromes. In a canine model, however, vasopressin caused both systemic and pulmonary vasoconstriction while impairing RV contractility.[71] Our present practice is to avoid vasopressin for acute right heart syndromes unless catecholamine-dependent septic shock is present.

PROSTAGLANDINS

Prostaglandin E_1 (PGE_1) is a potent pulmonary vasodilator that exhibited promise in the treatment of ARDS. When infused at a dose of 0.02 to 0.04 μg/kg per minute to patients with severe ARDS and mean PA pressure greater than 20 mm Hg, PA pressure fell 15% despite an increase in cardiac output. At the same time, however, systemic blood pressure fell to a similar degree, and intrapulmonary shunting rose significantly.[78] In an oleic acid model of porcine ARDS, PGE_1 lowered pulmonary artery pressure, but stroke volume and stroke work did not improve significantly.[79] In patients with ARDS given prostacyclin (4 ng/kg per minute), pulmonary artery pressure fell, RV ejection fraction rose, and cardiac output increased significantly.[35] A small series of patients with chronic pulmonary hypertension have been given aerosolized prostacyclin, and they demonstrated pulmonary vasodilation, increased cardiac output, and improved arterial oxyhemoglobin saturation.[89] Systemic blood pressure fell somewhat, but to a much lesser degree than when prostacyclin was infused intravenously (for similar degrees of pulmonary vascular effect). When compared for acute hemodynamic effects in patients with primary pulmonary hypertension (PPH), aerosolized prostacyclin (approximately 14 ng/kg per minute over 15 minutes) was demonstrated to be a pharmacologically more potent acute vasodilator than inhaled NO (NO 40 ppm for 15 minutes).[90]

In a similar comparison in ARDS patients, gas exchange parameters were comparably improved when inhaled prostacyclin (7.5 $\pm$ 2.5 ng/kg per minute) was compared with inhaled NO at a dose lower than that in the PPH study (17.8 $\pm$ 2.7 ppm).[91] This may suggest that in patients with right heart syndromes and long-standing pulmonary hypertension, inhaled prostacyclin may afford greater efficacy.

Although not conclusively demonstrated, inhaled prostacyclin has been used with some success in perioperative acute RHS.

ADENOSINE

Adenosine is an endogenous vasodilator that has a very short half-life (less than 10 seconds) due to rapid metabolism by adenosine deaminase. When used following cardiac surgery, adenosine lowered pulmonary artery pressure, raised cardiac output, and did not cause hypotension.[46,92] Adenosine was infused centrally at a dose of 50 μg/kg per minute.

PHOSPHODIESTERASE INHIBITORS: AMRINONE, MILRINONE, DIPYRIDAMOLE, AND SILDENAFIL

Amrinone is an inotrope and vasodilator with potential in the acute right heart syndromes. In a canine model of massive embolism, amrinone (0.75 mg/kg bolus followed by 7.5 μg/kg per minute) lowered pulmonary artery pressure, raised cardiac output, and raised systemic blood pressure.[75] Limited data are available for the use of milrinone in acute RHS and its use is limited by a long half-life and limited ability of titration.[76] Additionally, milrinone has been shown to be less efficacious than inhaled NO in treating pulmonary hypertension post–cardiac surgery.[82] Another phosphodiesterase inhibitor, dipyridamole, has been evaluated as an adjunct to NO in pediatric patients with acute RHF, and shown to have some additional pulmonary vasodilatory effects.[93,94]

Significant interest has arisen in the therapeutic potential of the selective type 5 PDE inhibitor sildenafil, presently approved for male erectile dysfunction. Impressive acute reductions in pulmonary arterial pressures have been demonstrated with oral and intravenous administration in animal models of acute lung injury[95] and RHS, in patients with established pulmonary hypertension,[96] and in 93 patients with pulmonary hypertension complicating pulmonary fibrosis.[97] Additionally, synergistic effects of selective PDE inhibitors in combination with inhaled and intravenous vasodilators has been demonstrated in acute lung injury–associated right heart syndromes.[98–100]

NITRIC OXIDE

Nitric oxide brings together the potential for hemodynamic as well as gas exchange improvement. When patients with ARDS and pulmonary hypertension were given NO via endotracheal inhalation at a dose of 18 ppm, PA pressure fell, right ventricular ejection fraction rose, and RV end-systolic and end-diastolic volumes fell.[35] There was no detectable change in mean arterial pressure, and arterial oxygen pressure rose significantly. Increasing the dose of NO to 36 ppm had no incremental effect. These findings have been confirmed in similar patients with ARDS who were managed with permissive hypercapnia (mean arterial carbon dioxide pressure = 71 mm Hg) and given a lower dose of NO (5 ppm), although the effect was more modest.[80] Disappointingly, survival has not been

improved in four large randomized controlled studies of NO in ARDS patients.[83–86]

ANTIPROLIFERATIVE AGENTS

Both prostacyclin and the newer nonselective endothelin receptor antagonists (ETRA) have been demonstrated to have antiproliferative activity on the pulmonary vasculature. This mechanism has been suggested to account for the modest functional improvement in patients with chronic pulmonary hypertension.[101,102] Although single case reports suggest beneficial effects of the orally administered nonselective ETRA bosentan, this agent has not been subjected to rigorous evaluation in patients with acute right heart syndromes, and it may have limited potential in critically ill patients because of significant associated hepatic toxicity.

VENTILATOR MANAGEMENT

Ventilator manipulation has the potential to dramatically affect the circulation in patients with shock, including those with acute RHS. For example, in animal models of shock, institution of mechanical ventilation significantly prolongs survival, an effect much greater than that seen with fluid therapy or vasoactive drugs. Of particular interest in patients with RHS is the maintenance of oxygenation, the role of hypercapnia (including permissive hypercapnia), and the effects of tidal volume and positive end-expiratory pressure (PEEP).

Hypercapnia increases pulmonary artery pressure. In patients with ARDS, reducing minute ventilation as part of the strategy of permissive hypercapnia leads to small but real increases in mean pulmonary artery pressure.[103–105] In most patients with ARDS who do not exhibit right heart limitation, this effect of hypercapnia is probably unimportant. However, in the subset of patients with severe pulmonary hypertension, permissive hypercapnia may lead to unacceptable hemodynamic deterioration.

The effect of PEEP on right ventricular function is complex, controversial, and highly variable from patient to patient.[106,107] Many studies are limited by the failure to correlate hemodynamic pressures to juxtacardiac pressure. The effect of PEEP can be expected to differ depending on whether atelectatic or flooded lung is recruited, or whether relatively normal lung is overdistended. In a study of patients with ARDS, PEEP had little effect on RV function when given in amounts up to that associated with improving respiratory system compliance.[106] At higher levels of PEEP, the dominant effect was to impair RV systolic function.

The dominant effect of mechanical ventilation is related to its effect on preload. Sustained airway pressure increases in volume-repleted patients with normal RV function result in a mild increase in right atrial pressure that is offset by increases in abdominal pressures that sustain venous return. However, it remains to be determined if this is true for patients with acute RHS and elevated right heart pressures.[108] Large-tidal-volume breathing impairs RV systolic function, presumably by increasing pulmonary vascular resistance in alveolar vessels. In a canine model with normal lungs, raising the tidal volume above 10 mL/kg caused a detectable rightward and downward shift of the RV function curve.[109]

These effects of mechanical ventilation on right ventricular function suggest the following strategy in patients with critical compromise of the RV: (1) give sufficient oxygen to reverse any hypoxic vasoconstriction; (2) avoid hypercapnia; (3) keep PEEP at or below a level at which continued alveolar recruitment can be demonstrated and seek to minimize self-controlled PEEP (Auto-PEEP); and (4) use the lowest tidal volume necessary to effect adequate elimination of carbon dioxide. Of course, the acute effects of each intervention should be measured to confirm that cardiac output increases. These principles are consonant with the goals of ventilation in most patients with ARDS, except that when there is an RHS, hypercapnia should be avoided if it leads to further hemodynamic deterioration.

MECHANICAL THERAPY

In contrast to the now well-defined role for mechanical assist devices in decompensated left heart failure,[110] there remains relatively little experience with mechanical therapy for the failing right heart. Notably, progressive right ventricular dysfunction complicates left ventricular assist device implantation or orthotopic heart transplantation for decompensated left heart failure[111,112] and is associated with progressive end-organ dysfunction.[113] The presently available approaches include extracorporeal and paracorporeal pulsatile and centrifugal pump ventricular assist systems.[75,76] An alternative approach uses a right atrial catheter to draw blood into a centrifugal pump and a percutaneously placed pulmonary artery catheter as the outflow cannula.[114] Small implantable centrifugal pumps are under development.

Chapter 27

PULMONARY EMBOLIC DISORDERS: THROMBUS, AIR, AND FAT

NUALA J. MEYER
GREGORY A. SCHMIDT

KEY POINTS

- *Pulmonary embolism (PE) is common, underdiagnosed, and lethal, yet readily treatable.*
- *Prophylaxis and accurate diagnosis are essential to improving outcome.*
- *The cause of death in PE is most often circulatory failure (acute cor pulmonale) due to right heart ischemia.*
- *There is no perfect diagnostic test for PE; accurate diagnosis requires both an informed clinical pretest probability and a stepwise application of tests including D-dimer, helical CT angiography, and lower extremity duplex.*
- *A careful risk assessment may identify patients ideal for outpatient therapy. Conversely, patients with hypotension, cancer, heart failure, hypoxemia, and present or prior deep vein thrombosis are at significantly higher risk for death, recurrence, or major bleeding from PE, and are best managed in an appropriately monitored setting.*
- *Low molecular weight heparin (LMWH) is approved and recommended as the initial therapy for PE, and should be used in most patients unless there exists a compelling reason to do otherwise. When LMWH is not used, unfractionated heparin is typically used to maintain the partial thromboplastin time at 1.5 to 2.5 times control. Numerous new anticoagulants are being tested and may soon be approved for the treatment of PE.*
- *Critically ill patients may especially benefit from aggressive use of vena caval interruption.*
- *Thrombolytic therapy is life-saving in patients with massive embolism and circulatory instability.*
- *Air and fat embolism usually present as acute respiratory distress syndrome, and are managed with mechanical ventilation, oxygen, and positive end-expiratory pressure.*

This chapter will cover diseases involving embolism to the pulmonary circulation, including pulmonary thromboembolism, as well as the less common conditions of venous air embolism and fat embolism. Thromboembolism is predominantly an acute circulatory insult, with important but less dramatic consequences for gas exchange. In contrast, both air and fat embolism usually present as acute hypoxemic respiratory failure (AHRF). All three of these forms of embolism may cause acute right heart failure, which is more fully discussed in Chap. 26.

Pulmonary Thromboembolism

Pulmonary embolism (PE) is a dramatic and life-threatening complication of underlying deep venous thrombosis (DVT). Therefore, much of the management of PE is grounded in the prophylaxis, diagnosis, and treatment of DVT. Much of our knowledge about DVT and PE is derived from patients who are not critically ill. When generalizations regarding clinical manifestations, utility of diagnostic tests, and efficacy of therapeutic approaches are extrapolated to the critically ill population, it is with some risk.

Pulmonary thromboembolism is a common yet underdiagnosed illness which accounts for substantial morbidity and mortality. It was estimated nearly 25 years ago that 630,000 persons each year suffer PE in the United States alone, with nearly 200,000 deaths (Fig. 27-1).[1] The incidence of PE over the past two decades may be decreasing[2] but this is controversial.[3,4] Recent hospital-based studies estimate an incidence of 1 case per 1000 persons per year, with 200,000 to 300,000 annual hospitalizations.[5,6] Data on mortality from PE are less problematic; a recent analysis of all U.S. death certificates between 1979 and 1998 found that PE mortality has decreased substantially over the past 20 years, from over 35,000 deaths in 1979 to fewer than 25,000 deaths in 1998.[7] Accurate estimates for its incidence and lethality are notoriously difficult to calculate, for reasons largely related to difficulties in diagnosis and data collection.[3,8] However, there is general consensus that venous thromboembolism is underdiagnosed. Failure to diagnose PE is a serious management error since 30% of untreated patients die, while only 8% succumb with effective therapy.

ICU patients are not a homogenous group of patients and the incidence of thromboembolism ranges widely across subsets of patients (Table 27-1). For example, in one study of medical ICU patients, 33 percent were found to have deep venous thrombosis, despite prophylaxis in more than half of them.[9] Among patients with DVT, half of them had thrombi in the proximal lower extremity, a site associated with a high risk of embolization. In addition, 15% of thrombi were catheter-associated thrombi in the upper extremities. One prospective study found that 33% of ICU patients with a central venous catheter had a sonographically detectable thrombus in the internal jugular or subclavian vein; of note, none of these patients were symptomatic, and none developed a symptomatic pulmonary embolus.[10] In trying to devise prophylactic and diagnostic plans, intensivists should take into account the patient mix in their own ICUs.

In spite of great strides in the understanding of venous thromboembolism, PE continues to cause substantial morbidity and mortality. Critically ill patients form a unique and challenging subset of those at risk. The presence of indwelling lines and forced immobility make these patients particularly susceptible to venous thromboemboli. Diagnosis, which is difficult even in ambulatory patients, is further impeded by barriers to communication and physical examination. Moreover, alternate explanations for hypoxemia, lung infiltrates, respiratory failure, and hemodynamic instability are readily available, such that a diagnosis of pulmonary thromboembolism may not be seriously considered. Finally, critically ill patients are likely to have limited cardiopulmonary reserve, so that pulmonary emboli may be particularly lethal.

PATHOPHYSIOLOGY

Venous thrombosis begins with the formation of microthrombi at a site of venous stasis or injury. Thrombosis impedes flow and generates further vascular injury, favoring progressive clot formation. In some patients, clot becomes substantial and propagates to a proximal vein where it has the potential to embolize to the pulmonary circulation. Most clinically relevant pulmonary emboli originate as proximal venous thrombi in the leg or pelvic veins. However, in the ICU, the routine placement of upper body catheters for vascular access, monitoring, drug administration, and nutrition raises the likelihood of important upper body sources of thrombi. How significantly these line-related upper body thrombi contribute to PE in critically ill patients is unknown, but they clearly have embolic potential.[15] Such upper extremity thrombi have important implications for diagnostic strategies based on detection of lower extremity thrombi and therapies such as inferior vena caval interruption which presume a lower extremity source.

PE occurs when thrombi detach and are carried through the great veins to the pulmonary circulation. Pulmonary vascular occlusion has important physiologic consequences which lead to the manifestations of illness as well as to clues to diagnosis. PE has an impact most notably on gas exchange and the circulation.

GAS EXCHANGE

Physical obstruction to pulmonary artery (PA) flow creates dead space in the segments served by the affected arteries. This creation of dead space has several effects on the partial pressure of carbon dioxide (P_{CO_2}) and end-tidal CO_2 (ET_{CO_2}), which can provide clues to diagnosis. If minute ventilation ($\dot{V}E$) does not change, as occurs in a mechanically ventilated, muscle-relaxed patient, P_{CO_2} will rise. However, most patients augment $\dot{V}E$ more than necessary to maintain elimination of CO_2, so that P_{CO_2} typically falls with PE. In health, the ET_{CO_2} is nearly the same as arterial CO_2. After pulmonary embolization, since end-tidal gas is a mixture of alveolar gas (in which the partial pressure of carbon dioxide [P_{ACO_2}] approximates Pa_{CO_2}) as well as the newly created physiologic dead space gas (in which P_{CO_2} approximates inspired P_{CO_2}, or is nearly zero), ET_{CO_2} falls in proportion to the degree of dead space and no longer approximates Pa_{CO_2} (Fig. 27-2). This principle of a fixed alveolar-to-arterial gradient for P_{CO_2} has been used to distinguish acute exacerbations of chronic obstructive pulmonary disease (COPD) from pulmonary embolism in patients with acute ventilatory failure.[16] While not yet studied in the critically ill population, the steady-state end-tidal alveolar dead space fraction—which can be easily derived once one has both an accurate Pa_{CO_2} and end-tidal pressure of carbon dioxide (ET_{CO_2})—has a sensitivity of 79.5% and a negative predictive value of 90.7% in hospitalized patients with PE.[17]

A widened alveolar-to-arterial gradient for oxygen [$(A\text{-}a)P_{O_2}$] is present in the majority of patients with PE. However, since in PE hyperventilation is the rule, Pa_{O_2} may not be low. In fact, only 63% of patients with proven PE demonstrate a Pa_{O_2} <70.[18] Therefore, a normal Pa_{O_2} does not conclusively exclude a diagnosis of PE. There have been several efforts to use various combinations of the Pa_{O_2}, the P_{CO_2}, and the

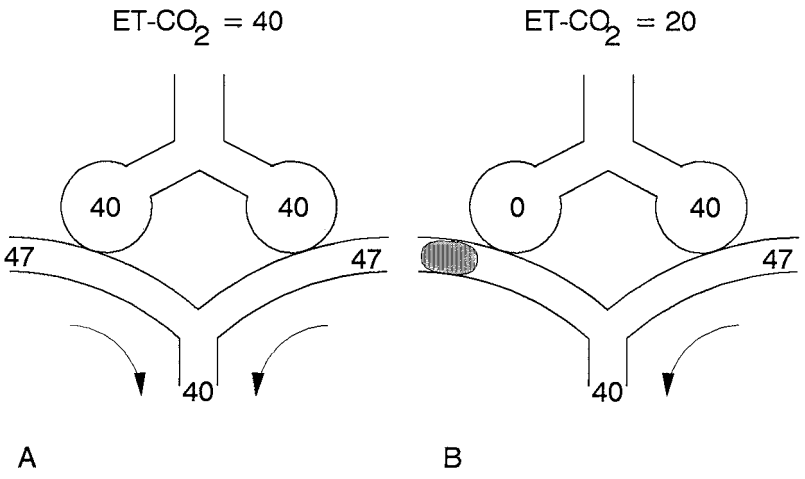

FIGURE 27-2 End-tidal CO_2 in PE. Panel *A* demonstrates the normal end-tidal CO_2, reflecting the alveolar CO_2 of 40. Panel *B* illustrates the effect of obstruction of blood flow to half of the ventilated alveoli. The end-tidal CO_2 falls in proportion to the fraction of ventilated alveoli that are no longer perfused. All numbers are P_{CO_2}, in millimeters of mercury.

(A-a)P_{O_2} to predict the likelihood of (or adequately exclude) pulmonary embolism, but these have all been shown to have insufficient discriminant value, even in patients without antecedent cardiopulmonary disease.[19]

The mechanisms of hypoxemia have been elucidated by applying the multiple inert gas elimination technique (MIGET) to patients with PE.[20,21] Shunt is found in only a few patients. In some, this may be due to opening of a probe patent foramen ovale when right atrial pressure rises following PE (see below), with a consequent intracardiac right-to-left shunt. Since shunt is more likely to be found when patients are studied after some delay, atelectasis due to impaired surfactant production may contribute. In most patients, however, the most important pulmonary derangement is mismatching of ventilation and perfusion. In addition, the fall in cardiac output ($\dot{Q}_T$) that accompanies most pulmonary emboli leads to a fall in mixed venous saturation. This lowered venous saturation magnifies any hypoxemia due to shunt or ventilation-perfusion ($\dot{V}/\dot{Q}$) mismatch (Fig. 27-3).

While impaired oxygenation is important and often provides a clue to the diagnosis of PE, it is typically responsive to modest oxygen enrichment of inspired gas. Severe hypoxemia is usually seen only in patients with profound shock. If oxygen-refractory hypoxemia is present without obvious hypoperfusion, a patent foramen ovale should be suspected. Ventilatory failure is usually not a significant problem either, since most patients are able to double or triple $\dot{V}_E$ if necessary, in order to maintain a normal (or reduced) P_{CO_2}. In fact, the greatest impact of PE is on the circulation, not on gas exchange. Although there are exceptions (e.g., some patients with severe COPD), morbidity and mortality from PE relate to cardiovascular compromise, not respiratory failure.

CIRCULATION

PE obstructs the pulmonary vascular bed mechanically as well as via humoral and other mechanisms. This increases right ventricular afterload, which when compounded by tachycardia, increases right ventricular oxygen consumption. The right ventricle dilates and thins, its wall tension rises, and coronary perfusion is impeded. At the same time, pulmonary vascular obstruction hinders $\dot{Q}_T$ and contributes to hypoxemia. Therefore, just at the time when the right ventricle demands an increase in oxygen delivery, the left ventricle may not be able to supply it. The superimposition of increased right heart oxygen demand on decreased oxygen supply puts the right ventricle at risk for ischemia, precipitating failure of the right heart (cor pulmonale). Acute right heart dysfunction is the likely cause for sudden death in patients with massive PE. There are substantial animal and human data supporting this hypothesis, which is further discussed in Chapter 26.

Of particular interest to the intensivist is the patient with a sublethal, yet large, PE. With increased afterload, the right ventricle dilates to a larger end-diastolic volume. This is associated with elevated right atrial and ventricular pressures and abnormally low $\dot{Q}_T$. One consequence of raised right atrial pressure is the potential for right-to-left shunting across a probe patent foramen ovale, causing oxygen-refractory

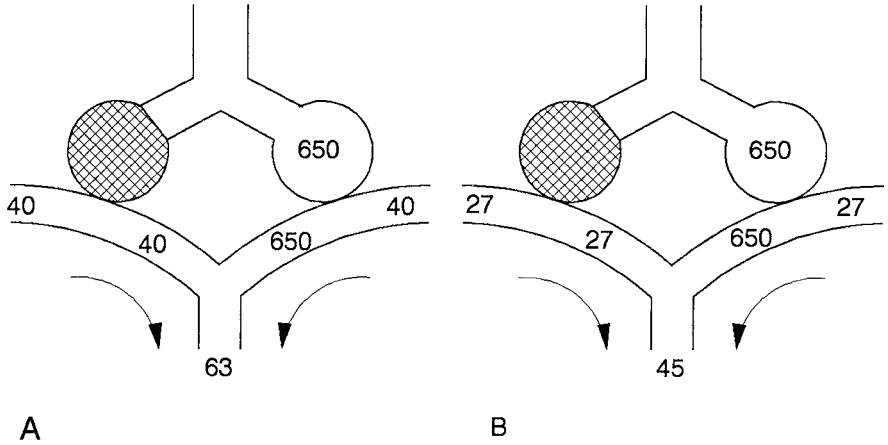

FIGURE 27-3 Effect of the mixed venous oxyhemoglobin saturation on arterial saturation in the setting of venous admixture. Panel *A* shows the effect of a 50% shunt on P_{O_2} in a patient breathing 100% oxygen who has a normal mixed venous P_{O_2} of 40 mm Hg (75% saturation). Panel *B* illustrates the same patient after the mixed venous P_{O_2} has fallen to 27 (50% saturation). Note that the P_{O_2} and saturation have fallen significantly despite the fact that the fraction of inspired oxygen (F_{IO_2}) and the lungs have not changed at all. All numbers are P_{O_2} in millimeters of mercury.

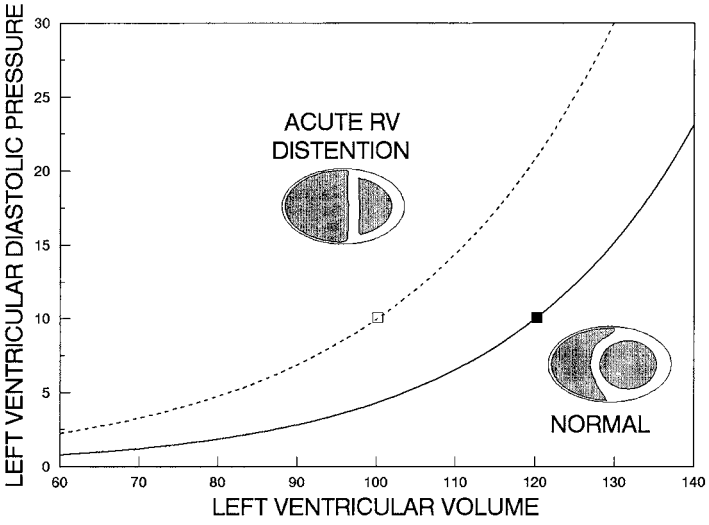

FIGURE 27-4 Left ventricular diastolic pressure-volume (PV) relationship before and after right ventricular dilation. The normal PV relationship (solid line) shows that large increments in diastolic volume are accompanied by small changes in pressure. With right ventricular distention (broken line), increments in volume are associated with relatively greater pressure changes. Note that at the same LV filling pressure of 10 mm Hg, the normal ventricle contains 20 mL more blood than following RV distention. This is associated with a correspondingly higher stroke volume and cardiac output. Pressures are in millimeters of mercury and volumes are in milliliters.

hypoxemia. This could allow paradoxical embolization of thrombus to the systemic arteries. The increase in right ventricular pressure and volume also affects the left heart. A change in shape of the right ventricle and corresponding shift of the interventricular septum from right to left alters the diastolic pressure-volume characteristics of the left ventricle (Fig. 27-4) and may be detected echocardiographically. The consequent reduction in left ventricular compliance impairs diastolic filling, thereby reducing left ventricular preload and creating yet another obstacle to cardiac output. An alternative explanation for the apparent decrease in left ventricular performance is reduced preload due to a fall in transmural filling pressure. Pericardial constraint might explain the fact that the left ventricular end-diastolic pressure (or wedge pressure) does not fall.[22]

Clinical Manifestations

HISTORY, EXAMINATION, AND LABORATORY DATA

Most patients with PE will complain of dyspnea, chest pain, and apprehension.[23] Less common symptoms are cough, diaphoresis, and hemoptysis. It is notable that most patients will not have symptoms of venous thrombosis. Syncope is uncommon but described in all large series of PE (Table 27-2).

The majority of patients will demonstrate tachypnea and tachycardia. Pleural rub and signs of DVT are seen only occasionally. Fever is more common than is generally appreciated and seen in half of patients,[23] but only rarely is the temperature >38.5°C. Patients with large emboli may have the typical findings of any patient with low output shock such as hypotension, narrow pulse pressure, and poor peripheral perfusion. Occasionally, unanticipated failure to come off mechanical ventilation or unexplained episodes of respiratory distress may be hints to a diagnosis of PE. Rare patients with PE have disseminated intravascular coagulation, systemic embolization, or acute respiratory distress syndrome (ARDS) as their presenting manifestation.

Most patients will demonstrate hypoxemia or at least a widened (A-a)P_{O_2}. However, since a small but significant fraction will have normal oxygenation,[18] the blood gas value should not dissuade a physician from considering the diagnosis when the rest of the clinical picture is suggestive. In fact, as described above, the blood gas does not provide data that are useful in discriminating patients with PE from those without. The chest x-ray may demonstrate areas of oligemia (Westermark's sign) and rare patients will develop a pleural based, truncated cone (Hampton's hump); however, most films have only nonspecific findings. In fact, the greatest utility of the chest film is in making (or excluding) alternative diagnoses such as pneumonia, pneumothorax, or aortic dissection. Nevertheless, the typical (albeit nonspecific) findings of basilar atelectasis, elevation of the diaphragm, and pleural effusion should always suggest PE when there is no apparent alternative explanation. Electrocardiography (ECG) may reveal signs of right heart strain such as rightward axis shift, right bundle-branch block, or right precordial strain, but often shows only sinus tachycardia.

SIGNS FROM MORE INVASIVE MONITORING

Valuable signs of PE may come from many of the devices used to monitor critically ill patients. The intensivist may derive clues from the ventilator, expired gas analysis, the PA catheter, or during echocardiography. The sensitivity and specificity of these monitors for the diagnosis of PE are not known. Nevertheless, wise physicians attempt to incorporate all available data into their synthesis of the patient. This is especially important in the ICU, where the history and physical examination are often difficult or impossible to obtain.

THE VENTILATOR

To maintain P_{CO_2}, the patient with PE must augment the $\dot{V}_E$. Therefore, any unexplained increase in $\dot{V}_E$ should prompt consideration of PE. Of course, any cause of rising dead space (airflow obstruction, hypovolemia, or positive end-expiratory pressure [PEEP]) or CO_2 production (anxiety, pain, fever, or sepsis) will also increase $\dot{V}_E$. However, when none of these conditions is apparent, especially when supporting clues are evident, PE becomes more likely.

EXPIRED CARBON DIOXIDE

As described above, the increment in dead space after PE causes a detectable fall in ET_{CO_2}. With technologic improvements in ventilators, noninvasive assessment of expired CO_2 is becoming increasingly practical in the ICU. A corollary of the fall in ET_{CO_2} with PE is that if $\dot{V}_E$ does not rise (e.g., in a muscle-relaxed patient), the total excretion of CO_2 (expired CO_2 concentration $\times$ $\dot{V}_E$) must fall. Therefore Pa_{CO_2} will rise progressively until a new steady state is reached at a higher Pa_{CO_2}. This can be demonstrated numerically by the alveolar dead-space fraction (AVDSf) as follows:

$$\text{AVDSf} = (Pa_{CO_2} - ET_{CO_2})/Pa_{CO_2}$$

When combined with a negative D-dimer value, as will be discussed shortly, an AVDSf of less than 0.15 has been shown to exclude PE in hospitalized patients with a sensitivity of 97.8% and a negative predictive value of 98%.[17] In calculating the AVDSf, however, one must take care to ensure proper calibration of the blood gas analyzer, as even small changes in Pa_{CO_2} measurements will cause large differences in AVDSf. Again, in the muscle-relaxed patient there are many explanations for a rising arterial CO_2, but if no explanation is forthcoming, especially if the CO_2 production is known to be constant, consideration of PE is warranted.

PULMONARY ARTERY CATHETER

The most obvious clues from the pulmonary artery catheter (PAC) are the elevations in right atrial, right ventricular, and PA pressures and concomitant fall in $\dot{Q}_T$ that occur with PE. With the reduced $\dot{Q}_T$, one also sees a widening of the arterial-to-venous oxygen content difference [$(a\text{-}v)P_{O_2}$] (Fick principle) and a decrement in the mixed venous oxygen saturation ($S\bar{v}_{O_2}$) or the central venous oxygen saturation. An oximetric catheter may facilitate early recognition of the fall in venous oxygenation. A final clue from the PAC may lie in the difference between the PA diastolic pressure and the pulmonary capillary wedge pressure (Ppw). Normally, flow through the pulmonary circulation is pulsatile, so that by the end of diastole, there is no more flow from the PA to the left atrium. Without flow, there can be no pressure gradient from the PA to the left atrium. Thus the end-diastolic PA pressure and the Ppw are nearly equal. However, when there is obstruction of the pulmonary vascular bed, flow is not completed by the end of diastole and a pressure gradient remains. A discrepancy between the PA diastolic pressure and Ppw may provide a clue to PA obstruction.[24]

Unfortunately, each of these observations is certainly nonspecific (and likely insensitive) so that only rarely do such changes indicate PE. For example, cardiac dysfunction (systolic or diastolic) causes a rise in right heart pressures and a fall in $\dot{Q}_T$; any cause of low $\dot{Q}_T$ causes a widened $(a\text{-}v)P_{O_2}$; and any cause of acute lung injury may raise the PA diastolic-to-Ppw gradient. A further layer of complexity is added by the recent observation in a trial of surgical patients that pulmonary embolism was disproportionately associated with the PAC compared with central venous catheters (0.8% vs. 0%).[25] Given the limitation of the PAC as a diagnostic tool and the risk of actually causing PE, it cannot be advocated for the diagnosis of PE.

ECHOCARDIOGRAPHY

The role of echocardiography in the evaluation of suspected PE is evolving, but seems most helpful in determining a patient's prognosis. While its attractions include portability—especially for the evaluation of critically ill patients—noninvasiveness, potential to elucidate competing diagnoses (such as myocardial infarction or pericardial disease), and rapid availability, echocardiography is insensitive, and should not be used to diagnose PE. In prospective trials of unselected patients, sensitivities of between 29% and 52% are reported for various echocardiographic criteria of right ventricular strain or dysfunction or tricuspid regurgitation.[26,27] Many patients with PE have normal echocardiograms. Occasionally, a study requested for evaluation of a low flow state may unexpectedly reveal findings strongly suggestive of PE.[28,29] These include a dilated, thin-walled, poorly contracting right ventricle, and bowing of the interventricular septum to the left. Very rarely, echocardiography may demonstrate a thrombus in the right atrium or right ventricle (Table 27-3), clinching the diagnosis of PE.

When echocardiography exhibits right ventricular dysfunction, it reliably predicts an increased risk of mortality from pulmonary embolism. One study examined 126 patients with PE with echocardiography on the day of diagnosis, and found moderate RV dysfunction to impart a sixfold increased risk of in-hospital death compared to normal RV function.[30] Even in patients assessed to be hemodynamically stable at presentation, right ventricular dysfunction portends a worse

TABLE 27-3 Echocardiographic Signs of Pulmonary Embolism

Visualized thrombus in right atrium, right ventricle, or pulmonary artery
Loss of respirophasic variation in inferior vena caval diameter

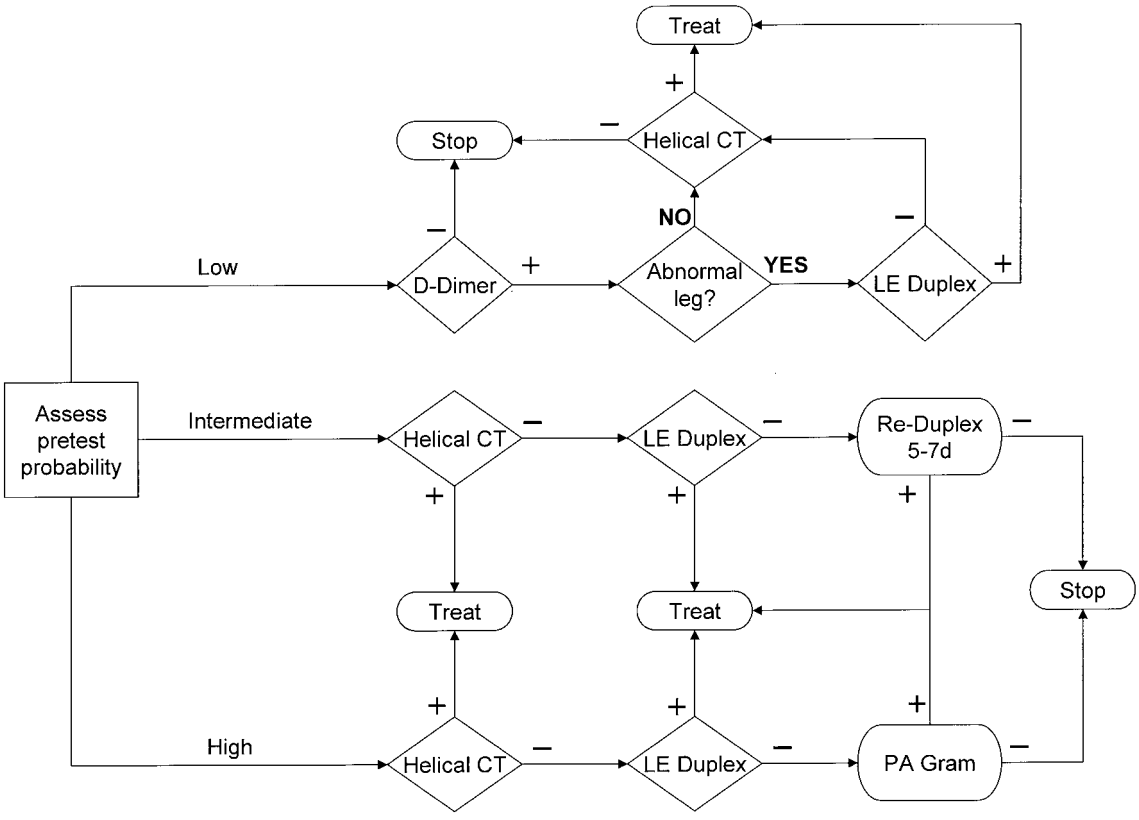

FIGURE 27-5 Algorithm for evaluation of a critically ill patient suspected of having a pulmonary embolus. If alternate diagnoses are not confirmed by examination, chest x-ray, and ECG, the pretest probability of pulmonary embolism should be assessed. D-dimer may be useful in some patients at low suspicion when this test is negative. Helical computed tomographic (CT) angiography may not be sufficiently sensitive to act as a screening test, and unless the clinical suspicion is low, negative studies should be followed by additional testing. Ventilation-perfusion scanning may be useful in occasional patients when CT angiography cannot be performed. Echocardiography is not sufficiently reliable for routine use, but it may greatly aid diagnosis in the patient with shock. "Treat" means treatment for PE is generally indicated; "STOP" means PE is very unlikely and an alternate explanation for the patient's symptoms or signs should be sought. These decisions hinge critically on clinical judgment and experience.

prognosis; one study found that 10% of such patients develop shock and 5% died in the hospital, compared to a 0% mortality among patients with normal RV function.[31] In another series of hemodynamically stable patients, recurrent embolism was strongly associated with baseline echocardiographic abnormalities in right ventricular wall motion.[32] A word of caution is prudent, however, in that the classic echocardiographic findings of PE are nonspecific, and are common to a number of causes of acute right ventricular pressure overload such as ARDS, other forms of severe hypoxemia, or status asthmaticus (see Chap. 26).

Diagnosis

SPECIAL PROBLEMS IN THE ICU
