Immune thrombocytopenic purpura (ITP) is confirmed by finding antiplatelet antibodies in the patient's serum or on the patient's platelets. When a drug is suspected to be the cause, these studies can be done in the presence and absence of the candidate drug in an effort to help confirm the diagnosis. Since the testing may take some time, often an empirical decision is made to stop administration of one or more suspect drugs, when possible. Immune-mediated thrombocytopenia also may be associated with such conditions as collagen-vascular disease, lymphomas, and viral infections, including HIV-1.

The first step in therapy consists of discontinuation of any potential offending agents (e.g., quinidine, trimethoprim-sulfamethoxazole, diphenylhydantoin, thiazides). In addition, drugs that impair platelet function are contraindicated. It is often difficult to sort out a responsible drug in patients with complex medical conditions who are taking multiple medications, but in our experience, a frequent offender in the ICU setting is intravenous furosemide given repetitively. Corticosteroids may improve platelet survival by loosening the attachment of antibodies to platelets and decreasing the reticuloendothelial clearance of the antibody-coated platelets. A longer-term effect of corticosteroids is suppression of antibody production. Administration of platelets is usually of temporary benefit because their survival is shortened, presumably by mechanisms similar to those affecting the patient's platelets. Another intervention that may help to improve platelet survival is infusion of intravenous γ-globulin, 0.4 to 1 g/kg per day for 3 to 5 days.[7] This agent is thought to work by causing reticuloendothelial blockade and, possibly, because of the presence of anti-idiotypic antibodies in the preparation, by reducing the amount of antiplatelet antibody available to attach to platelets. In some patients receiving platelets, pretreatment with intravenous γ-globulin may help to prolong survival of the platelets. A benefit may not be seen for several days, and the resulting increase in platelet number, which may be life-saving and permit surgical procedures, is temporary. Subsequent repeat doses may be effective again, but cost becomes an important consideration when selecting this as an ongoing treatment.

Splenectomy may be an effective treatment for immune thrombocytopenia, but often the ICU patient is not a good candidate for the procedure, and therefore, the emphasis is more on the medical interventions just outlined. Intravenous human anti-Rh_o(D) IgG also may be effective in treating patients with immune thrombocytopenia who are Rh-positive and still have their spleen.[8] The mechanism of benefit is not fully understood, but the rationale is to coat circulating Rh-positive red cells with the anti-D antibody, thereby inducing intrasplenic sequestration of the red cells, resulting in reduced available reticuloendothelial capacity to remove antibody-coated platelets. Careful monitoring of the expected (usually limited) hemolysis is necessary. Some patients may be already significantly anemic and unable to tolerate a significant fall in RBC count. Patients who have received anti-D should receive Rh-negative red cells if transfusion is needed. Other agents, such as azathioprine, vincristine, colchicine, danazol, rituximab, mycophenolate mofetil, and cyclophosphamide, or devices (e.g., staphylococcal protein A column treatment of plasma) may be helpful, but they are usually used in subacute and chronic management situations or for individuals with persistent thrombocytopenia after splenectomy.

POSTTRANSFUSION PURPURA (PTP) Abrupt, often apparently unexplained, delayed appearance of severe thrombocytopenia may occur following blood transfusion in rare predisposed (usually $P1^{A1}$-negative) individuals. The life span is shortened for both $P1^{A1}$-positive donor platelets (to which isoantibodies have been produced) and the patient's

own platelets (mechanism unclear). Infusions of intravenous γ-globulin (0.4 g/kg per day for 2 to 5 days) have been followed by good responses in patients with this potentially serious problem, regardless of the antibody implicated.[9]

THROMBOTIC THROMBOCYTOPENIC PURPURA (TTP) In TTP, intravascular clumping of platelets accounts for secondary vaso-occlusion and thrombocytopenia. Recent discoveries[10] have supported a proposed pathogenetic mechanism to explain the TTP syndrome (see Chap. 70 for an in-depth discussion of this subject).

Triggers of the acquired syndrome include infections (e.g., HIV-1), various drugs (including the antiplatelet agents ticlopidine and clopidogrel), chemotherapeutic agents (especially mitomycin), and malignancies. The important diagnostic clues are schistocytes on blood smear, a low platelet count (usually with a disproportionately low incidence of hemorrhagic symptoms), a negative direct Coombs' test in the face of laboratory evidence of hemolysis, and (usually) normal findings on coagulation studies. Evidence of vaso-occlusion by platelet hyaline agglutinates may be seen in biopsy specimens from tissues such as skin, marrow, gingiva, and kidney. Treatment with corticosteroids and plasma exchange[11] usually results in significant improvement. Also, favorable responses to intravenous vincristine, cyclophosphamide, rituximab,[12] and in otherwise refractory cases, splenectomy have been reported. Because exacerbation of the vaso-occlusive process has been noted following platelet transfusions, these should be avoided unless there is serious bleeding or an invasive procedure is mandatory.

DISSEMINATED INTRAVASCULAR COAGULATION (DIC) When thrombocytopenia is a manifestation of DIC,[13] usually other features of the process are present that permit recognition of the syndrome. Accompanying microangiopathic hemolysis, hypofibrinogenemia, elevated levels of FDPs and D-dimers, and prolonged clotting times are cardinal features. In advanced DIC, the bleeding diathesis associated with low platelet counts is compounded by qualitative platelet dysfunction owing to thrombin-induced platelet storage pool depletion, which may make platelet transfusions less effective. Schistocytes are seen less frequently in DIC than in TTP and, paradoxically, may be less evident in more advanced stages when fibrinolysis may be brisk, leading to breakdown of fibrin strands responsible for red cell shearing.

HEPARIN-INDUCED THROMBOCYTOPENIA (HIT) Bleeding is the most frequent complication of heparin therapy. An important cause of thrombocytopenia is the immune mechanism related to heparin.[14] This is of special interest in the ICU because of the almost ubiquitous exposure of patients to heparin owing to its use in access and monitoring lines and the common insertion of "heparin bonded" or "heparin coated" catheters. In addition, certain patient populations, especially those who have undergone cardiac or orthopedic surgery, appear to be at increased risk of sensitization by heparin.

It is common for patients to have a small, reversible drop in platelet count (usually within the normal range) within 1 to 2 days of the initiation of heparin therapy. This effect is thought to reflect some platelet aggregation caused by the presence of high-molecular-weight heparin species in the commercially available unfractionated heparin. The immune-mediated thrombocytopenia (seen in less than 1% of heparin-treated patients) typically appears at about 5 to 7 days after first exposure, but an anamnestic response due to persistent antibody from previous sensitization to heparin may cause thrombocytopenia to develop earlier in some patients, usually if they are within about 100 days of their initial sensitization. The clinical picture may range from no symptoms to life-threatening thrombotic events, which may be venous or arterial. Hemorrhage is less frequent, despite quite severe thrombocytopenia in some individuals. It is often necessary to make the decision about discontinuing heparin on clinical grounds.

The clinical criteria for diagnosis of HIT include an otherwise unexplained fall in platelet count below 150,000/μL or a fall of 50% or more of platelet count within the normal range. A history of any adverse reaction to heparin in the past or of necrotic changes at subcutaneous heparin injection sites should alert one to risk of serious vascular consequences on re-exposure to the drug. It is often difficult in the ICU setting to sort out mechanisms of thrombocytopenia, but a high index of suspicion is important in avoiding adverse consequences of unrecognized HIT. The "gold standard" confirmatory test (normalization of the platelet count after stopping heparin) also may be difficult to achieve because of other coexisting causes of thrombocytopenia (e.g., other drugs, sepsis).

Current notions of the pathogenesis of HIT suggest that the normally formed platelet factor 4 (PF4)–heparin complex is immunogenic in some individuals. Antibodies developed against the PF4-heparin target antigen form antigen-antibody complexes that can activate platelets after interacting with their Fc receptors. The result is intravascular obstruction by platelet clumps.

Laboratory confirmation of the presence of heparin-dependent antibodies may be helpful but is not always available in a timely fashion for decision making. In addition, false-negative tests are not infrequent. When available, various functional assays, such as heparin-induced platelet aggregation, [^{14}C]serotonin release, and flow cytometric methods, may increase the predictability of clinically significant vaso-occlusive events beyond the detection of sensitization using enzyme-linked immunosorbent assay (ELISA) techniques for antibodies to PF4.

It is important to emphasize that the severe antibody syndrome may occur with any type of heparin (although the incidence appears to be less with low-molecular-weight heparin[15]) given via either intravenous or subcutaneous route. If the syndrome is suspected clinically, all devices and practices that expose the patient to heparin should be discontinued (including use of heparin locks, flushes of indwelling lines, and indwelling catheters that are heparin-coated).

Patients with HIT are hypercoagulable whether or not a clinically recognized vaso-occlusive event has occurred. As a result, they require immediate alternative anticoagulation. Once sensitized by unfractionated heparin (UFH), patients should not receive low-molecular-weight heparin (LMWH) as an alternative because of the high rate of cross-reactivity of antibodies to UFH with LMWH. The commonly used anticoagulants in this setting are direct thrombin inhibitors that do not cross-react with heparin-induced antibodies. Hirudin and argatroban usually are selected—the choice being made based on the patient's comorbidities (hirudin depends on renal clearance; argatroban depends

on hepatic function status). Although each agent has a relatively short half-life, the lack of an antagonist for either increases the risk of bleeding complications. If patients require long-term anticoagulation with oral warfarin, it should not be started for at least 2 weeks because of reported adverse clotting problems when begun earlier in the course of HIT.

MECHANICAL SURFACE-RELATED THROMBOCYTOPENIA[16]
Variable lowering of platelet number is sometimes seen when platelets pass over or through foreign or distorted surfaces. Clinical situations of this type include cardiopulmonary bypass and the presence of intraaortic balloon pumps or pulmonary artery catheters. For cardiopulmonary bypass, at least, platelet-related bleeding during or after bypass is much more likely to be secondary to impaired platelet function (see below) than to severe depression of the platelet count.

SEQUESTRATION

Hypersplenism

Thrombocytopenia with or without anemia and neutropenia may be a feature of hypersplenism.[17] This state of increased local sequestration, usually with shortened intrasplenic survival, frequently is accompanied by increased spleen size that is detectable on physical examination or imaging studies. Bedside ultrasound is a safe noninvasive method for assessing the spleen in ICU patients.

Hypersplenism may be a chronic, stable condition antedating and then complicating a new problem (e.g., cirrhosis with splenomegaly predating acute deterioration for another reason). In addition, acute onset of hypersplenism with progressive splenic enlargement and sequestration may be a feature of such processes as splenic venous occlusion and sickle cell splenic sequestration crisis in children. It is unusual to encounter a platelet count of less than about 30,000/μL in "compensated" hypersplenism associated with cirrhosis and portal hypertension accompanied by splenomegaly. Bone marrow evaluation is expected to reveal increased megakaryocyte number and overall hypercellularity. The peripheral smear should show decreased platelet numbers but some large basophilic platelets.

In situations of progressive splenomegaly with associated thrombocytopenia (and risk of splenic rupture), splenectomy may be the only available therapy. If the splenic enlargement is secondary to leukemic or lymphomatous involvement, radiation therapy may be of some benefit in shrinking the spleen, but the effect may be temporary, and there is the risk of paradoxical thrombocytopenia or neutropenia rather than count improvement.

THROMBOCYTOSIS/THROMBOCYTHEMIA

Elevated platelet counts are seen commonly in critically ill patients because inflammation, bleeding, surgery, hemolysis, severe injury, and neoplasia are among the major causes of reactive thrombocytosis. Usually, the count is elevated to levels less than $1 \times 10^6/\mu$L, and no adverse effect is expected from such a secondary increase in qualitatively normal platelets.

In contrast, patients with elevated platelet counts secondary to myeloproliferative disorders[18] are at an increased risk of bleeding or thrombotic sequelae, especially when the platelet count exceeds $1 \times 10^6/\mu$L. The diagnosis of an underlying myeloproliferative disorder may have been established prior to the patient's presentation with a complication, or it may be suspected from associated clinical features such as splenomegaly, abnormal platelet morphology on smear, and bone marrow examination revealing panmyelosis (increase in all cell lines) as well as qualitative abnormalities in megakaryocytes, which are also markedly increased in number.

If the patient is asymptomatic, a prolonged bleeding time may portend hemorrhagic problems. No definitive laboratory tests predict impending thrombotic complications in such patients, but it appears that the risk may be increased in older persons with fixed vascular disease. It is especially important to avoid splenectomy, either intentional or inadvertent, at the time of abdominal surgery for other reasons because marked platelet elevations may cause fatal vaso-occlusive events.

Platelet levels may be reduced quickly and effectively in symptomatic thrombocythemic individuals by plateletpheresis. Treatment with anagrelide or hydroxyurea can be used to maintain normal platelet counts (the usual goal is to keep the platelet count less than 500,000/μL).[18] These drugs also can help to prevent secondary rises in platelet count following surgical procedures and other factors that may precipitate reactive thrombocytosis.

THROMBOCYTOPATHY

Qualitative platelet abnormalities are encountered frequently in the ICU setting.[19] Often they contribute to other, more serious bleeding diatheses, but on occasion they present a significant problem in their own right. Exposure to external agents, such as ethanol, aspirin, and nonsteroidal anti-inflammatory drugs (NSAIDs), prior to admission is common. Other drug-induced causes of thrombocytopathy in the hospital include exposure to the parenteral NSAID ketorolac (TORADOL) and glycoprotein (GP) IIb/IIIa inhibitors (e.g., abciximab, ticlopidine, clopidogrel). The resulting prolongation of bleeding time varies in duration and severity. Once the offending agent has been removed, the bleeding problem can be overridden promptly by administration of normal platelets or, in the case of aspirin or ticlopidine, by intravenous infusion of 1-diamino-8-D-arginine vasopressin (DDAVP), if necessary. Often, unless there is significant bleeding or invasive procedures are needed, it is sufficient to wait several days and let the patient's own production of new platelets unexposed to the offending agent correct the problem.

UREMIA

A more difficult problem is the thrombocytopathy associated with uremia. A variety of interventions may be helpful temporarily. Correction of the prolonged bleeding time may be needed prior to an intended surgical intervention (e.g., renal biopsy for diagnosis). The key step is appropriate dialysis; additional benefit sometimes is noted with administration of corticosteroids, infusions of cryoprecipitate[20] (usually 10 cryopacks every 12 hours), intravenous DDAVP[21] (0.3 μg/kg), platelet transfusions, and intravenous conjugated estrogens.[22] Intravenous DDAVP, if effective in reducing the bleeding time, may be repeated at 6- to 12-hour intervals, but tachyphylaxis is expected after 1 to 2 days of this therapy. It is also important to seek and correct other coexisting coagulopathies, such as vitamin K deficiency.

MYELOPROLIFERATIVE DISORDERS

Patients with myeloproliferative disorders may have platelet dysfunction, especially when platelet counts are elevated. Usually, normalization of the platelet count results in return of the bleeding time to normal, but individuals with long-standing polycythemia vera or myeloid metaplasia, for example, may still have abnormal bleeding, especially with surgical procedures, even when all counts have been normalized.

DRUGS

Aspirin

The classic drug inhibitor of platelet function is aspirin. It causes irreversible inhibition of cyclo-oxygenase, thereby leading to impaired prostaglandin metabolism. The net effect of aspirin is the result of inhibition of production of the platelet aggregant thromboxane A_2 versus decreased synthesis of prostacyclin—the potent endothelium-derived inhibitor of platelet aggregation. In most individuals on Western diets that contain limited amounts of the omega fatty acid precursors of prostacyclin synthesis, the net result is a prolonged bleeding time. When aspirin is discontinued, the exposed platelets remain impaired, but newly synthesized platelets with normal function soon begin to contribute to normalization of the bleeding time. Usually, the effect of aspirin on bleeding time has dissipated significantly by 3 days after discontinuation.

Nonsteroidal Anti-Inflammatory Drugs (NSAIDs)

NSAIDs cause reversible inhibition of cyclo-oxygenase and, therefore, a shorter period of bleeding risk than aspirin after discontinuation.

Antibiotics

Antibiotics of the penicillin family, epitomized by carbenicillin, may cause a complex coagulopathy. In addition to disturbance of the synthesis of vitamin K by the intestinal flora, a thrombocytopathy characterized by a prolonged bleeding time is recognized. These phenomena usually are not of major clinical significance, but they may add to other coagulation defects and affect the interpretation of coagulation laboratory evaluations. When bleeding from these mechanisms is serious, platelet transfusion after discontinuation of the drug should compensate for the impaired function of platelets exposed to the drug.

DYSPROTEINEMIAS

Abnormal immunoglobulin concentrations, as seen in myeloma and Waldenstrom's macroglobulinemia, interfere with platelet function (causing prolonged bleeding times) presumably by physically "coating" platelet surfaces and thus limiting the access of clotting factors to the phospholipid surfaces of platelets, which are needed to promote key reactions in the clotting cascade. In addition, prolongation of the TT is often noted.

CARDIOPULMONARY BYPASS[16]

Acquired thrombocytopathy is regularly produced by contact of platelets with membrane surfaces in bypass circuits. In some patients this effect may add to other causes of increased bleeding risk after bypass (such as hypofibrinogenemia and inadequate heparin neutralization). Transfusion of donor platelets (if clinically urgent) is expected to normalize the bleeding time once bypass is discontinued.

THROMBIN-INDUCED STORAGE POOL DEFECT

Thrombocytopathy may contribute to the bleeding problems in DIC. During active DIC (e.g., in acute promyelocytic leukemia), an acquired platelet function defect with prolonged bleeding time may appear owing to release of granule contents by excess thrombin. This is likely to be especially troublesome when patients are thrombocytopenic as well. Control of the DIC is the key to successful correction of this problem. Infusion of donor platelets is of benefit for only limited periods because these platelets are also exposed to excess thrombin while the DIC is active.

Fibrin Generation Disorders

SAMPLE COLLECTION AND INTERPRETATION

Accurate values for clotting times, which form the basis for assessment of the integrity of the coagulation cascade, depend on collection of the correct quantity of blood relative to the amount of anticoagulant present in the sample tube; in addition, extraneous contamination by heparin must be avoided. It is important not to overfill collection tubes; rather, the vacuum should be allowed to determine the correct amount of specimen per tube, and the tube then should be inverted promptly to ensure adequate mixing with anticoagulants. Rapid delivery to the testing location decreases problems with cascade activation in the tube (which leads to prolonged clotting times). When drawing from heparinized lines, a double draw (discarding at least 10 mL initially and using the second aliquot) should prevent heparin contamination. Unexpectedly long PTTs that are not corrected by mixing the sample with an equal volume of pooled normal plasma but that are corrected by incubating the sample with heparin neutralizer powder (triethylaminoethyl cellulose) should indicate the presence of heparin contamination.

Consideration of the results of PT and PTT in combination can help to identify the site(s) of cascade deficiency (Table 69-4). Prolonged clotting times should be restudied after the patient's plasma is mixed with an equal volume of pooled normal plasma to differentiate between absence of the factors in question and inhibition of their activity by circulating inhibitors. If the clotting time is corrected by this mixing test, a deficiency is present; if the clotting time of the mix remains prolonged, an inhibitor (such as heparin or one directed against a specific clotting factor) is present.

ISOLATED FACTOR DEFICIENCIES

Isolated severe factor deficiencies may antedate and complicate the need for intensive care, as in hemophilia A or B, or may be acquired as a consequence of the critical illness, as in the case of hypofibrinogenemia secondary to DIC.

HYPOFIBRINOGENEMIA

Low functional fibrinogen levels in ICU patients most commonly result from decreased hepatic synthesis of fibrinogen or increased removal due to the action of thrombin and plasmin during DIC. Bleeding risk is increased by the anticoagulant effect of nonclottable fibrin split products in high titer. Spontaneous clinical hemorrhage from hypofibrinogenemia is not expected above a concentration of 100 mg/dL in plasma and usually is not a serious risk until levelsg of 50 mg/dL

TABLE 69-4 Use of Combined PT and PTT Results to Determine Site(s) of Fibrin Generation Cascade Defects

	PT Normal	PT Elevated
PTT Normal	Result 1	Result 2
PTT Elevated	Result 3	Result 4

Result 1: Normal results on screening tests of cascade (factor levels at least 30% to 35% of normal)
Result 2: Isolated low factor VII level—may be due to congenital deficiency or early liver disease, vitamin K deficiency, or warfarin effect
Result 3: Intrinsic pathway abnormality—low levels of factors VIII, IX, XI, or XII; typical pattern in hemophilia A and von Willebrand's disease
Result 4: Due to common pathway abnormality—factors I (fibrinogen), II, V, X— and/or combined intrinsic and extrinsic pathway defects. Seen in advanced liver disease, vitamin K deficiency, full warfarin and heparin effects, and DIC.

are reached. Fibrinogen may be replaced with fresh frozen plasma (FFP) or, more efficiently in terms of volume, with cryoprecipitate; each cryopack is expected to raise the fibrinogen level approximately 4 to 10 mg/dL in an adult. Although the plasma half-life of fibrinogen is approximately 4 days under normal circumstances, serial plasma fibrinogen level determinations will dictate the frequency of infusions (as often as every 6 to 12 hours, especially in acutely ill patients with a shortened fibrinogen half-life).

HEMOPHILIA A (FACTOR VIII DEFICIENCY)

Critical illness in a patient with hemophilia A requires careful correction of the pre-existing coagulopathy, especially when the situation is complicated by such new problems as ITP, DIC, sepsis, and hepatic or renal dysfunction. Appearance of an inhibitor to factor VIII and development of a progressive pseudotumor may further increase the complexity of management. Preparation of the severe hemophiliac for surgery consists of checking to exclude an inhibitor and then replacing with factor VIII concentrate to achieve the desired percent correction (100% equals 1 unit of factor VIII per milliliter of the patient's plasma). For major surgery, a starting level at or above 100% is desirable. Additional doses are given intraoperatively. The doses are dictated by the amount of bleeding and stat factor VIII levels. The shortened half-life of factor VIII during bleeding leads to increased requirements for replacement (both higher doses and shorter intervals between doses). To give a sample calculation: Suppose that a 70-kg patient with a hematocrit of 40% has a blood volume of 4900 mL (70 mL/kg) and a plasma volume of 2940 mL (60% of the blood volume). If the starting factor VIII level is less than 1%, approximately 3000 units of factor VIII concentrate will be needed to achieve correction to the 100% level. It is important to assess the adequacy of correction by monitoring the factor VIII level before invasive procedures and to continue support for 10 to 14 days after a major surgical procedure or hemorrhage to prevent serious delayed bleeding. Maintenance postoperative factor VIII support usually is given every 8 to 12 hours; the goal is to prevent the between-dose nadir in factor VIII plasma levels from falling below 40% to 50%. Several recombinant factor VIII products are available.

Similar considerations apply to patients with hemophilia B (Christmas disease), except that replacement is with FFP, prothrombin complex, or recombinant factor IX in severe deficiency states.

FACTOR VII DEFICIENCY

Factor VII deficiency is a much less common inherited deficiency than the preceding. It is a non–X-linked disorder with a variable severity, which in some patients presents as a severe hemophilia-like condition. Replacement with FFP or prothrombin complex is appropriate. The relatively short half-life of factor VII (4 to 7 hours) may require dosing at 6- to 8-hour intervals during major hemostatic challenges, but less frequent maintenance doses may be sufficient beyond the fourth day following some orthopedic procedures.[23]

Isolated factor VII deficiency is caused most often by vitamin K deficiency or liver disease or occurs during the initiation of warfarin anticoagulation. When factor VII deficiency cannot be corrected with vitamin K therapy, factor replacement with FFP or, when indicated, prothrombin complex can be used. Recombinant activated factor VII (rVIIa) also is available.

FACTOR XI DEFICIENCY

Factor XI deficiency is usually inherited, although in advanced liver disease a deficiency of factor XI may coexist with low levels of the other factors synthesized in liver parenchymal cells. FFP is the only currently available replacement product. For severely deficient patients with a bleeding tendency, preoperative plasma exchange may be used to establish safe hemostatic levels that can then be maintained by follow-up plasma infusions.

FACTORS II, V, AND X

These deficiencies may appear in isolation or coexist with others. Isolated factor X deficiency with significant bleeding may be seen in amyloidosis. FFP (or prothrombin complex for factors II and X) replacement therapy is indicated, if needed, but it may not readily correct an amyloid-associated factor X deficiency because of rapid clearance of the factor, which attaches to the amyloid fibrils. Splenectomy may be helpful in such instances.

FACTOR XII

Factor XII deficiency causes a prolonged PTT without a clinically significant bleeding diathesis. Some workers have suggested that, paradoxically, patients who are severely deficient in factor XII may be hypercoagulable. It is important to identify this factor deficiency both because needed invasive procedures can be done in its presence when it is an isolated

abnormality and to avoid unnecessary correction of the PTT with FFP.

FACTOR XIII

Deficiency of factor XIII[24] is usually lifelong and may be associated with significant bleeding problems of the delayed type. In homozygotes there is an increased risk of fatal intracranial bleeding; spontaneous abortion also has been noted. Rarely, an acquired deficiency is seen in patients who develop an inhibitor while taking a drug such as isoniazid. The diagnosis cannot be made from the usual clotting or bleeding time tests. Rather, this deficiency must be suspected and tested for directly. Clot dissolution in 5 *M* urea during overnight incubation indicates deficiency (<1% activity). The deficiency is readily corrected with FFP, cryoprecipitate, or a placental concentrate. Only 1% to 2% of the normal factor XIII activity is adequate for hemostasis and intact clot stability. The long half-life of this factor (8 days) permits long dosing intervals and relatively easy prophylaxis when a hemostatic challenge is anticipated.

VON WILLEBRAND'S FACTOR (VWF)[25]

Deficiency of VWF results in a bleeding disorder more akin to that associated with platelet dysfunction than to that of the hemophilias. Cardinal findings include a prolonged bleeding time and a moderately prolonged PTT with depression (usually mild) of the factor VIII coagulant (VIII:C) level. Decreased levels of ristocetin cofactor and von Willebrand's antigen also are found. Rapid screening for von Willebrand's disease using an in vitro platelet function analyzer can be helpful in diagnosis.[3] The most common variety of this disorder (type I) is characterized by a defect in secretion of normal VWF from vascular endothelial cells. Less commonly, qualitative defects in the multimeric structure of the factor (type II) or a severe deficiency in its synthesis (recessively inherited type III) is seen. Type I patients may respond to infusion of DDAVP (0.3 μg/kg IV) with a rise in VWF and other released endothelial products, some of which may have anticoagulant effects (such as prostacyclin [PGI_2] and tissue plasminogen activator). Usually there is a net hemostatic benefit, which is seen as an improved bleeding time over a several-hour period. Repeat doses may be given, but tachyphylaxis after 1 to 2 days precludes effective long-term therapy with DDAVP or reliance on it alone for major surgical procedures.

The Duke bleeding time was considered by some to be the best indicator of bleeding risk prior to invasive procedures, but critical review of the bleeding time[26] raises questions as to the predictability of bleeding from the result of this test in individual cases. A more extensive workup, including both functional studies (ristocetin cofactor, PTT, VIII: C, ristocetin-induced platelet aggregation) and antigenic studies (VIII-related antigen and multimer analysis), is useful in characterizing the type and potential severity of the defect. In acute situations when the diagnosis is known, measuring the VIII-related antigen level, if available, is a helpful way to monitor the patient's status and adequacy of replacement. The platelet function analyzer also may be used for rapid confirmation of improvement after treatment. The usual goal of therapy is normalization of the VWF level during active bleeding and before anticipated surgery or another invasive procedure. For severe deficiency and prolonged treatment, virucidal-treated factor VIII concentrates, which contain high levels of VWF (e.g., HUMATE P), are indicated. Monoclonal antibody–purified factor VIII concentrates are not useful because VWF is depleted from these products. DDAVP may be contraindicated in type IIB and platelet-type (or pseudo-) von Willebrand's disease—two conditions in which platelet aggregation and thrombocytopenia may ensue.

INHIBITORS[27]

Coagulation factor inhibitors may create life-threatening situations, especially in otherwise critically ill patients. The potency of the inhibitor can be determined by titration of the effect of plasma dilutions on the result of mixing the patient's plasma with pooled normal plasma (see above).

FACTOR VIII INHIBITORS

The most commonly encountered coagulation factor inhibitors are directed against factor VIII. They are seen most frequently in hemophiliac patients receiving supplementary factor replacement, but they also can occur sporadically in elderly individuals, in the postpartum period, and in persons with an autoimmune diathesis or lymphoma.[28] Factor VIII inhibition usually is measured in Bethesda units (BU); levels greater than 10 BU indicate more potent inhibitors. Testing to exclude a factor VIII inhibitor should be done before any significant invasive procedure is undertaken in a hemophiliac in order to make it possible to predict the response to factor replacement. It is also important to confirm that the expected response to factor administration has occurred before proceeding with an invasive procedure. For lesser titers, infusion of factor VIII concentrate often can override the inhibitor in the short term, although in some patients this approach will elicit a rise in the inhibitor titer. Other modes of therapy for high-titer inhibitors include bypassing the factor VIII–dependent step with prothrombin complex concentrate (PCC) or activated PCC, use of porcine factor VIII concentrates, and infusions of rVIIa. Combined immunosuppressant programs that include steroids, cytotoxic agents, plasma processing over columns that remove immunoglobulin G (IgG) and IgG-containing immune complexes,[29] and high-dose intravenous immunoglobulin are approaches to the subacute and chronic management of hemophiliacs with inhibitors. Recent favorable experience with rituximab has been noted.[30]

Inhibitors found in nonhemophiliacs tend to be more responsive to simpler immunosuppressive treatments, such as treatment with azathioprine and prednisone. There is a significant risk of bleeding in these individuals when the inhibitor is not controlled. If an underlying tumor or autoimmune disorder is present, its management may help to reduce the level of inhibitor. Surgical procedures in patients with inhibitors obviously are fraught with high risk, and meticulous hemostatic correction perioperatively is necessary. Correction needs to be maintained for at least 10 days after major procedures (as in uncomplicated hemophilia) to prevent delayed bleeding.

LUPUS ANTICOAGULANTS

The presence of the so-called lupus anticoagulant[31] is important to recognize because, although it is usually associated with a prolonged PTT, it may imply a hypercoagulable state rather than a bleeding diathesis. Rare individuals with lupus anticoagulants have a bleeding diathesis. Prolongation of the PT in addition to the PTT may be an indicator of such a case.

This phospholipid inhibitor was first identified in patients with de novo systemic lupus erythematosus (SLE), but it is known to occur also in drug-induced SLE syndromes, in individuals with other autoimmune diseases, and in otherwise normal persons. The typical laboratory result is a prolonged PTT and/or Russell's viper venom time (RVVT) with evidence of an inhibitor and interference on several of the coagulation factor assays. An abnormally steep rise in the PT with serial dilution of thromboplastin in vitro is a characteristic finding (the tissue thromboplastin inhibition [TTI] test). This latter phenomenon may be mimicked by the presence of heparin and warfarin anticoagulation; therefore, it is preferable to perform the test, if possible, before anticoagulation is begun. Absorption of the patient's plasma with platelet phospholipid in vitro may remove the inhibitor and lead to normalization of the PTT, TTI, and RVVT test results, thus enhancing the specificity of diagnosis.

Most patients with the lupus anticoagulant do not have coagulation problems, but approximately 25% have clinically important hypercoagulability. It is unclear whether empirical prophylactic long-term anticoagulation with warfarin is useful. Perioperative prophylactic dose heparinization is recommended to offset added surgical hypercoagulable risks. If thrombotic problems—typically venous (deep venous thrombosis, pulmonary emboli)—do occur, chronic anticoagulation with warfarin is recommended. Results of the PT are sometimes unpredictable in patients with lupus anticoagulants. Chromogenic factor X levels may be more reliable for monitoring the degree of warfarin effect. Increased risk for arterial clotting events also is present.

The potency of lupus anticoagulants may diminish spontaneously as a result of the discontinuation of an offending drug (e.g., procainamide, phenothiazines) or in response to immunosuppressive therapy (e.g., with prednisone).

FACTOR V INHIBITORS[32]

Some patients exposed to topical bovine thrombin used as a surgical sealant may develop an inhibitor to factor V (a contaminant of the bovine product). On occasion, there can be significant lowering of the human factor V level because of cross-reactivity. The antibodies eventually disappear in a period of weeks, but treatment with plasma and platelets (thought to be site of factor V protected from the inhibitor) may be needed in individuals who bleed significantly.

COMBINED FACTOR DEFICIENCY STATES

VITAMIN K DEFICIENCY[33]

The combination of poor dietary intake and antibiotic therapy that is so common among ICU patients predisposes them to vitamin K deficiency. Impaired absorption of fat-soluble vitamins, as in biliary obstruction, may contribute as well. Prolongation of the PT initially and then of both the PT and the PTT is characteristic. Documentation of selected reduction of the levels of factors II, IX, and X is rarely needed to make this diagnosis; usually the initial decline in factor VII in the absence of other explanations (such as liver disease or warfarin anticoagulation) is sufficient. Vitamin K supplementation may be given orally, subcutaneously, intramuscularly, or intravenously. The oral and subcutaneous routes are preferred, if feasible, to avoid a risk of hematoma or, rarely, anaphylaxis after intravenous dosing.

DYSFIBRINOGENEMIA

A qualitative abnormality of fibrinogen may or may not be associated with clinically significant hypofibrinogenemia.[34] The diagnosis is made by finding a disproportionately low functional level of fibrinogen relative to the antigenic fibrinogen level. In addition to the variety of inherited fibrinogen abnormalities associated with bleeding, clotting, and wound dehiscence problems that have been recognized, an acquired decrease in fibrinogen function is seen commonly in the presence of parenchymal liver disease[35] and hepatomas.

If it becomes clinically necessary to correct the hypofibrinogenemia, infusion of cryoprecipitate is the method of choice (see above). A functional level of 100 mg/dL or greater is the usual goal of therapy.

Fibrinolytic Disorders

DEFINITIONS AND LABORATORY TESTING METHODS

Clot strength and stability are the keys to prevention of rebleeding and consequent development of hemorrhagic infarction after initial hemostasis. The covalent cross-linking of fibrin mediated by factor XIII is important for clot strength, and carefully regulated activity of the fibrinolytic system allows eventual clot degradation once the vessel is strong enough to handle re-established flow. The details of regulation of the fibrinolytic process, including its intensity and timing, are incompletely understood.

Fibrinolytic activity is mediated by plasmin, which is derived from the inactive plasma precursor plasminogen. Plasminogen can be activated by various endogenous kinases, including tissue plasminogen activator and urokinase, as well as by exogenous agents such as streptokinase. The activity of plasmin is regulated by a series of inhibitors, the most important of which is α_2-antiplasmin. The activity of the fibrinolytic system is assessed indirectly in vitro by measurement of concentrations of substrate (fibrinogen) and plasmin-generated breakdown products of fibrinogen and fibrin (FDPs, D-dimer). Lesser degrees of fibrinolysis may be detected by measuring the level of plasmin-antiplasmin complexes.

PRIMARY FIBRINOLYSIS

It is helpful to distinguish so-called primary fibrinolysis, in which plasmin is generated from plasminogen by an activator in the plasma, from secondary fibrinolysis, in which plasmin is generated within a formed clot by an activator that is also present. Primary fibrinolysis (fibrinogenolysis) is seen in states of tissue injury such as liver disease or therapeutic administration of activators such as urokinase and streptokinase. Secondary fibrinolysis is the normal mechanism of clot degradation initiated by tissue plasminogen activator. The latter process is accelerated pathologically in DIC.

SECONDARY FIBRINOLYSIS

The in vitro tests of clot lysis, such as the euglobulin lysis time, are sensitive to generation of circulating plasmin and therefore give shortened times in primary fibrinolysis but normal times in secondary fibrinolytic states (e.g., DIC). Levels

of fibrinogen and FDPs do not distinguish the two mechanisms. D-dimer is a unique degradation product of cross-linked fibrin that is not seen among the products of plasmin digestion of fibrinogen. As such, it is helpful in distinguishing fibrinogenolysis from fibrinolysis. This test is especially helpful in evaluating states of increased clot formation such as DIC. However, it must be emphasized that elevated D-dimer levels do not indicate the mechanism of clot generation. For example, high levels of D-dimer may be present during the dissolution of a hematoma, and it would be wrong to assume that DIC necessarily was the cause of the original clot.

Complex Coagulopathies

ACUTE DISSEMINATED INTRAVASCULAR COAGULATION[13]

The most important complex coagulopathy in intensive care medicine is acute DIC. DIC is essentially a state of increased propensity for clot formation; it may be triggered by a variety of stimuli related to such diverse underlying disorders as sepsis, tissue injury, and neoplasm. There may be clinical and laboratory evidence of hypercoagulability, but in acute cases, consumptive coagulopathy with hemorrhagic manifestations may predominate. The full-blown state is characterized by thrombocytopenia, prolonged clotting times, depressed circulating levels of cascade factors (especially factor VIII), and increased fibrinolysis manifested by high FDP and D-dimer levels as well as hypofibrinogenemia. There may be associated hemolysis with evidence of microangiopathic changes on blood smear (schistocytes) in some patients. Organ dysfunction secondary to vaso-occlusion or hemorrhage may be evident. DIC should be suspected when such a complex coagulopathy appears, especially if the clinical setting would predispose the patient to it.

The key step in management is treatment of the underlying condition that is responsible for the hypercoagulable state (e.g., antibiotic treatment for infection). Transfusion of blood products, including RBCs, platelets, FFP, and cryoprecipitate, if needed for the correction of severe hypofibrinogenemia, may protect the patient from hemorrhagic complications while the mechanism triggering the DIC is being eliminated. Although, in theory, blood product support may temporarily "feed the fire," often patients benefit from such treatment without requiring heparin therapy with its attendant potential complications.

In cases of purpura fulminans and massive thromboembolism, where the pace of the process is catastrophic, a trial of heparin therapy is appropriate (or drotrecogin in severe sepsis), along with blood product support, especially in patients who have potentially treatable underlying disorders that can be expected to respond reasonably promptly with appropriate specific therapy. The doses of heparin required are variable because of heparin resistance in DIC (owing to low levels of antithrombin III and elevated levels of PF4). The necessary dose may vary initially from 5 to 10 units/kg/h, given by continuous intravenous infusion up to full therapeutic levels. The criteria usually used to determine whether heparin is helpful include clinical observation of lessened bleeding and a rise in fibrinogen levels and platelet counts.

There are obvious risks to the use of heparin because of uncertainty as to the optimal dose and because the addition of an anticoagulant drug makes it difficult to interpret the results of clotting tests. Heparin therapy usually is not indicated for patients with bleeding in critical areas, such as intracranial locations. In addition, isolated antifibrinolytic therapy with agents such as ε-aminocaproic acid is contraindicated because of the risk of extensive thrombotic complications. For more chronic, low-grade DIC, subcutaneous heparin (e.g., 5000 units every 8 to 12 hours) or low-molecular-weight heparin may be helpful in preventing clinical thrombotic complications.

Laboratory parameters for following DIC include clotting times, platelet count, and fibrinogen level (assuming they are not disturbed simultaneously by an underlying process such as leukemia or liver failure). FDP levels are good markers for the detection of fibrinolysis but tend to lag as indicators of improvement.

MASSIVE TRANSFUSION

Patients who have had one to two blood volumes replaced with stored RBCs within 24 hours are subject to the development of a complex coagulopathy, the most important feature of which is thrombocytopenia owing to both dilutional and consumptive mechanisms.[36,37] In addition, there may be impaired platelet function and lowered levels of plasma factors VIII and V. Successful management of this coagulopathy depends on recognition of the developing pattern and administration of sufficient platelets and FFP to offset the effects of dilution. More serious disturbances of hemostasis appear if DIC develops as a consequence of the underlying shock and/or tissue injury (see above). There has been recent interest in use of rVIIa to help control hemorrhage and thereby reduce the need for massive transfusion.[38,39]

ANTIBIOTIC THERAPY

Use of multiple or broad-spectrum antibiotics predisposes the patient to combined coagulation defects. Vitamin K deficiency is common. Impaired platelet function manifested by prolonged bleeding time has been observed with carbenicillin[40] and related antibiotics.

LIVER DISEASE[41]

Because of the key role of the liver in clotting factor and thrombopoietin synthesis, coagulopathies are an important part of liver dysfunction. Not only are clotting times prolonged, but if there is associated hypersplenism, thrombocytopenia also may be present. Underproduction of thrombopoietin and immune thrombocytopenia secondary to hepatits C, alcohol, and folate deficiency are also potential factors contributing to lowered platelet counts. Platelet dysfunction (usually mild) also may be present. In addition, primary fibrinolysis secondary to liver cell injury may occur, creating a picture that may mimic DIC. It is not unusual to see DIC superimposed on liver failure causing a severe complex coagulopathy. The pattern of fibrinolysis and the factor VIII:C level may be helpful for distinguishing the coagulopathy of advanced liver failure from DIC. Primary fibrinolysis (short euglobulin lysis time) and elevated factor VIII:C levels are seen in liver disease; findings of secondary-type fibrinolysis (normal euglobulin lysis time) and low factor VIII:C levels (as well as more elevated levels of D-dimer) favor DIC. Placement of shunts to drain

ascites into the venous circulation may be associated with accelerated DIC and bleeding risk.

Therapy for the coagulopathy of liver disease consists of replacement of clotting factors and platelets as well as correction of vitamin K deficiency. If volume considerations permit, FFP is used first. Often it is necessary to use prothrombin complex for adequate correction prior to invasive or surgical procedures. The risks of administration of this product include enhanced coagulation and, in some instances, DIC owing to the presence of activated clotting factors in the concentrate. Prothrombin complex concentrates replace only the vitamin K–dependent factors, not all the clotting factors made in the liver. Other approaches to life-threatening hemorrhage in patients with liver failure have included use of fibrinolysis inhibitors and, more recently, rVIIa.[39]

RENAL DISEASE[41]

Uremic patients are likely to have a bleeding diathesis, which most commonly is a thrombocytopathy characterized by a prolonged bleeding time. The disease underlying the renal failure also may, of course, predispose the patient to a coagulopathy (e.g., immune thrombocytopenia due to SLE, factor X deficiency secondary to amyloid, low antithrombin III and factor IX levels in nephrotic syndrome of various causes). The thrombocytopathy becomes especially important if surgical interventions such as renal biopsy are needed. Adequate acute or subacute hemostasis usually can be achieved by using one or more of the treatments discussed earlier, but chronic protection from bleeding is more difficult to achieve. Hemostasis may be improved in uremia after treatment with recombinant human erythropoietin.[42]

DYSPROTEINEMIAS[43]

Patients with multiple myeloma or Waldenstrom's macroglobulinemia may have significant bleeding problems in addition to the thrombocytopenia that may accompany advanced disease or be a consequence of treatment. Both impaired platelet function (prolonged bleeding time) and prolonged TT secondary to interference with the conversion of fibrinogen to fibrin may be seen. The mechanism of these effects is not fully understood but is thought to involve the physical "coating" of the platelets by the paraproteins, which reduces the exposure of the phospholipid template that is needed for key steps of the cascade. Steric hindrance of the process of fibrin formation also may play a role. These adverse effects on coagulation tend to improve with a decline in paraprotein levels (owing to chemotherapy-induced decreased production and/or to removal by plasmapheresis).

Coagulation Status: Guidelines for Invasive Procedures

GENERAL CONSIDERATIONS

The following guidelines should be used in the management of patients with coagulopathies:

1. Invasive procedures should be performed only when absolutely necessary in patients who have coagulopathies or can be expected to develop them as a result of their disease or its therapy.
2. Intervention(s) should be as limited as possible, and procedures that can be performed under direct vision are preferred. Direct vision allows the operator to be sure that primary hemostasis has been achieved and facilitates follow-up for detection of delayed bleeding.
3. The clinician should be certain that the preliminary coagulation status is fully delineated so that potential bleeding risks can be anticipated accurately and the correct therapeutic agents can be available.
4. If a preparatory treatment (e.g., infusion of factor VIII concentrate) or a change in medication (e.g., discontinuation of an anticoagulant drug) is indicated, the clinician should check that the expected beneficial effect actually has occurred before the procedure is begun.
5. The timing of procedures for which supportive products will be needed should be coordinated with the providers (e.g., the blood bank or pharmacy) so that an adequate supply is available for the anticipated duration of support. One should be liberal in estimating needs so that unexpected complications can be covered.
6. The patient should be monitored carefully for both immediate and delayed bleeding to detect status changes early. Other health care personnel should be alerted to the potential for bleeding and the appropriate therapy based on previous evaluation.
7. In a patient who has been evaluated and treated for a coagulopathy, it is important to be alert to the possible effects on coagulation of changes in either medical status (e.g., the onset of sepsis) or medications. Reassessment may be necessary if the patient shows a decreasing response to therapy that was effective initially.

SPECIFIC COAGULOPATHIES

VASCULITIS

Patients with vasculitic rashes may have very long bleeding times that prohibit skin incision. Discontinuation of an offending drug and trial of corticosteroids may be useful. Administration of platelets is not indicated unless thrombocytopenia or thrombocytopathy coexists.

THROMBOCYTOPENIA

For procedures that will be performed under direct vision, such as limited biopsies or peripheral line insertions, platelet counts of 50,000 to 80,000/μL usually are adequate, depending on the extent of the planned intervention. For major surgical procedures, insertion of lines in large central vessels, or closed-space needle biopsies, initial counts in the range of 80,000 to 100,000/μL are preferred (assuming that platelet function assessed by the bleeding time is normal). Lumbar punctures usually are performed safely at platelet counts of greater than 50,000/μL.

THROMBOCYTOPATHY

Thrombocytopathic bleeding can be very difficult to manage, especially if the environment into which new platelets are transfused is deleterious to their function. Thus, in uremia, for example, multiple transfusions of normal platelets may be ineffective. Other methods of therapy discussed in earlier sections of this chapter may be helpful in this situation. The

bleeding time may not be corrected significantly in some patients. The predictive value of the skin incision bleeding time in individual patients has been questioned, but it seems prudent to attempt to shorten a prolonged bleeding time, when possible, before an invasive procedure is performed.

Drug-induced thrombocytopathies may be easier to manage if the drug has a reasonably short half-life or if its inhibitory effect on platelet function is reversible (as with NSAIDs, for example). After the drug has been discontinued and its effect has dissipated, new platelets produced by the patient's marrow and (if needed for an acute intervention) transfused normal platelets will correct the prolonged bleeding time. In urgent situations, DDAVP infusions may be used to override, at least temporarily, the thrombocytopathic effects of aspirin and ticlopidine.[44]

THROMBOCYTHEMIA

Patients with myeloproliferative disorders and elevated platelet counts (usually in excess of $1 \times 10^6/\mu L$ but sometimes in the range of 0.5×10^6 to $1 \times 10^6/\mu L$) may have excessive bleeding, either spontaneously or following trauma or surgery. It is generally advisable to lower the platelet count into the normal range, but even when this goal is achieved, some patients have considerable bleeding difficulties. The bleeding time may be a helpful predictor. It is wise, when possible, to avoid or minimize invasive procedures in these individuals. Similar precautions are indicated in individuals with a bleeding diathesis due to a myelodysplastic disorder.

FIBRIN GENERATION CASCADE DEFECTS

A PT and PTT that are at least normal should be insisted on, if they are achievable, for procedures in which excess bleeding could seriously compromise the outcome (e.g., intracranial neurosurgery) or for closed-space procedures in which mechanical hemostasis is difficult to achieve or in which the extent of bleeding may not be obvious until it is significant. More precise correction of factor levels than that produced by achieving normal clotting times is indicated for such procedures in patients with known factor deficiency states, such as hemophilia A.

For procedures done under direct vision or for line placements, there may be a greater tolerance for impaired clotting times. The clotting times should not exceed 1.2 to 1.3 times the baseline value under these circumstances. In contrast to platelet-related problems, bleeding in patients with cascade deficiencies may be delayed in onset and, therefore, unexpected by uninformed medical and nursing staff. The risk of bleeding with liver biopsy, for example, may be reduced by using transjugular or laparoscopic techniques.

FIBRINOLYTIC STATES

Hyperfibrinolytic states leading to short clot survival, hypofibrinogenemia, and elevated levels of FDPs may be associated with serious bleeding during and after procedures. Intracranial bleeding, thrombotic events, and recent major surgical procedures are contraindications to the initiation of fibrinolytic therapy because of the risk of clot breakdown. If possible, invasive procedures should not be performed while the patient is in a fibrinolytic state. If bleeding occurs during fibrinolytic therapy, the usual approach is to discontinue the drug, provide blood product support (including cryoprecipitate as a source of fibrinogen, if needed), and wait until the fibrinolytic state subsides.

ANTICOAGULANT DRUG EFFECTS

Unfractionated Heparin

The heparinized patient who needs to undergo an invasive procedure usually can be managed by discontinuation of heparin approximately 6 hours beforehand. In urgent circumstances, neutralization with protamine sulfate can hasten preparation.

Low-Molecular-Weight Heparin (LMWH)

Invasive procedures, e.g., epidural anesthesia, have been complicated by bleeding in patients who stopped LMWH therapy shortly beforehand. Because of lack of a predictably effective antagonist, it is important to know the anticoagulated status of these patients before procedures are initiated. LMWH levels can be helpful in assessing residual presence of these agents and possible bleeding risk.

Warfarin

After discontinuation or tapering of warfarin therapy prior to an intended procedure, it may take 2 days or more for the PT to normalize. In emergent situations, use of FFP or prothrombin complex (if volume overload is a problem) can provide immediate correction by supplying the missing factors. Oral or intravenous vitamin K (1 to 5 mg) has its onset of effect approximately 8 to 12 hours after administration. The use of vitamin K in higher doses may lead to a subsequent state of warfarin resistance. The use of prothrombin complex may be associated with induction of a hypercoagulable state. This agent should be reserved, therefore, for urgent indications. During the period following tapering of warfarin, temporary heparinization can allow more flexible planning of interventions; heparin should be discontinued 6 hours before an invasive procedure. In patients unable to receive heparin or LMWH, warfarin can be continued throughout the perioperative period, with FFP used to override its anticoagulant effect, until it is safe to re-establish anticoagulation.

Direct Thrombin Inhibitors

Although their half-lives are short, hirudin and argatroban effects need to be monitored closely by following the PTT level once they have been discontinued to be certain that there is no lingering anticoagulation prior to an invasive procedure. Lack of an effective antagonist for either of these drugs makes rapid reversal of their effects problematic.

Drotrecogin Alfa (XIGRIS)[45]

Drotrecogin alfa is a recombinant activated protein C product with antithrombotic and profibrinolytic properties used in the management of patients with severe sepsis. Its major side effect is risk of bleeding, especially on day 1 of the 96-hour infusion period. Forty-three percent of serious bleeding events were procedure-related.[46] Coexisting thrombocytopenia of $30{,}000/\mu L$ or less was a frequent concomitant risk factor. It is recommended that infusion of the drug be discontinued 2 hours prior to an anticipated procedure and that the platelet count be maintained above $30{,}000/\mu L$. The drug variably affects the PTT and assays of intrinsic pathway factors but has little effect on the PT or assays of factors that influence the PT. If otherwise

safe, it is recommended that a 12-hour period elapse after a significant procedure before cautiously restarting the infusion.

Chapter 70

THROMBOTIC THROMBOCYTOPENIC PURPURA, HEMOLYTIC UREMIA SYNDROMES, AND THE APPROACH TO THROMBOTIC MICROANGIOPATHIES

LAWRENCE TIM GOODNOUGH

KEY POINTS

- *The thrombotic microangiopathies (TMAs) include the spectrum of thrombotic thrombocytopenic purpura (TTP) and hemolytic uremic syndromes (HUS) as well as related obstetric syndromes.*
- *The hallmarks of TMA are a microangiopathic hemolytic anemia (MAHA) and thrombocytopenia.*
- *TMA must be distinguished from other coagulopathies, such as disseminated intravascular coagulation (DIC) and collagen vascular disease with vasculitis, since therapeutic approaches differ.*
- *The clinical presentation of TTP/HUS is characterized by a pentad of findings: MAHA, thrombocytopenia, neurologic abnormalities, renal dysfunction, and fever.*
- *Plasma exchange is the therapy of choice for TTP/HUS, with adjunctive therapies including plasma infusion, corticosteroids, splenectomy, and/or immunosuppressive agents.*
- *TTP/HUS is a hematologic emergency, and patients are at risk of developing tissue anoxia, lactic acidosis, renal failure, or catastrophic central nervous system injury.*
- *Plasma exchange may be complicated by catheter accidents, air embolus, citrate toxicity, and pulmonary edema.*

Moschcowitz's original description of TTP in 1925 was based on a triad of findings: anemia (of the microangiopathic hemolytic type), thrombocytopenia, and neurologic symptoms. In 1966, 271 cases of TTP were reviewed, and the features of fever and renal impairment were added to form a clinical pentad.[1] Subsequent series have confirmed that renal involvement is common, with proteinuria, hematuria, or azotemia seen in 80% of patients with TTP.[2,3] Hemolytic uremic syndromes (MAHA, thrombocytopenia, and renal failure) are regarded as part of a spectrum of TMA, which at one end consists of TTP with predominantly neurologic findings and minimal renal abnormality, and at the other end consists of profound renal dysfunction with little or no central nervous system (CNS) pathology. The latter syndromes are more common in childhood, in the postpartum period, and following use of chemotherapeutic (mitomycin C) or immunosuppressive (cyclosporine) agents. On occasion, the evolution of renal manifestations in TTP can become indistinguishable from HUS, so that attempts at rigid distinction are generally unrewarding.[4]

The age of onset of TTP/HUS ranges from infancy to the eighth decade, with a peak incidence in the third decade. Females are more frequently affected than males by a ratio of 2:1. Childhood HUS often presents with antecedent illness, typically gastroenteritis related to enterotoxin-producing strains of *Escherichia coli* or *Shigella*. TMA associated with pregnancy includes several syndromes with considerable overlap, making prospective differentiation difficult.[5,6] Pregnancy-induced hypertension (PIH; eclampsia and pre-eclampsia) is often associated with subtle laboratory abnormalities consistent with a degree of underlying TMA; on occasion this becomes clinically significant. When *h*ypertension, *e*levated *l*iver enzyme levels, and a *l*ow *p*latelet count occur together as a syndrome in the peripartum period, the term HELLP syndrome is applied (see Chap. 105). TTP may also be encountered in the second or third trimesters of pregnancy; unlike thrombocytopenias associated with PIH, it may not improve rapidly with termination of the pregnancy and may require further treatment. Finally, postpartum HUS is distinguished by its onset after delivery. Characterization of TMA in pregnancy is often made in the context of this clinical information.

TTP syndromes have also been described as drug-induced in patients receiving antiplatelet agents,[7,8] chemotherapeutic agents[9] (such as mitomycin C), or immunosuppressive agents (such as cyclosporine or FK 506)[10] following organ transplantation. Transplantation patient populations are growing, and these patients are likely to be encountered in the critical care environment. Transplant patients are at risk for multiple complications that may be associated with coagulopathy and cytopenia, so making the correct diagnosis is challenging. TTP/HUS has also been associated with human immunodeficiency virus (HIV) infection,[11] and more recently TTP/HUS has been identified as a complication related to antiplatelet therapy such as ticlopidine[7] and clopidogrel.[8]

TTP/HUS has also been described as a complication in patients with collagen vascular disease such as systemic lupus erythematosus (SLE).[12] Vasculitic syndromes and end-organ involvement in these patients may mimic the clinical pentad associated with the TTP syndrome, making clinical differentiation between these two syndromes problematic.

Despite the well-described association of TTP/HUS syndromes with pre-existing comorbidities or inciting agents, most cases of TTP currently present as idiopathic, community-acquired syndromes, perhaps in association with an antecedent viral syndrome. Much progress has been made in recent years regarding the pathophysiology of TTP in this setting, which is discussed below.

Clinical Presentation

The clinical presentation of TTP varies with the extent and severity of the thrombotic lesions. Neurologic findings can be nonspecific and include headache alone or with changes in mental status. Often these seemingly minor manifestations of disease are discovered by careful history-taking to have preceded more fulminant findings associated with anemia, thrombocytopenia, or renal failure. Neurologic findings may be more obvious, including seizures, obtundation, focal neurologic deficits, or coma. Altered mental status in TTP has

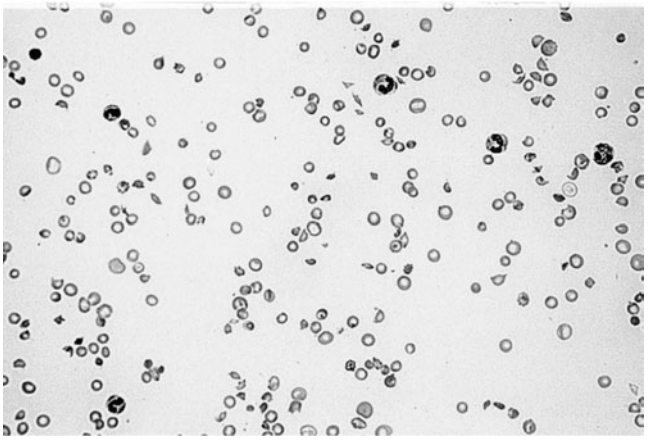

FIGURE 70-1 Admission (hospital day 1) peripheral blood smear (Wright-Giemsa stain) showing characteristic RBC morphology of microangiopathic hemolytic anemia (× 350) (see Color Plate 70-1).

also been described as secondary to nonconvulsive status epilepticus.[13] Fever is present in approximately two thirds of cases.

Although the presence or absence of renal failure may affect prognosis, the heterogeneity of patients with TMA is greater than this single clinical parameter.[4] Survival rates without (78%)[14] or with (83%)[15] acute renal failure have been reported not to be different. Thus while patients can be characterized according to their extent of neurologic or renal abnormalities, at present a clinical distinction for adult patients with TMA between TTP and HUS does not seem useful.

Laboratory findings in TTP/HUS are often striking. Thrombocytopenia may be profound, with platelet counts of $<50{,}000/\mu$L frequently observed. Anemia is of a microangiopathic type, and the peripheral smear is remarkable for fragmented red blood cells (RBCs), polychromatophilia, nucleated RBCs, and a markedly diminished platelet count (Fig. 70-1; Color Plate 70-1). Intravascular hemolysis frequently causes elevation of total bilirubin (predominantly the direct fraction) and lactate dehydrogenase (LDH). Urinalysis usually reveals proteinuria or hematuria; varying degrees of diminished glomerular filtration rate may be seen. Diagnosis of TTP/HUS by tissue biopsy has been advocated by some, but findings are often consistent with, but not specific for, TTP/HUS. Gingival biopsy, a previously popular test, lacks sensitivity and specificity.[16]

Pathophysiology

The earliest pathologic descriptions of TTP/HUS emphasized the presence of hyaline thrombi in the terminal arterioles and capillaries of the heart, liver, and kidneys. These hyaline deposits have subsequently been shown to consist largely of agglutinated platelets. A degree of associated fibrin deposition is regarded as a secondary phenomenon, since its presence is variable and patients with TTP do not routinely exhibit the coagulation abnormalities of DIC.

The pathogenesis of this diffuse microvascular thrombosis, while unclear,[17] is becoming better understood. The initial event is inappropriate platelet adhesion, aggregation, and mediator release on endothelial surfaces that results in vascular occlusion, with the characteristic hyaline thrombi of platelets and fibrin. Systemic endothelial cell damage appears to be a central component of the pathogenesis of TTP/HUS,[18] particularly in patients with virutoxin-mediated HUS associated with pathogenic *E. coli* or *Shigella*.[19] Endothelial damage stimulates the release of unusually large von Willebrand factor (vWF) multimers[20] that may cause platelet agglutination and microvascular occlusions.[21] Deficiency of a vWF cleaving protease (vWFCP, or ADAMTS13) was initially reported in patients with familial or idiopathic TTP, but not in patients with HUS.[22] However, other reports found reduced vWFCP levels in HUS,[23] and in other conditions with thrombocytopenia, including DIC and idiopathic thrombocytopenic purpura (ITP),[24] and in patients with liver cirrhosis, chronic renal insufficiency, and acute inflammatory states.[25] In one report, reduced vWFCP levels were observed in other thrombocytopenic disorders, and had only moderate sensitivity (0.45) and low specificity (0.30) in patients with a clinical diagnosis of TTP/HUS.[24] In a second report using a vWVFCP cutoff level of 30%,[26] the collagen-binding assay performed with a sensitivity of 94%, specificity of 93%, and a positive predictive value of 79%. Although vWFCP activity is decreased (<30%) in a substantial proportion of patients with thrombocytopenia of various causes, a severe (<5%) deficiency is more specific for TMA commonly labeled TTP.[27]

Inhibitors (characterized as IgG antibodies) against the vWFCP have been detected in one report in two thirds of plasma samples in the acute phase from patients with TTP-HUS.[28] Another report[29] found that 79% of patients with idiopathic, community-acquired TTP/HUS have low (<5%) levels of vWFCP; of these, vWFCP inhibitor was detected in 73%. vWFCP has recently been identified as a new member of the metalloproteinase family,[30] and was subsequently cloned.[31] Levy and colleagues[32] found that vWFCP is mutated in congenital TTP, thereby proving that the protease is directly involved in protection from microangiopathy. Finally, autoantibodies to vWFCP have also been found in patients who developed ticlopidine-associated TTP.[33]

A recent report suggested that in patients with TTP and normal vWFCP activity, factor V Leiden may be an important pathophysiologic risk factor.[34] While the vWFCP deficiency may not be specific for TTP,[23] its deficiency along with the presence of vWFCP inhibitor appears to correlate with a prolonged course and multiple relapses.[29,35] It is clear that disorders of diverse causes converge on a clinical phenotype that includes TMA,[36] and laboratory evaluations based on vWFCP levels and inhibitor assays will facilitate dissection of these potentially distinct entities.

Differential Diagnosis

The differential diagnosis of the thrombotic microangiopathies includes disease processes presenting with thrombocytopenia and MAHA (Table 70-1). Most commonly, the clinician must distinguish between TTP/HUS and the DIC syndromes or distinguish TTP/HUS from a collagen vascular disease (CVD) such as systemic lupus erythematosus (SLE) with vasculitis (Table 70-2). DIC may be associated with many diseases (see Table 70-1) and results in widespread generation and deposition of intravascular fibrin in small blood vessels,

TABLE 70-1 Differential Diagnosis of Microangiopathic Hemolytic Anemia

DIC syndromes
Purpura fulminans
Incompatible blood transfusion reaction
Sepsis
Amniotic fluid embolus
Dead fetus syndrome
Abruptio placentae
Massive tissue injury (trauma, burns)
Kasabach-Merritt syndrome (cavernous hemangioma)
SLE and other vasculitic syndromes
Pregnancy-associated syndromes
PIH
HELLP syndrome
HUS
Childhood-associated
Postpartum
Drug-induced (chemotherapy, cyclosporine, etc)
TTP

ABBREVIATIONS: DIC, disseminated intravascular coagulation; HELLP, hypertension, elevated liver enzymes, and low platelets; HUS, hemolytic uremic syndrome; PIH, pregnancy-induced hypertension; SLE, systemic lupus erythematosus; TTP, thrombotic thrombocytopenic purpura.

accompanied by a consumptive coagulopathy with clotting factor activation as a primary process. This condition is to be distinguished from TTP/HUS, in which the primary process is platelet aggregation at the vascular endothelial surface.

DISTINGUISHING THROMBOTIC THROMBOCYTOPENIC PURPURA FROM DISSEMINATED INTRAVASCULAR COAGULATION

DIC may be initiated by either endothelial injury (the intrinsic coagulation pathway) or release of tissue thromboplastin (the extrinsic coagulation pathway). Either process can cause platelets to undergo intravascular aggregation when exposed to collagen and thrombin. The clinical manifestations of DIC arise from injury related to intravascular thrombosis or from bleeding that results from consumption and depletion of clotting factors and platelets. Acute DIC syndromes usually present with bleeding and demonstrable hypo- or afibrinogenemia. In more chronic forms of DIC in which reticuloendothelial system clearance mechanisms, clotting factor production, and marrow cell production compensate for consumption, patients can present with thrombosis rather than hemorrhage. Typical thrombotic problems include deep vein or superficial thrombophlebitis, pulmonary embolus, cerebrovascular accidents, or nonbacterial (marantic) endocarditis.

TABLE 70-2 Laboratory Findings in Thrombotic Microangiopathies and Other Disorders

Parameter	TMA	DIC	SLE
RBC fragmentation	+++	+++	+
Thrombocytopenia	+++	+++	±
PT	Normal	Prolonged	Normal
PTT	Normal	Prolonged	Normal
Fibrinogen level	Normal	Low	Normal
Level of fibrin degradation products	Low	High	Low
Complement levels	Normal	Normal	Low

ABBREVIATIONS: DIC, disseminated intravascular coagulation; PT, prothrombin time; PTT partial thromboplastin time; RBC, red blood cell; SLE, systemic lupus erythematosus; TMA, thrombotic microangiopathy.

DIC shares with TTP the features of MAHA and thrombocytopenia (see Table 70-2). In one series, the frequency of MAHA as judged by peripheral smear was 68% in patients with DIC. In the same series, thrombocytopenia (platelet count $<150{,}000/\mu L$) was seen in 96% of cases of DIC; however, significant thrombocytopenia (platelet count $<50{,}000/\mu L$) was much less common (57%).

A number of laboratory findings will help to distinguish TTP from DIC (see Table 70-2). As noted above, hypofibrinogenemia is typical of fulminant, consumptive DIC. In addition, as clotting factors are consumed, prolongation of the prothrombin time (PT) and partial thromboplastin time (PTT) is seen. Also, the systemic generation of fibrin can lead to activation of the fibrinolytic system, either by activation of plasminogen by tissue activators released from vascular endothelium or by Hageman factor–dependent activation. Fibrinolysis results in the appearance of fibrin degradation products (FDPs) in the serum that can be measured. While none one of these laboratory tests alone can distinguish TTP from DIC, in the aggregate they are sufficient to permit a specific diagnosis (see Table 70-2 and Chap. 69).

Finally, the clinical context will often help to determine if DIC is a viable explanation for the observed abnormalities. Most often, the disease or disorder that is the precipitant of DIC is apparent. Amniotic fluid embolus, retained products of conception, and abruptio placentae are obstetric complications often associated with DIC. Septicemia is the substrate for DIC in many patients encountered in the ICU. The presentation of these patients may be fulminant, as in the Waterhouse-Friderichsen syndrome (shock, bleeding diathesis, and adrenal insufficiency in association with meningococcemia), or more indolent, as in the complex postoperative patient with a "smoldering" intra-abdominal source of infection. Trauma is a well-recognized cause of DIC and fibrinolysis resulting from the exposure of tissue thromboplastins and plasminogen activators to plasma.[37] In trauma patients, unexplained bleeding during or after a surgical procedure may be the first manifestation of DIC. In the setting of head injury, as many as 70% of patients have clinical evidence of DIC.[38]

In summary, TTP/HUS can usually be distinguished readily from DIC by the clinical context and laboratory parameters. It is important to apply this principle, as all of the defining features of TTP/HUS—thrombocytopenia, MAHA, fever, neurologic dysfunction, and renal abnormality—are so common in the critically ill that a clear approach to this possible diagnosis is warranted.

APPROACH TO THE PREGNANT PATIENT

Hematologic aberrations associated with PIH (pre-eclampsia/eclampsia; see Chap. 105) include MAHA, thrombocytopenia, and alterations of the coagulation mechanism. Evidence of MAHA can be found in 2% to 15% of women with PIH, and thrombocytopenia has been reported in as many as 18% of patients. Thus a subset of patients with PIH will have

two of the cardinal hematologic abnormalities of TTP/HUS.[5] It has been suggested that PIH and TTP/HUS share pathophysiologic features, specifically aberration in prostaglandin metabolism at the platelet-endothelial cell interface. In this regard it is interesting that plasma exchange has been reported to be a successful therapy in PIH. A subset of patients with PIH and thrombocytopenia may have marked elevation of liver function tests (HELLP syndrome). Right upper quadrant pain is often present and may mimic cholecystitis or peritonitis.

Postpartum HUS is characterized by predominant renal involvement; neurologic signs and fever are usually absent. It has been suggested that this syndrome is a clinical counterpart of the generalized Schwarzman reaction. It is hypothesized that bacterial endotoxins or vasoactive amines are discharged into the maternal circulation and either stimulate the coagulation cascade or initiate thrombosis by damage to the vascular endothelium.

As mentioned above, DIC syndromes accompany major complications of pregnancy. Usually these processes are associated with a catastrophic process such as amniotic fluid embolus or abruptio placentae. Less apparent and more indolent DIC may be encountered with retained products of conception.

Finally, TTP/HUS itself is encountered in pregnancy but is rare, with approximately 70 cases reported. It is likely that most pregnant patients with thrombocytopenia and MAHA are best classified as having PIH with hematologic abnormalities.[10] The key features distinguishing these patients from the group with HELLP syndrome are the emergence of disease in late pregnancy, relatively mild hematologic irregularities, and prompt resolution of thrombocytopenia, MAHA, neurologic symptoms, and liver function abnormalities following delivery. HUS begins postpartum, with a predominance of renal dysfunction. DIC differs from TTP as described above (see Table 70-2). The small remaining group of patients whose clinical presentation is best described as TTP/HUS are best managed in pregnancy with the usual treatments (see below), with expeditious delivery or termination of pregnancy.[39,40]

DISTINGUISHING THROMBOTIC THROMBOCYTOPENIC PURPURA FROM COLLAGEN VASCULAR DISEASE

An association between TTP/HUS and SLE has been reported. In one review, evidence of SLE was found in 7 of 64 cases initially diagnosed as TTP/HUS.[1] TTP/HUS has also been reported in association with other CVDs, including rheumatoid arthritis, ankylosing spondylitis, and polyarteritis nodosa. On the other hand, vasculitis in association with SLE or another CVD may mimic TTP/HUS with findings of renal failure, fever, neurologic disturbance, thrombocytopenia, and MAHA. Serum complement levels are usually low in patients with vasculitis and normal in those with TTP/HUS (see Table 70-2). Antinuclear antibodies are positive in the great majority of patients with SLE. These CVD screening tests are indicated in all patients with a tentative diagnosis of TTP/HUS. If a diagnosis of a specific CVD can be made, therapy should be directed at that disorder, rather than at the associated hematologic problems.

Therapy

TTP/HUS is a hematologic emergency. Patients will often need ICU admission because of profound anemia, shock, lactic acidosis, respiratory failure, or deteriorating neurologic function. Intubation and mechanical ventilation may be required because of ventilatory failure complicating CNS involvement or because of direct lung injury associated with pulmonary vascular involvement by TTP.[41]

PLASMA EXCHANGE

Once a diagnosis of TTP is made, plasma exchange is the therapy of choice. Since 1961, mortality for this disease has declined from >90% to <50%, likely owing to the institution of plasma exchange therapy. Some studies, however, have suggested that the overall mortality from TTP has actually increased in the United States in recent years.[3] The prognosis of TTP is improved by prompt recognition and treatment, so that emergency apheresis should be conducted in any patient diagnosed with TTP/HUS. Plasma exchange of 150% of the plasma volume is instituted (3 to 4 L for normal-sized individuals) with plasma replacement. Two intravenous sites are required for the procedure, which uses 17 gauge (draw line) and 18 gauge (return line) catheters. Ideally, plasma exchange is conducted through a double-lumen dialysis catheter. Special precautions should be taken when placing large-bore central catheters in these thrombocytopenic patients, such as ultrasound guidance or placement in a compressible vessel (jugular or femoral vein).

Potential complications of plasma exchange include those related to line placement, air embolus, citrate toxicity, pulmonary edema, and risks associated with plasma transfusion (hives, urticaria, rash, anaphylactoid reactions). In one series over a 6-year period, 54 major complications, including 3 deaths, were identified to be related to plasma exchange in 42 (28%) of 142 consecutive patients with TTP/HUS.[42] The risk of air embolus is reduced when the procedure is performed by experienced personnel. Machine safety devices include bubble traps and a bubble alarm that stops the machine when air is detected in the lines. Citrate toxicity can occur from the plasma citrate anticoagulant infused into the patient and is compounded by associated renal dysfunction. Citrate toxicity causes hypocalcemia and metabolic alkalosis and presents as oral paresthesias, numbness or tingling in the extremities, or a prolonged QT interval on the electrocardiogram. Hypocalcemia can be prevented by routinely administering 1 ampule of calcium gluconate by constant infusion per liter of plasma exchanged. An additional one half ampule may be administered if symptoms are experienced during the procedure. Periodic monitoring of ionized calcium levels is useful as well. In all cases, the relative benefits and risks of the procedure should be discussed with the patient or guardians, and informed consent obtained.

Plasma exchange should be performed daily until evidence indicates that the disease is in remission. The patient should have normal end-organ function, including normal mental status and renal function. The most sensitive indicator of response is a rising platelet count, which should be normal (>150,000/μL) for a number of days (3 to 5) before plasma exchange is discontinued. The LDH level is also a sensitive indicator of tissue hypoxia[43] and can be used to monitor the

response to therapy. RBC morphology on peripheral smear [see Fig. 70-1 (Color Plate 70-1) should be examined sequentially, although improvement in cell fragmentation can lag behind clinical responses (such as improving mental status) by several days. Bone marrow reticulocyte response may not occur for 3 to 5 days, depending on the pace of presentation of the disease. The patient should be given folate (1 mg or more daily) in this setting of poor dietary intake, plasma exchange, and increased marrow requirement.

The usual course of plasma exchange lasts 5 to 14 days. Patients can be moved from the ICU when mental status has normalized and hematocrit and platelet count are increasing. The shortest treatment requirement we have observed is 3 days. Late responses in occasional patients have occurred after 14 days of therapy. Continued plasma exchange may be required for up to 4 weeks as long as the patient remains stable or is improving. Studies have suggested that under conditions of massive plasma replacement, plasma depleted of the largest multimers of von Willebrand factor (cryoprecipitate-poor plasma) might be preferable for the treatment of patients with recurrent or refractory TTP.[44] Patients have been reported to respond to this cryosupernatant fraction as replacement fluid, despite having been refractory previously to plasma replacement therapy;[45] the current standard for initial therapy, however, remains apheresis with plasma replacement.[46]

SALVAGE THERAPIES FOR PATIENTS WHO RECUR OR FAIL TO GAIN REMISSION

Early relapse rates of up to 37% have been reported in patients with TTP/HUS, and 40% of centers routinely use a tapering schedule of apheresis.[47] Occult infections have been described in association with refractory or recurrent TTP/HUS.[48]

With the emerging evidence that some fraction of patients with TTP-HUS may have an autoimmune disease, along with the recognition that sustained treatment with plasma exchange is not without risk,[42] there has been a re-examination of the potential usefulness of salvage therapies for patients with refractory TTP-HUS. Cryosupernatant plasma has been suggested to have a theoretical benefit over fresh frozen plasma (FFP) because it is depleted of vWF, and a retrospective study suggested efficacy.[45] Glucocorticoid therapy is commonly utilized in patients with TTP-HUS; despite one favorable review[49] on its value, no randomized study assessing an impact on the prognosis of TTP-HUS has been performed.[50]

Splenectomy has been reported to be of value[51–60] in patients who do not have a complete or lasting response to plasma exchange. The value of splenectomy may be due to the removal of a major site of synthesis of a pathogenic IgG.[28] In one report[51] in patients who failed exchange, 9 (70%) of 13 refractory patients treated with splenectomy survived.

ADJUNCTIVE THERAPIES

In patients with an incomplete clinical response, splenectomy should be considered. High-dose steroid therapy has been advocated by some,[61] but without convincing evidence of benefit.[50] Our current approach is to use steroids only in patients who do not respond to plasma exchange and in those with a concurrent diagnosis of collagen vascular disease. Vincristine, presumably acting as an immunosuppressant, has also been reported to produce sustained remissions in a small series.[62]

In view of the pathophysiology of TTP/HUS, antiplatelet agents seem to be a rational addition to treatment. However, clinical trials have not shown a convincing impact of these drugs, including intravenous prostacyclin. Aspirin is difficult to give to an obtunded or comatose patient, and we discourage nasogastric tube placement for this purpose because of the risk of bleeding. Dipyridamole can be given intravenously. While larger series have shown that plasma exchange therapy coupled with antiplatelet agents results in complete remission in approximately two thirds of patients,[63] antiplatelet therapy is no longer routinely used.

Plasma infusion therapy is useful in many patients, particularly those with chronic relapsing TTP/HUS. While plasma infusion (12 U every 24 hours) can be used acutely in patients at facilities that lack apheresis capability, this therapy should not delay the institution of plasma exchange nor prevent the transfer of the patient to a fully equipped referral unit.

Platelet transfusion is relatively contraindicated in TTP, because of clinical evidence that it is associated with relapse.[64] If a diagnosis of TTP has been made, we do not recommend routine use of platelet support, except during invasive procedures. Heparin has been advocated for patients with HUS, but a randomized trial in pediatric patients failed to show benefit.[65] Supportive therapy for HUS often requires renal dialysis, and plasma exchange may be considered for patients with HUS and rapid disease progression.[40]

Therapy with rituximab, a chimeric anti-CD20 monoclonal antibody directed against B lymphocytes, along with cyclophosphamide therapy has been described to successfully treat a patient with TTP/HUS that was chronically refractory (more than 2 years) to previously administered therapies including apheresis, steroids, splenectomy, vincristine, and cyclosporine therapy.[66] This patient had a severe deficiency of vWFCP (ADAMTS13) activity and an antibody to ADAMTS13. Even during periods of clinical hematologic remission, the anti-ADAMTS13 was detectable and the ADAMTS13 levels remained low. Two courses of cyclophosphamide followed by rituximab therapy subsequently resulted in sustained clinical remission, along with disappearance of the ADAMTS13 inhibitor and detectable levels of ADAMTS activity (>17%) after more than 18 months of follow-up (see Fig. 70-2).

Prognosis

Despite a recent single-institution report of a 91% survival rate in patients with TTP,[61] a review of 52 patients treated over 10 years at our own institution revealed a 33% mortality from TTP/HUS.[51] This is in the same range as a 22% mortality rate reported in a Canadian clinical trial of plasma exchange in patients with TTP.[14] A recent review of mortality data in the United States indicated that, despite a reduction in mortality related to TTP from nearly 100% of cases before the era of plasma exchange to an approximately 70% survival rate currently, the incidence of TTP-related deaths in the United States has increased over time.[3] African-Americans and African-American females in particular, are affected disproportionately. The increased incidence of HIV infection and

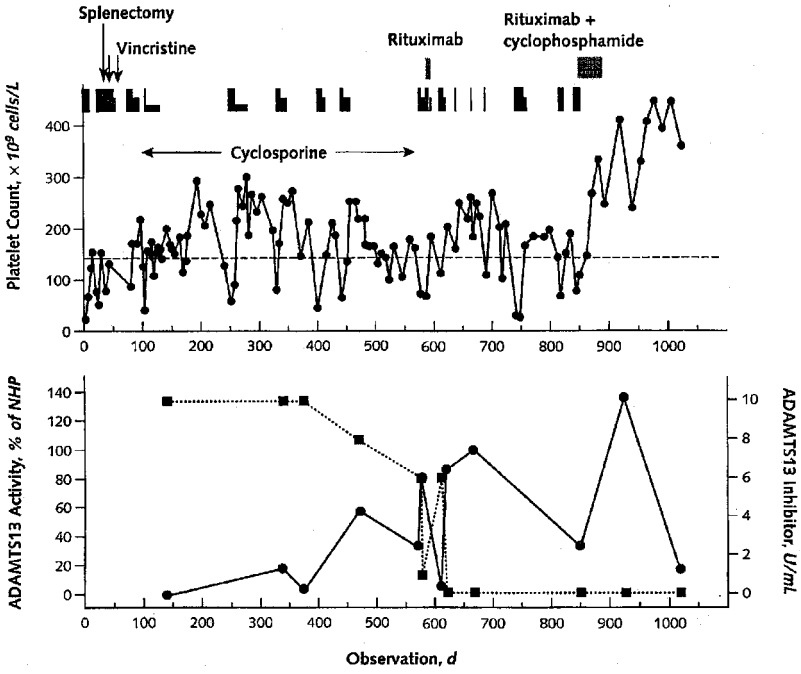

FIGURE 70-2 Platelet count (*top*) and ADAMTS13 activity (*bottom*) in a patient with TTP. Arrows indicate splenectomy and vincristine doses. Black bars indicate plasma exchange treatments; bars of full height, half height, and one third height represent treatment daily, every other day, or twice per week, respectively. The dashed line in the top panel represents the lower limit of normal platelet count (140×10^9 cells/L). In the bottom panel, the solid line represents ADAMTS13 activity and the dotted line represents ADAMTS13 inhibitor. NHP, normal human plasma. *(Reprinted with permission from Zheng et al.[66])*

related disease has contributed to some of the increase in TTP mortality in recent years, but it does not completely explain most of the increase, which began before the onset of the HIV epidemic.

Chapter 71
ACUTE LEUKEMIA

RICHARD A. LARSON
MICHAEL J. HALL

KEY POINTS

- *Many patients, especially children and younger adults, can be cured of acute leukemia with the use of intensive chemotherapy and skillful supportive care.*
- *The prognosis for the leukemia patient depends on the specific type of leukemia, defined by cytogenetics and immunophenotype, its stage, prior therapy, and coexisting chronic medical problems.*
- *Infection and bleeding are due to the severe pancytopenia caused by either the leukemia itself or its myelosuppressive treatment; these problems resolve as the normal bone marrow recovers.*
- *The success of chemotherapy for acute leukemia depends not only on the drug susceptibility of the individual patient's leukemia but also on the ability of that patient to survive the toxicity of treatment.*
- *Blood transfusions should be used to maintain a hematocrit greater than 30% and a platelet count greater than 10,000/μL.*
- *Hyperleukocytosis with malignant myeloblasts must be treated as a medical emergency with leukapheresis and chemotherapy.*
- *Central nervous system (CNS) leukemia can be treated successfully with radiotherapy, intrathecal chemotherapy, and high-dose systemic chemotherapy.*
- *Tumor cell lysis, aminoglycoside antibiotics, disseminated intravascular coagulation, elevated lysozyme levels, hyperuricemia, and direct infiltration by leukemia cells can lead to acute renal failure, which is often reversible with proper care.*
- *Necrotizing enterocolitis requires aggressive medical management with antibiotics, blood transfusions, nasogastric suction, bowel rest, and maintenance of normal serum proteins and electrolytes.*
- *Hyperuricemia is proportional in severity to the leukemia tumor burden, and it responds to effective chemotherapy together with administration of fluids, bicarbonate, rasburicase, and allopurinol.*

Acute leukemia is a malignant proliferation of bone marrow or lymphoid cells that is uniformly fatal when left untreated. However, with the use of intensive chemotherapy and skillful supportive care, many patients, particularly children and younger adults, can be cured of this devastating disease. Not uncommonly, use of the medical ICU is necessary during the treatment of acute leukemia to manage either the complications of the disease itself or the complications of intensive cytotoxic therapy (Table 71-1). Such newly diagnosed patients deserve maximum aggressive supportive care in the medical ICU because most of the acute complications of leukemia resolve as a complete remission (CR) is achieved. The successful treatment of patients with acute leukemia requires a multidisciplinary approach with close collaboration among intensive care physicians, hematologic oncologists, infectious disease specialists, and the blood bank. Twenty-four-hour physician coverage is necessary to respond to emergencies that otherwise could lead to rapid deterioration of a patient in the midst of treatment.

Appropriate decision making requires an understanding of the pathophysiology and clinical history of the leukemic disorders. The likelihood of a successful outcome from intensive care management depends in part on the specific type of leukemia and its stage; i.e., the prognosis depends on whether the patient is newly diagnosed and not yet treated or is in an advanced stage following multiple relapses. Knowledge of prior therapy aids in the evaluation of complications, especially with regard to opportunistic infections or organ dysfunction. Since accurate diagnosis and optimal initial treatment and supportive care are essential to achieving the best chance of curing acute leukemia, it is highly desirable that newly diagnosed patients be referred to regional oncology centers where appropriate expertise and resources are readily available.

This chapter briefly reviews the treatment strategy for acute leukemia and then focuses on the serious metabolic, circulatory, and infiltrative complications that most often necessitate ICU care. The far more common bleeding and infectious complications and direct drug toxicities are dealt with in Chaps. 47, 68, 69, and 74.

Differential Diagnosis

Leukemia and other cancers result from genetic alterations in somatic cells. When mutational damage alters normal growth-regulatory mechanisms in a hematopoietic stem cell, a clone of neoplastic cells may proliferate, overwhelming the normal bone marrow through a selective growth advantage, although not necessarily by more rapid growth. Cooperating mutations also affect differentiation and apoptotic pathways. Leukemia cells usually retain characteristics of their original cell lineage, allowing classification[1,2] (Table 71-2). However, because these cells are neoplastic, aberrant expression of proteins not usually manifested by normal cells in a particular hematopoietic lineage may be detected, yielding a "mixed cell" phenotype. The acute leukemias include acute myeloid (nonlymphocytic) leukemia (AML) and acute lymphoblastic leukemia (ALL), as well as the blastic transformations of chronic myelogenous leukemia (CML) and the myelodysplastic syndromes (MDS). Therapy-related AML occurs in patients following treatment with cytotoxic chemotherapy or radiotherapy for an earlier cancer or other disease.

Acute leukemia almost always causes marked abnormalities in the peripheral blood counts. Anemia may be mild, moderate, or severe, and the red blood cells may be macrocytic. Most patients will have moderate to severe thrombocytopenia. Although an elevated white blood cell count

TABLE 71-2 World Health Organization (WHO) Classification of Acute Leukemias and Their Clinical Features

Subtype	Type	Characteristic Features
Acute Lymphoblastic Leukemia		
	• Precursor B-cell ALL	80% of cases; t (9;22) portends a poor prognosis
	• Precursor T-cell ALL	20% of cases; 50% have a mediastinal mass
Acute Myeloid Leukemia (AML)		
	• AML with recurrent cytogenetic abnormalities	
	— t (8;21)	Neutrophil maturation
	— inv (16) or t (16;16)	Monocyte maturation; abnormal eosinophils
	— t (15; 17) (APL/M3)	Auer rods, DIC; responsive to ATRA
	— 11q23 abnormalities	Also in therapy-related leukemias
	• AML with multilineage dysplasia	Often pancytopenia, in older patients
	• AML and myelodysplastic syndromes, therapy-related	Related to prior alkylating agents, radiation, or topoisomerase II inhibitors; poor prognosis
	• AML otherwise uncatagorized	(FAB designation noted)
	—Minimal differentiation	(MO); No myeloperoxidase activity; ~5% of cases
	—Without maturation	(MI); ~10% of cases
	—With maturation	(M2); myeloid sarcomas, Auer rods; ~40% of cases
	—Myelomonocytic leukemia	(M4); Auer rods; ~25% of cases
	—Monoblastic and monocytic leukemia	(M5a/M5b); often with CNS involvement, gingival/skin infiltration; ~15% of cases
	—Erythroid leukemias	(M6); ~5% of cases
	—Megakaryoblastic leukemia	(M7); <5% of cases; often with extensive marrow fibrosis
	—Basophilic leukemia	<1% of cases
	—Panmyelosis and/or myelofibrosis	Rare; poor prognosis
	—Myeloid sarcoma	Rare; AML presenting as a solitary tumor mass
	• Acute leukemias of ambiguous lineage	~2–4% of cases; can be bilineal, biphenotypic, or undifferentiated
Chronic Myelogenous Leukemia–Blast Phase		Resembles acute leukemia; t (9;22) and/or BCR/ABL positive
	—Lymphoid blast phase	~30% of case; B-cell immunophenotype
	—Myeloid blast phase	~70% of cases; splenomegaly, fever, leukostasis, myeloid sarcomas
Burkitt Leukemia/Lymphoma		Aggressive mature B-cell neoplasm (TdT negative); high tumor burden in marrow and lymph nodes; EBV-related; *MYC* gene translocations diagnostic; high proliferative fraction

and readily recognizable circulating blast cells frequently are present, not all patients have leukocytosis. Some patients actually present with leukopenia, and malignant cells may not be observed in the peripheral blood. A careful review of a blood smear often demonstrates dysplasia in one or more cell lines. In elderly patients, AML frequently evolves from an MDS; mature granulocytes (called *pseudo-Pelger-Huet cells*) often are hypocellular with poorly condensed nuclear chromatin, and platelets may be large and may lack normal granulation. An overt or subclinical preleukemic phase may have been present for several months. The presence of greater than 20% blast cells in the marrow is the somewhat arbitrary dividing line between acute leukemia and the "preleukemic" disorder MDS.

The diagnosis and subclassification of acute leukemia rest on the interpretation of an adequate bone marrow sample. A marrow aspiration specimen, together with a bone marrow needle core biopsy from the posterior iliac crest, provides essential information. Auer rods are observed often in malignant myeloblasts. Cytochemical reactivity reveals myeloperoxidase or nonspecific esterase activity in myeloid leukemias, whereas such activity is absent in lymphoid leukemias.

Immunophenotypic analysis using flow cytometry or immunohistochemical techniques detects cell-surface antigens, whose presence supports the diagnosis. Cytogenetic analysis of bone marrow specimens provides important diagnostic and prognostic information.[3,4] Metaphase cells are karyotyped after direct preparation or short-term (24- to 48-hour) unstimulated culturing. Characteristic recurring chromosomal abnormalities include the presence of extra chromosomes, the loss of certain chromosomes, and structural rearrangements such as translocations, deletions, insertions, and inversions. Many distinct subtypes of acute leukemia can now be defined according to their characteristic morphologic, cytochemical, immunophenotypic, and cytogenetic features. These disorders have a more predictable clinical course than less well-defined leukemias, and this distinction is reflected in the current World Health Organization (WHO) classifications.[2]

Management of Acute Leukemia

The optimal chemotherapy for patients with acute leukemia has not yet been determined.[5–7] Recent clinical trials have identified different risk groups that are more or less likely to respond to standard chemotherapy programs (Table 71-3). Treatment is given in two or three phases: remission induction, consolidation, and in some cases, maintenance. The goal of *remission-induction chemotherapy* is to induce a complete remission. Any lesser response does not improve survival. *Complete remission* is defined by the absence of detectable leukemia in the bone marrow and blood, the regeneration of normal marrow elements, and the return to normal levels of all three blood cell lines for at least a month. This response reflects a reduction in the tumor cell mass by more than 3 logs (i.e., >99.9%). However, as many as 10^8 malignant cells may still persist at this point. If no postremission therapy were given, most patients with acute leukemia would relapse within 2 to 4 months. Thus *consolidation chemotherapy* (sometimes called *intensification therapy*) is directed at destroying any clonogenic leukemia cells that remain undetected after initial treatment. Consolidation therapy uses several monthly cycles (commonly one to four) of myelosuppressive chemotherapy, each sufficiently intense to produce bone marrow hypoplasia and peripheral blood pancytopenia. Various strategies using allogeneic bone marrow transplantation or high-dose chemotherapy followed by reinfusion of autologous marrow or blood stem cells collected earlier during remission are being tested as postremission consolidation treatments. Low-dose outpatient maintenance chemotherapy that does not lower the blood count has not been proved to increase the fraction of patients with AML who are cured, although 18 to 24 months of maintenance treatment seems useful for patients with ALL.

Patients who suffer a relapse of acute leukemia after completion of all therapy often can achieve a second remission with reinstitution of the original induction chemotherapy regimen. However, patients who relapse in the midst of initial treatment or while receiving maintenance therapy are less likely to achieve a second remission and rarely have long survival. Second and subsequent periods of remission usually are progressively shorter. The risks and costs of marrow/stem cell transplantation are easily justified for patients who have had a relapse of leukemia because otherwise disease-free survival is generally (but not always) short. Patients who are younger than 50 years of age and have a human leukocyte antigen (HLA)–identical sibling are good candidates for allogeneic transplantation. Many centers offer transplantation to selected patients up to 60 years of age. It may be possible to extend the upper age limit with the use of T-cell depletion from the donor marrow to diminish the incidence and severity of graft-versus-host disease (GVHD), as well as the introduction of less toxic "reduced intensity" stem cell transplant regimens. The use of marrow stem cells from a matched but unrelated donor is also feasible.

The success of chemotherapy for acute leukemia depends not only on the drug susceptibility of the individual patient's leukemia but also on the ability of that patient to survive the rigors of treatment. Significant advances have been made in the supportive care of patients undergoing intensive cytotoxic therapy. Prevention and early treatment of infection have been foremost. Prior to treatment, all patients should have a thorough dental evaluation and a computed tomographic (CT) scan of the sinuses to identify and eliminate potential sources for infections. Patients are placed in protective isolation in single rooms; in this way, these immunocompromised patients are protected from common infectious agents in the hospital environment. Laminar airflow rooms are not

TABLE 71-3 Common Chemotherapy Regimens for Acute Leukemia

AML
Remission Induction
Cytarabine and anthracycline* (7 days + 3 days)
Cytarabine, Daunorubicin, and Etoposide (7+3+3 or ADE)
High-dose cytarabine (HiDAC) and Daunorubicin
Post-remission Consolidation
High-dose cytarabine (HiDAC)
Cytarabine and Daunorubicin
Cytarabine and 6-thioguanine
Stem-cell transplantation (autologous or allogeneic)
Reinduction After Relapse
High-dose cytarabine (HiDAC) and mitoxantrone
Gemtuzumab ozogamicin (Mylotarg)
Mitoxantrone and etoposide
APL
Induction
ATRA (all-trans retinoic acid) plus daunorubicin (or idarubicin) with or without cytarabine
Consolidation
ATRA plus daunorubicin
Reinduction After Relapse
Arsenic Trioxide[24]
ALL
Induction
Daunorubicin, vincristine, prednisone (or dexamethasone), +/− L-asparaginase +/− cyclophosphamide
Consolidation
High-dose cytarabine
High-dose methotrexate
CNS prophylaxis with intrathecal methotrexate
Maintenance
6-Mercaptopurine and methotrexate +/− vincristine and prednisone.

*Daunorubicin, idarubicin, or mitoxantrone have been used.

necessary for successful treatment, but patients generally are restricted from eating fresh fruits and vegetables to decrease their enteric bacterial flora. Strict attention to thorough handwashing by all medical and nursing personnel and visitors is necessary.

Infection/Sepsis

Patients with leukemia are severely immunocompromised by both their disease and their treatment. Because chemotherapy damages mucosal barriers, these patients are susceptible to infection by endogenous organisms. Most common are gram-negative enteric bacteria, gram-positive cocci, and fungi such as *Candida* and *Aspergillus* species. Patients with ALL also are susceptible to *Pneumocystis*, mycobacterial, and viral infections. Prophylactic use of oral antibiotics such as fluoroquinolones can decrease the incidence and severity of infections in leukopenic patients. Antiviral and/or antifungal prophylaxis is also employed commonly in patients with profound or prolonged leukopenia.

Standard practice dictates that broad-spectrum antibiotic therapy must be initiated promptly and empirically in a granulocytopenic patient at the time of the first fever greater than 38.5°C (101.5°F). The Infectious Disease Society of America recently published guidelines on the management of these patients.[8] Blood, urine, and sputum cultures should be obtained, but the source of infection is rarely identified in part because there is little inflammatory response in the tissues. The first priority must be to prevent septic shock. Ceftazidime or imipenem as a single agent or the combination of a semisynthetic penicillin plus an aminoglycoside is widely used, but the choice of regimen depends in part on renal function and history of allergies. High-risk patients also should be given vancomycin without delay because nosocomial gram positive organisms may be resistant to methicillin. Should initial cultures reveal a pathogen, antibiotic therapy should be adjusted for maximum bactericidal activity based on susceptibility testing in vitro.

Pulmonary infiltrates in febrile leukemia patients should be managed aggressively in an attempt to identify the etiology and treat the underlying cause (Table 71-4). In general, however, broad-spectrum treatment continues until the chemotherapy is completed and the granulocyte count recovers to near normal.

Patients with acute leukemia are characterized by bone marrow failure owing either to replacement by leukemia cells or to chemotherapy-induced hypoplasia. Red blood cell transfusions are given to maintain a hematocrit of approximately 30%. A higher hematocrit should be maintained in hypoalbuminemic patients to keep the blood volume expanded and tissues perfused. While the general practice in critically ill patients has been to restrict red blood cell transfusion until the hematocrit falls much lower than this threshold, we believe that leukemia patients are a unique population not well represented in trials of transfusion strategies. If red blood cell transfusion is, in fact, immunosuppressive, it is unlikely to have much additional impact in chemotherapy-immunosuppressed leukemic patients. Further, these patients may benefit from the additional margin of safety that a higher hematocrit provides in case of thrombocytopenia-related hemorrhage.

TABLE 71-4 Evaluation and Treatment of Pulmonary Infiltrates in Febrile Patients with Acute Leukemia

Chest radiographs—posteroanterior and lateral
Sputum specimens for Gram staining and for bacterial, fungal, and acid-fast bacillus (AFB) cultures and sensitivity testing
Broad-spectrum empirical antibiotic therapy with
Ceftazidime (+/− vancomycin)
or
Imipenem (+/− vancomycin)
or
Ciprofloxacin + vancomycin
or
Piperacillin + aminoglycoside
Bronchoscopy with lavage and biopsy within the first 12–24 hours to evaluate new pulmonary infiltrates
CT-guided needle biopsy should be considered if bronchoscopy does not yield diagnostic material
After 72 hours of fever without a specific diagnosis, open lung biopsy should be considered

Bleeding is a common problem, and the risk rises as the platelet count decreases (see Chap. 69). Platelets should be transfused prophylactically to maintain a platelet count of greater than 10,000/μL to decrease the risk of spontaneous hemorrhage, such as a stroke or gastrointestinal bleeding. A higher platelet count is necessary to treat active bleeding. No salicylates or other drugs that interfere with platelet function should be given, nor should intramuscular injections be given to a thrombocytopenic patient. The use of single-donor platelets collected by apheresis will decrease the rate of alloimmunization in leukemia patients. Patients who become alloimmunized may benefit from HLA-matched platelets or antibody–cross-matched platelets to achieve adequate post-transfusion platelet counts. Blood bank techniques to remove leukocytes by filtration or centrifugation from red blood cell or platelet transfusion units may slow the rate of alloimmunization.

Granulocyte transfusions are rarely necessary for patients receiving chemotherapy for acute leukemia. The indications for their use generally are limited to severely granulocytopenic patients who remain febrile and bacteremic despite receiving antibiotics that have bactericidal activity against the particular organism in vitro. In this situation, the phagocytic activity of exogenous granulocytes can be lifesaving. One or two leukapheresis products are transfused daily for 4 to 7 days. Complications include respiratory distress from leukoagglutination, transmission of cytomegalovirus (CMV), and rapid alloimmunization. Pulmonary infiltrates may worsen as granulocytes migrate into infected lung tissues.

Over the past several years, the hematopoietic growth factors filgrastim (granulocyte colony-stimulating factor [G-CSF]) and sargramostim (granulocyte-macrophage colony-stimulating factor [GM-CSF]) have become available commercially in the United States. Pegfilgrastim (NEULASTA), a long-acting form of G-CSF also has become available recently for clinical use. They are now used routinely to support cancer patients with solid tumors or lymphoma who have received myelosuppressive chemotherapy. The American Society of Clinical Oncology has adopted guidelines for the use of colony-stimulating factors in clinical practice.[9] Colony-stimulating factors have been shown to reduce

significantly the incidence of febrile neutropenia when used prophylactically in certain patients who receive intensive chemotherapy regimens. Specifically, it is recommended that patients who receive a chemotherapy program previously associated with a greater than 40% incidence of febrile neutropenia be treated prophylactically with colony-stimulating factors to reduce this risk. In addition, there is evidence that administration of colony-stimulating factors may reduce the risk of febrile neutropenia in subsequent cycles of chemotherapy for patients who had a documented occurrence in an earlier cycle. Most randomized, controlled trials have not demonstrated significant long-term clinical benefit (response rate or outcome) from using myeloid growth factors in patients with AML. However, modest benefits in decreased duration of neutropenia and hospitalization have been observed. For adults with ALL, clinical trials have demonstrated statistically significant shortening of the duration of neutropenia following remission-induction chemotherapy when G-CSF was used. The clinical benefit was greater in older patients.

The current data do not support the routine use of colony-stimulating factors as adjuncts to antibiotic therapy in febrile neutropenic patients. Nevertheless, their use along with antibiotics may be reasonable in high-risk patients. Specifically, neutropenic patients with clinical features that predict a poor outcome, such as pneumonia, documented fungal infection, or sepsis syndrome, are reasonable candidates for therapy with colony-stimulating factors.[9]

Soft Silastic right-atrial catheters (e.g., double- or triple-lumen Hickman or Groshong catheters) that tunnel under the skin and enter the innominate vein are used widely. They allow direct access to a large vein for infusion of chemotherapy agents, antibiotics, and blood transfusions and also allow painless blood sampling for laboratory monitoring. Parenteral hyperalimentation can be administered easily through these catheters, if necessary. Although a boon to both patient and physician, such chronic indwelling lines are not without hazard. They must be placed in a sterile fashion by a skilled surgeon or invasive radiologist, especially in a thrombocytopenic patient. A vigorous skin preparation preoperatively reduces the likelihood of a staphylococcal or corynebacterial subcutaneous tunnel infection or bacteremia. Although most gram-negative bacteremias can be treated successfully in a granulocytopenic patient by antibiotics alone without removing the catheter, gram-positive infections or candidal infections of the tunnel or vein may require catheter removal.

Hyperleukocytosis

A small proportion of patients with leukemia have an extraordinary elevation of circulating leukocytes. Hyperleukocytosis (>100,000 blast cells per microliter) is a true medical emergency, but the risks of circulatory complications begin to rise at counts above about 50,000/μL (Table 71-5). These patients present special problems because of the rheologic effects of leukemia blast cells in the circulation of the lung, brain, and other organs; the metabolic consequences when massive numbers of leukemia cells are destroyed simultaneously by cytotoxic drugs; and perhaps other mechanisms.[10] Although in some cases the blood viscosity is markedly increased because of the elevated leukocrit, in most cases the whole blood viscosity will not be increased above normal because hyperleukocytosis is associated most frequently with severe anemia.[11] However, red blood cell transfusions can precipitate a hyperviscosity syndrome in a patient with hyperleukocytosis and should be delayed, if possible, until the white blood cell count falls. Nevertheless, viscosity may be high in the microcirculation. The high oxygen consumption and invasiveness of leukemia cells may interact with slow flow through the capillaries to lead to hypoxemia and vascular damage.

The contribution of blood cells to the viscosity of blood is a function of the deformability of individual cells and their fractional volume. Immature leukocytes are much larger and

TABLE 71-5 Diagnosis and Management of Leukostasis Syndrome

Leukostasis begins to occur when the peripheral blast count rises above 50,000/μL.
Blast counts greater than 100,000/μL should be treated as a medical emergency.
The signs and symptoms of leukostasis are due to increased blood viscosity and are manifestations of decreased small vessel perfusion of end organs: mental status alterations (CNS), respiratory failure (pulmonary capillaries), renal failure (renal glomeruli), and cardiac arrhythmias (cardiac microvasculature).
Cerebral perfusion should be assessed by examination of the retinal vessels and mental status; renal perfusion should be assessed by careful measurement of urine output; perfusion of the heart and lungs should be assessed by cardiopulmonary monitoring (pulse oximetry).
Hydration should be maintained vigorously with saline infusion to decrease viscosity.
Since the viscosity of blood is a function of both the leukocrit and the hematocrit, red blood cell transfusions should be withheld until the WBC count has been reduced (unless the patient is severely anemic).
If specific chemotherapy will not be started immediately, then oral hydroxyurea should be given in a dose of 2 g every 6 hours.
A temporary large-bore catheter should be placed and leukapheresis begun as soon as possible; leukapheresis should be continued daily until the WBC count is below 100,000/μL.
Specific chemotherapy should be begun as soon as the patient is stable.
For mental status changes due to leukostasis, cranial irradiation with a single dose of 400 cGy should be considered.
Respiratory compromise with hypoxemia due to leukostasis (not infection) can be treated with 400 cGy of thoracic irradiation and supplemental oxygen.

less deformable than erythrocytes. Leukemic myeloblasts are considerably larger than lymphoblasts, which are, in turn, larger than leukemic lymphocytes. Thus the incidence of significant leukostasis is highest in CML in the blast phase, followed by AML and then ALL. In contrast, leukostasis is rare in patients with chronic lymphocytic leukemia (CLL) despite white blood cell counts as high as 500,000/μL. Similarly, well-hydrated patients with CML in the chronic phase can tolerate total white blood cell counts of 200,000/μL without difficulty because only a small fraction of the cells are blasts or promyelocytes, and most are mature granulocytes.

Leukostasis and hypoxia in the capillary beds can induce respiratory distress, cardiac arrhythmias, and central nervous system (CNS) symptoms leading to coma. Death follows rapidly unless the circulation can be restored. Emergency measures include leukapheresis to remove a large mass of tumor cells directly from the bloodstream.[10] A single efficient leukapheresis can decrease the leukocyte count by approximately 50% within 2 to 3 hours. A centrifuge technique rather than a filtration method should be used because blast cells do not adhere to glass-wool filters. Prompt use of antimetabolite drugs such as oral hydroxyurea or intravenous cytarabine can reduce cell proliferation rapidly and decrease the blast count transiently. A single dose of cranial irradiation (200 to 400 cGy) can ameliorate CNS symptoms due to leukostasis. Diffuse pulmonary infiltrates and respiratory distress also may respond to thoracic irradiation. Once the circulation through the capillaries has been restored, systemic chemotherapy should be initiated promptly. Prophylactic platelet transfusions must be given to prevent bleeding as the circulation is restored to hypoxic tissues. The invasiveness of leukemic myeloblasts may lead to injury and disruption of vascular endothelium. Lysis of these cells in situ releases proteolytic enzymes, causing further tissue damage and bleeding.

Tachypnea and pulmonary infiltrates in a patient with hyperleukocytosis can mimic pulmonary embolism or infection. Care must be taken to rule out "pseudohypoxemia," which results from the in vitro consumption of oxygen within an arterial blood-gas sample by blast cells in transit to the laboratory.[12] Such blood specimens should be transported rapidly on ice. Rarely, marked thrombocytosis can produce a similar artifact in addition to pseudohyperkalemia.

Myeloid Sarcoma

Leukemia is, from its genesis in the marrow, spleen, or thymus, a systemic disease. Malignant cells circulate through the bloodstream and lymphatics and can infiltrate the parenchyma of any tissue. ALL cells migrate preferentially to lymphoid organs such as lymph nodes, spleen, and liver, causing organomegaly. When malignant myeloblasts form a solid tumor, a granulocytic or myeloid sarcoma results. The older term *chloroma* ("green cancer") describes the greenish color that results from the myeloperoxidase reaction when a myeloid sarcoma is exposed to air. Myeloid sarcomas occur most often in patients with CML in blast phase or with myelomonocytic or monoblastic leukemia, and most commonly they involve bone and subperiosteum, lymph nodes, skin, soft tissues, and the gastrointestinal tract.[13] They most frequently cause pain but also may cause neuropathy or intestinal obstruction from their mass effect. They are quite responsive to local irradiation (1000 to 2000 cGy), but since they are a localized manifestation of a disseminated disease, systemic chemotherapy also must be used. Local therapy often is not necessary because myeloid sarcomas often shrink and disappear within a few days after chemotherapy begins.

CNS Leukemia

CNS infiltration by leukemia cells is more common in ALL than AML and is more common in children than in adults. Among patients with myeloid leukemia, the incidence of CNS involvement is greatest in children and in those with monoblastic leukemias or high circulating blast counts. Among the lymphoblastic leukemias, the risk is greatest in patients with the T-cell or mature B-cell (Burkitt) immunophenotypes.[14] When the vascular leptomeninges surrounding the brain and spinal cord are infiltrated by malignant cells, leukemia cells often (but not always) can be found in the cerebrospinal fluid (CSF) by lumbar puncture. Cranial neuropathy and spinal radiculopathy result from the impingement of an expanding mass of leukemia cells on these nerves where they traverse narrow bony foramina. In contrast, a few malignant cells in the CSF at diagnosis probably are not significant because they often disappear during the initial induction chemotherapy treatment without specific attention to the CNS.

The most frequent symptoms in patients with overt CNS leukemia are those caused by increased intracranial pressure: vomiting, headache, papilledema, and lethargy. Diplopia results from oculomotor nerve palsy, especially of the abducens nerve. Facial nerve palsies are also common. Spinal radiculopathy and the cauda equina syndrome occur more commonly in adults than in children. Mass lesions in the brain substance itself or in the spinal cord are not common, and seizures are rarely present. Meningismus is also uncommon, and its presence suggests infection or subarachnoid hemorrhage.

The diagnosis is established by finding leukemia cells in the CSF. Usually, the CSF pressure is elevated in symptomatic patients, the glucose concentration is low, and the protein concentration is moderately elevated. CT scan or magnetic resonance imaging (MRI) may demonstrate thickening or contrast enhancement of the membranes around the base of the brain or the spinal nerves. Because spinal subarachnoid hemorrhage or focal hematomas can follow lumbar puncture in thrombocytopenic patients, platelets should be transfused to counts of greater than 20,000/μL and any coagulopathy corrected before a careful lumbar puncture is done.

CNS leukemia is usually rapidly responsive to irradiation or intrathecal chemotherapy. Standard treatment for symptoms is 2400 cGy to the whole brain in 12 fractions. The posterior orbits and upper cervical spine should be included. The spinal column is rarely irradiated except in patients with symptomatic radiculopathy because of the resulting damage to the underlying bone marrow. Dexamethasone 4 mg four times per day can alleviate symptoms of increased intracranial pressure. The spinal cord is best treated with preservative-free methotrexate (12 mg/m^2 to a maximum dose of 15 mg) injected intrathecally every 3 days for at

least six doses. Once the CSF is clear of malignant cells, intrathecal therapy should be administered once a month for the following year. Methotrexate can cause an inflammatory arachnoiditis with fever and nuchal rigidity. For this reason, hydrocortisone (50 mg) often is coadministered with the methotrexate. Alternative drugs for intrathecal use are cytarabine (DEPOCYTE, 50 mg), or less commonly, thio-TEPA. Slow diffusion of methotrexate out of the CSF into the systemic circulation can cause myelosuppression and gastrointestinal toxicity. This problem can be lessened by giving 5 mg leucovorin 36 hours after each dose. Leucovorin decreases methotrexate's toxic effects on normal tissues by replenishing the supply of reduced folate to cells. Too much leucovorin can interfere with subsequent doses of methotrexate. Administration of intrathecal chemotherapy via lumbar puncture has the disadvantage of not treating the ventricles at all and treating the top surface of the brain only poorly. For this reason, an Ommaya reservoir often is placed in symptomatic patients who require chronic CNS therapy to allow an intraventricular (and easier) route of administration.

Clinical trials have suggested that the CNS is a sanctuary site for leukemia cells and is poorly treated by many intravenously administered drugs. Patients can have an isolated CNS relapse even while they are in an apparent bone marrow remission. To diminish this risk in patients with ALL, all patients with lymphoblastic leukemia generally receive some prophylactic treatment of the CNS as part of their initial treatment program. Alternatives include high doses of cytarabine or methotrexate, two drugs that cross the blood-brain barrier and reach cytotoxic concentrations in the CSF even when administered intravenously. CNS prophylaxis is not commonly employed for AML.

Although uncommon, various paraneoplastic syndromes occur in patients with leukemia, such as Guillain-Barré polyneuritis and progressive multifocal leukoencephalopathy. It is not known to what extent the leukemia itself or its treatment with chemotherapy or irradiation is responsible for these disorders. High doses of cytarabine (2000 mg/m^2 for 6 to 12 doses) can cause irreversible cerebellar ataxia, especially in elderly patients and those with renal failure.

Enlargement of the Liver and Spleen

Marked leukemic infiltration of the liver and spleen is infrequent in AML and occurs principally in patients with ALL or CML in the blast phase. Signs and symptoms may mimic those of an acute hepatitis, with jaundice, tender hepatomegaly, and elevated serum transaminase levels. This problem usually resolves with effective chemotherapy, but the choice of initial chemotherapy may be restricted because many useful drugs are cleared through the liver. A biliary ultrasound examination should be performed to rule out bile duct obstruction. The spleen is rarely massively enlarged, although it may be palpable at diagnosis owing to leukemic infiltration. Vascular infarction can occur, causing painful subcapsular hematomas. A rub with respiratory variation sometimes will be heard over the left upper quadrant. Rarely, such an infarcted spleen ruptures, causing shock and signs of intraperitoneal hemorrhage. This is a surgical emergency. Splenic rupture also can occur during chemotherapy as the tumor cell mass is receding, but this event is extremely rare.

Infiltration of the Kidney

Infiltration of the kidneys is more common in ALL and monoblastic leukemias than in other types of AML. These patients present with oliguric acute renal failure. Renal ultrasound examination demonstrates homogeneous enlargement of both kidneys but no ureteral obstruction. Alternatively, enlarged retroperitoneal lymph nodes secondary to infiltration by leukemia cells can cause ureteral obstruction and renal failure without intrinsic renal disease. These signs resolve during the course of effective chemotherapy, but the inability to excrete the breakdown products of tumor cell lysis can precipitate hyperkalemia and hyperuricemia with their resulting metabolic complications (see below). One or two doses of radiation therapy (200 to 400 cGy) to include just the kidneys if they are enlarged (or the ureters as necessary) can re-establish renal excretory function prior to the use of systemic chemotherapy and thus alleviate the risk of tumor lysis syndrome.

Necrotizing Enterocolitis (Typhlitis)

Typhlitis is a necrotizing enterocolitis particularly of the terminal ileum, appendix, cecum, and right colon that occurs in granulocytopenic patients.[15] Although seen most often in young patients who have recently received intensive chemotherapy, typhlitis can occur in any granulocytopenic patient, such as those with aplastic anemia or acute leukemia not yet treated. Symptoms and signs are similar to those of inflammatory bowel disease: nausea, vomiting, abdominal pain and tenderness, profuse watery or bloody diarrhea, and fever. The intestinal mucosa is ulcerated, allowing enteric organisms to invade into and through the bowel wall. Ileus and bowel dilation result. Plasma proteins and electrolytes are lost into the bowel lumen, as occurs with toxic megacolon. Bowel perforation and peritonitis may follow. Jaundice and hepatitis are common, probably because of bacterial seeding through the portal vein.

Most patients are best managed with aggressive medical treatment: broad-spectrum antibiotics; transfusion of red blood cells, platelets, and fresh frozen plasma; maintenance of normal serum electrolyte levels (especially of potassium); and bowel rest with nasogastric suction. Narcotic analgesics and bowel paralytic agents such as LOMOTIL (diphenoxylate hydrochloride and atropine sulfate) should be avoided because they increase the risk of ileus. Granulocyte transfusions in this setting can prove lifesaving in severely neutropenic patients. With appropriate treatment of the transmural gastrointestinal infection and the recovery of granulocytes, this problem usually resolves without sequelae. Patients with clear evidence of bowel perforation require surgery with ileal diversion or bowel resection. Peritoneal lavage can establish the correct diagnosis if blood or feculent material is recovered. Although the perioperative mortality is high in such cases, the likelihood of a granulocytopenic patient surviving a disseminated peritonitis without surgery is small. Radiographic evidence of air within the bowel wall *(pneumatosis intestinalis)* does not in itself necessitate surgery, nor should a granulocytopenic patient who is otherwise doing well necessarily undergo laparotomy for intraperitoneal free air. Antibiotic-associated pseudomembranous

colitis *(Clostridium difficile)*, radiation enteritis, and graft-versus-host disease (GVHD) are other causes of abdominal pain and bloody diarrhea in leukemia and stem cell transplant patients.

Hyperuricemia and Tumor Lysis Syndrome

Uric acid is the product of nucleic acid catabolism, and its level is increased in diseases in which cell turnover rates are high. Uric acid is excreted largely by the kidneys through both glomerular filtration and tubular excretion. Uric acid nephropathy in leukemia may be present at diagnosis, or it may occur as a complication of therapy. Hyperuricemia may be exacerbated and uricosuria increased as a result of successful cytolytic therapy, as well as by drugs such as thiazide diuretics, probenecid, and aspirin. Hyperphosphatemia due to tumor cell lysis can cause deposition of calcium phosphate precipitates in the calyces and tubules. In acid urine, uric acid quickly supersaturates and precipitates. Uric acid has a dissociation constant of 5.4. At pH 7.0 and above, over 99% of urates are in the ionized form and thus are water-soluble. At pH 4.5, on the other hand, 80% of urate is in the form of poorly soluble uric acid, and the combined solubility of uric acid and urate falls below 8 mg/dL. In leukemia patients, therefore, the production of organic acids, together with the decreased urine formation that results from dehydration owing to anorexia or fever, frequently leads to precipitation of urates in the renal tubules and collecting system. Direct infiltration of leukemia cells into the kidneys also appears to enhance the local accumulation of uric acid. Leukemia patients with prior renal disease are more likely to develop uric acid nephropathy. Intratubular precipitation of urates leading to obstruction of urine flow is the more critical cause of nephropathy rather than renal cell injury per se.

Effective management of hyperuricemia and hyperuricosuria in leukemia patients is based on reducing the production of uric acid and at the same time promoting the solubility of uric acid in the urine. An adequate urine flow (100 mL/h) should be established by oral and intravenous hydration. The blood volume must be expanded and acidosis corrected. Acetazolamide, a carbonic anhydrase inhibitor, can be given together with sodium bicarbonate to alkalinize the urine. The optimal urine pH is 7.0 to 7.5. Allopurinol (300 mg/d) will effectively inhibit the conversion of xanthine and hypoxanthine to uric acid. Allopurinol treatment with alkalinization of the urine markedly decreases the risk of uric acid nephropathy in nearly all cases of leukemia. Rasburicase (ELITEK) (0.20 mg/kg) is a recombinant human urate oxidase that, when administered intravenously, can rapidly metabolize serum uric acid. It may be used daily for 1 to 5 days when rapid decreases in serum uric acid are needed or when a large tumor cell lysis is predicted.[16] Allopurinol should not be used in combination with rasburicase but can be restarted after the hyperuricemia resolves. Rasburicase is not recommended for patients with glucose-6-phosphate dehydrogenase (G6PD) deficiency. Once the tumor cell mass has been reduced, these measures can be discontinued safely. Allopurinol causes an allergic dermatitis in approximately 10% of patients, but this side effect usually occurs only after more than a week of treatment, allowing time for leukemia cytoreduction. Fever and the Stevens-Johnson syndrome may follow the systemic rash if allopurinol is continued.

Lysozymuria and Renal Tubular Dysfunction

Lysozyme is a small protein (molecular weight = 14,000) with an unusually high isoelectric point (pH = 11) that has a remarkable capacity to lyse the cell walls of certain bacteria. Lysozyme (also known as muramidase) is present in high concentrations in granulocytes and monocytes as well as tissue macrophages. Patients with monocytic and myelomonocytic leukemia excrete large quantities of lysozyme in the urine.[17] Lysozyme is toxic to renal tubule cells and causes tubular dysfunction. Marked hypokalemia generally has accompanied lysozymuria in patients with monoblastic and myelomonocytic leukemias. These problems resolve with effective treatment of the leukemia.

Disseminated Intravascular Coagulation

Laboratory evidence of disseminated intravascular coagulation (DIC) is almost always present at diagnosis in patients with acute promyelocytic leukemia (APL), but it can accompany any leukemia or infection where there is rapid cell lysis or tissue destruction. The pathophysiology is still controversial, but the coagulation cascade appears to be initiated by the release of intracellular thromboplastic material.[18] The syndrome is characterized by the consumption of plasma coagulation proteins and platelets, resulting in prolongation of the prothrombin time (PT), thrombin time (TT), and partial thromboplastin time (PTT), together with a decrease in fibrinogen levels and an elevation in the levels of fibrin degradation products (FDPs) and D-dimer. Oozing from venipuncture sites is common. Fibrin thrombi usually are present in the renal glomeruli, leading to moderate renal insufficiency. Aminoglycoside antibiotics should be avoided because patients with DIC are unexpectedly susceptible to renal failure despite blood level monitoring. Trauma to circulating red blood cells from fibrin strands creates schistocytes, which are apparent on the blood smear. Deep vein thrombosis and pulmonary embolism may occur. The DIC in patients with leukemia is most intense shortly after chemotherapy begins, when the destruction of leukemia cells results in the release of procoagulant-rich granules. The DIC wanes as the tumor burden declines. However, a state of low-grade DIC may persist in the setting of ongoing tumor lysis, bacteremia, or sepsis.

Management of DIC is always directed at correcting the underlying tissue destruction, whether due to leukemia, infection, a burn or crush injury, or an obstetric complication. In the meantime, the consumption of coagulation proteins through fibrin formation and its associated secondary fibrinolysis can be brought under control by administration of exogenous cryoprecipitate, platelets, and fresh frozen plasma, as well as by the use of heparin. A continuous intravenous infusion of heparin at 5 units/kg per hour is well tolerated even in thrombocytopenic patients and allows fresh frozen plasma or cryoprecipitate to be transfused safely without concern about adding substrate for renewed intravascular coagulation. Nonetheless, there are no randomized clinical trials demonstrating

benefit from the use of heparin products in DIC. Subcutaneous and/or low-dose intravenous heparin should be used with great care in patients with DIC and particularly in actively bleeding patients. Cryoprecipitate infusions should be used to maintain the fibrinogen concentration at greater than 100 mg/dL. Several doses of vitamin K (10 mg/d) should be given. If the liver is functioning normally, the vitamin K–dependent factors II, VII, IX, and X, as well as antithrombin, will be repleted rapidly, thereby avoiding the need for transfusion of large volumes of fresh frozen plasma. If after 24 hours of heparin therapy the fibrinogen level has not stabilized and the FDP levels have not decreased, the heparin infusion should be increased to 10 U/kg per hour; a higher dose of heparin is rarely necessary. Lack of response to heparin may indicate a deficiency of the heparin cofactor antithrombin, which can be repleted by transfusion of fresh frozen plasma. The optimal approach to DIC in leukemia remains to be determined. It is usually possible to manage the coagulopathy associated with APL with all-*trans*-retinoic acid, intensive chemotherapy, and blood product support without the routine use of heparin.[19,20]

All-trans-*Retinoic Acid and the Retinoic Acid Syndrome*

All-*trans*-retinoic acid (tretinoin, ATRA) has emerged as a remarkably effective agent for inducing complete remissions in patients with acute promyelocytic leukemia (AML-M3 or APL).[21] Patients with this form of AML have a characteristic chromosomal translocation, t(15;17). The juxtaposition of the retinoic acid receptor-α (*RAR-*α) gene on chromosome 17 and the *PML* gene on chromosome 15 results in the expression of fusion gene products in the leukemia cells. The leukemic blasts undergo terminal differentiation in response to ATRA, and complete responses are achieved in the majority of patients. The best results are achieved when patients also receive cytotoxic chemotherapy concomitantly with ATRA. The success of ATRA has led to its incorporation into remission-induction regimens for all patients with APL.

ATRA has several advantages over standard induction chemotherapy: (1) Patients usually do not have an exacerbation of DIC with ATRA treatment, as can happen with chemotherapy. In fact, resolution of DIC often occurs within 24 to 48 hours. (2) Patients treated with ATRA alone do not suffer bone marrow aplasia and prolonged neutropenia, as do patients treated with chemotherapy. (3) The systemic side effects are generally less severe with ATRA than with chemotherapy.

However, ATRA does have its own unique toxicities, which must be anticipated to maximize the safety of this novel agent (Table 71-6). The two most significant toxicities of ATRA are hyperleukocytosis and the retinoic acid syndrome.[22] In contrast to patients receiving chemotherapy who undergo a rapid cytoreductive phase accompanied by increased DIC and tumor lysis syndrome, APL patients receiving ATRA sometimes exhibit a progressive leukocytosis, which may become marked. The leukocytosis occurs because ATRA causes differentiation of the leukemic blasts in the bone marrow, resulting in the accumulation of maturing forms in the peripheral blood. This is less likely to occur if early institution of concurrent cytotoxic chemotherapy (usually daunorubicin or idarubicin) at full doses or hydroxyurea is used. Leukapheresis has also been used to reduce the white blood cell count in these patients.

TABLE 71-6 Toxicities of All-*trans*-Retinoic Acid Therapy

Retinoic acid syndrome
Leukocytosis
Intracranial hypertension ("pseudotumor cerebri")
Headache
Hypertriglyceridemia
Hepatic toxicity
Congestive heart failure
Dry skin and mucous membranes; cheilosis

The retinoic acid syndrome occurs in approximately 25% of patients receiving ATRA and is characterized by fever, rapidly progressive respiratory distress with diffuse pulmonary infiltrates on chest radiograph, pleural effusions, and weight gain (Table 71-7). If the syndrome is unrecognized and left untreated, progressive hypoxemia, multiorgan failure, and death frequently occur. The syndrome may occur as early as 2 days after the initiation of treatment or as late as 3 or 4 weeks. The syndrome may be more common in patients with ATRA-induced leukocytosis, but it also occurs in patients with white blood cell counts of less than 10,000/μL. Clinically, the syndrome is similar to "capillary leak" syndromes associated with certain cytokines, such as interleukin 2. This fact has led to the hypothesis that the retinoic acid syndrome may itself be cytokine-mediated. Similar symptoms may occur in chemotherapy-treated APL patients, implicating the malignant cells and not the treatment as the primary problem. Early recognition of the syndrome and prompt treatment with steroids (e.g., dexamethasone 10 mg bid for 3 days) effectively reverse the syndrome in most patients. The syndrome may be confused with an infectious complication. Thus it is important to recognize the retinoic acid syndrome promptly so that patients are not treated solely for infection, which could delay the start of corticosteroid treatment.

Another potential complication of ATRA is intracranial hypertension, or "pseudotumor cerebri." This complication is

TABLE 71-7 Clinical Features and Management of the Retinoic Acid Syndrome

The constellation of fever, respiratory distress, pulmonary infiltrates on chest radiograph, pleural effusion, and weight gain make up the retinoic acid syndrome, which occurs in 25% of APL patients treated with ATRA.
Immediate therapy should be instituted with dexamethasone, 10 mg I.V. every 12 hours for 3 days.
If there is a question of infection versus retinoic acid syndrome, then dexamethasone should be instituted together with broad-spectrum antibiotics. It is important not to delay dexamethasone treatment while the patient's response to antibiotics is assessed.
Efforts to control leukocytosis (in response to ATRA) may improve the retinoic acid syndrome.
Supportive care for pulmonary and other affected organ systems should be given until the syndrome improves.
The syndrome may recur at any point during therapy with ATRA and can be re-treated successfully with dexamethasone.

more frequent in pediatric patients receiving ATRA. Such cases of pseudotumor have been treated with lumbar puncture, corticosteroids, and narcotic analgesia.

Lactic Acidosis

Marked elevations of blood lactate or pyruvate concentrations in patients with leukemia result from an increase in the rate of lactic acid production or a decrease in the rate of pyruvic acid use or both. Whether clinical acidosis results depends in part on other metabolic and respiratory factors that influence acid-base balance. Blood lactate elevations occur more commonly in patients with acute leukemia than in those with any other neoplastic disorder.[23] Lactic acidosis also may be secondary to inadequate oxygenation of the tissues due to hyperleukocytosis, septic shock, pulmonary edema, or severe anemia. The development of lactic acidosis despite an apparently adequate supply of oxygen to the tissues sometimes reflects disseminated fungal infection with small-vessel occlusion or extensive liver necrosis. Lactic acidosis associated with massive leukemia is seen most commonly in patients with ALL and especially mature B-cell or Burkitt ALL. Experiments in vitro suggest that although malignant leukocytes exhibit little lactic acid production under aerobic conditions, they can have considerable anaerobic lactic acid production. It has been estimated that a rapidly growing mass of leukemia cells crowded into organs where the cells may be poorly oxygenated and therefore are dependent on anaerobic glycolysis for energy could produce as much as 300 to 600 m*M* lactic acid per hour. Any interference with hepatic blood supply or hepatic metabolism can diminish the body's ability to handle this acid load, resulting in clinical acidosis.

The successful treatment of lactic acidosis in patients with acute leukemia depends on the institution of effective antileukemia therapy. Removal of lactic acid by hemodialysis or peritoneal dialysis also may be useful.

Chapter 72
ONCOLOGIC EMERGENCIES

ELIZABETH B. LAMONT
PHILIP C. HOFFMAN

KEY POINTS

- *Patients with malignancy are subject to life-threatening complications of the primary disease, its treatment, or coexisting medical diseases.*
- *Oncologic emergencies should be treated when they are associated with higher acute morbidity and mortality than the underlying malignancy.*
- *In patients who are terminally ill from their malignancy, restraint should be exercised in the diagnosis and management of oncologic complications.*
- *A high index of suspicion must be maintained for oncologic complications to be recognized because they often share features with other common medical illnesses.*
- *Frequent examination of critically ill patients is necessary because such patients (often intubated, bed-bound, hypotensive) are often unable to verbalize changes in their condition.*

This chapter details the epidemiology, pathophysiology, clinical presentation, diagnostic approaches, and treatment modalities of the most common oncologic emergencies. Because of the systemic nature of cancer, these emergencies often affect organ systems remote from the original cancer, making diagnosis challenging. To recognize these disorders, it is important to develop a differential diagnosis for common signs and symptoms that occur in critically ill patients (Table 72-1). Given the long natural history of many advanced cancers, the successful diagnosis and management of these emergencies may be rewarded with prolonged survival. However, when cancer patients become end stage, the same invasive diagnostic procedures and aggressive treatments may be onerous. Decisions regarding management of these patients may be best made through discussions among the patient, the primary oncologist, the family, and the treating physician.

Thoracic Syndromes

SUPERIOR VENA CAVA SYNDROME

Superior vena cava (SVC) syndrome is the clinical manifestation of SVC obstruction and occurs through external compression, thrombosis, or invasion of the vein. While previously in the realm of nonneoplastic entities such as syphilitic aortitis or histoplasmosis, SVC syndrome is now almost exclusively (>90%) secondary to malignancy.[1] The syndrome complicates 2% to 8% of primary thoracic malignancies, most frequently small cell carcinoma of the lung, followed by other lung cancer histologies, non-Hodgkin's lymphoma, and mediastinal germ cell tumors.[2–5] Studies estimate the risk of clinically evident subclavian vein thrombosis to be approximately 5%[6,7] in cancer patients with indwelling central venous catheters, and some small percentage of these apparently evolve to SVC syndrome.[8–10]

To understand the clinical manifestations of the syndrome, an appreciation of the regional anatomy is necessary (Fig. 72-1). Because the venous drainage from the upper extremities, upper thorax, and head is obstructed, SVC syndrome presents with symptoms related to engorgement of these areas. Both the degree of SVC compromise and the extent of collateral veins determine the varied clinical presentation, which can be as mild as slight facial and upper extremity edema or as dire as intracranial swelling, seizures, hemodynamic instability, and tracheal obstruction. Table 72-2 lists the frequency of symptoms in 66 patients admitted with SVC obstruction.[1] Because of the lore of the dire symptomatologies, physicians often react to suspected SVC syndrome with panicked urgency and are tempted to initiate treatment before a pathologic diagnosis can be made. However, some argue convincingly that the SVC syndrome is rarely so urgent as to preclude timely and methodical radiologic and pathologic evaluations prior to therapy.[11]

When a patient presents with suspected SVC syndrome, the first step is to obtain an imaging study to both confirm the diagnosis and assist in treatment decisions. Of the several imaging modalities available for diagnosing the syndrome, the best study is the one that can be obtained most expediently. Magnetic resonance imaging (MRI), contrast-enhanced computed tomographic (CT) scanning, radionuclide flow study, and traditional venography are all adequate modalities, but at most centers CT scan is the most readily available. CT scan and MRI also provide information regarding possible etiologies and thus can direct the approach to a tissue diagnosis. The approach to establishing a tissue diagnosis is defined by both the patient's clinical stability and the findings on examination and radiographic studies. Table 72-3 summarizes the diagnostic yields for several tests ranging from noninvasive approaches such as sputum cytology to the maximally invasive thoracotomy. Tissue diagnoses are important because they guide treatment; specifically, they identify patients for whom SVC syndrome should be treated with combination chemotherapy rather than with local measures such as radiation therapy or percutaneous vascular procedures. Patients with known thoracic malignancies clearly do not require a further tissue diagnosis.

Treatment of SVC syndrome is divided into supportive and definitive therapy. Acutely, patients should be supported with elevation of the head of their bed and supplemental oxygen. Although dexamethasone is sometimes used, its utility has never been supported by experimental data. The definitive treatment of SVC syndrome depends on the etiology. Studies of small cell lung cancer patients with SVC syndrome reveal systemic combination chemotherapy to be more efficacious than radiation therapy, with 73% to 100% of patients experiencing symptomatic relief within 7 days.[5,12,13] Conversely, for non-small cell lung cancer and for solid tumors metastatic to the thorax, such as breast cancer, radiation therapy is the preferred treatment modality and is associated with a 56% to 70% success rate within 2 weeks.[2] Finally, in patients with non- Hodgkin's lymphoma, single-modality chemotherapy and radiation therapy appear equally efficacious, with 100% of patients experiencing relief of symptoms within 2 weeks.[3] For these patients, chemotherapy is argued to be

the better modality because it also provides systemic therapy. Patients with recurrent or refractory symptoms may benefit from percutaneous stent placement. SVC stenting with thrombolytic therapy and/or systemic anticoagulation is associated with immediate relief of symptoms in more than 90% of patients and provides excellent palliation in most patients.[14–20] Vascular bypass surgery is a treatment modality available for similar patients, but the even higher morbidity and mortality in such patients make it an infrequently employed therapy. Finally, for patients whose SVC syndrome is secondary to venous catheter thrombosis, thrombolytic therapy given within 5 days of the onset of symptoms is associated with a greater than 80% success rate.[21,22] For thromboses of longer duration, catheter removal in the setting of systemic anticoagulation with heparin and warfarin may be a more successful approach.

MALIGNANT PERICARDIAL DISEASE

Pericardial disease in cancer patients can result from a variety of medical conditions, including radiation, uremia, infection, and malignancy. Autopsy series have shown that malignant involvement of the pericardium complicates 5% of cancers

FIGURE 72-1 Frontal (*left*) and lateral (*right*) sections of the thorax depicting the anatomic structures adjacent to the SVC. The shaded area indicates the most common site of obstruction in SVC syndrome.

and is usually clinically silent.[23,24] However, the series reveal that when malignant pericardial disease is symptomatic, it is often the direct or a supporting cause of death. Thoracic tumors are the most frequent tumors to invade the pericardium directly or hematogenously, with lung cancer first, followed by lymphoma and breast cancer.[23,24]

Malignant pericardial effusion leading to tamponade can be an immediately life-threatening complication of malignant pericardial disease and should be suspected in cancer patients with new cardiopulmonary complaints (see Chap. 28). Because the right-sided cardiac chambers are compressed by surrounding fluid, signs of both right-sided heart failure and left-sided heart insufficiency result. As Table 72-4 details, the presenting symptoms reflect these circulatory disruptions and are, in decreasing order of frequency, dyspnea, cough, orthopnea, chest pain, and pedal edema.[25] Examination often reveals hypotension, tachycardia, distended jugular veins, and a paradoxical pulse of greater than 10 mm Hg. Chest radiographs reveal cardiomegaly in most and pleural effusions in approximately half of patients. However, patients with prior chest radiotherapy may not have radiographic evidence of cardiomegaly due to radiation-induced fibrosis of the pericardium. Electrocardiographic (ECG) abnormalities are protean, usually nonspecific, and commonly include sinus tachycardia and decreased voltage in the limb leads but rarely electrical alternans (i.e., alteration in the amplitude of the R wave, as shown in Fig. 72-2).[24–26] Echocardiography confirms the diagnosis by revealing effusion associated with inspiratory increase in right ventricular dimensions and right atrial and/or right ventricular collapse. Classically, right-sided heart catheterization reveals equalization of intrapericardial, right atrial, right ventricular diastolic, and pulmonary capillary wedge pressures.[27] Since not all pericardial effusions in cancer patients are malignant, both the clinical setting and the results of a diagnostic pericardiocentesis or pericardial biopsy are critical to determining the etiology and therefore the correct treatment for this condition.

Management of malignant pericardial effusions can be challenging and is divided into temporizing and definitive therapies. The immediate management of a hemodynamically significant pericardial effusion is echocardiography-guided pericardiocentesis. In 97% of patients, the fluid is removed successfully, and symptoms resolve immediately.[28] Unfortunately, in approximately 50% of patients, the fluid reaccumulates, requiring subsequent pericardiocenteses. Several more definitive therapies targeted at decreasing the reaccumulation rate have been paired with pericardiocentesis, including radiation therapy, systemic chemotherapy, pericardial sclerotic therapies, and mechanical therapies. When administered following initial pericardiocentesis, these therapies have the following reaccumulation rates: radiation therapy 33%, systemic chemotherapy 30%, pericardial sclerosis with tetracycline 15% to 30%, and mechanical therapies (e.g., indwelling pericardial catheter placement, balloon pericardiotomy, thoracotomy with pericardiostomy) 0% to 15%.[29–32]

Of all the mechanical therapies, balloon pericardiotomy has the best reaccumulation profile, with 0% to 6% reaccumulation.[29–32] The procedure includes a pericardiocentesis followed by balloon catheter dilation of the pericardial needle entrance site. Typically, a balloon catheter is placed across the pericardial entrance site and inflated two to three times, each for 1 to 2 minutes for a total procedure time of 20 to 40 minutes. Side effects have been limited to asymptomatic pleural effusions in most patients.[29,30] Not only is balloon pericardiotomy more successful than other less invasive therapies, but it is also the most successful and least morbid of the other mechanical therapies, most of which require general anesthesia and thoracotomy. At centers with staff facile with this technique, patients requiring definitive management of malignant pericardial effusions should be evaluated for this therapy.

Even when fluid does not reaccumulate, cardiac function may not return to normal because of tumor infiltration of the epicardium. This causes diastolic dysfunction mimicking

pericardial constriction. This combination of tamponade and cardiac restriction is termed *effusive-constrictive pericarditis* and may complicate as many as 50% of malignant effusions presenting with hemodynamic compromise. Diagnosis rests on measurement of right side of the heart and pericardial pressures both before and after draining the effusion.[33] This complication may lead to critical hemodynamic deterioration in the days following pericardiocentesis, and while some patients may benefit from pericardiectomy, most will succumb.

RADIATION-RELATED PERICARDIAL DISEASE

Three well-described pericardial syndromes that can manifest in the months to years following radiation therapy to the mediastinum are acute pericarditis with or without tamponade, pericardial effusion with or without tamponade, and pericardial constriction.[34] Such cardiac complications have been described in patients receiving radiation therapy for a variety of tumors within or adjacent to the thoracic cavity (e.g., breast cancer, Hodgkin's disease, esophageal cancer, lung cancer), and one study reported a 9% rate of pericardial effusion in patients receiving radiation therapy to esophageal tumors.[35] The authors suggest that effusions may be predictable when considering elements of radiation administration, with fraction sizes of more than 2 Gy associated with increased risk. The symptoms associated with constrictive pericarditis typically develop insidiously over a period of months to years. Increasing abdominal girth and peripheral edema, along with progressive exertional dyspnea, are common complaints. As the disease progresses, symptoms suggestive of cardiac cachexia develop (e.g., weakness, dyspnea at rest, palpitations).

FIGURE 72-3 Right and left ventricular pressure recording in a patient with constrictive pericarditis. The tracing depicts equilibration of right and left ventricular diastolic pressures and the characteristic square-root sign of the diastolic waveform.

Patients generally have a normal or low blood pressure. Elevated venous pressure is demonstrated by jugular venous distention with a rapid *y* descent and rapid rebound. In contrast to cardiac tamponade, an inspiratory increase in jugular venous distention (Kussmaul's sign) occurs in constrictive pericarditis. The heart sounds are often distant. Hepatomegaly, pulmonary edema, and ascites are late clinical features of the syndrome. Chest radiographs show an enlarged cardiac silhouette in only slightly more than 50% of cases. Occasionally, intrapericardial calcifications are present; however, the absence of calcifications does not exclude constrictive pericarditis. ECG findings are nonspecific. Atrial fibrillation is observed in long-standing cases owing to elevated atrial pressure.

M-mode and two-dimensional echocardiography can demonstrate pericardial thickening, but most findings are nonspecific. Doppler echocardiography can demonstrate altered patterns of left ventricular filling that distinguish normal individuals from those with constrictive pericarditis. Patients with constrictive pericarditis typically have a rapid deceleration of filling velocity and a shortened filling period.

In constrictive pericarditis, cardiac catheterization will demonstrate equilibration of diastolic pressures in all four chambers. The ventricular pressure tracing will demonstrate the characteristic dip-and-plateau pattern, or square-root sign (Fig. 72-3). The early diastolic dip of ventricular pressure indicates abnormally rapid ventricular filling in constrictive pericarditis. The pulmonary artery pressure is slightly elevated, and the cardiac index is usually decreased. Angiography is able to demonstrate a thickened pericardium in most patients with constrictive pericarditis, and more recently, CT scan has been shown to effectively distinguish between restrictive myocardial disease and constrictive pericarditis by the presence of a thickened pericardium. Clinically significant pericardial effusions are managed with pericardial drainage as described earlier, and pericardial constriction is managed with cardiac surgery (e.g., pericardial stripping, pericardial resection).

Neurologic Emergencies

SPINAL CORD COMPRESSION

Malignant compression of the spinal cord complicates between 5% and 10% of all malignancies and requires emergent

initiation of therapy to stop what is often rapid and irreversible neurologic deterioration.[36] In 85% of patients, the condition results from the hematogenous spread of a previously diagnosed cancer to the vertebral body that then compresses the cord directly or causes vertebral body collapse, compressing the cord.[37] In a small number of patients (10%), the condition results from paraspinal malignancies such as lymphoma that compress neural structures traversing the foramina. The most common vertebral levels of spinal cord compression (SCC) are thoracic (70%), lumbosacral (15%), and cervical (15%), and up to 50% of patients have tumor in more than one, often noncontiguous vertebra.[37,38] Clinical series have shown that the tumors most likely to cause SCC are, in decreasing order of frequency, breast carcinoma, lung carcinoma, lymphoma, prostate carcinoma, renal cell carcinoma, and myeloma, together accounting for nearly 70% of histologies.[37]

The presenting symptoms and signs of malignant SCC in 130 patients are detailed in Table 72-5.[37] While back pain is the presenting complaint in almost all patients (96%), the pain can be either localized or radicular, and it can be challenging to distinguish SCC from benign conditions such as degenerative joint disease or disk disease. Characteristics suggestive of SCC include a history of pain worsening with Valsalva maneuver, cough, or recumbency. Subsequent examination reveals clear, objective weakness (usually bilateral and symmetric) in 87% of patients. Sensory deficits are noted in 78% and autonomic dysfunction (like urinary retention or incontinence) in 57% of patients. Patients with autonomic dysfunction at the time of diagnosis form an important poor-prognosis subgroup in which 66% lose ambulation.

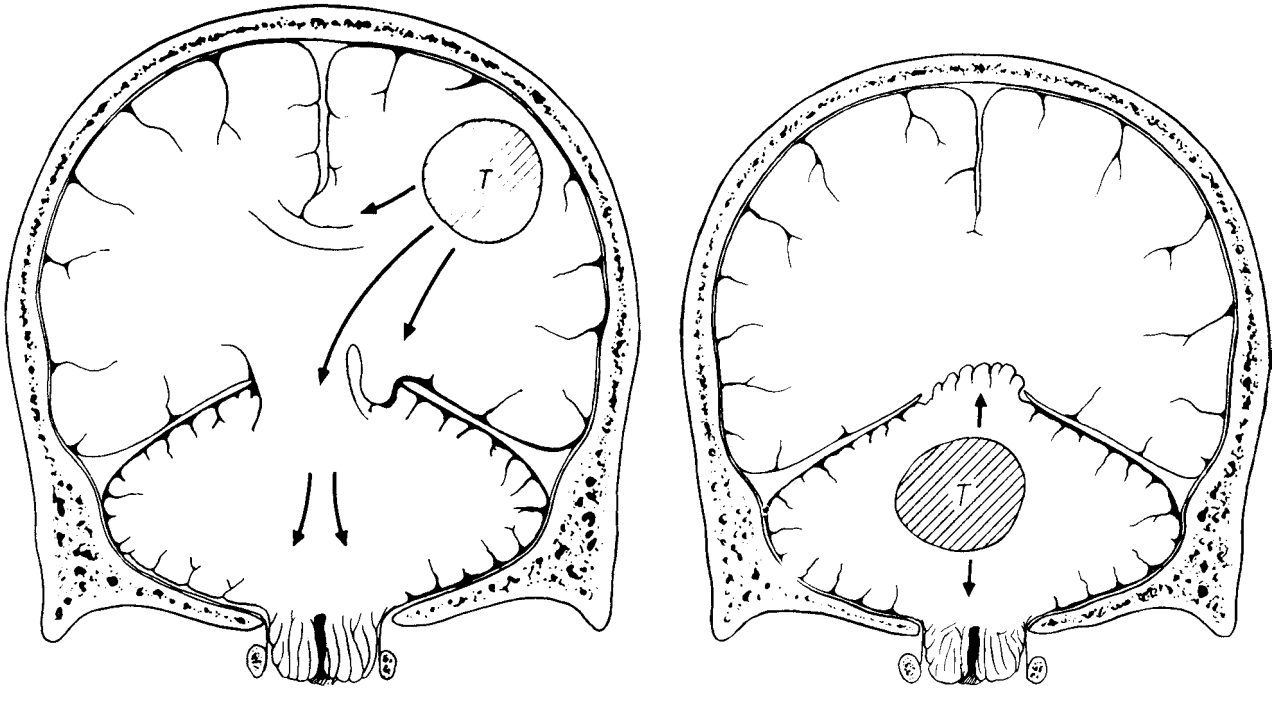
After the suspicion of malignant SCC is raised by history and/or physical examination, dexamethasone should be administered (see details of dosing below), and radiologic evaluation must be obtained quickly. The absence of objective neurologic signs of SCC should not dissuade the clinician from the appropriate diagnostic evaluation. Nearly all patients (>80%) with SCC will have abnormal plain radiographs.[36,38,39] The anteroposterior (AP) view can reveal pedicle pathology such as erosion or displacement; the lateral view can reveal vertebral body pathology such as collapse; and the oblique view can reveal foramina pathology such as encroachment or enlargement. Since plain films are both highly sensitive and specific for malignant SCC, they are preferable to bone scans, which, although quite sensitive for malignant bony disease, are less sensitive for SCC.[40] An important exception to this rule occurs in lymphoma patients, 60% of whom will have no abnormalities on plain films.[41] Subsequent imaging with gadolinium-enhanced MRI will both confirm the diagnosis and determine the extent of disease for radiation planning.[42,43] Of note, an MRI examination of the entire spine is often necessary, irrespective of the site of pain, because multilevel disease is often present, particularly in patients with prostate cancer and myeloma. If MRI is unavailable or contraindicated, the more invasive metrizamide myelography with or without CT scan can confirm the diagnosis.

In most cases, pretreatment neurologic function portends posttreatment function, with most ambulatory patients (approximately 80%), fewer paretic patients (<50%), and even fewer paraplegic patients (<10%) ambulatory after therapy.[37,38,40] Therapy for SCC is divided into temporizing therapy and definitive therapy. Acutely, patients should be given dexamethasone 10 mg intravenously, followed by 4 mg every 6 hours to continue until the completion of definitive therapy. The steroid will decrease cord edema and thereby transiently improve neurologic signs and symptoms in some patients. Radiation therapy and surgical decompression via laminectomy are the two definitive treatment modalities. Series examining the effect of laminectomy followed by radiation therapy compared with radiation therapy alone reveal radiation therapy alone to be equally efficacious and far less morbid than the more invasive therapy in most patients.[37–44] However, there are several instances in which surgery with radiation therapy is preferable to radiation therapy alone, including patients in whom a tissue diagnosis is needed, in whom the tumor is radio-refractory such as sarcoma or melanoma, in whom there is spinal instability requiring surgical stabilization, and in whom disease occurs in a previously irradiated field. Finally, for those patients whose SCC results from bony metastases, regular bisphosphonate therapy is an appropriate approach to decreasing the risk of subsequent skeletal complications of the malignancy. Ninety milligrams of intravenous pamidronate infused over 2 hours every 4 weeks has been found in placebo-controlled, randomized trials to reduce skeletal complications in patients with myeloma and patients with breast cancer metastatic to the bone.[45,46] Zolendronic acid, a newer bisphosphonate that can be infused more rapidly, appears to offer equivalent protection against skeletal events.[47]

CEREBRAL HERNIATION SYNDROMES

In cancer patients, cerebral herniation syndromes result from space-occupying brain tumors that increase intracranial pressure and thereby compress the brain against rigid cranial

elements (see Chap. 65). Herniation can result from primary central nervous system (CNS) tumors or from those metastatic to the CNS, with lung cancer, breast cancer, melanoma, renal cell carcinoma, and lymphoma the most common.[48] With increased intracranial pressure, patients initially experience intermittent bilateral frontal or occipital headaches. The headaches often awaken patients from sleep or are present on awakening in the morning. They can be accompanied by signs of elevated intracranial pressure, such as projectile vomiting, unsteady gait, and papilledema. As intracranial pressure increases further, cerebral function decreases, leading to inattention, apathy, psychomotor retardation, and somnolence. Because the brain is compartmentalized by the falx cerebri and tentorium, increased pressure in one compartment is equalized into the other compartments through characteristic herniations. MRI may reveal the herniation, as well as the causative tumor and edema (Fig. 72-4).



Management of malignant cerebral herniation syndromes centers around decreasing intracranial pressure through several simultaneous interventions and then initiating definitive antitumor therapy. First, the patient should be loaded with dexamethasone 10 mg intravenously, followed by 4 mg every 6 hours, to mitigate cerebral edema and thereby reduce intracranial pressure. The patient then should be intubated for both airway protection and hyperventilation to a Pa_{CO_2} of roughly 30 mm Hg. Hypocapnia to this level results in cerebral vasoconstriction, which will decrease intracranial volume and thereby reduce intracranial pressure. The effect, however, is of a short duration (48 to 72 hours) because renal bicarbonate wasting will act to normalize cerebral pH and thereby normalize cerebral blood flow.[49] Finally, a loading dose of the osmotic diuretic mannitol 100 g, followed by 25 g as needed, may further reduce intracranial edema. The patient should be evaluated emergently by a radiation oncologist for more definitive therapy with cranial radiation therapy.

CARCINOMATOUS MENINGITIS

Carcinomatous meningitis results from the direct or hematogenous seeding of the meninges by tumor cells and should be suspected in cancer patients presenting with deficits in multiple areas of the neuraxis. Autopsy studies suggest that malignant involvement of the meninges is common, occurring in 8% of cancer patients. These studies reveal that patients with acute leukemias have the highest rates of leptomeningeal disease, followed by patients with non-Hodgkin's lymphoma, small cell lung cancer, and breast cancer.[48]

The diagnosis of carcinomatous meningitis is often elusive, with symptoms that can be both diffuse and localized. Diffuse symptoms result from decreased brain metabolism that is seen with malignant CNS disease, from cerebral spinal fluid (CSF) obstruction causing hydrocephalus and increased intracranial pressure, or from diffuse meningeal irritation. These patients present most frequently with headache and have signs of altered mental status on examination. Localized signs result from spinal and/or cranial nerve root invasion. In cases of spinal nerve root involvement, the most frequent presenting complaint is lower motor neuron weakness, and the most frequent examination findings are reflex asymmetry and weakness. Spinal sensory nerves also can be affected, resulting in complaints of paresthesias and findings of sensory loss. Cranial nerves damaged by tumor deposits result in cranial nerve palsies. Among those with cranial

nerve involvement, the most frequent presenting complaint is double vision, and the most frequent examination finding is ocular muscle paresis due to compromise of cranial nerves III, IV, and VI.[50]

Carcinomatous meningitis is diagnosed most reliably through examination of the CSF, not through neuroimaging. Once a head CT scan excludes a concomitant mass lesion that could cause herniation during lumbar puncture, the patient should undergo a lumbar puncture, followed by CSF examination. Table 72-6 details the initial CSF results of 90 patients with leptomeningeal metastases. It reveals that 97 percent of patients with carcinomatous meningitis have CSF abnormalities with the following distribution: elevated protein 81%, elevated white blood cell count 57%, positive cytology 54%, elevated opening pressure 50%, and depressed glucose 31%. The cytology yield increases to 86% if three lumbar punctures are performed.[50] MRI with gadolinium can identify leptomeningeal deposits as areas of enhancement but is positive in only 33% to 66% of cases.[51,52]

Successful treatment of carcinomatous meningitis can arrest or sometimes reverse neurologic loss, extending patient survival from weeks to months.[50] The treatment modalities are intrathecal chemotherapy and/or radiation therapy. Because the blood-brain barrier hinders the passage of systemic chemotherapeutic agents into the brain, chemotherapy must be administered intrathecally through a ventricular reservoir (e.g., Ommaya shunt) or through a lumbar puncture. Standard regimens are methotrexate 10 mg twice weekly (with systemic leucovorin to prevent bone marrow suppression), thiotepa 5 to 10 mg twice weekly, or cytarabine 90 mg twice weekly until clinical neurologic improvement occurs or until CSF cytology clears of malignant cells. The interval between doses is then increased to weekly or monthly. While acute side effects are transient nausea and vomiting, the late side effects are myelosuppression and mucositis from systemic absorption of the chemotherapeutic agent. Radiation therapy is a second treatment option for established cranial or cauda equina neuropathies and may be given either singly or in association with intrathecal chemotherapy. Focal areas of disease are irradiated rather than the entire neuraxis because the latter is associated with substantial myelosuppression. The acute side effect is transient nausea. A rare complication of concomitant methotrexate and radiation therapy is leukoencephalopathy.[50] With these therapies, approximately 50% of patients will experience either improvement or stabilization of their disease.[50] Since carcinomatous meningitis is often a late finding in the course of a patient's malignancy, and since treatment often has limited success, the decision of whether to treat needs to be considered carefully, taking into account the patient's performance status and the state of his or her systemic cancer. It is not unusual for patients with carcinomatous meningitis to be at such a point in their illness (i.e., have widespread and refractory cancer) that the complication is managed with supportive care alone and not chemotherapy or radiation.

Metabolic Complications

LACTIC ACIDOSIS

Tumor-induced lactic acidosis is an extremely rare condition that occurs in malignancies with exceptionally high proliferative indices, such as Burkitt's lymphoma; small noncleaved, non-Burkitt's lymphoma; or acute lymphoblastic leukemia. Although the mechanism has not been established definitively, it is likely a function of tumor cell hypoxia leading to anaerobic metabolism (glycolysis) that generates lactate. Concomitant hepatic impairment by the malignancy may reduce the patient's ability to metabolize the lactate produced. The diagnosis of lactic acidosis should be suspected in cancer patients with large tumor burdens who have anion-gap acidoses and no history of toxic ingestion or clinical or laboratory evidence of diabetic ketoacidosis or uremia. Such patients usually have high levels of serum lactate dehydrogenase (LDH), indicating high tumor cell turnover. The mainstay of treatment of this condition is treatment of the malignant cause of the acidosis with urgent chemotherapy. The role of exogenous sodium bicarbonate in the management is controversial, with several animal and human studies reporting increased cellular acidosis, increased serum lactate concentration, and higher mortality in subjects treated with bicarbonate.[53–56] Although standard texts recommend supplemental bicarbonate therapy in patients with a blood pH of less than 7.1, it is not clear that this improves clinical outcome in this patient population.

TUMOR LYSIS SYNDROME

Tumor lysis syndrome is another complication of rapidly proliferating tumors. Tumor lysis syndrome is a life-threatening condition caused by the rapid release into the plasma of large quantities of cytoplasmic solutes, most notably potassium, uric acid, and inorganic phosphate, liberated by tumors with high proliferative indices (e.g., Burkitt's lymphoma) either because of rapid cell turnover or because of cell lysis by cytotoxic chemotherapy. Uric acid nephropathy may result from intrarenal precipitation of massive amounts of uric acid. Uric acid crystals in the renal collecting system obstruct urine flow, raising intrarenal pressure and thereby decreasing vascular perfusion. The end result is acute oliguric renal failure. Patients may develop lethargy, seizures, nausea, and vomiting and eventually symptoms and signs of volume overload. Laboratory evaluation typically reveals elevated potassium, uric acid, and inorganic phosphate levels and often creatinine. Urine evaluation can reveal uric acid concentrations of 150 to 200 mg/dL and both uric acid and sodium monourate crystals.[57]

The management of tumor lysis syndrome is primarily preventive, with the goal to decrease uric acid production and

increase its urine solubility. Decreased production is achieved through the use of allopurinol, a xanthine oxidase inhibitor. Treatment with allopurinol should precede chemotherapy by 2 to 3 days, if possible. The initial dose of between 300 and 800 mg daily should reflect tumor burden. The dose eventually may be decreased to between 100 and 300 mg daily and should continue through the period of cytoreduction. The dose should be reduced for renal insufficiency. Increased uric acid solubility can be achieved by maximizing urine output and by making the urine alkaline through the use of sodium bicarbonate or acetazolamide.[58,59] Urinary output of 3 L/d (125 mL/h) and a urinary pH of 7 or greater often are recommended. The use of recombinant urate oxidase (rasburicase), a catalyst in the oxidation of uric acid to allantoin, in the prophylaxis or treatment of patients with hyperuricemia in the setting of leukemia and lymphoma shows promising results.[60] The drug has the advantage over allopurinol of both blocking uric acid formation and increasing its solubility and requiring administration only hours prior to chemotherapy administration. For patients in whom uric acid nephropathy develops despite these measures, hemodialysis can both acutely decrease serum uric acid and correct the volume and electrolyte effects of acute renal failure.[61]

HYPERCALCEMIA

Hypercalcemia is the most common life-threatening metabolic disorder associated with malignancy. It has been estimated that between 10% and 20% of cancer patients become hypercalcemic during the course of their disease.[62] Cancers commonly associated with hypercalcemia include both solid tumors, in particular squamous cell histologies, and hematologic malignancies, in particular multiple myeloma.

Dysregulation of bone resorption is the principal factor implicated in the hypercalcemia of malignancy, although defects in renal clearance and intestinal absorption also have been described. Current evidence suggests that this disorder is most often due to increased bone resorption secondary to diffusible factors produced in excess by cancer cells or direct malignant bone invasion. The best characterized of the diffusable factors is parathyroid hormone–related peptide (PTHrP). In cancers metastatic to bone, the bony destruction that was originally attributed to the tumor cells themselves in most cases may be secondary to high local concentrations of PTHrP resulting in osteoclast activation. Other diffusible factors also have been implicated in tumor-related osteolysis and subsequent hypercalcemia, notably tumor necrosis factor and interleukin 6 in multiple myeloma.[63,64]

The clinical manifestations of hypercalcemia of malignancy are protean and depend on both the rate of increase of serum calcium concentration and the absolute value. A slow rise to 14 mg/dL may be imperceptible, whereas a rapid elevation to 12 mg/dL could result in coma. The typical presentation is with nausea, vomiting, anorexia, fatigue, weight loss, and dehydration. Table 72-7 lists many of the common signs and symptoms. Serum calcium has diuretic properties, leading in the hypercalcemic state to volume contraction and eventually dehydration. In the setting of volume contraction, the kidney actively resorbs sodium at the distal tubule under the stimulation of antidiuretic hormone. In addition to resorbing sodium, the Na^+, K^+ pump resorbs calcium and wastes potassium. This action leads to further increases in total body calcium and deficiency of potassium. The increased calcium, in turn, causes more volume loss, resulting in further resorption of sodium and calcium and loss of potassium. Therefore, when patients become hypercalcemic, they enter a self-perpetuating physiologic cycle of increasing hypercalcemia.

Treatment is focused on reversing the physiologic progression of hypercalcemia, as well as on attenuating the underlying pathologic process that initiated the elevation. To interrupt the physiologic progression acutely, one should rehydrate patients with intravenous fluids and correct hypokalemia. Treatment of the underlying pathology consists of both anticancer therapies and initiation of bisphosphonate therapy to attenuate release of calcium from the bone. Since the randomized trial showing pamidronate to be superior over saline alone, bisphosphonates, like pamidronate, became the cornerstone of the treatment for hypercalcemia of malignancy through their inhibition of osteoclast activity.[65] A newer bisphosphonate, zoledronic acid, has the advantage over pamidronate of both more rapid administration and more rapid resolution of hypercalcemia. A large randomized study comparing zoledronic acid with pamidronate revealed that a single 4-mg dose of zoledronic acid infused over 5 minutes was superior to a single 90-mg dose of pamidronate infused over 2 hours in normalizing serum calcium concentration within 10 days (88% versus 70%) and in the duration of response (32 versus 18 days).[66] Other therapeutic measures may be required in acute, symptomatic hypercalcemia resistant to hydration. For example, calcitonin given at the dose of 200 to 400 MRC units intramuscularly or subcutaneously every 12 hours will rapidly lower serum calcium concentration and, although its effects are short-lived, may be useful in the period before bisphosphonate therapy takes effect.

SYNDROME OF INAPPROPRIATE SECRETION OF ANTIDIURETIC HORMONE

The syndrome of inappropriate secretion of antidiuretic hormone (SIADH) was first described in the 1950s by investigators who reported the finding of hyponatremia associated with renal sodium loss and high urine osmolality in two lung cancer patients.[67] The authors correctly theorized that cancer-produced antidiuretic hormone (arginine vasopressin) was responsible for the syndrome.[68] The tumor most frequently associated with SIADH is small cell lung cancer, although many other cancers have been reported to cause the syndrome. Up to 15% of small cell lung cancer is complicated by SIADH.[69] However, as shown in Table 72-8, a host of other mechanisms can be responsible for SIADH in cancer patients, including infections, drugs, pulmonary processes, and CNS processes.

Antidiuretic hormone is normally synthesized in the posterior pituitary and functions as a critical physiologic regulator of water balance. It acts primarily on the collecting tubules of the nephron to stimulate upregulation of water channels, permitting increased free water resorption. It is controlled by a complex network of signals derived from volume and osmoreceptors in the hypothalamus, left atrium, and pulmonary veins and from circulating angiotensin II. Excessive autonomous secretion of ADH leads to excess water resorption out of proportion to sodium, resulting in progressive water intoxication and hyponatremia. The hyponatremia can lead to CNS toxicity, with headaches and fatigue ultimately progressing to confusion, seizures, coma, and death.

The mainstay of treatment of SIADH caused by tumors is therapy for the underlying malignancy. When this is not sufficient, or when the serum sodium concentration is less than 130 mEq/L, fluid restriction is the next step. For relatively mild cases, restriction of free water to 1 L/d may be adequate to correct the serum sodium concentration. Greater fluid restriction occasionally may be required, although it is difficult to accomplish, especially in the outpatient setting. Another approach is serum sodium correction with 3% saline in patients with acute (<48 hours), symptomatic hyponatremia. Care needs to be taken to avoid too rapid correction of the serum sodium concentration, however, because central pontine myelinolysis[70] and volume overload may occur because patients with SIADH are euvolemic. Specifically, the rate of change in the serum sodium concentration should not exceed 1 to 2 mEq/L per hour, and an absolute change of greater than 20 mEq/L in 24 hours should be avoided. After the serum sodium concentration reaches 120 to 125 mEq/L, therapy should be shifted to free water restriction. For chronic cases of hyponatremia, in which free water restriction is not feasible, pharmacologic therapy with demeclocycline has proven to be effective. Demeclocycline inhibits the renal effects of antidiuretic hormone and, when used in doses of 600 to 1200 mg/d, usually restores the serum sodium concentration to normal in 5 to 14 days.[71]

TABLE 72-8 Causes of SIADH

Carcinomas
Small cell lung cancer
Bronchial carcinoids
Prostate
Adrenal
Head and neck
Duodenal, colorectal
Pancreas
Esophagus
Hodgkin's and non–Hodgkin's lymphoma
Pulmonary disorders
Viral, bacterial pneumonias
Abscess
Tuberculosis

Meningitis
Encephalitis
Cerebritis
Primary or metastatic tumors
Abscess
Head trauma–skull fractures
Subdural hematoma
Subarchnoid hemorrhage
Pain
Drugs
Morphine
Nicotine
Cyclophosphamide
Vincristine
Alcohol
Chlorpropramide

Urologic Emergencies

HEMORRHAGIC CYSTITIS

Hemorrhagic cystitis results from inflammation of the bladder and presents with dysuria, hematuria, and urinary frequency. In cancer patients, the condition can result from chemotherapy, radiation therapy, or viral infections. Cyclophosphamide and ifosfamide are the most frequent chemotherapeutic agents implicated in hemorrhagic cystitis and act through their metabolite acrolein to damage the bladder mucosa. While previously complicating greater than 40% of bone marrow transplants, hemorrhagic cystitis now occurs in less than 5% due to preventive management with hydration and the drug mesna.[72–76] Vigorous intravenous hydration generates a high urine output that limits bladder exposure to acrolein. Mesna is a thiol that is activated in the kidney and inactivates acrolein in the bladder. Because its half-life is shorter than that of cyclophosphamide, it must be started prior to cyclophosphamide and continued after the completion of the cyclophosphamide infusion. For patients in whom hemorrhagic cystitis develops despite these measures, emergent urologic consultation must be obtained regarding possible bladder irrigation, cystoscopy with clot extraction and fulguration, or chemical hemostasis with formalin. In refractory cases, vascular ligation or even cystectomy may be required.

Disorders of Blood Viscosity

Hyperviscosity syndrome (HVS) and leukostasis are disorders resulting from a malignant excess of blood components and requiring rapid evaluation for possible emergent apheresis, chemotherapy, and radiotherapy.

HYPERVISCOSITY SYNDROME

HVS results from high levels of serum paraprotein often elaborated by Waldenstrom's macroglobulinemia (IgM) or multiple myeloma (IgG, IgA, and very rarely light-chain disease). HVS is characterized by a clinical triad of visual changes, bleeding, and neurologic changes, with patients often presenting with blurred vision, "dizzy headache," and mucosal oozing.[77,78] The visual and neurologic symptoms result from sludging of blood through end arterioles, and the bleeding results from paraprotein-induced platelet dysfunction, clotting factor inhibition, and fibrin inhibition. Funduscopic examination can reveal tortuous vessels with a sausage-like appearance termed *fundus paraproteinaemicus*, as well as retinal hemorrhage and papilledema. The diagnosis is made by observing a serum paraprotein concentration in the setting of an elevated blood viscosity (usually >4.0 cP). Treatment is plasmapheresis to decrease the paraprotein acutely, followed by chemotherapy to decrease production of the paraprotein. Of note, some IgM paraproteins are cold-reactive, making plasmapheresis with a room-temperature cell separator problematic. These patients should undergo plasmapheresis with prewarmed equipment in a warm room.

LEUKOSTASIS

Leukostasis is a rare condition that results from an excess of the blood's cellular elements. The signs and symptoms result from end-organ ischemia, infarction, and hemorrhage due to microvascular thrombi from leukocyte aggregates. Patients may present with visual changes, confusion, and dyspnea. Evaluation may reveal mental status changes, papilledema, cardiogenic or noncardiogenic pulmonary edema, liver dysfunction, renal failure, and priapism. Blood rheology studies and clinical reports reveal the risk of leukostasis to be a complex function of white blood cell type, maturity, and number, as well as hematocrit and platelet count (see Chap. 71). Patients with acute leukemias or the accelerated phase of chronic myelogenous leukemia (CML) with blast counts greater than 50,000/μL are at a far greater risk for leukostasis than patients with chronic lymphocytic leukemia (CLL) with lymphocyte counts of even 500,000/μL.[79,80] Leukemia patients who present with leukostasis should not receive blood product transfusions until their white blood cell count has been decreased substantially through leukapheresis, chemotherapy, or both because additional blood products will exacerbate their condition through increasing blood viscosity. Patients with pulmonary or CNS leukostasis may require emergent local radiation therapy to arrest organ compromise.

Chapter 73

HEMATOPOIETIC STEM CELL TRANSPLANTATION AND GRAFT-VERSUS-HOST DISEASE

STEPHEN W. CRAWFORD
RODNEY J. FOLZ
KEITH M. SULLIVAN

KEY POINTS

- *The principles of and approaches to the critical care of hematopoietic stem cell transplant recipients are similar to those for other immunosuppressed hosts.*
- *Specific complications tend to occur within well-defined time periods and are influenced by the type of stem cell transplant.*
- *The primary distinguishing features of hematopoietic stem cell transplant recipients are the high prevalence of graft rejection, graft-versus-host reactions, and chemoradiotherapy-related toxicities.*
- *Acute graft-versus-host disease represents a major problem to allogeneic hematopoietic stem cell transplantation.*
- *Hepatic veno-occlusive disease is the most common lethal chemoradiotherapy-related toxicity after hematopoietic stem cell transplantation.*
- *When prophylactic treatment is used, diffuse pneumonia due to cytomegalovirus is uncommon after hematopoietic stem cell transplantation.*
- *Idiopathic pneumonia syndrome remains a major cause of mortality, and no treatment has been proved effective.*

Hematopoietic Stem Cell Transplantation

Transplantation of human marrow precursors (hematopoietic stem cell transplantation [HSCT]) has become the primary therapy for several malignant and nonmalignant diseases. HSCT serves as a "salvage" therapy for restoring marrow function after marrow-ablating doses of chemoradiotherapy have been given to eradicate malignant cells in leukemias, myelodysplastic syndromes, multiple myeloma, malignant lymphomas, and assorted solid tumors, such as breast carcinoma and neuroblastoma. HSCT also can be used to replace dysfunctional hematopoietic or lymphoreticular precursors and to correct congenital or acquired deficiencies, such as aplastic anemia, thalassemia, and congenital immunedeficiency syndromes.[1]

Antigenic differences between the marrow donor and recipient may result in graft rejection or, since the marrow graft contains immunocompetent lymphocytes, may initiate graft-versus-host (GVH) reactions. The antigenic determinants that mediate tissue graft rejection responses are primarily the human leukocyte antigens (HLAs). These are encoded by genes of the major histocompatibility complex (MHC) located on chromosome 6.

Donor marrow precursor stem cells may be obtained from several sources. Autologous hematopoietic stem cells from the marrow or peripheral blood of the patient can be used in the treatment of malignant disease if the cells are free of malignancy and were harvested before chemoradiotherapy conditioning. This type of material can be cryopreserved for an extended period prior to reinfusion. Syngeneic stem cells from an identical twin also are ideal because they are genetically indistinguishable from those of the recipient.

In many cases, HSCT is undertaken with allogeneic but phenotypically similar marrow or peripheral blood stem cells. In the best case, an HLA-identical sibling is available to serve as the donor, thus minimizing the antigenic disparity. Siblings have a 25% chance of being HLA identical. Allogeneic HSCT also may be performed using partially HLA-matched donor sources. International tissue typing banks may make it possible to identify unrelated volunteer donors who are HLA identical.

IMMUNOLOGIC ALTERATIONS

Intensive chemoradiotherapy conditioning regimens produce predictable alterations in host defenses related to granulocytopenia and ablation of humoral and cell-mediated immunity. Circulating granulocytes generally recover within the first 3 weeks after marrow infusion. Normal numbers of lymphocytes are seen within a month after HSCT, but antibody production is often delayed for 3 or more months. Host immunoglobulins may circulate for 3 months. At 1 year, serum levels of IgM and IgG are usually normal, but serum and secretory IgA levels remain low for a longer period. T-cell–dependent antigen production, response to vaccination, and skin reactivity to antigens may be delayed for months to a year. Alveolar macrophages of host origin persist for weeks to months before being replaced by donor cells (Fig. 73-1).

Patients with chronic graft-versus-host disease (GVHD) have persistently decreased cell-mediated immunity and antigen-specific antibody responses. These alterations are caused by the GVHD and are independent of immunosuppressive treatment.

Complications of Hematopoietic Stem Cell Transplantation

The morbidity and mortality of HSCT are related primarily to relapse of malignancy, conditioning-related toxicities, infection, and donor-recipient antigenic disparity (leading to graft rejection or GVHD)[2] (Table 73-1). Specific complications tend to occur within well-defined periods of immunologic alteration after intensive conditioning regimens.[3] Knowledge of these periods makes diagnostic decisions in the HSCT recipient easier than in many other immunosuppressed hosts. At major transplantation units about 40% of HSCT recipients require intensive hemodynamic monitoring or critical care procedures, such as hemodialysis or mechanical ventilation. The following section discusses the incidence and presentation of

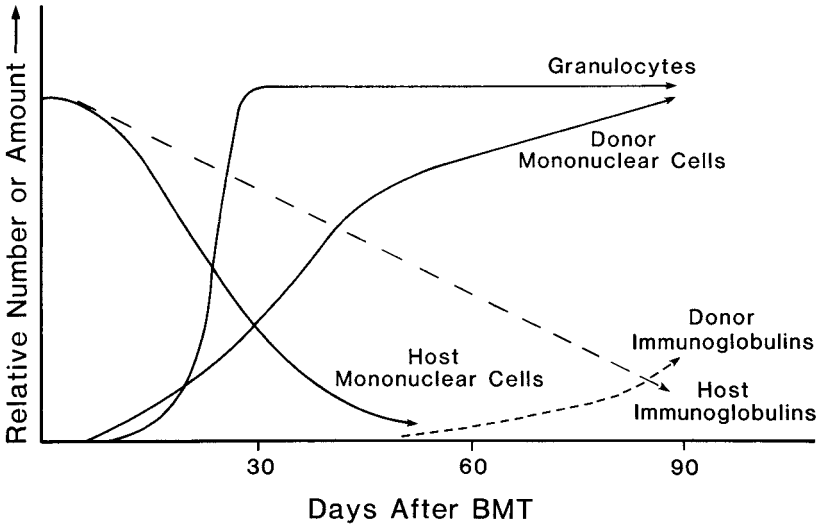

FIGURE 73-1 Alterations in host defense marrow transplantation.

complications that are of concern to the critical care provider. With the exception of the immunologic aspects, complications of HSCT are similar to those of intensive antineoplastic therapy.

COMPLICATIONS OF CYTOREDUCTIVE CHEMOTHERAPY

Infections are very common after HSCT. Bacteremia or serious bacterial infection is noted in up to 50% of HSCT recipients. Infection with *Aspergillus* species and colonization and infection with *Candida* also have become major clinical problems.[4,5] The risks for bacterial and fungal infections are related mainly to the routine use of central venous access lines (e.g., Hickman catheters), prolonged neutropenia, and immunosuppression to prevent GVHD.

TABLE 73-1 Complications after Marrow Transplantation

Rejection of marrow graft
Relapse of malignancy
Conditioning-related toxicity
Hepatic VOD
Oral mucositis
Idiopathic pneumonia
Leukoencephalopathy
Neuropathy
Myopericarditis
Hepatitis
Infection
Venous access line infection
Bacteremia, fungemia
Pneumonia
Viral
Fungal
Bacterial
P. carinii
GVHD
Acute
Chronic
Idiopathic pneumonia
Obliterative bronchiolitis

Gastrointestinal manifestations of conditioning-related toxicities are common. Desquamation of the oropharyngeal and gastrointestinal mucosa (mucositis) secondary to high-dose radiotherapy and administration of antimetabolites generally occurs within the first 3 weeks after transplantation. The mucositis and the opiate analgesics administered to temper the pain increase the risk of pulmonary aspiration and necessitate intravenous alimentation.

Although relatively uncommon, congestive cardiomyopathies and pleuropericarditis syndromes associated with preparative regimens involving cyclophosphamide and anthracycline are seen occasionally. Central nervous system (CNS) complications also may be seen with specific drug treatments. Both Guillain-Barré syndrome and peripheral neuropathies have been described after cytarabine treatment. Toxicity due to cyclosporine may cause an altered sensorium and coma. Complications of cancer therapy, such as cyclophosphamide-induced hemorrhagic cystitis, tumor lysis syndromes, and chemotherapy-related neurologic and pulmonary reactions, also may be observed.

RELAPSE AND REJECTION

Relapse of the primary malignancy and rejection of the donor marrow are fatal complications. Fortunately, immune-mediated graft rejection is relatively uncommon (<1% of patients) in recipients of HLA-identical marrow prepared with total body irradiation (TBI). Its incidence rises with increasing degree of HLA disparity and is also elevated in previously transfused patients with aplastic anemia who were not prepared with TBI. Recurrence of malignancy after transplantation is seen in approximately 20% of patients who undergo transplantation while in early-stage leukemia (i.e., in a first remission or a chronic phase) and in 50% to 70% of patients who undergo transplantation while in advanced leukemia (a relapse or blast crisis).[6] Most relapses occur with host-type cells and signal ineffective antineoplastic treatment. Extramedullary conditioning–related toxicities limit the intensity of the cytoreductive regimens that can be used. A second transplantation following repeat preparative conditioning may be successful, but mortality remains high owing to prolonged pancytopenia.

TABLE 73-2 Grading of GVHD

Grade	Degree of Organ Involvement
1	+ to ++ skin rash; no gut involvement; no liver involvement; no decrease in clinical performance
2	+ to + + + skin rash; + gut involvement or + liver involvement (or both); mild decrease in clinical performance
3	++ to + + + skin rash; ++ to + + + gut involvement or ++ to + + + liver involvement (or both); marked decrease in clinical performance
4	Similar to grade 3 but with ++ to + + ++ organ involvement and extreme decrease in clinical performance

GRAFT-VERSUS-HOST DISEASE

This clinicopathologic syndrome is an immunologic reaction of donor lymphocytes to "foreign" antigens present on the surface of host cells. Transplantation (HLA) antigens are important, as are "minor" antigens not detected by current typing techniques. Overall, acute GVHD occurs in 20% to 50% of allograft recipients and in up to 80% of recipients of HLA-nonidentical grafts.[6] GVHD is categorized as acute or chronic according to time of presentation, organ involvement, and histology.

ACUTE GVHD

Incidence

Acute GVHD occurs within the first 3 months after HSCT. The reactions are seen in 20% to 50% of HLA-identical marrow recipients. The incidence increases with patient age and with the degree of HLA disparity between host and donor.

Manifestations

The histologic hallmark of acute GVHD is lymphocytic infiltration of the epidermis and gastrointestinal tract. The clinical syndrome is composed of dermatitis, enteritis, and hepatitis. The severity of GVHD is commonly determined by a grading system (Table 73-2). The grade depends on the stage of GVHD in the skin, liver, and gut (Table 73-3). Fever, diffuse macular dermatitis (often leading to bullae and desquamation), cramping abdominal pain, watery to bloody diarrhea, and jaundice with cholestasis and hepatocellular necrosis may be seen. The most dramatic presentation, in the absence of prophylactic immunosuppression occurs as early as 7 days after HSCT. This hyperacute GVHD is accompanied by exfoliative dermatitis, shock, and hyperpyrexia. Mortality increases with increasing severity of acute GVHD and often is related to associated infectious complications.

Immunology

The principal effector cells responsible for GVHD appear to be immunocompetent donor cytotoxic T-lymphocytes. These cells differentiate and proliferate in response to host histocompatibility antigens. It is likely that lymphokine production from sensitized lymphocytes recruits additional effector mononuclear cells to participate in the alloimmune response.

Although histocompatibility matching is an important first step in trying to reduce the severity of acute GVHD, this tactic alone is ineffective in preventing GVHD. Almost all recipients of unmodified allogeneic marrow develop GVHD if not given posttransplant immunosuppression. Methotrexate and cyclosporine appear to be equally effective in decreasing the incidence of acute GVHD. Their combined use gives better results than the use of either agent alone. Attempts at removing donor T-lymphocytes from the marrow inoculum have been effective in lessening GVHD, but this advantage is offset by an increase in the rates of graft rejection and recurrent leukemia.

CHRONIC GVHD

Incidence

Chronic GVHD is seen in 20% to 50% of allograft recipients. It develops more than 3 months after HSCT. While it usually occurs in patients who experienced acute GVHD, 20% to 30% of cases occur in patients without prior acute GVHD.

Manifestations

Chronic GVHD mainly involves skin, mucous membranes, and liver. The characteristic pigmentation and sclerosis of the skin, lichenoid oral plaques, esophagitis, polyserositis, and oral and ophthalmic sicca syndrome resemble the manifestations of collagen-vascular disorders. Elevated alkaline phosphatase and transaminase levels occur in 90% of patients. Chronic wasting due to anorexia is common in untreated patients. Chronic pulmonary diseases are seen in 10% to 20% of patients and are divided between diffuse pneumonias and obliterative bronchiolitis.

Mortality from chronic GVHD is related to type of onset and extent of the disease. Mortality is lower when the disease is limited to the skin and liver and when it occurs in the absence of prior acute GVHD. Death is usually caused by infection.

Immunology

Minor differences in histocompatibility antigens and deficient thymic function may play a role in the immunopathogenesis of chronic GVHD. Patients with GVHD have an increase in

TABLE 73-3 Staging of Acute GVHD

Stage	Skin	Liver	Gut
+	Maculopapular rash over <25% body surface	Bilirubin level, 2–3 mg/dL	Diarrhea of 500–1000 mL/day
++	Maculopapular rash over 25% to 50% body surface	Bilirubin level, 3–6 mg/dL	Diarrhea of 1000–1500 mL/day
+ + +	Generalized erythroderma	Bilirubin level, 6–15 mg/dL	Diarrhea of >1500 mL/day
+ + ++	Desquamation and bullae	Bilirubin level, >15 mg/dL	Pain or ileus

nonspecific suppressor lymphocyte function and lack the specific suppression of cytotoxic reactivity to host alloantigens. Cytokine mediators may propagate autoimmune-like tissue injury.

Chronic immunodeficiency persists as long as the disease is active and places these patients at risk for opportunistic infection. Immunoglobulin deficiencies are common and likely are responsible for the increased incidence of fatal infections with *Streptococcus pneumoniae.*

HEPATIC VENO-OCCLUSIVE DISEASE

Liver disease is a common and complex problem after HSCT. The most serious complication is hepatic veno-occlusive disease (VOD) (Table 73-4).

Incidence

The incidence of hepatic VOD ranges from less than 2% among patients who undergo transplantation for nonmalignant conditions without TBI conditioning to 20% to 60% for those with malignancy who undergo conditioning with chemotherapy and TBI. Higher rates are seen with increasing age of marrow recipients and prior hepatitis. The mortality rate of hepatic VOD is approximately 30%. There is no known effective treatment, although there has been some recent interest in defibrotide, a novel oligodeoxyribonucleotide.[7]

Presentation

Hepatic VOD is distinguished from other liver diseases in part by the timing of presentation. Occurring within 2 weeks of HSCT, it appears earlier than hepatic manifestations of acute GVHD. Typically seen are progressive weight gain with peripheral edema, a peaking of hepatic enzyme levels within 2 weeks, jaundice, ascites, and painful hepatomegaly. Metabolic encephalopathy and renal failure consistent with the hepatorenal syndrome may occur.

Pathogenesis

The pathologic lesion is terminal hepatic venule occlusion and hemorrhage. Subendothelial thickening with edema and deposition of fibrin and clotting factors is later replaced by cellular debris and a fibrotic reaction involving terminal venules and sinusoids. Hepatocellular injury around the terminal venule is prominent.

Endothelial cell damage from high-dose chemoradiotherapy is a likely inciting event. Deposition of coagulants and microthrombosis probably lead to venular obstruction. The resulting passive congestion and ischemia cause necrosis of surrounding hepatocytes. Toxicities of antimetabolic drugs and viral hepatitis may impair cellular metabolic repair mechanisms and contribute to hepatic injury.

PNEUMONIA

Incidence and Pathogenesis

Historically, pneumonia develops in 40% to 60% of HSCT recipients; however, the rate may be substantially lower among those undergoing nonmyeloablative transplants.[8–10] Both infectious and noninfectious etiologies are seen, and the prevalence of these varies with the time after HSCT (Table 73-5).

TABLE 73-4 Gastrointestinal Disease after Marrow Transplantation

		DAYS AFTER TRANSPLANTATION		
	Pretransplant	Days 0–20	Days 20–100	Beyond Day 100
Liver disease	Viral hepatitis, leukemia, drug effect, tuberculosis	VOD, bacteremia, drug effect, fungal infection, parenteral nutrition, early GVHD	Acute GVHD, viral hepatitis, persistent VOD, fungal infection, drug effect, EBV lymphoma	Chronic GVHD, viral hepatitis (chronic), drug effect, infection (mycobacteria)
Ascites	—	VOD, peritonitis	Persistent VOD, acute GVHD, peritonitis, hepatic vein obstruction, pericarditis, pancreatitis	Chronic hepatitis (viral, chronic GVHD)
Diarrhea	Fungal infection, parasites, drug effect	Conditioning therapy, drug effect, infection, early GVHD	Acute GVHD, infection, drug effect	Persistent acute GVHD, infection, bacterial overgrowth (chronic GVHD)
Nausea/vomiting	Bacteremia, liver disease, drug effect	Conditioning therapy, drug effect, infection, early GVHD	Infection (herpesvirus), acute GVHD, drug effect	Drug effect, chronic GVHD
Esophageal symptoms	Infection, reflux esophagitis	Esophagitis (fungal, bacterial)	Esophagitis (viral), reflux esophagitis	Chronic GVHD, reflux esophagitis
Intestinal bleeding	Peptic ulcer	Esophagitis (infections), "stress ulcers," Mallory-Weiss tears	Esophagitis (infections), "stress ulcers," GVHD, viral ulcers (mostly CMV), EBV lymphoma	Persistent acute GVHD
Abdominal pain	—	VOD, conditioning therapy enteritis	Acute GVHD, infection, drug effect (ileus), liver abscess, cholecystitis, peritonitis, pancreatitis, cystitis, herpes zoster	Persistent acute GVHD, infection

TABLE 73-5 Incidence of Common Etiologies for Pulmonary Infiltrates after BMT

Complications	Approximate Incidence, %
COMPLICATIONS WITHIN 100 DAYS	
Pulmonary edema syndromes	0–50
Infectious pneumonia	20–30
Bacterial	2–30
Fungal	4–13
Viral	4–10
Protozoal	<5
Idiopathic pneumonia	7–12
Pulmonary VOD	Rare
COMPLICATIONS AFTER 100 DAYS	
Bacterial bronchopneumonia	20–30
Idiopathic pneumonia	10–20
Viral pneumonia	0–10
Obliterative bronchiolitis*	2–11

*Obstructive airflow among marrow recipients with chronic GVHD

INFECTIOUS PNEUMONIA

The true incidence of bacterial bronchopneumonia is unknown but ranges from 2% (documented by open lung biopsy) to over 25% (noted at autopsy).[11] Commonly isolated bacteria can include *Pseudomonas aeruginosa, Mycobacterium avium* complex, *Enterobacter cloacae,* and *Serratia.*[12,13] The frequency of invasive fungal disease due to *Aspergillus, Zygomycetes,* and *Candida* species is increasing. *Aspergillus* infection most often involves the lung and is seen in 10% to 25% of patients with HSCT.[4,5] Both fiberoptic bronchoscopy and fine-needle aspiration may be useful in diagnosing *Aspergillus* infection.[12,14,15] Invasive *Candida* infection is also prevalent in HSCT patients, and autopsy data suggest that 50% of infected patients have pulmonary involvement.[11,16] *Zygomycetes* appears to be an emerging pathogen that has a particularly rapidly progressive course and is reported to occur in up to 1.2% of HSCT patients.[17,18]

Cytomegalovirus (CMV) pneumonia occurs primarily among HSCT recipients with previous CMV infection (documented by positive serology) or in seronegative recipients who receive stem cells from seropositive donors. Among seronegative recipients of seronegative stem cells, use of either seronegative or leukocyte-filtered blood products markedly decreases the rate of CMV infection.[19] In the absence of pre-emptive antiviral therapy, between 30 and 150 days after HSCT, 60% to 80% of diffuse pneumonias are due to CMV.[20,21] The rate of CMV pneumonia can be reduced dramatically by the administration of ganciclovir either prophylactically or at the time of first viral excretion.[22] Other herpesgroup viruses, such as herpes simplex virus (HSV) and varicella-zoster virus (VZV), are seen less commonly because of the prophylactic administration of acyclovir. Likewise, *Pneumocystis carinii* pneumonia (PCP) is rare after a pretransplant course of trimethoprim-sulfamethoxazole prophylaxis. Respiratory syncytial virus (RSV) and parainfluenza virus are common causes of diffuse pneumonia during outbreaks in the community.

NONINFECTIOUS CAUSES OF PULMONARY INFILTRATES

In 20% to 30% of patients with suspected pneumonia after HSCT, no infection is demonstrated. The causes of noninfectious pulmonary disease after HSCT include pulmonary hemorrhage, edema, acute respiratory distress syndrome (ARDS), idiopathic interstitial pneumonia, and drug toxicity. Less common are thromboemboli, vasculopathy, and a leukemic/lymphoma infiltrate. Lymphangitic carcinoma also may be present. Noninfectious pneumonia is recognized to represent a spectrum of lung injuries owing to multiple causes with a common clinical presentation. These diffuse noninfectious pneumonias are now referred to collectively as the *idiopathic pneumonia syndrome*[23] (Table 73-6).

Presentation

The etiologies and severity of the lung diseases seen vary with the time after HSCT. Focal or patchy infiltrates in the first 30 days after HSCT (a period of granulocytopenia) frequently represent bacterial or fungal infection. Bacteria are an unusual cause for diffuse infiltrates. Focal radiographic lesions with a masslike appearance that develop or persist despite antibiotics are pulmonary fungal infections in most cases.[15,24] Occasionally, *Pseudomonas, Legionella,* and rarely, *Nocardia* species are identified in localized lesions.

Pulmonary edema related to excess intravascular fluid administration, cardiotoxic chemotherapy, or ARDS from chemoradiotherapy injury or sepsis, in addition to pulmonary hemorrhage (diffuse alveolar hemorrhage) due to thrombocytopenia, cause most diffuse infiltrates occurring in the first 30 days. These patients frequently suffer from multiorgan disease owing to conditioning-related toxicities or grade 2 to 4 (moderate to severe) acute GVHD. Thus pancytopenia, hepatic and renal failure, desquamating skin lesions, and mucositis complicate both evaluation and management. Within 30 days, diffuse infiltrates often are acute in onset and progress rapidly to respiratory failure. During this time, respiratory syncytial virus and parainfluenza virus are the major infectious causes of diffuse infiltrates, particularly during endemic months.[25]

Beyond 30 days, viral pneumonias, especially CMV, predominate as causes for diffuse pulmonary infiltrates in seropositive patients not receiving ganciclovir. Onset ranges from insidious to rapid progression from tachypnea to hypoxia with respiratory failure. Unfortunately, similar presentations are seen with idiopathic pneumonia or PCP. There is little to distinguish these etiologies clinically. After 30 days, the CMV pneumonia is usually milder and slower in onset. However, progression to profound respiratory failure often follows.

Late after HSCT (>100 days), diffuse pulmonary disease is most often insidious in onset. These late pneumonias occur predominantly among allogeneic marrow recipients with chronic GVHD.[26] Viral pneumonias (CMV or VZV) are seen but become less common after day 100. *Pneumocystis* infection occasionally presents in patients with chronic GVHD and inadequate trimethoprim-sulfamethoxazole prophylaxis. Late-onset noninfectious pneumonia, possibly due to late radiation- or cyclophosphamide-induced pulmonary damage, is identical in presentation clinically to other diffuse pneumonias.

TABLE 73-6 Criteria for Diagnosis of Idiopathic Pneumonia Syndrome

1. Evidence of widespread alveolar injury:
   - Multilobar infiltrates on chest radiography or computed tomography
   - Symptoms and signs of pneumonia
   - Evidence of abnormal physiology

   and
2. Absence of active lower respiratory tract infection documented by:
   - Negative bronchoalveolar lavage, lung biopsy, or autopsy with examination of stains and cultures for bacteria, fungi, and viruses, including cytomegalovirus (CMV) centrifugation culture, cytology for viral inclusions and *Pneumocystis carinii*, and immunofluorescence monoclonal antibody staining for CMV, respiratory syncytial virus, influenza virus, parainfluenza virus, and adenovirus.

OBLITERATIVE BRONCHIOLITIS

Incidence

Early estimates suggest that about 10% of allogeneic HSCT recipients develop progressive airflow obstruction usually more than 3 months after HSCT. However, more recent estimates, which use less stringent airflow obstruction parameters, indicate that the incidence may be as high as 26% overall and up to 32% incidence among patients with chronic GVHD.[27] The major risk factor is chronic GVHD, and most, but not all, patients have an obliterative bronchiolitis pattern histologically.[28] Other significant risk factors include age greater than 60 years at the time of transplant and pretransplant FEV_1/FVC ratio of less than 70%.[27] The relationship between airflow obstruction and GVHD has led to speculation that expression of class II histocompatibility antigen on bronchial epithelial cells triggers a cytotoxic lymphocyte response.

Manifestations

The diagnosis depends on demonstration of airflow obstruction by pulmonary function testing. Some HSCT recipients are asymptomatic when this alteration is detected. Typical manifestations are insidious progression of dyspnea on exertion and cough.[29,30] There may be few physical findings, and the chest radiograph may be normal. Rarely, the onset is acute, and profound wheezing is noted, particularly when symptoms are seen early after HSCT. Both viral and fungal airway infections may present similarly.

Although this disorder often is progressive and results in death because of respiratory failure, the rapidity of onset and rate of progression predict the outcome. Control of chronic GVHD with increased immunosuppression may achieve stabilization of the airway disease.

Diagnosis and Management of HSCT Complications

PRINCIPLES OF CARE

INFECTION CONTROL

Infection is a major cause of morbidity and mortality among severely immunosuppressed HSCT recipients. Prophylactic daily administration of oral trimethoprim-sulfamethoxazole for the 2 weeks prior to HSCT and twice weekly after adequate granulocyte engraftment has virtually eliminated the occurrence of PCP. Patients with sulfa allergies should undergo desensitization. Prophylaxis with either pentamidine or dapsone is associated with more failures than trimethoprim-sulfamethoxazole.[31]

Prophylactic measures have decreased the incidence of herpesvirus infections. Pretransplant serologic testing identifies previously infected recipients who are at risk for reactivation infection with CMV and HSV. Transmission of CMV infection can be avoided by providing the recipient with blood products from CMV-seronegative donors.[19] Similarly, the rate of HSV reactivation after HSCT can be reduced by prophylactic treatment with acyclovir after HSCT. Surprisingly, this treatment also decreases the incidence of CMV infection by about a third, even though acyclovir has little in vitro activity against CMV. The use of ganciclovir as prophylaxis for seropositive patients or as pre-emptive treatment at the first evidence of viral excretion or viremia significantly reduces the incidence of CMV pneumonia.[22]

GVHD PROPHYLAXIS

Morbidity and mortality increase with increasing grades of GVHD. GVHD causes direct organ damage and may lead to fatal hepatic failure, gastrointestinal bleeding, or diffuse exfoliative dermatitis. In addition, it increases the incidence of other potentially fatal complications, such as CMV enteritis, pneumonia, and bacterial and fungal infection. Virtually all allograft recipients who do not receive in vivo immunosuppressive prophylaxis develop acute GVHD. As noted earlier, prophylaxis with a combination of methotrexate and cyclosporine decreases the incidence of acute GVHD to about 25%.

SEPSIS SYNDROME

Hypotension and fever are common in marrow recipients, especially during the period of neutropenia. Whereas the basic approach to these situations is similar to that described elsewhere for other neutropenic hosts (see Chap. 47), the HSCT recipient poses several distinct problems.

Bloodstream infection is noted in up to 50% of HSCT recipients, and coagulase-negative staphylococci and *Candida* species predominate. This prevalence influences antibiotic choices and frequently prompts the empirical addition of antistaphylococcal and antifungal agents.

Systemic viral infections are seen with higher frequency after HSCT than after conventional chemotherapy. Herpesviruses, CMV in particular, almost uniformly reactivate after allogeneic HSCT in previously infected patients who develop acute GVHD, and the infection may present with

a septic appearance. CMV viremia has been associated with high cardiac output and a low systemic vascular resistance (SVR), which are suggestive of the sepsis syndrome. It is unclear whether this response is due to viremia or to concomitant processes often associated with CMV infection, such as GVHD.

A diagnostic dilemma posed by sepsis syndrome is differentiation of true bacterial or fungal sepsis from acute GVHD. The cardiovascular responses to systemic cytotoxic lymphocyte activation in acute GVHD may be indistinguishable from those of endotoxemia. As with endotoxemia, acute GVHD may be associated with high levels of circulating tumor necrosis factor (TNF) and other vasoactive cytokines. In our experience, a profoundly decreased SVR and relative hypotension are seen with the acute onset of GVHD. In patients with uncompromised myocardial function, stroke volume increases, and cardiac output may exceed three times normal. These patients have fever, diffuse cutaneous hyperemia, and bounding peripheral and precordial pulses. Diffuse pulmonary infiltrates, azotemia, and altered sensorium may follow in severely ill patients.

GVHD increases the risk of infection and subsequent sepsis, and the two conditions often coexist. Allogeneic HSCT recipients with clinical sepsis therefore should be presumed to have infection. Empirical antibiotic coverage should be started and modified on the basis of culture results and local patterns of endemic infection and resistance. The assessment of potential GVHD should be made on clinical grounds and biopsy of appropriate tissues. Often the pattern of dermatitis strongly suggests acute GVHD, and biopsy may confirm this suspicion.

Confounding the evaluation and treatment of sepsis syndrome in the marrow recipient is the frequent finding of relative intravascular volume expansion. Up to 50% of HSCT recipients develop pulmonary edema within the first weeks after HSCT. This problem generally is attributable to excessive administration of crystalloid fluids. In addition to exogenous fluid administration, intravascular volume is often replete owing to fluid and sodium retention from hepatic VOD. Thus brisk volume replacement often is not necessary in these patients to maintain arterial blood pressure when SVR declines. However, blood loss, often from occult gastrointestinal sources, may complicate the volume management of the marrow recipient with sepsis.

One critical determinant of survival in such situations appears to be cardiac function. An inability to respond with an increased cardiac output is associated with high mortality. The clinical assessment of the intravascular volume necessary to provide adequate left ventricular filling is extremely difficult in these rapidly changing patients. Given the potential complexities of diagnosis and management, central hemodynamic monitoring may be useful to guide fluid and vasoactive therapy. Positive inotropic support may be provided for patients who have an inadequate stroke volume despite "normal" pulmonary artery occlusion pressures.

GVHD

Diagnosis and management of acute GVHD are crucial to success in allogeneic HSCT. These aspects of care often involve the critical care physician in collaboration with the oncologist. Acute GVHD occurs most frequently during the initial hospitalization for HSCT. Such patients are at risk of death as a result of multisystem involvement by the GVHD and frequently require intensive care management. In addition to the acute illness associated with the onset of acute GVHD, risks of potentially fatal bacterial or fungal infection are also present.

In contrast to acute GVHD, chronic GVHD mainly represents a limitation to long-term survival. The major life-threatening problems relate to infectious complications resulting from prolonged deficits in antigen-specific antibody production, increased nonspecific suppressor lymphocyte activity, and phagocytic dysfunction. Thus acute disseminated bacterial infections and opportunistic pulmonary infections pose the greatest threats. These occur primarily in the ambulatory care setting and only later involve the critical care physician.

ACUTE GVHD

Since acute GVHD is a clinicopathologic syndrome, the presentation may only suggest the diagnosis. Dermatitis, jaundice, and enteritis may be caused by various insults, such as chemoradiotherapy, disseminated infection, or drug toxicity. Histologic confirmation of the diagnosis is made by biopsy (often repeated) of affected organs. Skin is involved most often and is biopsied; however, liver and gastrointestinal tract are also amenable to this approach. Thus invasive procedures usually are necessary to confirm the diagnosis of acute GVHD in the presence of skin, liver, or gastrointestinal tract disease. Occasionally, fever is the major manifestation, and biopsy of other organs is too risky. In this case, "blind" biopsy of skin becomes necessary for diagnosis.

However, verification of the diagnosis does not eliminate the possibility of coexisting causes of similar features, such as infection. Repeated blood cultures should be prompted by persistent fever. Nausea and vomiting should be evaluated by endoscopy to exclude viral, bacterial, or fungal infection, and diarrheal stool should be examined and stained for bacterial pathogens. Vigilant search for other etiologies should continue. Exfoliative dermatitis should be biopsied to exclude toxic epidermal necrolysis due to drug sensitivity. Liver and endoscopic gastrointestinal tract biopsies may be necessary to exclude infectious complications.

Treatment of established acute GVHD is often difficult. Current strategies use increased immunosuppression with corticosteroids (methylprednisolone, 2 mg/kg per day), antithymocyte globulin (ATG), and continued methotrexate and cyclosporine administration.[32] The survival rates for steroid-resistant GVHD are poor, and death is most often due to infection. The administration of monoclonal antibodies directed against T-lymphocytes shows promise as a method of "turning off" the disease.

Supportive care of the marrow recipient with acute GVHD assumes great importance because of the difficulties posed by treatment and the threat of fatal infectious complications. Continued surveillance for viral, bacterial, or fungal infection is mandatory. A chest x-ray is obtained at least weekly, and abnormalities are evaluated aggressively. Prophylactic broad-spectrum antibiotics should be continued for the duration of neutropenia or in the presence of fever and immunosuppressive therapy.

Adequate nutrition is vital but often poses problems in the presence of severe enteric GVHD. Malabsorption is

common, and return to oral feeding often is delayed. Total parenteral nutrition (TPN) may be required for prolonged periods. Cramping and diarrhea may necessitate parenteral opiate analgesics, even at the risk of ileus.

Depression of marrow function and systemic viral infection sometimes are manifestations of severe acute GVHD. Thrombocytopenia due to decreased platelet production may be compounded by rapid turnover because of fever and bleeding. Support of hemostasis usually requires repeated transfusions of platelets. Vitamin K should be given when the prothrombin time is elevated, but it may fail to correct the problem in the presence of hepatic failure, necessitating the administration of plasma to correct the hemostatic defect. Bleeding from the gastrointestinal tract is common and may be severe. A thorough evaluation for the site(s) of severe or persistent bleeding is recommended. Often diffuse intestinal hemorrhage because of ulceration from GVHD is found at endoscopy. However, focal bleeding from infectious ulcers or peptic disease may be identified. Angiography or nuclear medicine studies may be useful, and surgical correction of localized bleeding may be successful.

HEPATIC FAILURE

Differential Diagnosis

Liver disease is common after HSCT. The etiologies are varied, and their interactions are complex (see Table 73-4). Hepatic VOD and GVHD account for the majority of cases and, in part, can be differentiated on the basis of time of presentation and biochemical patterns.[33] However, drug toxicities (of cyclosporine, antibiotics, and antimetabolites) and infections, especially viral (hepatitis B, hepatitis C, CMV, HSV, and EBV) and bacterial or fungal, also may cause liver disease. Renal impairment prevents the normal excretion of conjugated bilirubin, and continued hemolysis contributes to jaundice beyond that expected for the degree of liver disease.

Levels of hepatic transaminases rise and peak within 2 weeks of transplantation in hepatic VOD. Fluid retention and jaundice develop early in the course and may be severe. Hepatic VOD must be distinguished from passive hepatic congestion from right-sided heart failure, pancreatitis, hepatic vein thrombosis, invasive fungal disease, or septicemia with peritonitis.

Liver disease due to GVHD tends to occur after day 20 and in the presence of clinical disease in other organs. Elevations in alkaline phosphatase may peak at 20 times normal levels, much higher than seen in hepatic VOD.

Imaging modalities such as computed tomographic (CT) scanning and ultrasonography are useful in defining liver density, focal lesions, collateral circulation, and the presence of ascites. Percutaneous liver biopsy carries risks of hemorrhage in thrombocytopenic patients but may be critical in defining pathology and providing culture material in difficult cases. Transjugular approaches to the hepatic vein for liver biopsy may prove to be safer. Occasionally, paracentesis is required to exclude fungal or bacterial infection and to relieve pressure in patients with respiratory embarrassment.

Management

The management of VOD of the liver is primarily supportive and may be ineffective in preventing progressive hepatic failure. Restriction of fluid and sodium intake, along with judicious use of loop diuretics, may prevent extracellular fluid accumulation. However, ascites and edema often develop prior to overt jaundice and suggest that active sodium retention owing to renal disturbance is important. A major cause of mortality is the development of the hepatorenal syndrome. Care must be exercised to avoid compromising renal perfusion while trying to decrease ascites. Intravascular volume usually is maintained with replacement of blood products to ensure renal perfusion. However, hemodialysis may be necessary. Renal failure in these settings is often multifactorial. The administration of multiple nephrotoxic drugs appears to play a part.

Surgical shunting procedures to decompress the portal circulation are risky and have unproven benefit in this setting. Management of ascites with peritoneovenous shunt likewise poses great risks. Potential treatments to limit venule obstruction by microthrombosis may include prophylactic anticoagulation or thrombolytic therapy. This theoretical approach is certainly not without risk in the setting of prolonged thrombocytopenia. Thrombolytic therapy with recombinant tissue plasminogen activator has been successful in improving hepatic blood flow in some patients. This therapy is associated with a case-fatality rate of 10% and a response rate of 40% to 50%, and it should be used only for patients likely to die. Defibrotide, an agent with antithrombotic properties, as well as potentially beneficial endothelial effects, has been reported to be effective in some patients with hepatic VOD, particularly when given early in the course.[7]

Liver disease caused by GVHD requires intensive therapy for the GVHD. Specific interventions do not appear to be beneficial. Hepatic encephalopathy is approached as it is with any chronic liver disease (see Chap. 84). Modifications in dietary protein intake and clearing of the gastrointestinal tract with lactulose should be instituted.

PNEUMONIA

DIAGNOSTIC APPROACH

The clinical presentations of pulmonary disease after HSCT have been reviewed in this chapter and in the recent literature.[3,34] The diagnostic approach to pulmonary disease after HSCT differs from that for other categories of immunosuppressed hosts owing to the difference in prevalence of specific etiologies.

In the 30 days after HSCT, also referred to as the *preengraftment* or *neutropenic phase,* there is a low prevalence of infectious causes for diffuse pulmonary infiltrates.[8] Empirical treatment with broad-spectrum antibiotics is recommended, and diuresis and sodium restriction frequently improve the clinical status of the patient. Occasionally, pulmonary artery wedge measurement (or cardiac echocardiography) may be helpful to exclude pulmonary edema and guide therapy. Correction of bleeding disorders, including adequate platelet support, and maintenance of euvolemia may help to prevent further pulmonary hemorrhage, if present. If clinical deterioration ensues or respiratory viruses such as respiratory syncytial virus are present in the community, nasal saline irrigation and/or fiberoptic bronchoscopy with bronchoalveolar lavage (BAL) is recommended to exclude treatable pulmonary infection.[35]

More than 30 days after HSCT, most centers perform fiberoptic bronchoscopy with BAL, unless pulmonary edema

is strongly suspected as the cause of diffuse pulmonary infiltrates. These specimens are processed with rapid-detection techniques for viral pathogens, especially CMV. The techniques include direct fluorescent monoclonal antibody stains and centrifugation culture (shell vial) for CMV.[21,36] High sensitivity for the detection of virus in as little as 16 hours has been reported for these tests. In addition to bacterial, fungal, and cytologic stains, a quantitative bacterial culture is performed.

Experience has shown that in the HSCT recipient, open lung biopsy for the evaluation of diffuse infiltrates is unlikely to reveal pathogens not detectable by BAL. Thoracotomy may be reserved for HSCT recipients with nondiagnostic BAL (sometimes repeated) who have high risk of undiagnosed infection, such as *P. carinii* infection, if prophylaxis was not given.

Focal pulmonary lesions are evaluated aggressively because these more likely represent bacterial or fungal infection. CT scan of the chest often reveals a masslike appearance of the lesion with a zone of attenuation highly suggestive of invasive pulmonary fungal infection. Additional lesions not appreciated on plain chest radiograph also may be seen. This finding often alters the approach to diagnosis.

The diagnostic approach to localized lesions in part depends on their radiographic appearance and location(s). Areas of bronchopneumonia usually can be approached with fiberoptic bronchoscopy and BAL. Peripheral lesions may be amenable to percutaneous needle aspiration biopsy for diagnosis; the diagnostic yield for masslike lesions is about 67%, but the negative predictive value is only 50%.[24] Thus a nondiagnostic evaluation should prompt repeat of the procedures or progression to more definitive measures. The most definitive study appears to be biopsy at thoracotomy. Complete surgical resection of pulmonary fungal infection may be both diagnostic and curative in selected patients.

TREATMENT

Bacterial Pneumonia

Fever in the HSCT recipient should be presumed to represent bacterial infection, and empirical antibiotics should be given after appropriate samples for culturing are obtained. Management is identical to that for other immunosuppressed or neutropenic hosts (see Chap. 47). HSCT recipients have a high prevalence of coagulase-negative staphylococcal infections, yet it is unclear how often these infections cause pneumonia. Late after HSCT, chronic GVHD increases the prevalence of systemic pneumococcal infections and mandates prophylactic penicillin or trimethoprim-sulfamethoxazole for the duration of active disease.

Viral Pneumonia

CMV pneumonia previously was fatal in over 85% of affected HSCT recipients. Multiple experimental treatment modalities were unsuccessful in altering the outcome. Favorable responses to combination therapy with ganciclovir and high-titer anti-CMV immunoglobulin are reported.[36–38] Various treatment regimens have been used successfully, usually initially involving administration of ganciclovir 2.5 mg/kg every 8 hours for at least 2 weeks, together with CMV immune globulin 400 to 500 mg/kg three to five times weekly for between 2 and 3 weeks. In some series, continued therapy with lower-dose ganciclovir and CMV immune globulin for a period of several weeks after successful therapy has been suggested to avoid early relapse.

Treatment of other herpes-group viruses is with intravenous acyclovir at doses of 500 mg/m^2 every 8 hours for at least 7 days. Except for CMV, HSV, and VZV, the efficacy of therapy for other viral respiratory infections in this setting remains unproven; however, there are anecdotal reports of success with aerosolized ribavirin, in combination with intravenous immunoglobulin, as treatment for respiratory syncytial virus and parainfluenza virus pneumonias, provided treatment is started early in the disease.

Fungal Pneumonia

Aspergillus species infection is documented in up to 18% of HSCT recipients, but also seen are *Mucormycosis, Fusarium, Rhizopus,* and *Petriellidium*.[39,40] Pulmonary involvement by filamentous fungi is the rule in infected patients. Disseminated yeast infection, especially with *C. albicans,* has declined; however, approximately 50% of patients with invasive *Candida* infection have pulmonary involvement.[16] Mortality rates are as high as 88% for these infections.[5,41]

The major risk factor for invasive fungal infections is the presence of GVHD; however, the level and duration of neutropenia, patient age, total number of other infections, and corticosteroid administration play significant roles.[39,40] The frequency of *Aspergillus* infections is similar between recipients of allogeneic and autologous transplants, but these tend to occur during periods of neutropenia prior to engraftment among autologous marrow recipients and after engraftment among allogeneic marrow recipients.[42] Autologous recipients have fewer *Candida* but not *Aspergillus* infections compared with allograft recipients. Emergence of resistant species (*C. krusei* and *C. glabrata*) is increasing and has been shown to be associated with the widespread use of fluconazole.[42–44]

Among 20 patients with *Aspergillus* infection detected during life and reported by Wingard,[39] only 1 recovered. Early diagnosis and treatment, however, may improve survival rates. Favorable outcome with pulmonary filamentous fungal infection has followed treatment with amphotericin at 1 mg/kg per day to a total dose of 2 g or more.[39,45] The optimal therapy and dosing for invasive aspergillosis has not been established but likely includes amphotericin. Although most successful treatment of these pulmonary fungal infections after HSCT also has included surgical resection, the precise role of surgery is not clear. Recovery by HSCT recipients without complete surgical resection has been noted. Adjunctive therapy with granulocyte transfusions and/or granulocyte colony-stimulating factor (G-CSF) remains investigational.

Treatment for invasive *Candida* infection also is largely empirical. Amphotericin in doses of at least 0.5 mg/kg per day until clinical response occurs is employed commonly. Alternative therapeutic approaches to deep-seated fungal infections recently became available. Recent advances in amphotericin B include the development of lipid formulations. The clinical responses to these formulations are as good (or as bad, depending on your perspective) as those seen with conventional amphotericin B. The reduced toxicity profiles allow administration of significantly higher doses of amphotericin B. However, it is unclear that these higher doses lead to improved efficacy.

The most frequently used second-generation triazole antifungal agent is itraconazole. In a prospective, randomized

study in patients with hematologic malignancies, response rates were better (but not statistically different) for itraconazole (47%) compared with amphotericin B (38%) when used as empirical antifungal therapy.[46] There were no differences in rates of breakthrough fungal infection or deaths. However, the amphotericin B patients experienced significantly more drug-related adverse effects. Such studies suggest that itraconazole may be a reasonable alternative to conventional amphotericin B for empirical therapy.

Voriconazole is a newer triazole antifungal with a broad spectrum of activity against most human fungal pathogens, including *Candida, Aspergillus,* and *Cryptococcus* species, filamentous fungi, and dimorphic fungi. Twice-daily dosing (both intravenously and orally) is available. Studies suggest that voriconazole may be a reasonable alternative to either conventional amphotericin B or liposomal amphotericin.[47,48]

Caspofungin acetate represents the first of a new class of antifungal drugs (echinocandins or glucan synthesis inhibitors) that inhibit the synthesis of β-(1,3)-D-glucan, an integral component of the fungal cell wall. Of note, β-(1,3)-D-glucan is not present in mammalian cells. Caspofungin is not an inhibitor of any enzyme in the cytochrome P450 (CYP) system, unlike the triazoles. The agent has in vitro and in vivo activity against *Candida* species, *Aspergillus* species, and *Histoplasma capsulatum.* Caspofungin has a very low toxicity profile. Because it has a different site and mechanism of action, there is reason to believe that it may be useful in combination with currently available antifungals, such as amphotericin or the triazoles.

Other Infections

Management of *P. carinii, Legionella* species, *Nocardia,* and other unusual infections in HSCT recipients does not differ substantially from that used elsewhere. Few data exist to suggest that the outcome of these infections after HSCT is different from that in other patient populations. Survival is more closely related to the underlying immune deficiencies, GVHD, or conditioning-related toxicities.

Idiopathic Pneumonia

No proven treatment exists for the diffuse idiopathic pneumonia syndrome after HSCT.[23] A biopsy of the lung most often reveals a histologic pattern either of diffuse alveolar damage or mononuclear interstitial infiltrate. About 60% of patients die with progressive respiratory failure, whereas in 25% the process resolves.[49] Supportive management, including assisted mechanical ventilation, is appropriate. However, the overall mortality rate in patients requiring mechanical ventilatory support approaches 95% by 6 months after the insult.[50] Treatment of ARDS-like conditions after HSCT with corticosteroids has not been evaluated in clinical trials, but it is practiced routinely in many centers. We advocate managing idiopathic pneumonia, especially if it occurs more than 100 days after HSCT, in the same manner as idiopathic pulmonary fibrosis in the nontransplant population. In the presence of active GVHD, increased immunosuppression to control that condition is also advised. Improved outcome of patients with diffuse alveolar hemorrhage has been reported with corticosteroid therapy in uncontrolled studies.

Airflow Obstruction

Obstructive airflow in the presence of chronic GVHD is managed primarily by addressing the GVHD with increased immunosuppression. This approach has been noted to halt the progression of pulmonary disease in about half the cases. Improvement in airflow has been noted in only 8% of patients. Treatment and prevention of potential coexisting infection with early and aggressive antibiotic treatment and prophylactic trimethoprim-sulfamethoxazole are encouraged. Evaluation of possible airway infection with bronchoscopy before intensifying the immunosuppression is reasonable. Most patients with chronic GVHD and airflow obstruction have hypogammaglobulinemia. It has been proposed that this deficiency contributes to the pathogenesis of the airflow obstruction by permitting recurrent sinopulmonary infection. We recommend the routine intravenous replacement of immunoglobulin for those with low class or subclass levels.

Respiratory Failure

Studies of intensive care for respiratory failure of patients with cancer and hematologic malignancies have reported low survival rates. Approximately 3% of HCST recipients receiving mechanical ventilation survived to 6 months after transplantation.[51,52] Studies of pediatric HCST recipients find the same poor prognosis as noted among adults; however, limited studies suggest an improving survival trend.[53,54] Improvement in survival rates may be seen with increased use of noninvasive ventilation and earlier intervention, as well as with less intensive radiochemotherapy regimens ("mini-allotransplantation").[3,55]

Multiple-organ failures after HSCT appear to be based on common pathophysiologic derangements and are highly fatal. Pulmonary dysfunction, CNS dysfunction, and hepatic dysfunction are all associated with significant decreases in the levels of antithrombin III and protein C and an increase in the platelet transfusion requirement.[56] Patients with these organ dysfunctions have higher levels of interleukin 6, interleukin 10, and TNF-α than patients who never develop these complications. Mortality rates for patients with these organ dysfunctions vary from 15% in patients with only one organ dysfunction to 100% in patients who have progressed to all three. Patients who develop none of these organ dysfunctions have a mortality rate that approaches zero.[56]

Studies support the idea that severe multiorgan failure with mechanical ventilation after HSCT is fatal.[51,57] Severe lung injury combined with hemodynamic instability or hepatic-renal insufficiency is a sensitive and highly specific predictor of nonsurvival in mechanically ventilated marrow transplant recipients. These overwhelmingly negative results justify a standard of care for mechanically ventilated bone marrow transplant patients that restricts prolonged intensive care. Such information should be used to counsel patients and families to the expected outcomes of such situations.

Chapter 74

TOXICITIES OF CHEMOTHERAPY

APURVA A. DESAI
GINI FLEMING

KEY POINTS

- *Drug toxicity is most often a diagnosis of exclusion.*
- *Dose, schedule, and drug combinations are key parameters used to determine the likelihood of drug toxicity.*
- *Not all toxicities are known, and drug regimens are modified constantly.*
- *Therapy is supportive for most chemotherapy-related toxicities.*
- *Pelvic and spinal irradiation potentiates the myelosuppressive effects of chemotherapeutic agents.*
- *Bleomycin and gemcitabine are among the causes of drug-related interstitial lung disease.*
- *Most cardiac events in cancer patients are related to pre-existing heart disease or direct invasion of the heart by cancer; nonetheless, drug toxicity must be considered, particularly when high-dose cyclophosphamide and anthracyclines have been administered.*
- *In high-dose regimens, cytosine arabinoside, ifosfamide, and methotrexate may produce dramatic central nervous system syndromes.*
- *Renal injury is often dose limiting for cisplatin.*
- *Cytokines such as interleukin-2 have a wide range of toxicities involving virtually all organ systems.*
- *Many commonly used chemotherapeutic agents and several recently introduced targeted anticancer agents are associated with hypersensitivity reactions.*
- *Thrombotic microangiopathy is associated with various chemotherapeutic agents, particularly gemcitabine and mitomycin-C.*

As more intensive anticancer regimens are being used to achieve cure, an increasing number of oncology patients are admitted to ICUs for complications of treatment. Several principles about drug-induced toxicity should be kept in mind.

Drug toxicity is often a diagnosis of exclusion. The toxic reaction to an antineoplastic drug or drugs is frequently nonspecific clinically and even pathologically. Other causes always should be considered. Infection, a tumor effect, and toxicity from other drugs such as antiemetics or antibiotics frequently are elements of the differential diagnosis.

Dose, schedule, and combination make a difference. Most antineoplastic drugs are given in combination, and drugs and radiation are often combined. The toxicities of a given combination may be more severe than the effects of the individual agents would suggest. Moreover, different drug schedules, such as a continuous infusion versus a single bolus dose, may have very different spectrums of side effects for the same agent. Formerly, the dose-limiting toxicity of most agents was myelosuppression, but the introduction of colony-stimulating factors and the rapidly increasing use of autologous stem cell or marrow reinfusion for rescue after very-high-dose drug regimens have exposed a plethora of new toxicities.

Not all toxicities are known. New drugs and new combinations of drugs are being tried constantly and may be used widely before all toxicities are well characterized. Moreover, the diagnosis of drug reactions that are sporadic rather than dose-related is often difficult, particularly in cancer patients who have many symptoms regardless of treatment. The tables in this chapter list the most common or notorious toxicities and are not intended to be comprehensive.

Treatment is supportive. The importance of a diagnosis of treatment-related toxicity is generally that the offending agent can be stopped, and useless remedies or diagnostic procedures can be withheld. Only rarely is specific therapy indicated.

Fever and Hypersensitivity Reactions[1]

A great many commonly used antineoplastic agents can cause acute hypersensitivity reactions. These are particularly common with L-asparaginase, taxanes (paclitaxel and docetaxel), and platinum agents. None of these drugs should be administered without antianaphylaxis medications close at hand. Hypersensitivity reactions were the treatment-limiting factor in early trials of paclitaxel, and this agent is now administered routinely after premedication with corticosteroids and antihistamines, which has significantly reduced the incidence of severe reactions. For the taxanes, the reactions may be related partly to the excipients in which they are formulated. With platinum agents, the hypersensitivity often occurs in the second or third use of the regimen. Several recently approved monoclonal antibodies such as rituximab (RITUXAN) and trastuzumab (HERCEPTIN) are also associated with hypersensitivity reactions.[2,3] Most of the hypersensitivity reactions associated with antibodies can be managed by slowing the rate of infusion of the agent and by premedicating patients with corticosteroids and antihistamines.

Antitumor drugs also may cause fever in the absence of other symptoms of allergy. Bleomycin, which may cause very high fevers, is particularly notorious. Febrile reactions are also often observed with cytarabine.

Myelosuppression[4,5]

Complications of myelosuppression, including infections and bleeding, account for many therapy-related ICU admissions in cancer patients. Management of these problems is discussed elsewhere. Granulocytes (circulating half-life = 6 hours) usually are affected the earliest and most severely, followed by platelets (half-life = 5 to 7 days); red blood cells (RBCs) (half-life = 120 days) are relatively spared unless the patient has received high doses or multiple courses of chemotherapy. Bleeding and other causes of anemia must be considered before a very low hemoglobin level is attributed to antineoplastic chemotherapy alone. There is variation in which cell lines are most suppressed; the nitrosoureas and mitomycin C, for example, typically produce a late, severe thrombocytopenia. For most drugs, the granulocyte count reaches its nadir 7 to 14 days after the administration of a

TABLE 74-1 Granulocytopenia Induced by Antineoplastic Drugs

Drug	Nadir, days	Recovery, days
Most agents	7–14	21–28
Busulfan	21–28	42–56
Melphalan	21	28–40
Mitomycin C	21–28	40–55
Nitrosoureas (BCNU, CCNU)	21–28	35–60

single dose, and recovery occurs by 21 to 28 days. Some agents produce a more delayed pattern (Table 74-1). Patients who have received pelvic or spinal irradiation or who have had multiple courses of chemotherapy suffer more severe and prolonged myelosuppression. The critically ill cancer patient also may have a multitude of other causes for cytopenias, but if doubt exists as to the cause of abnormal blood counts, a bone marrow biopsy should be performed. This procedure can be performed safely on even the sickest patients and is an invaluable aid in excluding many possible diagnoses, particularly marrow infiltration by tumor. Hematopoietic growth factors, such as granulocyte colony-stimulating factor (G-CSF), may be useful in some circumstances.[6] Empirical institution of broad-spectrum antibiotic therapy based on clinical presentation can be lifesaving for febrile neutropenic patients.[7]

Mucositis and Diarrhea[4]

Like the cells in the bone marrow, cells of the gastrointestinal tract, from mouth to rectum, proliferate rapidly and therefore are particularly susceptible to damage by antineoplastic drugs. The effects of toxicity range from mild mouth sores to ulcerative stomatitis and severe bloody diarrhea. Breakdown of the mucosal barrier also contributes to morbidity and mortality by providing a portal for the entry of infectious agents, particularly in a neutropenic patient. Agents that commonly cause stomatitis or diarrhea at standard doses are listed in Table 74-2. High-dose chemotherapy regimens used in preparation for bone marrow transplantation frequently cause severe mucositis.

TREATMENT

Candida and herpesviruses commonly cause or worsen stomatitis and esophagitis. *Clostridium difficile* always should be considered in hospitalized patients with diarrhea, particularly those receiving antibiotics, even if they also have received diarrhea-producing anticancer therapy.

Patients' mouths should be kept scrupulously clean with the use of soft swabs and saline or peroxide rinses. The discomfort caused by stomatitis may be severe. If topical anesthetics do not control the pain, systemic narcotics should be administered in ample doses. Diarrhea and stomatitis often severely compromise enteral feeding. Intravenous alimentation should be considered early.

TABLE 74-2 Antineoplastic Drugs that Cause Stomatitis or Diarrhea

Drug	Effects
Anthracyclines	Stomatitis
Bleomycin	Stomatitis
5-Fluorouracil	Stomatitis, anal sores, diarrhea
Capecitabine	Stomatitis, diarrhea
Cytarabine	Stomatitis, diarrhea
Cyclophosphamide	Stomatitis
Dactinomycin	Stomatitis, diarrhea
Taxanes	Stomatitis
Vinca alkaloids	Stomatitis
Methotrexate	Stomatitis
Irinotecan (CPT-11)	Diarrhea
Gefitinib	Diarrhea

IRINOTECAN[8]

Irinotecan (CPT-11) is an agent used frequently in the treatment of colon cancer and is somewhat unusual in having severe diarrhea in the absence of mucositis as one of its most significant side effects. Two distinct types of diarrhea have been described. The first is an early-onset diarrhea occurring during infusion of the drug or within 30 minutes of infusion. This reaction is part of an acute cholinergic response and can be controlled with atropine, 0.5 to 1.0 mg intravenously. The second type usually appears 6 to 10 days after drug administration, may be linked to a secretory process in the small intestine, and can be massive (>10 L/d). Early recognition and aggressive treatment with loperamide and octreotide can be useful in controlling this late-onset diarrhea.

Pulmonary Toxicity

A large number of antineoplastic drugs can cause pulmonary symptoms (Table 74-3). Furthermore, lungs are a common site for metastases and infections, complicating the diagnostic process in patients with advanced cancer. Pulmonary toxicity syndromes reported include acute pleuritic chest pain, hypersensitivity lung disease, and noncardiogenic pulmonary edema,[9–12] but the vast majority of cases fall into the pneumonitis/fibrosis category described below. This type of toxicity classically is associated with the "three B's": busulfan, bleomycin, and BCNU (carmustine), and for many agents, it is sporadic rather than dose related.[11] Methotrexate lung toxicity may be similar in terms of symptoms but is believed to be a form of hypersensitivity reaction.[13–15] Unlike lung toxicity associated with other antitumor agents, it also may be associated with hilar adenopathy. Some of the newly approved agents, such as all-*trans*-retinoic acid (tretinoin) and gefitinib (IRESSA) have been associated with unique pulmonary toxicities.[16–18] All-*trans*-retinoic acid (ATRA, TRETINOIN) is a derivative of vitamin A used in the treatment of acute promyelocytic leukemia (APL). It is associated with the unique *retinoic acid syndrome*, consisting of high fever, fluid retention, pulmonary infiltrates, and respiratory distress, which may occur in as many as 25% of APL patients treated with ATRA. This can be seen as soon as 2 days after beginning therapy. The syndrome has been attributed to pulmonary leukostasis but is not always associated with exceedingly high peripheral white blood cell (WBC) counts. Treatment with dexamethasone may be helpful. Gefitinib, an oral inhibitor of the epidermal growth factor receptor (EGFR) tyrosine kinase, was approved for the treatment of refractory lung cancer and has been reported to cause interstitial lung

TABLE 74-3 Antineoplastic Drugs that Have Pulmonary Toxicity

Agent	Type of Toxicity	Incidence, %	Comments
Bleomycin	Pneumonitis/fibrosis	2–40	Chest x-ray may be atypical; eosinophilia may be seen on lung biopsy; steroids felt to be useful
	Hypersensitivity pneumonitis	Rare	
	Acute chest pain	Rare	Substernal pressure or pleuritic pain; self-limited over 4–72 h
Busulfan	Pneumonitis/fibrosis	4	Insidious onset after prolonged therapy; poor prognosis
Carmustine (BCNU)	Pneumonitis/fibrosis	20–30	Toxicity is dose-related; common in pretransplantation regimens; effects may appear years after therapy has ended
Cyclophosphamide	Pneumonitis/fibrosis	<1	May potentiate toxicity of bleomycin, BCNU
High-dose cytarabine	Noncardiogenic pulmonary edema	4–20	Care is supportive, but corticosteroids are occasionally helpful; prognosis is variable
Gemcitabine	Noncardiogenic plumonary edema	1–5	Care is supportive, but corticosteroids are occasionally helpful; prognosis is variable
Methotrexate	Hypersensitivity pneumonitis	8	Prognosis is good; dramatic response to corticosteroids reported
	Acute pleuritic pain	Rare	May be associated with pleural effusion or friction rub; subsides over 3–5 days
	Noncardiogenic pulmonary edema	Rare	Few reports, most with intrathecal injection
Mitomycin C	Pneumonitis/fibrosis	3–12	High mortality reported
Procarbazine	Acute hypersensitivity		Onset within hours after drug dose; recovery rapid
Tretinoin (ATRA)	Retinoic acid syndrome	10–20	Corticosteroids suggested
Vinorelbine	Acute dyspnea	5	Readily reversible chest pain
Gefitinib	Interstitial lung disease	1–3	One-third of cases can be fatal
Trastuzumab	Organizing pneumonia	Rare	Case reports only

disease (ILD) in about 1% of the patients worldwide; approximately one-third of the reported cases have been fatal.[18] Patients often present with acute onset of dyspnea, with or without cough and low-grade fever. Prompt discontinuation of the agent with adequate supportive care is recommended when ILD is suspected. Trastuzumab also has been reported recently to cause organizing pneumonia[19]; however, details regarding the prevalence or underlying mechanisms of the toxicity are not well understood. If such pulmonary toxicity is determined eventually to be class-specific, then as an increasing number of monoclonal antibodies get approved for the treatment of cancer, such toxicities will become more common.

CLINICAL PRESENTATION

The onset of pneumonitis/fibrosis associated with the classic cytotoxic agents may occur after prolonged, continuous treatment, as is typical for busulfan; after only a few cycles of therapy, as may occur with bleomycin; or even years after therapy has ended, as can occur with BCNU. Signs and symptoms frequently are nonspecific and range from mild to life threatening. Patients invariably present with dyspnea. A dry cough, fatigue, fever, and end-expiratory rales are common but not universal features. Hemoptysis is not typical, and this finding should suggest another diagnosis. The symptoms typically appear gradually over several weeks, but acute presentations are not unusual. A patient with this disorder who is ill enough to arrive in the ICU generally will be hypoxic, with diffuse pulmonary infiltrates visible on chest x-ray, and the full spectrum of possible causes for this presentation, including infection, irradiation, cardiogenic edema, pulmonary embolus, hemorrhage, leukoagglutinin reaction, and progressive tumor, must be considered.

HISTOPATHOLOGY

The histopathology closely resembles that of idiopathic diffuse interstitial pulmonary fibrosis. There is endothelial cell swelling, necrosis of type I pneumocytes, and atypical proliferation of type II pneumocytes, with generalized fibrosis in end-stage disease. The character of the inflammatory infiltrate, when one is present, is variable; a finding of eosinophilia suggests a hypersensitivity reaction, which may be particularly responsive to corticosteroids.[14,15]

DIAGNOSTIC TESTING

The chest x-ray in drug-associated pneumonitis/fibrosis generally is normal or reveals a basilar or diffuse reticulonodular pattern, but atypical findings on chest x-ray should not rule out this diagnosis. Bleomycin is particularly notorious for occasionally producing a nodular appearance, which may mimic recurrent tumor, and methotrexate may be associated with a pleural effusion or hilar adenopathy. Pulmonary function tests reveal a reduced diffusing capacity for carbon monoxide (D_{LCO}) and, sometimes, a restrictive ventilatory defect. Since the histologic findings are not specific, even a lung biopsy may not absolutely establish the diagnosis of drug-induced toxicity, although it is usually helpful. In the case of acutely ill cancer patients with hypoxia and diffuse pulmonary infiltrates, both the choice of which patients are appropriate candidates for lung biopsy and the timing of the procedure remain controversial.[20,21]

TREATMENT

Treatment for drug-associated pneumonitis/fibrosis is supportive. The precipitating agent should be discontinued. While there are no good data establishing the efficacy of

TABLE 74-4 Antineoplastic Drugs that Have Cardiac Toxicity

Drug	Effect	Incidence, %	Comments
Anthracyclines	Acute ECG changes	Common	Almost always benign and reversible
	Acute myocarditis/ pericarditis syndrome	Rare	
	Chronic cardiomyopathy	1–2	May appear years after treatment
Cyclophosphamide	Acute hemorrhagic cardiac necrosis	Unusual	Only in very high doses
5-Fluorouracil/Capecitabine	Angina/myocardial infarction	Rare	Usually within hours of drug dose; asymptomatic ECG changes more common
Mitoxantrone	Cardiomyopathy	1–2	Drug is structurally related to anthracyclines, but incidence of cardiomyopathy is probably somewhat less; risk is <1% if cumulative dose < 120 mg/m^2
Paclitaxel	Arrhythmias	10–20	Most common is asymptomatic bradycardia
Vinca alkaloids	Angina/myocardial infarction	Rare	Scattered case reports
Trastuzumab	Cardiomyopathy	More common when combined with chemotherapy	Often managed medically

corticosteroid therapy, there are many anecdotal reports of its usefulness, and it is often given a trial. The syndrome may be reversible, particularly in mild cases, or it may be progressive even in the absence of further exposure to the drug.

BLEOMYCIN[22]

Bleomycin is a particularly frequent and well-studied cause of pneumonitis. Bleomycin is thought to cause direct injury to the pulmonary capillary endothelium and type I pneumocytes, which leads to stimulation of an inflammatory cascade. Bleomycin toxicity is sporadic rather than dose related below a threshold cumulative total dose of 450 to 500 mg; above this threshold, the incidence rises dramatically.

Attempts have been made to predict and prevent pulmonary toxicity by serially monitoring the D_{LCO}. Stopping therapy in patients with a significant decrease in D_{LCO} is strongly recommended, but this practice has not been shown to alter the incidence of fatal toxicity. Many patients may present with acute decline in pulmonary function weeks to months after a normal D_{LCO}. Age over 70 years, prior or concurrent radiation therapy to the lungs, and concurrent treatment with cyclophosphamide or methotrexate are reported to potentiate bleomycin lung toxicity. Pre-existing lung disease has not been shown to be a risk factor.

The danger posed by oxygen therapy after treatment with bleomycin is a source of some controversy in the scant literature on the subject. Some small studies have reported a high incidence of severe postoperative respiratory distress in bleomycin-treated patients, which they attributed to a high intraoperative concentration of inspired oxygen (F_{IO_2}).[22–24] Most authors recommend limiting intra- and perioperative F_{IO_2} in these patients to the lowest safe concentrations.

Cardiovascular Toxicity[25]

The vast majority of cardiac events in cancer patients are related to pre-existing heart disease or to involvement of the myocardium or pericardium by tumor, not to anticancer drugs, most of which produce cardiac damage rarely and sporadically, if at all (Table 74-4). Anthracyclines are the exception. Doxorubicin and daunorubicin have very similar effects on the heart; doxorubicin is used much more commonly, and its cardiac effects have been better studied. Trastuzumab also has been reported to cause cardiac dysfunction in patients that is similar to the cardiomyopathy associated with anthracycline therapy.[26] Cardiovascular toxicity is also associated with the use of immunomodulatory agents such as interferon and interleukin-2 (IL-2), which will be addressed separately in the section describing the toxicities associated with biologic agents.

ELECTROCARDIOGRAPHIC CHANGES AND ARRHYTHMIAS

Cisplatin and other drugs may produce secondary effects through alterations in plasma potassium, calcium, and magnesium levels. Direct effects appear to be caused mainly by the anthracyclines and paclitaxel. Electrocardiographic (ECG) changes occur in up to 40% of patients during doxorubicin infusion. The most frequently noted effects are nonspecific ST-T wave changes, but premature atrial and ventricular contractions, sinus tachycardia, and decreased QRS voltage are also common; almost every conceivable type of arrhythmia has been reported. While sudden death attributed to acute anthracycline-induced arrhythmia has been reported, it is extremely rare; cardiac monitoring during drug infusion is not warranted. The ECG changes are, with the possible exception of the decreased QRS voltage, transient. They are not a reason to discontinue therapy and are not associated with the subsequent development of heart failure.

PACLITAXEL[27,28]

Paclitaxel causes asymptomatic, reversible sinus bradycardia, with heart rates ranging from 30 to 50 beats per minute, in up to 29% of patients during a 24-hour infusion. More serious bradyarrhythmias, including third-degree heart block, have been observed but are rare. Myocardial infarction and atrial

and ventricular tachyarrhythmias also have been noted, but their relationship to paclitaxel therapy is uncertain.

MYOCARDIAL ISCHEMIA AND INFARCTION[29]

Anticancer drugs very rarely cause myocardial ischemia or infarction. Radiation therapy to the heart may result in accelerated atherogenesis, but this effect becomes symptomatic only years after treatment. The vinca alkaloids have been reported to precipitate myocardial infarction in a few instances, sometimes when given with bleomycin, which is known to cause Raynaud's phenomenon and other vasospastic symptoms. Up to 4% of patients treated with 5-fluorouracil (5-FU) have been reported to suffer anginal symptoms, and a greater number have transient asymptomatic ECG changes suggestive of ischemia[30]; prolonged infusions appear to cause more problems. Myocardial infarction may occur. The mechanism is unknown, but agents such as nitrates and calcium channel blockers, which reverse vasospasm, may be helpful. Capecitabine, an orally administered prodrug of 5-FU, causes many of the toxicities associated with prolonged infusion of 5-FU, including cardiac toxicities.[31]

CARDIOMYOPATHY AND PERICARDITIS

The anthracyclines and high-dose cyclophosphamide may produce fatal cardiomyopathies. Trastuzumab, which is used in the treatment of breast cancer, also has been associated with cardiomyopathy.

ANTHRACYCLINES AND TRASTUZUMAB[26,32–35]

The *myocarditis-pericarditis syndrome* consists of an acute drop in ejection fraction seen in the hours to weeks after drug administration. This reaction sometimes is associated with a pericardial effusion and may result in the sudden death of the patient from severe congestive failure. Fortunately, it is exceedingly rare.

The classic subacute presentation of cardiomyopathy, on the other hand, develops in from 1% to 10% of patients receiving 550 mg/m^2 of doxorubicin, with a steep rise in incidence in patients treated with cumulative doses greater than 600 mg/m^2. Symptoms usually appear around 30 to 60 days after what appears to have been the precipitating dose of doxorubicin, but they may be noted a year or more after the end of treatment. Patients develop tachycardia, dyspnea, cardiomegaly, and peripheral and pulmonary edema. Pathologic changes are similar to those seen in cardiomyopathy of other causes.

Total dose is the single most important risk factor for the development of doxorubicin-related cardiomyopathy. There is no cutoff dose below which cardiomyopathy never occurs. Many patients, even those with severe failure, respond well to conventional therapy, and the ejection fraction gradually may return toward normal. However, some of these patients have recurrent symptoms 5 or more years later. Less commonly, such late cardiac decompensation is seen in patients who never had subacute symptoms. There has been particular concern over anthracycline-treated survivors of childhood cancers, up to 57% of whom have abnormalities of left ventricular contractility after treatment. Adults, however, are affected by late cardiac symptoms as well, and these sequelae may occur in patients who received only moderate cumulative doses of doxorubicin. There is no specific therapy for anthracycline-induced cardiotoxicity once it has occurred; care is supportive. Further administration of anthracycline is contraindicated.

Detailed data analyses from various clinical trials conducted with trastuzumab[26] suggest that its cardiotoxic potential is highest when it is used with other chemotherapeutic agents, especially anthracylines. Single-agent therapy with trastuzumab seems to be safer, and most patients' clinical symptoms are well controlled with congestive heart failure therapy. Ongoing clinical trials with the agent potentially will provide greater insight into the risk factors and mechanisms that lead to the cardiac dysfunction associated with this agent.

CYCLOPHOSPHAMIDE AND IFOSFAMIDE[25,36,37]

Both cyclophosphamide and ifosfamide have minimal cardiac toxicity at standard doses. However, when used at high doses, both agents can cause severe myopericarditis and arrhythmias. The major nonhematologic dose-limiting toxicity of cyclophosphamide is a severe hemorrhagic myopericarditis, which usually is seen only at doses higher than 1.5 g/m^2, as are used typically in marrow-ablative regimens. Total ifosfamide doses far in excess of 1000 mg/m^2 usually have been associated with cardiotoxicity, and these patients generally develop cardiac toxicity within 2 weeks of receiving the drug. In its most virulent form, cyclophosphamide-induced cardiotoxicity appears within 48 hours of the last drug dose. Patients die rapidly of cardiogenic shock. More typically, edema, tachycardia, and tachypnea develop 7 to 10 days after therapy, usually preceded by a decrease in QRS amplitude on the electrocardiogram. Not all patients who have a decrease in QRS amplitude will develop symptoms. However, a hemorrhagic or serosanguineous pericardial effusion develops frequently, with possible signs of tamponade. Pericardiocentesis usually does not produce any clinical improvement, possibly because of the severity of the underlying myocardial damage.

Treatment is supportive. If patients survive the acute phase, complete recovery can be expected, and there may be no residual evidence of cardiac damage even at autopsy.

Neurotoxicity[1]

Only rarely will the neurologic toxicity (Table 74-5) of an anticancer drug be severe enough to be the primary reason for admission to the ICU. Neurologic problems are common in cancer patients, but local effects of tumor produce most of them, e.g., brain or epidural metastases. The antiemetic and pain medications given to patients often include combinations of high doses of corticosteroids, narcotics, and benzodiazepines, all of which can cause dramatic neurologic changes that must be considered when symptoms developing acutely after therapy are being evaluated.

PERIPHERAL NEUROPATHY

Peripheral neuropathies are frequent side effects of some very widely used anticancer drugs. Paclitaxel and docetaxel can cause glove-stocking paresthesias and, rarely, motor dysfunction. Symptoms often improve within months after therapy is stopped. Cisplatin likewise commonly causes a peripheral neuropathy that is primarily sensory and may progress to disabling ataxia. Symptoms may continue to worsen

TABLE 74-5 Antineoplastic Drugs that Have Neurologic Toxicity

Drug	Incidence, %	Comments
	ENCEPHALOPATHY	
L-Asparaginase	25–50	Ranges from drowsiness to stupor; onset usually on the day after start of therapy; generally resolves rapidly when therapy is over
High-dose busulfan	15	Acute obtundation, seizures; prophylactic anticonvulsants often used
High-dose carmustine (BCNU)	10	Severe acute or chronic encephalomyelopathy; time of onset variable; usually not reversible
High-dose cytarabine	10–20	Ranges from disorientation to coma; onset usually 5–7 days after start of therapy; prognosis variable
Fludarabine	Rare at conventional doses	Optic neuritis, altered mental status, paralysis; may appear weeks after treatment
Hexamethylmelamine	Variable	Toxicity ranges from depression to hallucinations; usually reversible when drug is withdrawn
Ifosfamide	5–30	Frequency greater with higher doses; ranges from mild somnolence to coma; onset hours after infusion, recovery usually within days; use of methylene blue might reverse or shorten the duration of toxicity
High-dose methotrexate	2–15	Onset usually 1 week after administration; most common presentation is a strokelike syndrome; usually reversible
Mitotane	40	Lethargy, somnolence, dizziness, vertigo
Pentostatin	Rare at conventional doses	Lethargy, seizures, coma
Procarbazine	10	Usually mild drowsiness or depression, rarely stupor or manic psychosis
High-dose thio-TEPA	Dose-dependent	Somnolence, seizures, coma; dose limiting extramedullary toxicity
Vincristine/vinblastine	Rare	SIADH
	ACUTE CEREBELLAR SYNDROME	
High-dose cytarabine	10–20	Ranges from mild dysarthria to disabling ataxia; onset is 5–7 days after start of therapy; prognosis is variable
5-Fluorouracil	<1	Usually seen with large bolus doses; reversible in 1–6 weeks
	ACUTE PARAPLEGIA	
Intrathecal administration of cytarabine, methotrexate, thio-TEPA	Rare	These are the only drugs normally given intrathecally; all cause acute reversible arachnoiditis fairly often, paralysis exceedingly rarely; paralysis may or may not be reversible
	PERIPHERAL NEUROPATHIES	
Cisplatin		Dose-dependent ototoxicity; distal sensory neuropathy
Oxaliplatin	Common	Acute and chronic sensory neuropathy; reversible pharyngolaryngeal dysesthesias; cold exposure may exacerbate symptoms
Hexamethylmelamine	Variable	Peripheral paresthesias and weakness
Procarbazine	10–20	Decreased tendon reflexes, mild distal paresthesias
Paclitaxel, docetaxel	Common	Distal sensory neuropathy
Vinca alkaloids	See text	Symmetric areflexia and distal paresthesias; symmetric motor weakness starting with dorsiflexors; jaw pain; cranial nerve palsies; paralytic ileus
Thalidomide		Peripheral neuropathy

ABBREVIATION: SIADH, syndrome of inappropriate antidiuretic hormone secretion.

after treatment is completed and may persist for years. Cisplatin also can cause tinnitus and deafness and, more rarely, Lhermitte's sign (painful electric shock–like sensations elicited by neck flexion or extension), autonomic neuropathy, seizures, transient cortical blindness, and retinal injury. Acute and chronic neuropathy also has been the dose-limiting toxicity of oxaliplatin, a recently approved third-generation platinum agent.[38] Oxaliplatin causes an acute and reversible sensory neuropathy in up to 95% of patients treated with the agent and causes a more chronic sensory neuropathy in 15% to 20% of patients who have received cumulative dose in excess of 780 mg/m^2. A few patients who have received more than 1000 mg/m^2 of the agent have been described to develop Lhermittes's sign and urinary retention. Most cases of chronic peripheral neuropathies associated with oxaliplatin have been reversible. An acute and reversible syndrome of pharyngolarngeal dysesthesias has been reported to occur in 1% to 2% of patients. This toxicity often is extremely distressing to the patient owing to the overwhelming sensation of difficulty with breathing and swallowing. These symptoms frequently are triggered or exaggerated by cold exposure. Given the disturbing subjective nature of the toxicity and the fact that it is common and reversible, all patients need to be educated regarding this toxicity to avoid panic and unnecessary medical interventions.

Vinca alkaloids are tubulin poisons that disrupt microtubule function in neuronal axons. Vincristine is the most neurotoxic vinca alkaloid. The most common toxic manifestation of vincristine is a symmetric mixed sensorimotor neuropathy, which may, in severe cases, progress to quadriparesis. It is dose related and gradual in onset. Deep tendon reflexes are lost. Peripheral nerve conduction velocities are characteristically normal despite severe clinical deficits. Paresthesias and motor weakness may or may not improve gradually. No treatment is known to heal vinca-related neuropathies. Vincristine has been administered intrathecally accidentally; this is invariably fatal.

The approval of thalidomide for the treatment of multiple myeloma has increased the clinical use of the agent. Both reversible and irreversible sensory neuropathies have been well documented with the use of thalidomide in up to 60% of patients with chronic use. Nerve conduction studies indicate that the symptoms most probably result from axonal damage. The symptoms can range from mild reversible parasthesias to more severe irreversible sensory neuropathies if the agent is not withdrawn in patients with progressive peripheral neuropathy. Central nervous system manifestations are common, including sedation, dizziness, muscle incoordination, fatigue, unsteady gait, tremulousness, mood changes, confusion, and weakness.[39,40]

CRANIAL NERVE PALSIES

Various cranial nerve palsies, including vocal cord paralysis, dysphagia, optic atrophy (rare), ptosis, ophthalmoplegias, and facial nerve paralysis, are seen in up to 10% of vincristine-treated patients. Unlike the peripheral nerve findings, cranial neuropathies may be abrupt in onset and mimic a brainstem stroke. They tend to be bilateral and usually are reversible with discontinuation of the drug.

AUTONOMIC NEUROPATHY

Autonomic symptoms, including ileus, bladder atony, impotence, and orthostatic hypotension, may occur even in patients with no sign of peripheral nerve toxicity. Severe paralytic ileus presenting as an acute abdomen is not rare and can occur acutely or following long-term administration of vincristine, vinblastine, or vinorelbine. It is usually reversible over the course of several days. Nasogastric tube drainage is the only standard therapy; metoclopramide has been reported to be helpful and may be tried if there is no suspicion of mechanical obstruction.

L-ASPARAGINASE

Between 25% and 50% of patients receiving L-asparaginase on a wide variety of dosing schedules will have some evidence of cerebral dysfunction, adults more often than children. The toxicity ranges from mild depression and drowsiness to confusion, stupor, and coma. Evidence of encephalopathy often occurs on the first day after administration and usually clears rapidly after the end of therapy. The syndrome resembles hepatic encephalopathy and may or may not be associated with high ammonia levels. The electroencephalogram (EEG) in most cases shows a diffuse slowing that returns to normal when the drug is stopped. L-Asparaginase itself does not cause focal neurologic abnormalities, but thrombotic and hemorrhagic cerebrovascular accidents due to asparaginase-induced clotting abnormalities have been reported. Patients on L-asparaginase can develop exceedingly low fibrinogen levels (with elevated prothrombin time), and this can be corrected with cryoprecipitate.

CYTOSINE ARABINOSIDE[41]

Cytosine arabinoside (Ara-C, cytarabine) is not neurotoxic when used at conventional doses (100 to 200 mg/m^2). However, at high doses (e.g., 2 to 3 g/m^2 twice daily, as given for the treatment of acute leukemia), a 10% to 20% incidence of cerebellar and cerebral toxicity is observed. Larger cumulative doses and age over 55 years are associated with more frequent and more irreversible neurologic damage.

The cerebellar changes are more common and usually more severe than the cerebral ones. The onset of symptoms is usually 5 to 7 days after the start of Ara-C therapy (within 24 hours of the final dose on a typical schedule). Mild cerebellar findings may include intention tremor, dysarthria, and horizontal nystagmus; in severe cases, limb and truncal ataxia may render the patient completely unable to walk or even eat unaided. Cerebral symptoms range from mild somnolence to disorientation, memory loss, and coma. Seizures have been reported. EEGs show diffuse slowing; findings on lumbar puncture and computed tomographic (CT) scan are normal. Toxicity may abate over a few days to weeks or may be irreversible. Rarely, it is fatal. Supportive care and withdrawal of Ara-C are the only therapies. Intrathecal Ara-C has not been associated with cerebellar toxicity, although it rarely may cause a paralysis similar to that described below with intrathecal methotrexate.

METHOTREXATE[42]

Like Ara-C, methotrexate used in conventional doses is not neurotoxic. However, when used at very high doses (1 to 7 g/m^2), cytotoxic levels are achieved in the cerebrospinal fluid (CSF), and a 2% to 15% incidence of various transient

central nervous system (CNS) syndromes has been reported. The time of onset ranges from several hours to several weeks after treatment, with a mean of about a week. Signs develop abruptly and often resemble a stroke, with, for example, hemiplegia and a speech disorder. Neurologic findings may fluctuate; focal or generalized seizures are common. Electrolyte levels and results of radiologic studies are normal, EEGs show a variety of abnormalities, and examination of the CSF may or may not reveal an elevated protein level. The mechanism of these neurologic reactions is unknown, and care generally is supportive. There are reports that aminophylline can reverse early neurotoxicity in children, presumably by displacement of adenosine from its receptor by aminophylline.[43] In any case, patients recover completely over several days, and symptoms may or may not recur with subsequent courses.

Intrathecal methotrexate also can cause neurologic damage. The most common symptom is an acute arachnoiditis, which resolves over 12 to 72 hours without sequelae. Rarely, the presentation is severe enough to mimic bacterial meningitis. Very rarely, an acute reaction, which may include paralysis, cranial nerve palsies, or seizures, is seen. Examination of the CSF may show increased pressure, high protein concentrations, and a reactive pleocytosis. Recovery often, but not always, is complete. A necrotizing leukoencephalopathy sometimes occurs after the combination of cranial irradiation and intrathecal methotrexate, but this is a delayed effect that usually begins insidiously months after treatment.

IFOSFAMIDE[44,45]

High-dose ifosfamide therapy is associated with encephalopathy that can present with a wide variety of symptoms ranging from subtle sensorimotor deficits to severe mental status changes and even death. Early recognition of the toxicity and discontinuation of the agent are sufficient to reverse the toxicity over a period of 24 to 48 hours in most cases. Intravenous methylene blue can be useful in reversing the neurologic deficits associated with ifosfamide encephalopathy.

Renal and Urinary Toxicity[46]

Cisplatin is the only antineoplastic drug used frequently in current oncologic practice that causes renal failure at conventional doses. Hyperuricemic nephropathy with or without a full-blown tumor lysis syndrome may occur following rapid cell lysis in sensitive cancers with large tumor volumes; it is not the effect of any particular drug and is discussed elsewhere. Uric acid levels also can be rapidly lowered by the use of rasburicase.

Cyclophosphamide and ifosfamide can cause a hemorrhagic cystitis that is difficult to manage and occasionally is fatal and is described separately in the next section. Table 74-6 lists the common renal abnormalities caused by antineoplastic drugs.

CISPLATIN[47,48]

Renal injury characterized pathologically by focal necrosis of the distal tubules and collecting ducts is a dose-limiting toxicity of cisplatin. Acute renal failure can occur. Vigorous pretreatment hydration with saline solution minimizes but does not eliminate the damage; all patients will have some decline in glomerular filtration rate with a sufficient dose. Aminoglycoside therapy and pre-existing renal dysfunction are believed to increase the incidence. The creatinine level begins to rise a few days after therapy, peaks at 3 to 14 days, and then usually declines toward pretreatment levels. Toxicity is cumulative; multiple courses and higher doses produce more severe and less reversible damage.

Cisplatin also causes a variety of electrolyte disorders. Renal magnesium wasting, not necessarily associated with azotemia, is seen in half the patients receiving cisplatin and may persist for years. Although serum magnesium levels often are strikingly low, and symptomatic muscular irritability has been reported, most patients are asymptomatic. Of particular concern in the ICU are the hypocalcemia and hypokalemia that frequently accompany the magnesium wasting and that may be refractory to treatment if serum magnesium levels are not corrected first. Aminoglycosides should be used with extreme caution. Oral magnesium therapy is of

TABLE 74-6 Antineoplastic Drugs Producing Renal and Electrolyte Abnormalities

Agent	Toxicity	Comments
Cisplatin	Magnesium, calcium, potassium, sodium wasting; renal insufficiency	—
Cyclophosphamide	Impaired free water excretion	Transient; seen with doses >50 mg/kg
Ifosfamide	Proximal tubular defect	—
High-dose methotrexate	Acute renal failure	Usually reversible
Mitomycin C	Renal failure with microangiopathic hemolytic anemia (HUS/TTP)	Common with cumulative dose >60 mg
Nitrosoureas (BCNU, CCNU, methyl-CCNU)	Progressive renal failure appearing after large cumulative doses	Decrease in renal size may be noted; effect may occur years after therapy
Streptozotocin	Renal failure, proximal renal tubular acidosis, nephrotic syndrome	Transient proteinuria is earliest manifestation

uncertain benefit; intravenous or intramuscular doses should be administered. Renal salt wasting resulting in hyponatremia and symptomatic orthostatic hypotension also has been reported.

METHOTREXATE

High doses of methotrexate (>50 mg/kg) are potentially quite toxic and normally are given in the hospital with careful hydration and urine alkalinization to promote drug excretion. Plasma methotrexate levels are measured after drug administration, and leucovorin rescue is continued until the drug concentration has fallen to a safe level. Despite these precautions, an acute azotemia believed to result from the precipitation of methotrexate crystals in the distal nephron can be seen. Methotrexate-induced renal failure is usually, although not always, reversible over the 2 to 3 weeks following drug withdrawal. However, because the kidney is the primary route of excretion for methotrexate, dangerously high drug levels will persist for some time. This situation can produce other morbidity, particularly cytopenias and mucositis. A similar situation occurs when methotrexate has been given inadvertently to a patient with a third-space fluid reservoir, such as a pleural effusion or ascites, from which the drug is released only gradually. Administration of leucovorin until plasma levels of methotrexate fall below 5×10^{-8} M is beneficial in avoiding various toxicities described earlier. Doses of leucovorin need to be increased in patients with high plasma levels of methotrexate and will not completely prevent toxicity. Methotrexate also can be dialyzed using high-flux hemodialysis membranes[49]; hence hemodialysis also could be considered for reversing acute methotrexate toxicity along with high-dose leucovorin rescue. Carboxypeptidase-G2 is an enzyme that cleaves the terminal glutamate from methotrexate and can decrease methotrexate levels rapidly in patients with renal failure.[50] Food and Drug Administration (FDA) approval for this agent is being sought, but at this time it is only available for compassionate emergent use from the National Cancer Institute.

Thrombotic and Hemorrhagic Toxicity

All myelosuppresive agents potentially can cause thrombocytopenia and resulting bleeding complications. This section will focus more on some severe and specific complications associated with cancer therapies. Hemorrhagic cystitis is a well-described complication that occurs in patients treated with cyclophosphamide and ifosfamide. Thrombotic microangiopathies also have been described with various chemotherapeutic agents and will be discussed in this section. Among the recently approved agents, thalidomide has been associated with a significant risk of thromboembolic complications. This risk is much greater when the agent is administered in combination with various chemotherapeutic agents, and clinicians administering thalidomide need to be vigilant about the potential occurrence of this complication.[39,51]

HEMORRHAGIC CYSTITIS[52,53]

Urologic complications, including bladder fibrosis, bladder cancer, and hemorrhagic cystitis, are among the most troublesome side effects of cyclophosphamide and ifosfamide.

Susceptibility to hemorrhagic cystitis is somewhat idiosyncratic, and symptoms can occur after a few small doses, but the incidence is much higher with prolonged or high-dose therapy. Excretion of the BK human polyoma virus has been associated with a greater incidence of hemorrhagic cystitis in bone marrow transplant patients. Ifosfamide, an analog of cyclophosphamide, produces even more urothelial toxicity.

PREVENTION

Local bladder irritation from acrolein, one of the metabolites of cyclophosphamide, is believed to cause the damage. Sodium-2-mercaptoethane sulfonate (mesna) can help to prevent it by providing free sulfhydryl groups, which neutralize the acrolein in the urine. Ifosfamide should not be administered without sodium-2-mercaptoethane sulfonate. Sodium-2-mercaptoethane sulfonate is not useful in treating established cystitis. Adequate prehydration with frequent voiding to decrease the length of time the acrolein is in contact with the bladder is also an important prevention measure, particularly with high single doses of cyclophosphamide. Hypotonic solutions should not be used to hydrate patients receiving high-dose cyclophosphamide therapy.

CLINICAL PRESENTATION

The acute form of hemorrhagic cystitis appears within the first few days of drug treatment. Symptoms range from minimal hematuria with mild dysuria, urgency, and frequency to massive hemorrhage requiring transfusion. The thrombocytopenia seen with high doses of cyclophosphamide aggravates the blood loss. The bleeding usually is self-limited and will stop after a median duration of a month, even in severe cases, if the patient can be supported that long.

TREATMENT

Mild episodes do not require treatment other than cessation of drug therapy. In serious cases, vigorous hydration to promote urine flow, maintenance of adequate platelet counts (50,000/μL), and constant bladder irrigation through a large-bore catheter are indicated. The catheter must be kept free of obstructing clots, which can cause renal obstruction with severe pain.

Intravesical instillation of a variety of agents has been reported to control bleeding. Formalin is the best established of these agents, but formalin administration may have significant side effects, including pain, fibrosis, and renal papillary necrosis. It must be given with the patient under anesthesia. Urinary diversion also may be useful. In intractable cases, hypogastric artery embolization may be attempted, and severe intractable cases sometimes even require cystectomy with urinary diversion.[51–53]

MICROANGIOPATHIC HEMOLYTIC ANEMIA[54–60]

Thrombotic microangiopathy has been associated with various cancers as well as cancer therapies; thus it sometimes can cause a diagnostic dilemma. Among the various cancer treatments associated with the process, mitomycin C has been associated most closely with a syndrome of renal failure with microangiopathic hemolytic anemia. However, various other agents, such as bleomycin, cisplatin, interferon, and gemcitabine, also have been associated with microangiopathy. Thrombotic thrombocytopenic purpura/hemolytic-uremic syndrome (TTP/HUS) also can be a late complication (usually

occurring within 1 year) of both allogeneic and autologous bone marrow transplantation. In both settings, the symptoms resemble those of idiopathic HUS; hypertension, renal failure, and anemia predominate rather than fever and neurologic signs. Conventional plasmapheresis, which is standard therapy for sporadic TTP, does not appear to be as effective in these drug-induced disorders. The prognosis in mitomycin C–associated HUS has been reported to be very poor; staphylococcal protein A immunoadsorption may be useful. The severity of the presentation and the prognosis in transplant patients are variable. Plasma exchange with cryosupernatant, protein A immunoadsorption, intravenous immunoglobulin administration, and glucocorticoid administration are of uncertain benefit.

Hepatotoxicity[61]

Although a large number of cytoxic agents can damage the liver in a variety of ways, few of them do so regularly with any severity when used in conventional doses (Table 74-7). However, veno-occlusive disease (VOD) of the liver is a major toxicity of high-dose regimens given before transplantation.

VENO-OCCLUSIVE DISEASE OF THE LIVER[62]

VOD is seen sporadically and rarely with a number of cytotoxic drugs, particularly antimetabolites, at conventional doses. Much more important, it has an incidence of up to 20% and is a common cause of death in patients given a variety of high-dose chemotherapy regimens or chemoradiotherapy combinations prior to infusion of autologous or allogeneic marrow or stem cells. Clinically, VOD resembles Budd-Chiari syndrome. The diagnosis is based on the presence of at least two of the triad of jaundice, hepatomegaly or right upper quadrant pain, and ascites or unexplained weight gain. Hyperbilirubinemia, which generally precedes hepatomegaly and ascites by several days, usually is out of proportion to increases in transaminase concentrations.

Symptoms begin at a mean of 10 days after marrow reinfusion, whereas graft-versus-host disease, one of the major differential diagnoses in patients who have had an allogeneic transplant, more often develops after day 20. Most deaths associated with VOD occur by day 35 after transplantation, and the majority of recoveries are evident by this time. However, late-onset VOD occurs with some regimens. The pain may be acute and severe enough to suggest an abdominal catastrophe such as pancreatitis, bowel infarction, biliary obstruction, peritonitis, or pyogenic liver abscess. Drugs, such as cyclosporine, and sepsis may cause laboratory abnormalities that mimic those seen in VOD.

Pathologically, early VOD is characterized by subintimal edema and hemorrhage within small central venules and centrilobular congestion. This picture progresses to fibrous obliteration of the central venule lumina and centrilobular sinusoidal fibrosis.

Diagnosis of VOD remains largely based on the clinical picture. Percutaneous biopsy usually is contraindicated because patients generally are thrombocytopenic, may be refractory to platelet transfusions, and may have a coagulopathy caused by liver dysfunction. Transvenous liver biopsies and measurement of the hepatic venous pressure gradient (elevated in VOD) are safer but still may result in fatal hemorrhage. Ultrasound studies may show an increased mean hepatic artery resistive index or reversal of portal venous flow. However, definitive findings tend to occur late, when the disease is obvious clinically. No therapies for VOD have been evaluated in prospective, randomized fashion. Standard supportive care for liver failure is indicated (see Chap. 73 and 83).

Biologic Agents[63–68]

A number of cytokines are available for widespread use, and new ones are constantly undergoing testing. Each has a unique toxicity profile that depends on dose, schedule, and combination with other cytokines or with other anticancer

TABLE 74-7 Cytotoxic Agents that Have Hepatic Toxicity

Drug	Frequency of Toxicity	Comments
L-Asparaginase	Common	Fatty metamorphosis; decreased synthetic function; reversible
Azathioprine	Uncommon	Cholestasis/necrosis; hyperbilirubinemia; variable prognosis
High-dose cytarabine	Common	Elevated bilirubin and transaminases; reversible
Floxuridine (FUDR)	Common	Biliary sclerosis with hepatic intra-arterial infusion; chemical hepatitis
Methotrexate	Common	Cirrhosis, fibrosis, fatty metamorphosis; laboratory data may be normal; seen with prolonged daily therapy; variable prognosis
High-dose methotrexate	Common	Elevated transaminase levels, usually reversible in weeks
6-Mercaptopurine	Common	Cholestasis or necrosis; usually reversible
Mithramycin	Common	Necrosis; rarely seen with lower doses used for hypercalcemia
Nitrosoureas (BCNU, CCNU)	Occasional	Generally mild and reversible
Vincristine	Rare	May produce severe damage when combined with radiation to the liver

drugs, but they tend to share a spectrum of side effects, probably related to the "cytokine cascade," that are different from those of most chemotherapeutic agents. These include typical side effects of interferon, such as fever and myalgia, and a side effect of high-dose IL-2 treatment that consists of a sepsis-like capillary leak syndrome that can lead to hypotension and cardiovascular collapse. Attempts at fluid resuscitation may lead to pulmonary edema, and use of vasopressors may be necessary. The capillary leak syndrome, like most cytokine toxicities, resolves rapidly after discontinuation of therapy. Arrhythmias and myocardial infarction also may be seen and may result either from fluid shifts or from direct myocardial toxicity. CNS toxicity is frequent and may be related to the vascular leak phenomenon or to the function of cytokines as messenger molecules with the CNS. CNS toxicity usually is reversible, but it may persist for days after cessation of treatment.

A detailed list of the side effects of IL-2 treatment that are seen at the recommended doses for renal cancer (600,000 U/kg every 8 hours for 14 doses) is given in Table 74-8 as a prototype of cytokine toxicities.

TABLE 74-8 Toxicities of Interleukin-2

Toxicity	Comments
Febrile reaction complex	Dose-dependent fever and chills are ameliorated with antipyretics and meperidine
Cardiovascular toxicity	Capillary leak syndrome; see text. Rare cases of eosinophilic myocarditis
Central nervous system toxicity	Dose-dependent reversible somnolence, disorientation, cognitive deterioration; appears several days after beginning of a treatment course
Hematopoietic toxicity	Frequent anemia, occasional thrombocytopenia, rare neutropenia; lymphopenia with rebound lymphocytosis, dramatic eosinophilia
Gastrointestinal toxicity	Mild nausea, vomiting, diarrhea; mucositis is unusual but may be severe; profound, reversible cholestasis with hyperbilirubinemia and elevated alkaline phosphatase but normal transaminases
Infectious complications	Increase in staphylococcal bacteremia, often catheter-related
Renal toxicity	Oliguria and prerenal azotemia reversible when infusion discontinued
Cutaneous toxicity	Rash ranging from discrete nonpruritic maculopapular lesions to diffuse erythroderma with flaky exfoliation after resolution of redness
Other	Hypo- and hyperthyroidism, decrease in vitamin K–dependent coagulation factors, severe myalgias

Toxicities of Targeted Therapies[69–77]

The tremendous gains made in cancer biology in the past 10 to 15 years have led to the development of agents that inhibit specific targets such as surface receptors or intra- and extracellular proteins that are thought to play a key role in the development or progression of various malignancies, and these agents are often referred to as *targeted therapies.* Several new monoclonal antibodies and small-molecule kinase inhibitors have been approved by the FDA in the last 5 years for various therapeutic indications. With increasing use of targeted agents, a range of new clinical toxicities is being recognized and reported. Compared with various classic cytotoxic agents discussed earlier, the clinical experience with the newer targeted agents is limited; hence details regarding the prevalence and underlying pathologic mechanisms of the toxicities currently are sparse and will continue to evolve. This section describes some of the more severe adverse events that have been reported with the various targeted agents.

MONOCLONAL ANTIBODIES[26,69–71]

The past few years have seen several new humanized monoclonal antibodies approved for the management of hematologic and solid malignancies. It is anticipated that the common toxicities, such as acute infusion reactions, associated with the antibodies most likely will be similar for the different antibodies, whereas specific toxicities, such as cardiac toxicity associated with trastuzumab,[26] most likely will be related to the modulation of the targeted pathway by each specific antibody. Rituximab (RITUXAN) is a chimeric anti-CD20 antibody that is now used routinely for the treatment of various lymphoid malignancies. Recent case reports have implicated this antibody in various dermatologic and systemic toxicities.[69,70] The toxicities have ranged from mild cutaneous reactions to the much more severe Stevens-Johnson syndrome and serum sickness; the toxicities generally have resolved with discontinuation of therapy in conjunction with supportive care and steroids. The cytokines released by the targeted malignant cells, as well as the antibody itself, have been implicated as the cause of these adverse events. The specifics of the underlying pathology are poorly understood, but treating physicians should be aware of such severe toxicities because they are anticipated to become more common with increasing use of these agents. Some monoclonal antibodies that are currently in clinical use are conjugated to either a cytotoxic entity or a radioisotope.[71] The rationale behind their development is that the antibody will bring the lethal conjugated cytotoxic compounds specifically into proximity with the targeted neoplastic cells and potentially enhance the cytotoxicity of the agents. The radioisotope-labeled antibodies frequently are associated with prolonged myelosuppresion.

ANTIANGIOGENIC AGENTS[72–74]

Recognition of the importance of angiogenesis in the progression and propagation of various malignancies has led to an increased emphasis on the development of agents that inhibit the complex process of angiogenesis. Although thalidomide and the monoclonal antibody bevacizumab (AVASTIN) are the only antiangiogenic agents currently approved for cancer therapy, many other agents in this class are in advanced stages

of development and are anticipated to be approved in the near future. The most serious adverse events that have been described with this class of agents are bleeding, thromboses, and hypertension, and the underlying mechanisms of these toxicities are still being defined. Hence the recommendations for management or prevention of the vascular complications are also evolving. In general, for patients with the most severe complications, discontinuation of the antiangiogenic agent with the appropriate medical therapy is the most prudent approach currently. Reversible hypertension and proteinuria also have been observed routinely for various antiangiogenic therapies. Generally, both toxicities can be managed medically or can be reversed by discontinuation of the therapeutic agent.

The observation that thalidomide has modest antiangiogenic properties led to a renewed interest in its use as an anticancer agent, and the initial clinical investigation led to its approval for the treatment of multiple myeloma. Besides the well-publicized teratogenic and neurologic toxicities, it also has been associated with high rates of thromboembolic complications in several cancer clinical trials. Patients receiving thalidomide in combination with other chemotherapeutic agents seem to be the most susceptible to the thrombotic complications.[39,71] Various approaches to managing patients with these complications have been proposed from the more conservative approach of discontinuing thalidomide therapy in patients with marginal benefit from the agent to reinitiating thalidomide therapy after appropriate stable anticoagulation therapy has been established. Uniform management guidelines for such complications will emerge only after more clinical experience with this class of agents has been gained.

SMALL-MOLECULE TYROSINE KINASE INHIBITORS[75–77]

Many of the tyrosine kinase inhibitors that were thought initially to be highly specific are in some instances not as specific in their inhibitory capacity and are demonstrating activity against malignancies that they were not designed to treat initially.[75–77] Hence they are being described here as another class of cancer agents that will be used more routinely for management of different malignancies. The reader should note that the predominant toxicities of many kinase inhibitors will not always be the same and eventually will be dictated by the pathways predominantly inhibited by each agent. This section will limit the discussion only to currently FDA-approved agents.

One of the most publicized tyrosine kinase inhibitors is imatinib mesylate (GLEEVEC, STI-571).[75] Imatinib mesylate is an orally administered drug that inhibits the Bcr-Abl protein-tyrosine kinase. The Bcr-Abl fusion protein is the result of the pathognomonic 9,22 chromosome translocation that causes chronic myelogenous leukemia (CML). Imatinib mesylate treatment resulted in both hematologic and cytogenetic responses in CML patients and led to approval of the agent in United States in 2001. Subsequent studies also demonstrated that imatinib mesylate also was active against gastrointestinal stromal tumors (GISTs) that overexpress the platelet-derived growth factor receptor kinase.[75] Some of the common toxicities associated with the agent consist of mild nausea, emesis, edema, and dermatologic reactions. However, about 2% to 4% of patients have been reported to have severe fluid retention in the forms of pleural and pericardial effusions, as well as severe cutaneous reactions. The severe adverse events have been observed more commonly in patients receiving the higher doses ($\geq$600 mg/d) of the agent. Gefitinib, the epidermal growth factor receptor (EGFR) tyrosine-kinase inhibitor approved for the treatment of lung cancer, results in mild to moderately severe skin rash and diarrhea in most patients in addition to the rare but severe pulmonary toxicity discussed earlier.[18] Both toxicities are relatively easy to manage with dose reduction or supportive care when they are mild; however, in about 5% to 10% of the patients, both rash and diarrhea can be quite severe, requiring discontinuation of therapy and aggressive supportive care. Finally, as mentioned earlier in this section, oncologic therapies are anticipated to undergo some dramatic changes in the next few years with the introduction of several novel agents that differ from the traditional cytotoxic agents both in their mechanisms of action and in their typical toxicity profiles. As a result, clinicians will be challenged initially with limitations in information regarding some of the uncommon and potentially severe toxicities of the newer agents, and this will require diligence and patience while the clinical experience with such agents increases and some practice standards are established.

Chapter 75

ACUTE RENAL FAILURE

BHARATHI REDDY
PATRICK MURRAY

KEY POINTS

- *Prerenal azotemia and acute tubular necrosis account for the overwhelming majority of hospital-acquired acute renal failure cases, whereas acute glomerulonephritis and vasculitides are more common causes of acute renal failure developing outside the hospital.*
- *Acute renal failure occurs in at least 10% to 30% of patients admitted to an ICU and is associated with a mortality rate of about 50% despite advances in supportive care and technology.*
- *The most important diagnostic classification to be made in the evaluation of patients with acute renal failure is based on the site of the renal lesion (pre-, intra-, or postrenal).*
- *Since there are few specific therapies available in patients with established acute tubular necrosis, the major clinical focus is on prevention of ARF by identification of subjects at highest risk.*
- *All aspects of treatment of acute tubular necrosis, including renal replacement therapy, are basically supportive. The nondialytic measures of greatest importance are maintenance of nutritional, volume, and electrolyte homeostasis.*
- *Emergent renal replacement therapy is indicated in the management of acute renal failure when pulmonary edema, hyperkalemia, refractory acidosis, or symptomatic uremia develops.*
- *Prophylactic renal replacement therapy should be considered in patients with sustained anuria, persistent oliguria with progressive azotemia and glomerular filtration rate <10 mL/min, and to prevent uncontrolled positive fluid balance.*

Acute renal failure (ARF) is defined as rapid decline (over hours to days) in glomerular filtration rate (GFR). This manifests as a rapid increase in blood urea nitrogen (BUN; azotemia) and serum creatinine, and may or may not be accompanied by a decline in urine output; specific definitions (e.g., absolute or fractional increase of serum creatinine) vary widely between studies.[1] ARF occurs in 2% to 5% of general medical-surgical admissions, but up to 10% to 30% of ICU admissions. Acute renal failure can be classified into three broad etiologic/anatomic categories: prerenal ARF, intrarenal ARF, and postrenal ARF. Prerenal ARF is caused by renal hypoperfusion with intact renal parenchyma (55% to 60% of instances of ARF). Intrarenal ARF is caused by parenchymal renal diseases (35% to 40% of instances of ARF). Postrenal ARF is caused by urinary tract obstruction (~5% of instances of ARF).[2]

Most ARF in the ICU is caused by prerenal azotemia, and the rest predominantly by renal parenchymal injury with acute tubular necrosis (ATN); the former may convert to the latter. Despite advances in critical care and dialysis technologies, the mortality of ARF requiring dialysis in critically ill patients remains 50% to 80%.[3–5] Although there is evidence that isolated ARF itself increases mortality, it is clear that mortality of ICU ARF increases with every additional nonrenal organ failure present at the time of initiation of renal replacement therapy (RRT).[3,5] Emerging data suggest that renal ischemia-reperfusion injury and the uremic milieu actually contribute to the development of distant organ injury (increased pulmonary vascular permeability and cardiac and splanchnic organ apoptosis).[6–8] Outcome is particularly poor in septic ARF; in one study, mortality of septic ARF was 74%, compared to 45% in nonseptic cases.[9] ARF in the presence of shock (septic or cardiogenic) is an increasingly common occurrence in modern ICUs, and has driven the development of continuous renal replacement therapy (CRRT) to permit control of azotemia and fluid balance in hemodynamically unstable patients.[5,10] Although a broad differential diagnosis and therapeutic plan should be considered for every ICU patient with ARF, in most cases the approach is to reverse any element of prerenal azotemia, provide supportive care in the presence of ATN, and intervene with effective RRT when indicated, in anticipation of probable renal recovery in the event of patient survival.

Classification of Acute Renal Failure

PRERENAL ACUTE RENAL FAILURE

Prerenal azotemia is the most common cause of ARF in hospitalized patients. The main feature of prerenal ARF is the presence of intact renal parenchymal tissue and the rapid correction of GFR with restoration of renal perfusion. Uncorrected prerenal azotemia predisposes to the development of ATN. Prerenal ARF is caused by any condition leading to renal hypoperfusion, including systemic hypoperfusion with hypovolemia, cardiac failure, or vasodilatory shock, and/or regional hypoperfusion caused by renal vasoconstriction (Table 75-1; see Chap. 21).

Renal blood flow and GFR are relatively maintained during mild hypoperfusion, due to compensatory mechanisms.[11] Renal perfusion is largely preserved within a range of mean arterial pressure (MAP) between 80 to 180 mm Hg, if cardiac output is adequate. As MAP falls below 80 mm Hg there is a precipitous fall in renal blood flow and GFR.[12] There are two major mechanisms of renal blood flow autoregulation: a myogenic reflex and tubuloglomerular (TG) feedback. The myogenic reflex is mediated by stretch receptors in the afferent arterioles, which detect a decrease in perfusion pressure, leading to autoregulatory relaxation of afferent arterioles and vasodilation. TG feedback defends renal perfusion as follows: chloride concentration is continuously sensed in the tubular lumen by the macula densa, just distal to the thick ascending loop of Henle. When luminal chloride decreases (presumably reflecting decreased renal blood flow, GFR, intravascular volume, or a combination of these), a vasodilatory signal is transduced to the corresponding afferent arteriole (and vice versa if flow increases). Together these mechanisms autoregulate renal blood flow in the face of hypotension or hypertension. A third mechanism additionally helps autoregulate GFR. Increased renin secretion stimulated by hypotension/hypovolemia sensed in the afferent arteriole helps maintain GFR (but not renal blood flow) during hypotension, through the efferent arteriolar action of angiotensin II (discussed further below).

TABLE 75-1 Causes of Acute Renal Failure

Prerenal

Volume depletion: Gastrointestinal fluid loss or hemorrhage; renal losses (diuretics or glucosuria, salt-wasting nephropathy, diabetes insipidus, or adrenal insufficiency); cutaneous losses (burns, desquamation)

Volume redistribution: Peripheral vasodilation (sepsis or antihypertensives), peritonitis, burns, pancreatitis, hypoalbuminemia (nephrotic syndrome or hepatic disease)

Cardiac dysfunction: Pericardial tamponade, complications of myocardial infarction, acute or chronic valvular disease, cardiomyopathies, arrythmias

Vasodilatory shock: Sepsis, liver failure, postcardiotomy, anaphylaxis, or antihypertensives

Renal vasoconstriction: Cirrhosis, sepsis, hypercalcemia, drugs (cyclosporine, tacrolimus, nonsteroidal anti-inflammatory drugs, or pressors)

Renal

Ischemia: Trauma, surgery, sepsis, pigment nephropathy (hemolysis or rhabdomyolysis), cardiac or aortic hemorrhage

Nephrotoxic: Radiocontrast, antibiotics (aminoglycosides or amphotericin), nonsteroidal anti-inflammatory drugs, carbon tetrachloride, ethylene glycol, heavy metals (lead, mercury, arsenic, cadmium, or uranium), pesticides, fungicides, cyclosporine, or tacrolimus

Disorders of glomeruli and blood vessels: Poststreptococcal glomerulonephritis, infective endocarditis, systemic lupus erythematosus, Goodpasture's syndrome, microscopic polyarteritis, Wegener's granulomatosis, Henoch-Schöunlein purpura, idiopathic rapidly progressive glomerulonephritis, polyarteritis nodosa, malignant hypertension, thrombotic microangiopathies (hemolytic uremic syndrome, thrombotic thrombocytopenic purpura, postpartum renal failure, or antiphospholipid syndrome), renal artery embolism, renal artery dissection, bilateral renal vein thrombosis, or abdominal compartment syndrome

Acute interstitial nephritis:

Allergic: Semisynthetic penicillin analogues (e.g., methicillin, ampicillin, or nafcillin), cephalosporins, rifampin, ciprofloxacin, cotrimoxazole, sulfonamides, thiazides, furosemide, allopurinol, phenytoin, tetracyclines, or warfarin

Infectious: Streptococcal, staphylococcal, leptospirosis, infectious mononucleosis, diphtheria, brucellosis, Legionnaire's disease, toxoplasmosis, or cytomegalovirus

Infiltrative: Sarcoidosis, lymphoma, leukemia

Autoimmune/alloimmune: Systemic lupus erythematosus or renal transplant rejection

Postrenal

Malignancy: Lymphoma, renal adenocarcinoma, bladder ureteral carcinoma, gynecologic cancers, prostate cancer, other pelvic tumors, or metastatic disease

Inflammatory processes: Tuberculosis, inflammatory bowel disease, retroperitoneal abscess or fibrosis, postradiation therapy

Vascular diseases: Aortic aneurysm, renal artery aneurysm

Papillary necrosis: Diabetes mellitus, sickle hemoglobinopathy, analgesic abuse, prostaglandin inhibition, or hepatic cirrhosis

Intratubular: Uric acid, calcium phosphate, Bence Jones proteins, methotrexate, acyclovir, sulfonamide antibiotics, or indinavir

Miscellaneous: Nephrolithiasis, ureteral ligation, retrograde pyelography with ureteral edema, neurogenic bladder, neuropathic ureteral dysfunction, or obstructed urinary catheter

Of course, in addition to local autoregulation, systemic neurohumoral influences also play a prominent role in determining the renal response to shock. Systemic hypoperfusion activates the sympathetic nervous system and renin-angiotensin-aldosterone axis. Norepinephrine and angiotensin II are systemic vasoconstrictors, and tend to increase renal blood flow by preserving renal perfusion pressure. On the other hand, both hormones are renal vasoconstrictors, though they differ in their glomerular hemodynamic effects. Angiotensin II preferentially constricts efferent arterioles, and helps preserve glomerular filtration, increasing filtration fraction (the ratio of GFR to renal plasma flow) by creating "back-pressure" to augment net filtration pressure in the glomerular capillary. Norepinephrine causes balanced afferent and efferent arteriolar constriction, similarly increasing filtration fraction in the face of decreased renal blood flow, but to a lesser extent than angiotensin II. Both angiotensin II and norepinephrine stimulate intrarenal vasodilator prostaglandin production, thus attenuating their simultaneous effect of afferent arteriolar vasoconstriction and helping preserve renal perfusion.

Drugs may unfavorably alter the glomerular hemodynamic response to renal hypoperfusion. Nonsteroidal anti-inflammatory drug (NSAIDs) administration to patients with decreased effective arterial blood volume (due to hypovolemia or congestive heart failure) or renal vasoconstriction (due to cirrhosis) leads to a decline in renal blood flow and GFR. These patients are dependent on vasodilator prostaglandins to maintain renal perfusion, so NSAIDs leave renal vasoconstrictor influences unopposed. Angiotensin-converting enzyme inhibitors (ACEIs) and angiotensin receptor blockers (ARBs) can lead to prerenal azotemia in patients who are dependent on angiotensin II for maintenance of GFR. This phenomenon is most commonly seen in patients receiving ACEIs or ARBs in the presence of hypovolemia, bilateral renal artery stenosis, or unilateral renal artery stenosis with a solitary kidney.

Prerenal azotemia also leads to avid renal tubular sodium and water reabsorption throughout the nephron. Catecholamines and angiotensin II directly increase sodium transport and reabsorption in the proximal and distal nephron. Efferent arteriolar constriction by angiotensin II and increased filtration fraction simultaneously lead to decreased peritubular capillary hydraulic pressure and increased peritubular capillary oncotic pressure. The combination of high oncotic pressure and low hydraulic pressure in peritubular capillaries increases sodium and water absorption in the proximal tubule, a process termed *glomerulotubular balance*. Angiotensin II also leads to downstream production of aldosterone, another salt-retaining influence. Severe hypovolemia/hypotension (>10% to 15% decrease in MAP or blood volume) leads to nonosmotic vasopressin secretion, and avid water reabsorption in the collecting duct, along with systemic vasoconstriction. Finally, in hypovolemic patients decreased

atrial stretch downregulates production of atrial natriuretic peptide, also favoring sodium retention (the opposite is true if renal hypoperfusion is caused by congestive heart failure). Thus the combination of glomerulotubular balance and the tubular effects of catecholamines, angiotensin II, aldosterone, and vasopressin mediate the salt and water retention which is the hallmark of prerenal azotemia. Accordingly, patients with prerenal azotemia tend to have oliguria, low urine sodium, and concentrated urine with a urine osmolality exceeding 500 mOsm/kg. Low urine sodium (and fractional excretion of sodium; see below) and increased urine osmolality (with a high urine:plasma creatinine ratio) are not seen in patients who have prerenal ARF due to renal losses (ongoing diuretic therapy, salt-wasting nephropathies, osmotic diuresis, adrenal insufficiency, and central or nephrogenic diabetes insipidus). Other common laboratory features of prerenal ARF are increased serum BUN:creatinine ratio (caused by low tubular flow and increased urea reabsorption), decreased fractional excretion of urea (see below), polycythemia/high serum albumin (hemoconcentration), mild hypercalcemia, hyperuricemia, and acid-base abnormalities (metabolic acidosis from diarrhea or shock or lactic acidosis; metabolic alkalosis from diuretics or vomiting). Hyponatremia may also be present, depending on abnormalities in water balance (see Chap. 76). The renal response to volume challenge or vasoactive drug initiation may also be used to determine the presence or absence of a reversible, "prerenal" etiology of ARF.

POSTRENAL ACUTE RENAL FAILURE

Postrenal ARF (often called obstructive uropathy) accounts for 5% of all cases of ARF, and is more common in the elderly. Unilateral obstruction is not sufficient alone to cause ARF. Renal insufficiency due to obstruction occurs only when the obstruction involves a site that affects both kidneys, or a single functioning kidney. The most common cause of postrenal obstruction is bladder neck obstruction (prostatic hypertrophy, prostate cancer, and neurogenic bladder). Postrenal obstruction is also caused by bilateral ureteral obstruction or unilateral obstruction in patients with solitary kidney (stones, clots, sloughed renal papillae, retroperitoneal fibrosis, or retroperitoneal masses). Intratubular obstruction can be caused by crystals like uric acid, calcium oxalate, calcium phosphate, acyclovir, sulfadiazine, indinavir, methotrexate, or by paraprotein (myeloma cast nephropathy). Volume expansion, sometimes with urinary alkalinization (uric acid, methotrexate, or myeloma), is the primary treatment for these causes of intratubular obstruction.

Obstruction to urine flow by increased tubular hydrostatic pressure is only partly responsible for the reduced GFR of obstructive uropathy. ARF is also caused and sustained by renal vasoconstriction that occurs in response to ureteral obstruction, mediated by thromboxanes. Obstruction should be suspected in patients with recurrent urinary tract infections, nephrolithiasis, prostate disease, or pelvic tumor. Causes of obstructive uropathy are listed in Table 75-1. These patients usually have a preceding history of obstructive symptoms followed by sudden onset of anuria or oliguria. Polyuria and nocturia due to renal concentrating defect may be seen in patients with partial or intermittent obstruction. Other features of ARF secondary to obstruction are increased BUN:creatinine ratio, hyperkalemia, and defective urinary acidification with metabolic acidosis.

The two most important diagnostic tests when obstruction is suspected are bladder catheterization and renal ultrasonography. If urinary tract obstruction is strongly suspected, but ultrasound results are equivocal, then a "stone protocol" noninfused computed tomography (CT) scan should be performed. In some cases where false-negative ultrasound or CT scan results are suspected, cystoscopy and retrograde pyelograms may be required to definitively exclude the diagnosis of obstructive uropathy. For example, we would request retrograde pyelograms despite normal ultrasound images in a patient with anuric, hyperkalemic ARF and extensive pelvic tumor, potentially encasing the ureters and preventing dilation and hydronephrosis. Retroperitoneal fibrosis can similarly cause obstructive ARF without hydronephrosis. Early diagnosis is essential, as the extent of parenchymal damage is dependent on the duration of obstruction; complete recovery is possible up until 10 to 14 days of obstruction.

INTRINSIC ACUTE RENAL FAILURE

Intrinsic acute renal failure can be categorized anatomically, according to the site of the lesion: vascular, glomerular, or tubulointerstitial. We will discuss tubular and interstitial causes first, because they are far more common in hospitalized patients.

ACUTE TUBULAR NECROSIS

The most common cause of intrinsic ARF in hospitalized patients is acute tubular necrosis (ATN). ATN is caused by ischemia, nephrotoxins, or a combination of both, and accounts for approximately 85% to 90% of intrinsic ARF cases.[2,13] Ischemic ATN is commonly seen in patients with sepsis or severe cardiac failure, or postoperative patients, particularly after cardiac and aortic surgeries. Massive trauma or cardiac arrest are other causes of ATN. Prerenal failure can result in ischemic ATN if renal hypoperfusion is severe and not reversed by timely therapy. Although improving renal perfusion may reverse prerenal ARF (by definition), and diminish ischemic contributions to the pathogenesis of ATN, it is quite conceivable that in many cases ATN develops despite appropriate resuscitation and adequate renal perfusion. Zager has shown in an endotoxemic rat model of septic ARF that paired combinations of insults (renal cross clamp, systemic endotoxin, aminoglycoside, and temperature elevation) cause azotemia and renal pathologic findings of ATN, but these insults individually cause no renal dysfunction or injury.[13] We suspect that this synergistic injury model accurately reflects the pathogenesis of much ARF in the ICU. Positive pressure mechanical ventilation alters renal perfusion and function through a variety of mechanisms, both hemodynamic and inflammatory.[14] Other experimental data have shown that endotoxin, tumor necrosis factor, and numerous other inflammatory mediators are directly cytotoxic to renal endothelial and tubular cells.[15]

The diagnosis of ATN is usually made by clinical exclusion of alternative diagnoses such as obstruction or prerenal azotemia, and a lack of features suggestive of other intrinsic renal lesions. Characteristic urinalysis and urine chemistry findings frequently support the clinical diagnosis (see below). Ischemic ATN is usually reversible by tubular regeneration in surviving patients with previously

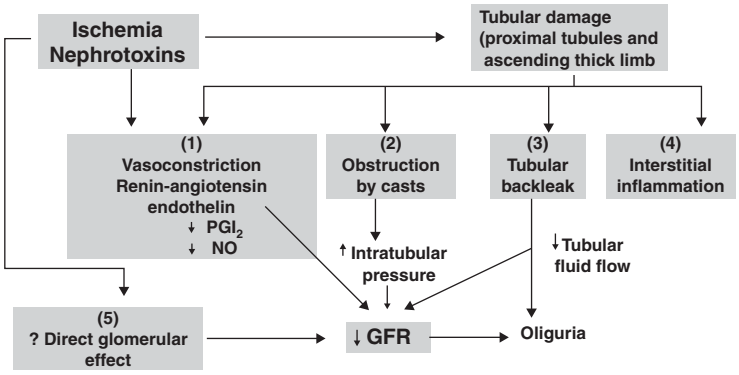

FIGURE 75-1 Pathophysiologic mechanisms of acute renal failure. Tubular damage by ischemia, nephrotoxins, or both, leads to decreased GFR by a combination of mechanisms. (1) Renal vasoconstriction via activation of tubuloglomerular feedback, and decreased vasodilator substances (PGI_2, prostacyclin; NO, nitric oxide) is a prominent functional mechanism of decreased GFR in ATN. (2) Backpressure from tubular obstruction by casts directly decreases GFR. (3) Backleakage of glomerular filtrate into peritubular capillaries decreases the efficiency of glomerular filtration, effectively decreasing GFR. (4) There is increasing evidence for a role of interstitial inflammation in the extension phase of ATN. (5) Direct glomerular effects (mesangial contraction, decreased filtration surface area) may also play a role in decreasing GFR in the presence of ATN. ***(Reproduced with permission from Lameire et al.[21])***

normal renal function. Failure to recover prompts consideration of a differential diagnostic list including bilateral cortical necrosis, renal atheroembolism, renal artery stenosis/thrombosis/dissection, and severe forms of other intrinsic lesions such as rapidly progressive glomerulonephritis (GN). Bilateral cortical necrosis causes irreversible renal failure and is associated with profound shock with disseminated intravascular coagulation, obstetric complications, hemolytic uremic syndrome, or snake bites.[16]

Cellular mediators that play a role in the pathogenesis of ATN include calcium, reactive oxygen species, phospholipases, proteases, adhesion molecules, and nitric oxide (NO).[17] ATN has several phases: prerenal, initiation, extension, maintenance, and repair.[18] It is not intuitive that renal tubular injury should cause decreased glomerular filtration and ARF. A decrease in glomerular ultrafiltration coefficient has been shown in several animal models of ARF, but this is a minor contributor to the observed decrement in GFR.[19,20] The pathophysiologic mechanisms that explain the reduction of GFR in ATN are hemodynamic abnormalities, tubular obstruction, and tubular backleakage of glomerular filtrate (Fig. 75-1).[21] Renal vasoconstriction is seen in ARF,[21,22] caused by activation of tubuloglomerular feedback; increased distal chloride delivery past injured tubular segments is sensed by the macula densa, causing vasoconstriction of the corresponding afferent arteriole. This reversible, functional mechanism seems to be the major cause of decreased GFR in ATN, and is in part protective. Severe hypovolemia would rapidly result if injured tubules failed to reabsorb the bulk of filtered sodium and water; thus the term "acute renal success" has been used to describe the development of decreased GFR ("acute renal failure") in the presence of tubular necrosis.[22] Furthermore, reabsorption of filtered sodium accounts for the bulk of renal oxygen consumption; continued glomerular filtration of sodium in ATN may aggravate hypoxic damage to sublethally injured tubules. The phenomenon of medullary hypoxia plays an important role in the pathogenesis of ATN. Low medullary blood flow is required for urinary concentration.[23] Reabsorption of sodium chloride by the medullary thick ascending limb of the loop of Henle (mTAL) is the major determinant of medullary oxygen consumption, resulting in a hypoxic environment under normal circumstances.[23,24] mTAL is vulnerable to ischemic injury if increased oxygen requirement is associated with decreased oxygen delivery. In addition, the inflammatory mechanisms that dominate as ATN progresses from initiation to extension and maintenance phases of ATN result in medullary congestion and hypoperfusion.[18]

The tubular factors that are also involved in the reduction of GFR in ARF are tubular obstruction and tubular backleakage. Necrotic cell debris incorporated into casts causes obstruction of proximal and distal tubules and has been shown to play a significant role in experimental ARF.[25,26] Backleakage of tubular fluid across denuded basement membranes and injured proximal tubule cells has been demonstrated in several experimental models of ARF.[27] Subsequently it has been shown that tubular backleakage and intratubular obstruction are important factors contributing to the reduction of GFR in human ischemic ARF.[28,29]

Nephrotoxic injury is the second major cause of ATN. Nephrotoxic ATN is caused by drugs (aminoglycosides, cisplatin, amphotericin, and chemotherapy), radiocontrast agents, heme pigments (myoglobin and hemoglobin), and myeloma light chain proteins. ARF due to aminoglycosides and radiocontrast agents accounts for most cases of nephrotoxic ATN. Nephrotoxicity of cancer chemotherapy is discussed in Chap. 74; malignancy and ARF are further discussed below. Three nephrotoxic ARF syndromes will be further discussed here: aminoglycoside nephrotoxicity, radiocontrast nephropathy, and ARF caused by nonsteroidal anti-inflammatory drugs (NSAIDs).

Aminoglycoside Nephrotoxicity

Aminoglycosides like tobramicin, gentamicin, amikacin, and netilmicin are widely used for the treatment of gram-negative infections. Although they are effective antibiotics, therapy with aminoglycosides is complicated by nephrotoxicity in 10% to 20% of patients.[30] Aminoglycosides are excreted by glomerular filtration and are reabsorbed by proximal tubular cells. The mechanism of aminoglycoside-induced renal injury is not well understood. Accumulation of aminoglycosides in the proximal tubules in high concentration results in disruption of a variety of intracellular processes. Aminoglycosides are tubular toxins, and the earliest morphologic changes consist of vacuolization of proximal tubules, loss of brush border, and the presence of myeloid bodies within proximal tubule cells. Clinical evidence also attests to the tubular toxicity of aminoglycosides; maximum urine osmolality falls, and renal wasting of Mg^{2+} and K^+ ensues. The relationship between this tubule damage and reduced GFR remains unclear, although in experimental models using high doses

TABLE 75-2 Risk Factors for Aminoglycoside Nephrotoxicity

Congestive heart failure
Elderly patient
Multiple myeloma

of aminoglycosides, tubule obstruction and backleakage can be demonstrated. In experimental models of aminoglycoside nephrotoxicity, relatively small doses decrease glomerular permeability, while larger doses cause renal vasoconstriction. The relevance of these hemodynamic changes to human aminoglycoside nephrotoxicity is not known.

ARF generally develops 7 to 10 days after aminoglycoside therapy is started. Aminoglycoside nephrotoxicity is associated with nonoliguric ARF, due to a concentrating defect caused by tubular injury. Aminoglycoside nephrotoxicity is also accompanied by potassium and magnesium wasting. Risk factors for aminoglycoside nephrotoxicity are summarized in Table 75-2. In patients with preexisting renal insufficiency the dosing interval should be adjusted and levels monitored to minimize the risk of ototoxicity and nephrotoxicity. Once-daily dosing of aminoglycosides decreases nephrotoxicity with no apparent loss of effectiveness.[31–33] In patients with acutely deteriorating renal function who require aminoglycoside therapy, monitoring may be very difficult and require frequent reassessment. Aminoglycosides should be discontinued whenever renal dysfunction develops; increasing trough levels and decreased calculated aminoglycoside clearance may signal decreased GFR before serum creatinine increases. Recovery of renal function is expected in most cases when nephrotoxicity is recognized early and aminoglycosides held, but may be delayed for days to weeks.

Radiocontrast Nephropathy

ARF due to radiocontrast agents occurs within 24 to 48 hours of intravenous radiocontrast administration, and is termed radiocontrast nephropathy. Vasoconstriction and direct tubular toxicity due to generation of oxygen free radicals are thought to be the pathogenetic mechanisms of radiocontrast nephrotoxicity. In most cases the ARF is mild and recovery typically begins with stabilization of serum creatinine at 3 to 5 days postcontrast.[34] Renal failure is usually nonoliguric. However, in patients with preexisting severe chronic renal failure radiocontrast nephropathy may be severe, irreversible, and require chronic dialysis.

The risk of nephrotoxicity due to contrast agents varies with the type and dose of agent. Low- or iso-osmolal agents are less nephrotoxic than ionic high-osmolal agents.[35,36] The incidence of ARF due to radiocontrast agents is less than 2% in patients with normal renal function, but is inversely related to GFR in patients with chronic renal insufficiency; in high-risk patients the incidence is as high as 60%.[37] There are several important risk factors for radiocontrast nephropathy, including chronic renal insufficiency, diabetic nephropathy, severe congestive heart failure, intravascular volume depletion, high contrast dose, and multiple myeloma (Table 75-3). Of note, the risk of radiocontrast nephropathy at any GFR level of chronic renal impairment is approximately double in diabetics compared to nondiabetics. The group at risk for radiocontrast nephropathy can be reliably identified, and a variety of prophylactic strategies have been used, several successfully.

A number of measures are used for prevention of radiocontrast nephropathy. Alternative imaging approaches (ultrasound, noninfused CT, or gadolinium-enhanced magnetic resonance angiography) are preferred to radiocontrast studies in patients with a high risk of radiocontrast nephropathy. Nonionic low-osmolal agents[35] and nonionic iso-osmolol agents[36] are less nephrotoxic, and these agents are used to decrease the incidence of ARF due to radiocontrast agents. Standard recommendations suggest that IV hydration with 0.45% saline is beneficial in reducing the incidence and severity of radiocontrast nephropathy,[38] but recently normal saline (1 mL/kg per hour for 12 hours pre- and postcontrast) was demonstrated superior for this purpose.[39] Most recently, Merten and colleagues showed that administration of an equimolar sodium bicarbonate solution was superior to normal saline for radiocontrast nephropathy prophylaxis, infused as 3 mL/kg per hour for 1 hour precontrast, then 1 mL/kg per hour for 6 hours.[40] In some studies the administration of acetylcysteine, a thiol-containing antioxidant, in combination with saline hydration has been shown to be beneficial in reducing the incidence of contrast nephropathy when administered in various oral regimens (1200 mg once or 600 mg every 12 hours before and after radiocontrast).[41–43] One successful study used intravenous acetylcysteine for radiocontrast nephropathy prophylaxis.[44] Although other studies did not show any benefit,[45,46] a recent meta-analysis of eight randomized controlled trials involving 855 patients reported that the use of acetylcysteine reduced the risk of radiocontrast by 59%.[46] However, further doubt has been cast over these inconsistent findings by emerging experimental data that suggest that the apparent efficacy of acetylcysteine in these studies may have been artifactual. Specifically, acetylcysteine causes a decrement in serum creatinine (but not cystatin C) by a GFR-independent mechanism,[47] perhaps by inhibiting creatinine phosphokinase function.[48] Nevertheless, given the available data, oral administration of acetylcysteine to patients at high risk of developing contrast nephropathy appears warranted, and should do no harm in combination with adequate volume expansion. Other approaches such as vasodilation with dopamine[49] or fenoldopam[50] failed to prevent radiocontrast nephropathy, and mannitol and furosemide appeared to increase the rate of ARF postcontrast in one study.[38] Prophylactic hemodialyis has not been shown to be beneficial in the prevention of contrast nephropathy.[51]

More recently, Marenzi and colleagues compared the effectiveness of hemofiltration with intravenous isotonic saline administration in patients with chronic renal insufficiency undergoing coronary interventions.[52] BUN and serum creatinine were measured at baseline, immediately before the procedure, and then daily for the following 3 days and at hospital discharge. In this study there was less likelihood of an increase in serum creatinine (the primary end point), less likelihood of requiring emergent hemodialysis, and less in-hospital and 1-year mortality in the hemofiltration group.[52] Adulteration of the primary end point by hemofiltration of creatinine in one arm is a fatal flaw of this study. Other flaws include an unbalanced level of care between the groups (floor vs. hemofiltration in the ICU), and more regulation of fluid balance in the hemofiltration group (and more pulmonary edema in the fluids-alone arm). Since hemofiltration is also expensive, associated with a variety of risks, and a limited resource, we do not recommend this approach to radiocontrast nephropathy prevention unless confirmed by additional prospective controlled studies.

Nonsteroidal Anti-Inflammatory Drugs and Acute Renal Failure

NSAIDs can cause hemodynamically mediated ARF. Vasodilatory prostaglandins (prostacyclin and prostaglandin E_2 [PGE_2]) are essential for the maintenance of renal blood flow and GFR in states of effective volume depletion, such as congestive heart failure, cirrhosis of the liver, nephrotic syndrome, and in states of true volume depletion.[53] Prostaglandins counterbalance the effects of vasoconstrictors such as angiotensin II and catecholamines. NSAIDs inhibit prostaglandins and thus would lead to unopposed effect of angiotensin II and catecholamines, leading to reduced GFR. Hyperkalemia may be prominent because NSAIDs impair renin secretion. Patients with chronic renal insufficiency are similarly at risk for NSAID-induced ARF, because vasodilator prostaglandins maintain hyperfiltration in remnant nephrons. Hemodynamically-mediated ARF is seen within days of taking NSAIDs in high-risk patients. Cyclooxygenase-2 (COX-2) selective drugs have the same renal effects as nonselective NSAIDs, because COX-2 is constitutively expressed and physiologically active in the kidney.[54] The second type of acute renal injury is allergic interstitial nephritis, as discussed below. Chronic NSAID use is also associated with papillary necrosis and is thought to occur in patients who are taking multiple analgesics.

ACUTE TUBULOINTERSTITIAL NEPHRITIS

ARF due to acute interstitial nephritis (AIN) is most often caused by allergic reaction to various drugs (allergic AIN), but there are also a variety of infectious (Legionnaire's disease, cytomegalovirus, and Hantavirus), autoimmune (lupus), alloimmune (renal transplant rejection), and infiltrative (sarcoidosis, leukemia, and lymphoma) disorders that can cause AIN (see Table 75-1). The most common drugs that cause allergic AIN are penicillins, cephalosporins, ciprofloxacin, rifampin, sulfonamides (furosemide, thiazide diuretics, and trimethoprim-sulfamethoxazole), cimetidine, allopurinol and NSAIDs.

Patients with AIN classically present with ARF temporally related to drug therapy or infection, associated with a triad of fever, rash, and eosinophilia.[55] Urinalysis findings include leukocyturia with eosinophiluria, leukocyte casts, and low-grade proteinuria. Although all these signs are present in the majority of patients with AIN, absence of these does not exclude the diagnosis of AIN. In particular, these findings are usually absent in NSAID-induced AIN. Proteinuria is mild to moderate except in NSAID-induced AIN, in which nephrotic syndrome caused by a minimal change lesion has been described. Tubular dysfunction (e.g., Fanconi's syndrome, distal renal tubular acidosis, or hyperkalemia) occurs in the majority of patients with AIN.

AIN is usually suspected from the history and laboratory findings. In the absence of urinary tract infection, detection of large numbers of urinary eosinophils (>5%) strongly suggests the diagnosis of drug-induced tubulointerstitial nephropathy (TIN). Hansel's stain of the urine is more sensitive than Wright's stain for the detection of urinary eosinophils.[56] The Hansel method correctly identified 10 of 11 patients with TIN, as opposed to only 2 of 11 correctly classified using Wright's stain. False-positive results with the Hansel technique are most commonly caused by rapidly progressive GN or acute prostatitis. Diagnosis can be confirmed by renal biopsy if ARF is progressive and treatment of an alternative diagnosis is considered (e.g., rapidly progressive GN), or if there is no recovery of renal function after discontinuation of the medication suspected to have caused AIN.

No therapy is recommended in patients with mild renal insufficiency, and in patients who respond after discontinuation of the offending medication. AIN is usually reversible after withdrawal of the offending agent and treatment of underlying disease; corticosteroid therapy is unproven, and generally recommended only in patients with biopsy-confirmed acute allergic interstitial nephritis who do not respond to conservative management, and have no contraindication to immunosuppression.

RAPIDLY PROGRESSIVE GLOMERULONEPHRITIS

Glomerulonephritis such as postinfectious glomerulonephritis, lupus nephritis, and Goodpasture's syndrome can cause acute or subacute renal failure (see Table 75-1). Rapidly progressive glomerulonephritis (RPGN) causing ARF is an emergency. The combination of ARF with an "active" urine sediment (heavy proteinuria, hematuria, leukocyturia, and erythrocyte/leukocyte/mixed cellular casts) should prompt urgent evaluation with renal biopsy and serologies. The underlying pathologic lesion is classically necrotizing crescentic glomerulonephritis, treated with high-dose pulse corticosteroid therapy to stabilize renal function, followed by intensive immunosuppression (with or without plasmapheresis). Causes include inflammatory disorders with immune complex deposition (lupus, postinfectious, or cryoglobulinemia), anti–glomerular basement membrane antibodies (Goodpasture's syndrome, when associated with pulmonary hemorrhage), and pauci-immune glomerulonephritis (usually with small-vessel vasculitis; see below). Associated clinical features such as pulmonary hemorrhage, sinus involvement, leukocytoclastic vasculitis, neuropathy, or other stigmata of autoimmune disease may increase the index of suspicion for this diagnosis, but it must be emphasized that a skilled urinalysis demonstrating an "active" sediment in a patient with ARF may make this diagnosis alone. In fact the presence of erythrocyte casts is pathognomonic of GN; associated with ARF, this is essentially diagnostic of RPGN.

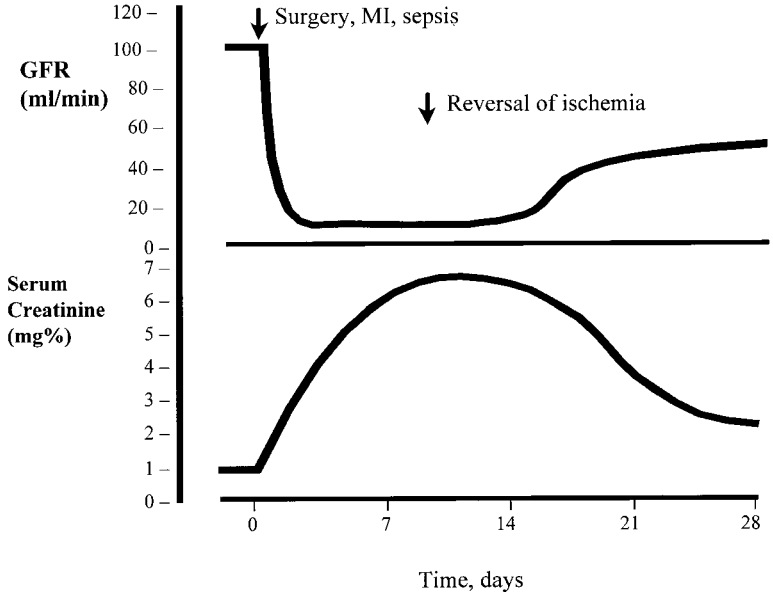

FIGURE 75-2 Dynamic relationship between serum creatinine and GFR in ARF. Moran and Myers demonstrated that elevation of serum creatinine lags significantly behind GFR decrements in ARF. In this example, an acute decrement in GFR to <10 mL/min (commonly a dialysis-requiring level) after a major ischemic insult is associated with a subsequent slow, daily rise of serum creatinine. The daily serum creatinine increment is determined by creatinine generation (muscle mass and catabolic state), volume status (volume of distribution of creatinine), and the new GFR level. Serum creatinine continues to rise until creatinine generation equals creatinine excretion at steady state. Only after a week is it fully apparent from the serum creatinine level how low the GFR is in this patient with ARF; this could have been inferred from the progressive daily serum creatinine increments, and measured by urine collection for an abbreviated creatinine clearance. (*Reproduced with permission from Star,[3] and modified with permission from Moran et al.*[61])

VASCULAR CAUSES OF ACUTE RENAL FAILURE

Vascular causes of ARF are categorized into small-vessel diseases and large-vessel diseases (see Table 75-1). Diseases involving small vessels include microscopic polyarteritis (vasculitis in polyarteritis nodosa and Kawasaki's disease involves medium-sized vessels), Wegener's granulomatosis, mixed cryoglobulinemia, and conditions that are categorized as thrombotic microangiopathies, including thrombotic thrombocytopenic purpura, hemolytic uremic syndrome, scleroderma renal crisis, malignant hypertension, and antiphospholipid antibody syndrome. Large-vessel renal vascular diseases include thromboembolic diseases and renal vein thrombosis. Atheroembolic disease should be considered in patients who develop ARF after instrumentation of the aorta, particularly in patients with known atherosclerotic disease.[57] Renal vein thrombosis is usually a complication of nephrotic syndrome, and if bilateral can cause ARF. Abdominal compartment syndrome (see Chap. 42) is present when the intra-abdominal pressure (IAP) reaches 20 to 25 cm H_2O, and unless decompressed, irreversible organ failure may result.[58] The pathogenesis of oliguria and ARF in abdominal compartment syndrome involves venous compression (decreased venous return and renal vein compression), ureteral compression with obstructive uropathy, and possibly changes in renovascular resistance and intrarenal blood flow distribution. Regardless of the underlying cause, a reduction in urine output with or without azotemia in the presence of a measured intra-abdominal pressure over 15 cm H_2O is cause for concern and should prompt intervention.

Renal Function Monitoring and Diagnostic Approach to Acute Renal Failure

MONITORING RENAL FUNCTION IN THE ICU

Attempts to develop strategies to prevent or treat ARF in the ICU have been hampered by the lack of sensitive real-time methods to monitor renal perfusion and function in the clinical setting.[59] There are no direct measures of renal perfusion in clinical use. Of the available research techniques for this purpose, para-aminohippuric acid (PAH) clearance is not a valid method to assess renal plasma flow because renal PAH extraction is impaired in critical illness, after cardiac surgery, post–renal transplantation, and in ARF.[60] Clinical indices such as plasma concentrations of urea nitrogen and creatinine, urine output, urine chemistries, and urinalysis may be assessed in combination to monitor renal perfusion and function, but alterations in these markers are insensitive, indirect, and often delayed manifestations of renal hypoperfusion and injury.[59] Although relatively insensitive, it should be recognized that progressive elevation of serum creatinine is a specific sign of decreased GFR and diagnostic of ARF. As depicted in Fig. 75-2, daily serum creatinine increments of 0.5 to 1 mg/dL (depending on muscle mass, and in the absence of rhabdomyolysis) signal severe depression of GFR.[61] In the absence of obstruction or renal hypoperfusion, this is usually diagnostic of ATN.

Direct measurement of GFR is probably the most relevant marker of renal function to monitor in the ICU, and can be used as an index of adequate systemic perfusion, a marker of organ dysfunction, a guide to medication dosing, and to determine timing of initiation of renal replacement therapy. GFR measurement methods more sensitive than monitoring serum creatinine and urea nitrogen have been validated in this population, but are not yet in widespread clinical use.[59,62] Abbreviated creatinine clearance measurements (2 to 4 hours) provide a more accurate estimate of GFR than serum creatinine alone, and are more timely than 24-hour urine collections.[63] Emerging data suggest that serial monitoring of serum cystatin C levels may provide a more sensitive index of early ARF than serum creatinine or BUN. Cystatin C is a nonglycosylated 13-kDa basic protein that is a member of the cystatin superfamily of cysteine protease inhibitors. It is produced by all nucleated cells, and its production rate is unaltered by inflammatory conditions or muscle mass; only thyroid dysfunction has been shown to alter serum levels independent of GFR in studies to date.[64–66] It undergoes purely renal excretion.

Serum cystatin C levels increase before serum creatinine levels in patients with progressive chronic kidney disease.[64,66] Emerging data suggest that plasma cystatin C levels similarly increase 1 to 2 days before serum creatinine in patients developing ARF in a variety of settings,[66] including radiocontrast nephropathy,[67] renal transplantation,[68,69] cirrhotic ARF,[70] malarial ARF,[71] and ARF in the ICU.[72,73] In the latter study of 85 critically-ill patients, Herget-Rosenthal and colleagues showed that ARF defined by elevation of cystatin C occurred 1 to 2 days before serum creatinine elevation; the area under the curve in receiver operating curve analysis was 0.82 and 0.97 on the 2 days prior to creatinine-defined ARF.[73]

In patients with azotemia and/or oliguria, traditional urine chemistry markers may provide useful information, interpreted in combination with other clinical and laboratory parameters (see below), including microscopic urinalysis.[59,74] Hopefully, more sensitive markers of early renal hypoperfusion and injury will prove clinically useful in the future.[75,76] Meanwhile, all clinically available renal function indices should be used in combination for assessment of renal perfusion and function in the ICU.

DIAGNOSTIC APPROACH TO ACUTE RENAL FAILURE

The diagnostic approach to ARF involves assignment of the cause to prerenal, renal, or postrenal categories, with further refinement of the diagnosis based on additional laboratory testing.

HISTORY AND PHYSICAL EXAMINATION IN ACUTE RENAL FAILURE

Any decrease in effective perfusion of the kidneys can result in the syndrome of prerenal ARF. This may be the result of an absolute decrease in the extracellular fluid (ECF) volume, redistribution of ECF from vascular to interstitial locations (third-spacing), or impaired delivery of blood to the kidneys such as can occur in patients with renal arterial stenosis, vasculitis, or depressed cardiac function. Third-space losses should be suspected in the presence of severe burns, pancreatitis, peritonitis, or recent abdominal surgery. Absolute decreases in the ECF volume are most common in the setting of gastrointestinal fluid losses or in patients receiving excessive doses of diuretics.

Decreases in weight, if known, can provide some information about the degree of ECF loss. However, weight changes are subject to misinterpretation if the nature of fluid loss is not taken into account (Fig. 75-3). The ability of pure water loss (which is spread out across the total-body water) to cause volume depletion is only one-third as great as an equivalent loss of isotonic fluid (all of which must come from the smaller ECF compartment). Thus the importance of changes in weight should be assessed relative to changes in serum sodium concentration.

The cardinal signs of ECF volume depletion are changes in hemodynamic parameters, jugular venous pressure, and in the skin. An orthostatic increase in pulse of 15 beats per minute or a decrease in diastolic blood pressure of 10 mm Hg can detect losses of 5% of the ECF volume. A postural increase in pulse (supine to standing) of at least 30 beats per minute is 96% specific for clinically-significant volume depletion, whereas systolic pressure may fall 20 mm Hg upon

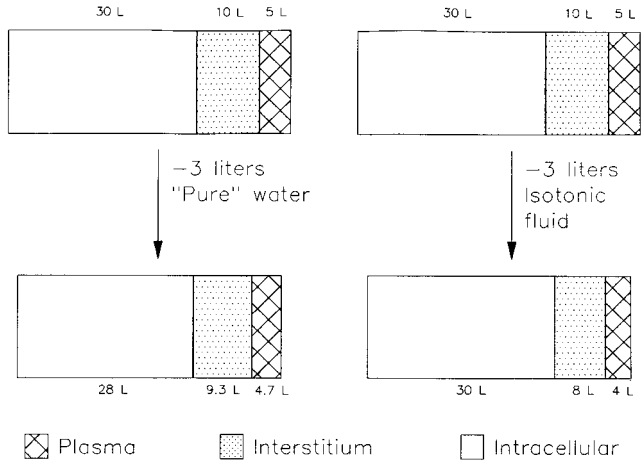

FIGURE 75-3 Effect of fluid loss on body water distribution. Because water is in osmotic equilibrium across biologic membranes, loss of 3 L of solute-free water will be spread across the total body water, resulting in a small decrease (0.3 L) in plasma volume. A similar loss of isotonic fluid, which does not obligate osmotic water movement, leads to a much greater decrease (1.0 L) in plasma volume. This is based on the assumption of 45 L of total body water, two-thirds of which is intracellular. Of the extracellular fluid, about one-third is plasma and the remainder extravascular (interstitium).

standing in 10% of normal individuals and in up to 30% of patients >age 65.[77] The inability of a patient to stand because of severe lightheadedness is a relatively specific sign of hypovolemia. In uncomplicated hypovolemia, estimated central venous pressure by examination of jugular venous pressure should be low. Skin changes that accompany volume depletion include cool, mottled extremities, dry mucous membranes and axillae, and skin tenting (particularly over the forehead and sternum, where age-related changes in skin elasticity are not as pronounced as elsewhere).

Obstruction of the urinary tract must be considered in every patient with an acute deterioration of renal function. The symptoms of acute urinary tract obstruction (severe flank pain, hematuria, and changes in urine flow) are often mistaken for urinary tract infection. Of more importance from a historical standpoint is the identification of preexisting conditions that predispose to urinary tract obstruction. Some of these are listed in Table 75-1. Physical findings suggestive of obstruction include palpably enlarged kidneys, pelvic or abdominal masses, bladder enlargement, prostatic hypertrophy, aneurysmal dilation of the aorta, and signs of inflammatory bowel disease. If oliguria or anuria develops in a critically ill patient with a Foley catheter in place, possible catheter occlusion should be assessed by sterile flushing and if necessary a catheter change.

Intrinsic ARF can be the final result of many diverse renal insults. While space limitations do not permit a thorough review of all aspects of the history and physical examination in intrinsic ARF, some points deserve comment. ARF due to therapeutic or recreational drugs (e.g., cocaine-induced rhabdomyolysis) is so common that a detailed drug history is mandatory.[78] The presence of a skin rash should suggest the possibility of a systemic vasculitis with renal involvement or acute tubulointerstitial nephritis. Palpable purpura due to leukocytoclastic vasculitis is characteristic

of Henoch-Schönlein purpura. One of the pulmonary-renal syndromes should be considered if prominent thoracic complaints accompany ARF. These include, among others, Goodpasture's syndrome, Wegener's granulomatosis, microscopic polyarteritis, systemic lupus erythematosus, and Churg-Strauss syndrome.

DIAGNOSTIC TESTS IN ACUTE RENAL FAILURE

The majority of cases of ARF can be diagnosed by history and physical examination. However, in a significant minority the cause remains obscure after initial assessment, and further evaluation is necessary.

Daily urine volume must be measured in all patients with ARF. Bladder catheterization is both diagnostic and therapeutic in patients with obstruction at the level of the bladder neck or urethra. Urine volume is determined by the requirement to excrete the daily obligate solute load (electrolytes and nitrogenous wastes) in appropriately concentrated urine. Assuming maximal urine concentrating ability (1400 mOsm/kg), the minimum daily urine output required to excrete the average daily solute load is 400 mL, below which positive solute balance and azotemia develop, thus the standard definition of oliguria (<400 mL/24 hours). In terms of monitoring urine output, if urine is maximally concentrated (1400 mOsm/kg), and excretion of 10 mOsm/kg per day (700 mOsm/d in a 70-kg person) is required to avoid solute retention, this mandates urine output of 500 mL daily (21 mL/h, or 0.3 mL/kg per hour). Of course, if solute appearance increases (patient size, hypercatabolism, or hyperalimentation) or maximal urinary concentrating ability is diminished (renal dysfunction or advanced age), higher urine volumes are required to maintain adequate solute excretion. Since such conditions are more the rule than the exception, it seems more appropriate to expect solute retention at urine outputs below the more typical ICU monitoring target of 0.5 to 1 mL/kg per hour (840 to 1680 mL/d). Of course, urine output targets must be sufficient to control fluid balance as well as solute excretion, so higher urine output values may be required for patients with large obligate fluid intakes.

ARF is classified as anuric (urine output <100 mL/d), oliguric (urine output <400 mL/d), or nonoliguric (urine output >400 mL/d). Causes of ARF associated with various urine flow patterns are listed in Table 75-4. Prerenal ARF with polyuria may be seen very rarely if excessive urine losses are the cause of the prerenal state. This occurs in adrenal or mineralocorticoid deficiency states and excessive diuresis. Although occasional polyuric patients with urinary indices suggestive of prerenal ARF have been described,[79] it is believed that the majority of them in fact have polyuric ATN rather than prerenal ARF. The continued use of an indwelling bladder catheter after the cause of ARF has been determined is frequently unnecessary and merely increases the risk of nosocomial urinary tract infection. This is particularly true in the oligo-anuric patient. Intermittent bladder catheterization once or twice daily can provide useful information with a lower risk of urosepsis. An external condom-type catheter does not provide sufficient information to replace the Foley catheter in persons with ARF. Because it is also associated with an increased risk of urinary infection, it cannot be recommended in this setting.

Urinalysis is also useful in patients with ARF. The urinary specific gravity tends to be >1.020 in patients with prerenal failure. On the other hand, patients with intrinsic or postrenal ARF are generally isosthenuric, with a urine specific gravity of approximately 1.010. Substantial proteinuria (3 g/d or more) strongly suggests the possibility of a glomerular disease, with nephrotic-range proteinuria (>3.5 g per 24 hours) pathognomonic of glomerular rather than tubular disease; this may be confirmed with a "spot" urine protein:creatinine ratio (>3 suggests nephrotic-range proteinuria will be confirmed by 24-hour urine collection). Glycosuria in the absence of hyperglycemia strongly suggests proximal tubular injury with Fanconi's syndrome. A positive reaction for blood in the urine is consistent with acute glomerular or tubular injury, urinary tract infection, or nephrolithiasis. If blood is present on dipstick but not microscopically, or if the findings are disproportionate (e.g., 4+ blood on dipstick with rare erythrocytes on microscopy), a pigment nephropathy (hemoglobinuria or myoglobinuria) should be considered. The urine sediment is usually unremarkable in prerenal and postrenal azotemia, except for occasional hyaline casts. In postrenal ARF due to stones, blood and crystals can be seen. Intrinsic ARF is often associated with a characteristic (or even diagnostic) urine sediment. A careful microscopic examination frequently can distinguish between GN, AIN, ATN, and TIN. Erythrocyte casts, often accompanied by proteinuria and numerous erythrocytes and leukocytes, are pathognomonic of GN. Detection of large numbers of leukocytes, leukocyte casts, and eosinophils in uninfected urine strongly suggests the diagnosis of drug-induced AIN. ATN is suggested by findings including muddy brown granular casts, free renal tubular cells, and tubular cell casts.

TABLE 75-4 Urine Flow Rates in the Diagnosis of Acute Renal Failure

Anuria (<100 mL/d)
Complete urinary tract obstruction
Bilateral renal arterial or venous occlusion
Bilateral cortical necrosis
Overwhelming acute tubular necrosis
Severe acute glomerulonephritis
Oliguria (100–400 mL/d)
Prerenal azotemia
Intrinsic acute renal failure
Tubular necrosis
Interstitial nephritis
Glomerulonephritis
Partial intermittent obstruction
Polyuria nonoliguria (>400 mL/d)
Tubular necrosis
Interstitial nephritis
Partial intermittent obstruction

Several measurements of urine composition have been suggested as ways to differentiate between prerenal azotemia and intrinsic ARF in the oliguric patient.[80] Urine electrolytes are most useful in this regard, especially the fractional excretion of sodium (FE_{Na}), calculated as

$$FE_{Na}(\%) = \frac{U_{Na} \times P_{Cr} \times 100}{P_{Na} \times U_{Cr}} \qquad (75\text{-}1)$$

where U_{Na} and P_{Na} are urine and plasma sodium concentrations, respectively, and U_{Cr} and P_{Cr} are urine and plasma

TABLE 75-5 Causes of Acute Renal Failure with Low Fractional Excretion of Sodium

Prerenal azotemia

Uric acid nephropathy

creatinine concentrations, respectively. Values of FE_{Na} <0.01 (1%) in oliguric patients suggest avid tubular sodium reclamation and prerenal azotemia with functioning renal tubules, whereas values >.03 (3%) suggest tubular injury. The FE_{Na} is less useful in patients who are not oliguric.[81] Contrary to common belief, however, it may be useful in diuretic-treated patients. Although an elevated value may be a result of ATN or the effects of the diuretic, a low level in the face of diuretic therapy strongly suggests volume depletion and prerenal ARF. Some causes of ARF presenting with a low FE_{Na} are listed in Table 75-5. A low U_{Na} (<10 mEq/L) as an isolated measurement is often used as evidence of a prerenal state. However, this measurement depends exquisitely on the state of water balance in addition to sodium balance. It cannot be said that it is any easier to use than FE_{Na}, since an independent evaluation of water balance must be made to interpret it. Therefore it is not recommended as an isolated measurement in the routine evaluation of ARF.

Most other urinary diagnostic indices do not show any clear-cut superiority over FE_{Na} in distinguishing prerenal azotemia from ATN; however, they are independently useful in the assessment of tubular function. Recent data suggest urinary fractional excretion of urea (FE_{UN}) is superior to FE_{Na} to distinguish prerenal azotemia from ATN, particularly in diuretic-treated patients. FE_{UN} is calculated as

$$FE_{UN}(\%) = \frac{U_{UN} \times P_{Cr} \times 100}{BUN \times U_{Cr}} \qquad (75\text{-}2)$$

where U_{UN} and BUN are urine and serum urea nitrogen concentrations, respectively, and U_{Cr} and P_{Cr} are urine and plasma creatinine concentrations, respectively. The normal FE_{UN} is 50% to 65%, reflecting reabsorption of approximately 50% of filtered urea in the proximal tubule; urea reabsorption is trivial in the thick ascending limb and distal convoluted tubule. Hypovolemia results in increased urea absorption, decreased urea clearance, and thus a lower FE_{UN}.[82] Loop and thiazide diuretics, which act at the thick ascending limb and distal convoluted tubule, do not interfere directly with urea reaborption and should not alter FE_{UN}. However proximal tubule diuretics and osmotic diuresis decrease proximal reabsorption of urea and may produce an inappropriately high FE_{UN}. Carvounis and colleagues prospectively evaluated 102 hospitalized patients with ARF.[74] Patients were divided into three groups: 50 were deemed prerenal; 27 were deemed prerenal with diuretics given up to the day of consultation (details were not provided as to whether diuretics were given 1 or 23 hours prior to the urine sample); and 25 were diagnosed with ATN. Patients with AIN, GN, and obstructive nephropathy were excluded. Fe_{Na} was <1%, as expected, in 92% of group 1 patients, but in only 48% of the prerenal patients treated with diuretics. In contrast, 90% of the group 1 patients and 89% of those given diuretics had a FE_{UN} <35%. The ATN patients evidenced a mean FE_{UN} of 59%. A FE_{UN} <35% had 85% sensitivity, 92% specificity, 99% positive predictive value and 75% negative predictive value for a prerenal state. In this study, the urine:plasma creatinine ratio also performed better than FE_{Na} to distinguish prerenal azotemia from ATN. One other urine chemistry test may be useful in hyperuricemic patients with ARF and possible urate nephropathy (tumor lysis syndrome and hypovolemia with hyperuricemia and acid urine): urine uric acid:urine creatinine ratios >1.1 are consistent with acute urate nephropathy.[83]

Several radiographic studies are useful in the evaluation of patients with ARF. Plain films of the abdomen can assess kidney size, detect >90% of renal stones, and detect skeletal abnormalities of secondary hyperparathyroidism, which imply chronic renal insufficiency rather than ARF. In our view, the potential hazards of intravenous pyelography make this test of little benefit in the work-up of ARF. Renal ultrasound is a sensitive and specific method for detecting hydronephrosis. It is probably indicated in nearly every patient with ARF unless obstruction can be proven more quickly in another manner (e.g., by bladder catheterization in a patient with symptoms of bladder neck obstruction) or if some diagnosis other than obstruction is made with certainty early in the evaluation. If clinical suspicion of obstruction persists despite an apparently negative ultrasound, retrograde pyelography is the definitive diagnostic maneuver.[84] Computed tomography of the kidneys does not have any advantages over ultrasound and retrograde pyelography in the detection of obstruction, but may help clarify its cause. Radionuclide scans of the kidneys may be useful in the evaluation of patients with suspected vascular accidents of the kidneys.

The great majority of the time, volume status can be ascertained by history and physical examination alone. Occasionally one is presented with a patient in whom the ECF volume status cannot be determined with certainty on clinical grounds, particularly subjects with significant third-space losses. A typical example would be a patient with sepsis, hypotension, noncardiogenic pulmonary edema, anasarca, and oliguria. In this case, the clinician is often faced with the contradictory choice of using either diuretics or intravenous fluids. It is obviously inappropriate to treat a patient as if volume overload and hypovolemia were present simultaneously; in this setting, invasive hemodynamic monitoring with a central venous pressure (and central venous oxygen saturation) or a pulmonary artery catheter (and mixed venous oxygen saturation) can be an invaluable diagnostic adjunct. Complementary information may be obtained from simultaneous echocardiography.

Clinical Acute Renal Failure Syndromes

There are a number of diseases that commonly lead to ARF. In many cases of ARF in the ICU, prerenal azotemia combines with exposure to nephrotoxins (endogenous or exogenous) to cause ATN. However, the suspicion of other causes such as obstruction or specific parenchymal lesions is increased in certain patient populations.

MALIGNANCY AND ACUTE RENAL FAILURE

ARF is seen in patients with malignancy and could be caused by malignancy itself or its treatment with chemotherapeutic agents (Table 75-6). The full differential diagnosis of ARF must be considered in cancer patients, including common causes such as prerenal azotemia, drug nephrotoxicity, and obstructive uropathy, as well as rarer causes such as tumor infiltration of the kidneys and radiation nephritis. Urinary tract obstruction leading to ARF is commonly seen in patients with malignancy. Ureteral obstruction is seen in patients with abdominal and pelvic metastasis. ARF is also caused by intratubular obstruction. This is usually seen in patients with acute uric acid nephropathy as part of tumor lysis syndrome, intratubular obstruction by light chains in patients with multiple myeloma, and in patients who received high-dose methotrexate.

A variety of chemotherapeutic agents are potentially nephrotoxic, including cisplatin, nitrosoureas, and methotrexate, as discussed in Chap. 74. In addition, mitomycin is known to cause hemolytic uremic syndrome thus leading to renal failure.

If large numbers of malignant cells suddenly die, as in spontaneous necrosis or successful chemotherapy of large tumors, ARF can occur as a result of tumor lysis syndrome. This is noted most commonly in patients with germ cell tumors or hematologic malignancies because of their rapid turnover.[85] The tumor lysis syndrome is due to the toxic effects of intracellular constituents, which cause ARF, hyperkalemia, hyperphosphatemia, hypocalcemia, and hyperuricemia. The most common pathogenetic mechanism involved is acute urate nephropathy. When serum uric acid levels exceed about 20 mg/dL, the risk of ARF is high. The urinary ratio of uric acid to creatinine is >1.1.[83] Uric acid crystals may be seen in the urinary sediment. Synergistic factors in the development of the acute nephropathy include volume depletion and acidosis. The usual pathophysiology of urate nephropathy is intratubular deposition of urate crystals, causing intrarenal obstruction.[86] Less commonly, ureteral obstruction may be seen.

Mitomycin
Radiation nephritis

Once oliguria occurs, diuretics are seldom useful in restoring urine flow. Allopurinol and alkaline diuresis are effective measures when instituted prophylactically, but do not reverse established urate nephropathy.[87] Rasburicase, a recombinant form of urate oxidase, has been shown to be effective in reducing plasma uric acid levels within 4 hours after the first dose;[88] urate oxidase converts uric acid to allantoin, which is more soluble than uric acid. Severe hyperphosphatemia (levels >20 mg/dL) can be associated with tumor lysis and subsequent ARF.[89] The pathogenesis of the renal dysfunction can be either intratubular crystallization of phosphate or metastatic calcification in the renal parenchyma. It is important to make the distinction between this entity and urate nephropathy, because urinary alkalinization promotes calcium phosphate crystallization. If hyperuricemia is prevented or controlled by volume expansion, allopurinol, or uricase, it may be preferable to avoid or stop urinary alkalinization if severe hyperphosphatemia develops, to avoid hyperphosphatemia ARF and the risk of tetany (hypocalcemia combined with metabolic alkalosis). Renal replacement therapy in tumor lysis syndrome is indicated in patients in whom the resolution of ARF is unlikely, and is also indicated in patients with life-threatening electrolyte abnormalities. Normalization of uric acid and phosphorus levels is required for recovery of renal function. Hemodialysis is far more effective in the clearance of uric acid compared to peritoneal dialysis.[85] Continuous renal replacement therapies (CRRT) have been used in the management of tumor lysis syndrome. The solute clearances vary depending on the specific prescription. In these patients the uric acid and phosphorus clearances were, respectively, 45 mL/min and 47 mL/min in continuous venovenous hemodiafiltration and 39 mL/min and 40 mL/min in continuous arteriovenous hemodialysis.[90,91] These clearances were achieved with high dialysate and high replacement fluid rates. CRRT cannot correct electrolyte abnormalities as rapidly as intermittent hemodialysis, but it is a much more effective treatment for severe hyperphosphatemia, because rebound elevation of serum phosphorus postdialysis is prevented. Sequential hemodialysis to control severe evolving electrolyte abnormalities, followed by CRRT to prevent rebound may be the best approach. If RRT does not result in diuresis within a week, ureteral catheterization should be performed to exclude ureteral obstruction.

THROMBOTIC MICROANGIOPATHY AND ACUTE RENAL FAILURE

Hemolytic uremic syndrome (HUS) and the closely related entity thrombotic thrombocytopenic purpura (TTP) are characterized by renal involvement early in their course. Renal disease tends to be more fulminant in HUS than in TTP. Nearly 100% of patients with HUS have ARF at some point in their course (which is severe in at least 60%) as compared with a total incidence of renal failure of even mild severity in TTP that is <50%. Clinical features of these disorders are more thoroughly discussed in Chap. 70.

In the syndrome of disseminated intravascular coagulation (DIC), the pathologic picture is cortical necrosis. This can be prevented in some experimental models by the infusion of the angiotensin antagonist saralasin. It is unknown if activated protein C will decrease the contribution of microvascular injury and DIC to the pathogenesis of septic ARF. Numerous

other causes of microangiopathic hemolytic anemia and thrombocytopenia can also cause ARF, including malignant hypertension, scleroderma renal crisis, and antiphospholipid syndrome.

PREGNANCY AND ACUTE RENAL FAILURE

The incidence of ARF complicating pregnancy has been decreasing for the past 25 years. This is attributable to improvements in prenatal care and obstetric science and fewer complications related to septic abortions. The timing of ARF in pregnancy has a bimodal distribution.[92] The early peak, which occurs during the first 20 weeks of gestation, is due to septic abortions, while the later peak (at 36 to 40 weeks) is secondary to preeclampsia and bleeding complications.

Preeclampsia and eclampsia are accompanied by decreases in GFR of 20% to 25% that are seldom clinically significant (see Chap. 105). However, in a small proportion of pregnant women, the renal dysfunction progresses to severe ARF. Women with preeclampsia are at increased risk for the development of cortical necrosis. Cortical necrosis also can occur as a complication of placental abruption (often with concealed blood loss) or prolonged intrauterine death. Although severe, irreversible renal failure may be seen, partial recovery of renal function due to patchy cortical necrosis is more common.[93] The diagnosis of complete cortical necrosis should be established by renal biopsy or arteriography to exclude patchy cortical necrosis and ATN, from either of which a degree of functional recovery is to be expected.

Coexisting ARF and fulminant hepatic failure have been described in gravid subjects. In women with acute fatty liver of pregnancy, ARF is present in over half. Although the mortality rate for both mother and fetus in this condition has been reported to be at least 70%, the prognosis may be improving because of increased recognition of less severe cases. The syndrome known by the acronym HELLP (*h*emolysis, *e*levated *l*iver enzymes, and *l*ow *p*latelets) is a variant of unusually severe preeclampsia. The great majority of these patients have evidence of hepatic dysfunction and sinusoidal congestion that may culminate in liver rupture. The mean creatinine clearance in these women is about 55 mL/min (less than half normal), while 10% have severe ARF with a creatinine clearance of <20 mL/min.

The rare but well-defined clinical entity of idiopathic postpartum ARF is characterized by the onset of ARF in the peripartum period following a previously normal pregnancy and childbirth.[94] The serum creatinine level rises rapidly within a few days to several weeks following parturition. There is often an associated consumptive coagulopathy. Other common clinical features include malignant hypertension, lethargy, seizures, and a dilated cardiomyopathy. The pathophysiology of this disorder is unknown. The outcome is poor; most patients have severe chronic renal failure, require dialysis, or die.

LIVER DISEASE AND ACUTE RENAL FAILURE

ARF frequently occurs in the setting of severe liver disease. Prerenal azotemia can be a consequence of ascitic redistribution of the ECF (or its excessive treatment with diuretics), GI fluid losses (e.g., vomiting, diarrhea, or hemorrhage), or cardiac dysfunction (e.g., alcoholic cardiomyopathy). If a coagulopathy is present, blood clots in the collecting system can cause obstructive uropathy. Cirrhosis may predispose to the occurrence of papillary necrosis. Intrinsic ARF in subjects with liver disease is classified into disorders that simultaneously injure liver and kidney and those in which the renal disease is a consequence of the hepatic process (Table 75-7). The kidney is generally much more sensitive to the effects of potential nephrotoxic agents if jaundice is present. A relatively specific glomerular lesion called *cirrhotic glomerulosclerosis* has been identified and is usually asymptomatic; however, it probably predisposes to ARF of other causes. More commonly, patients with hepatitis B or C with proteinuria have membranous nephropathy or membranoproliferative (cryoglobulinemic) glomerulonephritis. Hepatitis B is also associated with polyarteritis nodosa. The most serious of coexisting hepatic and renal diseases is the hepatorenal syndrome (HRS).

Papillary necrosis

HRS is difficult to distinguish from prerenal ARF in the setting of advanced liver failure; indeed, many authorities consider the two conditions to be part of a single spectrum. Perhaps the best operational definition of HRS is severe prerenal azotemia that does not respond to volume repletion. The principal functional abnormalities that have been described are renal vasospasm in the setting of peripheral vascular resistance that is abnormally low;[95] there is no "typical" structural lesion of HRS. Oliguria and a low FE_{Na} are frequent, if not

universal, findings; the diagnosis of HRS should be considered untenable in their absence.

The therapy of HRS has been very disappointing.[95,96] A trial of empirical volume expansion with colloid solutions, with an end point of clear-cut increases in ascites and peripheral edema, can be used diagnostically to differentiate prerenal ARF from HRS. Attempts to modify low systemic vascular resistance have generally been unsuccessful in reversing this condition, as have attempts at selectively increasing renal perfusion. Emerging data suggest potential utility of combination treatment with midodrine and octreotide in hepatorenal syndrome;[97] vasopressin and analogues may also be useful for this indication.[96] There is little information on the use of transjugular intrahepatic portosystemic shunt in patients with HRS. Dialysis is only recommended in patients who are awaiting liver transplantation or in whom recovery of the underlying liver lesion is possible.

Paracentesis, ascitic reinfusion, and use of peritoneovenous shunts have not produced substantial improvements in patient survival in the few available controlled studies. Attempts to redistribute ascitic fluid into the vascular tree and then excrete it with various combinations of albumin, furosemide, and dopamine have not improved long-term results. Hemodialysis and related modalities have not been shown to improve survival and generally cannot be recommended except in two general settings. If there is any doubt about whether the patient may have potentially reversible ATN (such as by demonstration of a FE_{Na} >1%) or if the patient is a candidate for hepatic transplantation, all supportive measures including dialysis should be considered.

Some diseases simultaneously affect both liver and kidney. These diseases are summarized in Table 75-7.

ACUTE RENAL FAILURE IN RENAL TRANSPLANTATION

The approach to the transplant patient with ARF is no different from that in any other patient, with the exception that several unique entities must be considered. It is simplest to consider these in relation to the time since transplantation occurred. Within the first few hours or days after surgery, technical problems are the first consideration. In addition to hypovolemia and ATN, these include vascular thrombosis, ureteral stenosis, urinary leaks, and obstructive fluid collections such as hematomas or lymphoceles. Hyperacute rejection, though often apparent at the time of surgery, may not be recognized for several hours or days. Thorough diagnostic evaluation is mandatory, including renal ultrasound, confirmatory tissue typing (particularly the direct cross-match), and occasionally angiography or transplant biopsy. Surgical intervention is often required in addition to the usual supportive measures.

During the period beginning approximately a week after surgery and continuing for the next several months, drug effects, acute rejection, and infectious processes are of particular concern. It is during this time that antirejection drug dosages are at their highest levels, and as a result complications related to these drugs are most frequent. The immunosuppressive drugs cyclosporine and tacrolimus are frequent causes of dose-dependent acute nephrotoxicity, and levels should be monitored closely; thrombotic microangoiopathy is a rarer adverse effect of these calcineurin inhibitors. The clinical diagnosis of acute rejection is often difficult to make, frequently requiring histologic confirmation or empirical antirejection therapy. Although an acute rejection episode occurs in the majority of renal transplant recipients within the first year following engraftment, it is increasingly uncommon thereafter. Thus a diagnosis of acute rejection several years after transplantation is less likely as long as the patient complies with therapy.

One of the most frequent and severe infections compromising renal function in transplant recipients is cytomegalovirus (CMV), which can cause dysfunction in many organ systems, including the central nervous system, lungs, liver, and kidneys. CMV is often suspected clinically on the basis of fever, multisystem organ involvement (including ARF), and progressive leukopenia. It is more common in patients who have received intensive immunosuppression for severe or recurrent rejection episodes.

Late causes of ARF in transplant recipients include recurrence of the patient's original renal disease, de novo transplant glomerulopathy, infections, transplant artery stenosis, and urologic problems such as stricture or rejection of the ureter. In addition to renal ultrasound, transplant biopsy is often useful in defining the cause of ARF late in the course of a kidney transplant.

Prevention of Acute Renal Failure

Frequently, ARF develops in hospitalized patients in whom it is predictable and can be prevented or ameliorated. To intervene effectively, it is important to identify the patients at risk (Table 75-8). There is an additive interaction among the risk factors. Unfortunately, most attempts to modify the course of ARF are probably too late if tubular damage has already begun[4].

Although ARF may be prevented or ameliorated by judicious use and monitoring of nephrotoxic drugs, and perhaps evolving cytoprotective and anti-inflammatory therapies, the major focus in ARF prophylaxis and therapy remains optimization of renal perfusion. The primary causes of renal hypoperfusion differ between the major types of shock, and therapies vary accordingly. The role of hemodynamic monitoring and support with fluids and vasoactive drugs in the prevention of ARF in the ICU is important, but there is little high-grade evidence to guide these therapeutic choices. As discussed above, renal perfusion is optimized by using fluids and vasoactive drugs to seek an adequate perfusion pressure and cardiac output. There is generally no adequate study to

guide the choice of specific fluid or vasoactive drug to improve renal function. It appears that colloids are not superior to crystalloids for prevention of ARF in critically ill patients. A large randomized, controlled prospective trial of albumin versus saline in almost 7000 critically ill patients found no demonstrable effect of one over the other on mortality, renal function, or the frequency of renal replacement therapy.[98] Of note, patients with cirrhosis were excluded from this trial, and limited data suggest that albumin is useful to prevent ARF in cirrhotic patients with spontaneous bacterial peritonitis,[99] or those undergoing large-volume paracentesis. As discussed above, for prevention of radiocontrast nephropathy normal saline is superior to half-normal saline,[39] and an equimolar solution of sodium bicarbonate is superior to normal saline.[40] Otherwise, despite the importance of fluid therapy in the prevention of ARF, the nature of the optimum fluid resuscitation regimen remains a disputed topic. Similarly, there are no proven advantages of any specific inotrope or vasopressor with respect to renal function. In patients with septic shock, the use of early goal-directed therapy, steroids in nonresponders to adrenocorticotropic hormone stimulation, and activated protein C may lead to a decreased incidence or severity of ARF, but there is no evidence in the literature that improved survival in the pivotal studies supporting these therapies is associated with a decreased incidence of ARF. Limited evidence suggests that tight glycemic control and lung-protective ventilation strategies may decrease the incidence of ARF in critically ill patients.[4,14]

Prevention of nephrotoxic injury is the other mainstay of ARF prevention in critically ill patients. Avoidance of potential nephrotoxins such as intravenous radiocontrast, aminoglycosides, amphotericin, and NSAIDs is prudent, when possible. Single daily dosing of aminoglycoside antibiotics is associated with a lower risk of nephrotoxicity and equivalent antimicrobial efficacy compared to multiple dosing strategies.[31–33] Drug modifications such as nonionic radiocontrast[36,37] and lipid-emulsified amphotericin B may also reduce the incidence of ATN. Aggressive diuresis must be avoided when possible, particularly in conjunction with the use of ACEIs or ARBs, and must be accompanied by careful monitoring of fluid balance and renal function. Monitoring the serum levels of potentially nephrotoxic drugs such as aminoglycosides, cyclosporine A, tacrolimus, and vancomycin is recommended, although studies proving that therapeutic drug monitoring decreases the incidence of ATN are lacking.

Numerous studies have sought to demonstrate efficacy of pharmacologic interventions for primary prevention of ARF (prophylaxis), or secondary prevention in ARF (ATN therapy to decrease dialytic requirement and improve outcome). Broadly speaking, these studies have been trials of diuretics or renal vasodilators. There have been other negative studies of agents including insulin-like growth factor and thyroxine, but these will not be further discussed here.

DIURETICS

Furosemide is a loop diuretic and vasodilator that may decrease oxygen consumption in the loop of Henle by inhibiting sodium transport, thus potentially lessening ischemic injury. By increasing urinary flow, it may also reduce intratubular obstruction and backleakage of filtrate. Based on these properties, furosemide might be expected to prevent ARF. However, there are few data to support its use. Furosemide was found to be ineffective or harmful when used to prevent ARF after cardiac surgery, and to increase the risk of ARF when given to prevent contrast nephropathy.[38,100]

Similarly, there is little evidence of benefit from diuretic therapy in established ARF. A single recent study in 100 patients with oliguric ARF after cardiac surgery suggested that a cocktail infusion of furosemide, mannitol, and dopamine improved renal function post–cardiac surgery compared to intermittent loop diuretics alone.[101] However, numerous studies in patients with established ATN have found no benefit of loop diuretics.[102–107] Their use did not accelerate renal recovery, decrease the need for dialysis, or reduce mortality. It was shown that the mortality rate of oliguric patients who responded to furosemide with a diuresis was lower than those who did not.[106–107] However, the clinical characteristics, severity of renal failure, and mortality rates were similar in patients with either spontaneous non-oliguric ARF or patients who became non-oliguric after furosemide. This implies that those patients able to respond to furosemide have less severe renal damage than nonresponders, rather than deriving any true therapeutic benefit from furosemide administration. Although administration of furosemide might facilitate improved fluid management if it induces a diuresis, a retrospective review of a recent trial in critically ill patients with ATN raised concerns of possible harm from loop diuretics in ARF. The authors found that diuretic use was associated with an increased risk of death and nonrecovery of renal function.[108] Most of the increased risk, however, was seen in those patients unresponsive to high doses of diuretics, implying they had more severe disease. Therefore, diuretics should be used with caution in critically ill patients, and iatrogenic hypovolemia and superimposed prerenal azotemia must be avoided. Diuretics should be withdrawn if there is no response, to avoid ototoxicity. Our current maximal, synergistic diuretic challenge combines furosemide 200 mg IV with chlorothiazide 500 mg IV. In patients who experience an increase in urine output, hypotension must be avoided, since kidneys with ATN are susceptible to further damage from decreases in perfusion pressure. To maintain the diuresis, a continuous infusion of drug is probably preferable to intermittent bolus administration.[109] Although there are no large randomized controlled trials, the overall evidence suggests that continuous infusion of diuretics as opposed to bolus administration is more effective and associated with less toxicity and delayed development of diuretic resistance.

Mannitol is an osmotic diuretic that can decrease cell swelling, scavenge free radicals, and cause renal vasodilatation by inducing intrarenal prostaglandin production.[110] It may be beneficial when added to organ preservation solutions during renal transplantation and may protect against ARF caused by rhabdomyolysis if given extremely early.[110–112] Otherwise, mannitol has not been shown to be useful in the prevention of ARF. In fact, mannitol may aggravate ARF due to radiocontrast agents.[38] Furthermore, mannitol may precipitate pulmonary edema if given to volume-overloaded patients who remain oliguric, can exacerbate the hyperosmolar state of azotemia, and may even cause acute renal failure ("osmotic nephrosis").[113]

RENAL VASODILATORS

ATRIAL NATRIURETIC PEPTIDE

Atrial natriuretic peptide (ANP) has been investigated in clinical trials for the treatment or prevention of ARF. ANP can lead to an increase in GFR due to arteriolar dilatation and also has a natriuretic effect. ANP improved renal function in animal studies and a phase II human ATN study.[114–115] However, larger randomized trials failed to show any benefit of ANP compared to placebo.[116–117] Hypotension was significantly more common in ANP-treated patients in these studies, and may have negated any potential benefit of renal vasodilation in these patients. Hence there is no convincing evidence to support the use of ANP in the prevention or treatment of ARF. A new, promising, but underpowered (61 patients) positive study of ANP to treat ARF immediately following cardiac surgery showed a decreased rate of postoperative renal replacement therapy compared to placebo-treated patients;[118] a larger prospective trial in this setting appears warranted.

DOPAMINE

Low-dose dopamine administration (1 to 3 μg/kg per minute) to normal individuals causes renal vasodilation and increased GFR, and acts as a proximal tubular diuretic. Due to these effects, numerous studies have used low-dose dopamine to either prevent or treat ATN in a variety of clinical settings. It has been given as prophylaxis for ARF associated with radiocontrast administration, repair of aortic aneurysms, orthotopic liver transplantation, unilateral nephrectomy, renal transplantation, and chemotherapy with interferon.[119–122] Yet despite more than 20 years of clinical experience, prevention trials with low-dose dopamine all have been small, inadequately randomized, of limited statistical power, and with end points of questionable clinical significance. Denton and associates reviewed the data on the use of renal doses of dopamine and concluded that there is no convincing data that renal-dose dopamine either prevents ARF or improves outcome in patients with established ARF.[120] Meta-analyses done by Kellum and Decker[121] and by Marik[122] similarly did not show any benefit of dopamine in the prevention or treatment of ARF. The Australian and New Zealand trial (ANZICS) studied the effects of low-dose dopamine in ICU patients with systemic inflammatory response syndrome and ARF.[123] This is a double-blind randomized study. The patients were randomly assigned to receive either dopamine at a dose of 2 $\mu g\ kg^{-1}\ min^{-1}$ or placebo. The investigators found no difference in the primary outcome measure, which was the peak serum creatinine concentration during trial infusion (Fig. 75-4). The proportion of patients reaching serum creatinine values above 3.4 mg/dL and proportion of patients requiring renal replacement therapy was similar in both groups (Fig. 75-5). There was no difference in the length of ICU and hospital stay, or mortality and time to renal recovery. This study convincingly demonstrated that low-dose dopamine does not improve outcome in critically ill patients with early ARF. Furthermore, there is concern for the potential harmful effects of dopamine, even at low doses. It can trigger tachyarrhythmias and myocardial ischemia, decrease intestinal blood flow, cause digital necrosis and hypothyroidism, and suppress T-cell function.[119] It has also been shown to increase the risk of radiocontrast nephropathy when given prophylactically to patients with diabetic nephropathy.[49]

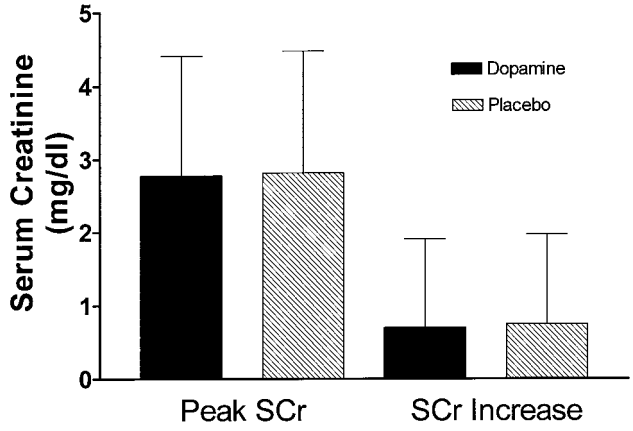

FIGURE 75-4 Primary end point of the ANZICS low-dose dopamine trial. In the ANZICS trial, there was no difference between low-dose dopamine and placebo in the primary outcome measure, which was peak serum creatinine attained during trial drug infusion. Peak urea and increments from baseline of creatinine and urea were also similar in the placebo and dopamine groups. ***(This figure was produced using data from Murray.[119] Adapted from Bellomo et al.[123])***

Nondialytic Supportive Care of Acute Renal Failure

When a diagnosis of intrinsic ARF has been firmly established and potentially reversible causes have been excluded or treated, the patient is then monitored for early detection of complications. Conservative measures consist of hospital observation with attention to blood pressure, volume status, neurologic function, and evidence of hemorrhagic or infectious complications. Electrolytes (Na^+, K^+, Cl^-, HCO_3^{2-}, Ca^{2+}, and PO_4^{3-}), BUN, and creatinine should be monitored daily, although the hyperkalemic patient will require more frequent monitoring.

Fluid intake should be adjusted to replace urine and insensible losses, while Na^+ and K^+ are allowed in amounts to replace urine and GI losses. Obviously, fluid and electrolyte

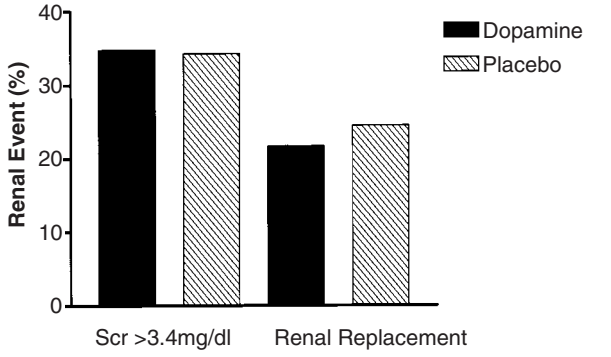

FIGURE 75-5 Secondary end points of the ANZICS low-dose dopamine trial. In the ANZICS trial, there was no significant difference between the dopamine and placebo groups in the number of patients whose serum creatinine concentration exceeded 3.4 mg/dL or who received renal replacement therapy. ***(This figure was produced using data from Murray.[119] Adapted from Bellomo et al.[123])***

TABLE 75-9 Therapy of Hyperkalemia

Drug	Dose	Onset	Duration	Mechanism
Calcium gluconate	10–20 mL IV	1–5 min	0.5 h	Membrane antagonist
Sodium bicarbonate	1–2 ampules (IV 50–100 mEq)	30 min	1–4 h	Cellular shift
Glucose + insulin	500 mL $D_{10}W$ with 10 U regular insulin IV	30 min	1–4 h	Cellular shift
Sodium polystyrene sulfonate	30–50 g with sorbitol PO, or as retention enema	1–2 h	4–6 h	Increased excretion

$D_{10}W$, 10% dextrose in water.

restriction will be more severe in the oliguric patient. A small daily reduction in weight is expected in the patient with ARF, but weight loss >1 kg daily indicates severe catabolism or volume loss. On the other hand, it should be emphasized that maintenance of weight or weight gain indicates volume expansion.

Clinical trials to determine the benefit of nutritional therapy with amino acids to improve renal failure show conflicting results.[124,125] The guiding principle of nutritional management in the nondialyzed case of ARF has traditionally been slowing the accumulation of nitrogen waste products and avoiding severe electrolyte perturbations. We recommend limiting potassium and phosphorus intake to avoid severe electrolyte disturbances, but we do not limit protein intake specifically to limit production of nitrogenous waste and avoid dialysis. Whether a patient with ARF is in the period before or after initiation of renal replacement therapy, protein intake should be prescribed to provide 1.0 to 1.5 g/kg per day (higher in more catabolic patients, and in those receiving CRRT, who have additional amino acid removal). Calories can be provided in the form of simple carbohydrates such as jelly and sugar. Caloric requirements increase in proportion to the severity of the underlying illness, and intake of 3000 kcal/d or more may be necessary to blunt catabolism. Should the patient be incapable of eating due to anorexia or other reasons, a small, soft feeding tube may be inserted into the stomach and tube feeding administered by constant infusion or intermittent bolus. In general, tube feedings with lower K^+ and Na^+ concentrations are chosen. For the patient who cannot tolerate enteral feeding, total parenteral nutrition (TPN) becomes necessary. Because of the volume of fluid required for TPN, earlier institution of dialysis and ultrafiltration is often necessary. A reasonable approach is to give sufficient calories to prevent negative nitrogen balance but not to overfeed patients to the point that hepatic and platelet complications develop or that dialysis imposes additional risks.

The management of various electrolyte abnormalities often associated with ARF is described in greater detail in Chap. 76 and will only be touched on here. Administration of excessive amounts of free water is the most common cause of hyponatremia in patients with ARF. Less important causes of hyponatremia in this setting include water production from carbohydrate metabolism and water release from injured tissue. Judicious fluid management will prevent any untoward complications from hyponatremia. Hyperkalemia is the most grave of the electrolyte perturbations that may complicate ARF. The clinical consequences of hyperkalemia are largely confined to the cardiovascular and neuromuscular systems. The earliest hyperkalemic effects are manifest in the electrocardiogram (ECG). ECG changes are uniformly present above a potassium level of 8 mEq/L; below 7 mEq/L, changes may not be evident. The treatment of hyperkalemia is summarized in Table 75-9.

Disturbances of divalent ion metabolism are common in ARF. Hyperphosphatemia is an almost universal accompaniment of oliguric ARF. Control of hyperphosphatemia in the acute setting is achieved by oral administration of aluminum hydroxide gels. Short-term administration of aluminum-containing compounds to patients with renal failure does not result in aluminum intoxication. However, concurrent administration of oral citrate compounds must be avoided because citrate enhances gut absorption of aluminum and accelerates the development of aluminum intoxication.

Hypocalcemia is an expected complication of ARF but is generally of no clinical significance and does not require intervention. However, severe depression of serum Ca^{2+} may complicate rhabdomyolysis-induced ARF. Nevertheless, calcium salts are contraindicated except as part of the treatment of life-threatening hyperkalemia or if hypocalcemic tetany develops. Hypercalcemia may be observed when rhabdomyolysis-induced ARF enters the diuretic phase, and Ca^{2+} deposited in damaged muscle is released. It is usually self-limited.

Uric acid levels may rise by 1 to 2 mg/dL per day in cases of ARF not due to rhabdomyolysis, but rarely does the level exceed 15 mg/dL. This plateau is thought to result from enhanced metabolism of uric acid by gut bacteria. Extreme elevations in uric acid levels have been observed in cases of exertional rhabdomyolysis and following treatment of some lymphomas.

Metabolic acidosis occurs commonly in ARF, and in cases of trauma or sepsis the fall in plasma bicarbonate may exceed 15 mEq per 24 hours. In the catabolic patient with ARF, acid is released from metabolism of sulfur- and phosphorus-containing compounds, which contributes to a rise in the anion gap. Acidosis may be treated with sodium bicarbonate; however, the additional volume is hazardous in the patient with compromised renal function, the buffering requires increased ventilation, and adverse intracellular effects

may result. Uncontrollable acidosis may mandate dialysis therapy.

Metabolic alkalosis may complicate ARF in the patient with nasogastric suction, but is a less frequent acid-base disturbance in these patients. Although nasogastric suction–induced metabolic alkalosis normally responds to saline supplementation, this maneuver is ineffective in ARF and carries the hazard of potential volume overload. Severe metabolic alkalosis in ARF may require dialysis using a reduced concentration of bicarbonate or acetate in the bath. Alternatively, 0.1 N hydrochloric acid may be administered by slow intravenous infusion. Development of metabolic alkalosis in the patient on nasogastric suction may be prevented or attenuated by use of histamine blockers such as cimetidine.

Infection continues to be a leading cause of death in the patient with ARF, and pneumonia, urinary tract infection, and wound infection are most common. Infection has been the cause of death in up to 70% of cases of ARF and has contributed to 50% of deaths occurring during the diuretic phase.[126] In several large series of ARF, the incidence of septicemia exceeds 50%, and intra-abdominal sepsis is known to be a particularly important determinant of survival. In the septic patient without an obvious source, intra-abdominal sepsis must be vigorously excluded. Imaging procedures of value for detecting an abdominal source include CT scanning and ultrasound, with CT the better of the two. The severity of infection in ARF is undiminished despite the advent of new antibiotics and other advances in general medical care. Prophylactic antibiotics are not recommended for the patient with ARF and may be harmful.

Prior to the use of antacids and histamine blockers (e.g., cimetidine and ranitidine) to prevent gastric stress ulceration in ARF, GI hemorrhage was the second leading cause of death. Now many centers report a dramatic decline in GI hemorrhage.[127] Recent advances in the therapy of uremic bleeding include use of 1-deamino-8-D-arginine vasopressin (DDAVP), cryoprecipitate, and conjugated estrogens.[128] These drugs are most useful in patients with clinically significant bleeding episodes who lack evidence of any other (nonuremic) coagulopathy. DDAVP is typically infused over 30 minutes in a dose of 0.3 μg/kg of body weight and is effective within minutes.[129] Unfortunately, because of the short duration of action of this compound (1 to 4 hours), frequent dosing may be required. The use of cryoglobulin infusions (10 units IV over 15 minutes) also may serve as a temporary expedient in patients with uremic bleeding. Conjugated estrogens (0.6 mg/kg IV daily for 5 days) have a very delayed onset of action (3 to 5 days), but the duration of the therapeutic effect can be as long as 14 days.[130]

RENAL REPLACEMENT THERAPY

In ARF, there is consensus that dialysis should be initiated if there are uremic symptoms or signs, or if volume overload, electrolyte abnormalities, or acidosis are refractory to medical management. The precise timing of RRT initiation is usually a matter of clinical judgment.[3,5] Absent the above clinical indications, hemodialysis (HD) is commonly initiated when the BUN concentration reaches 100 mg/dL, and repeated to maintain a predialysis BUN below 80 mg/dL.[5] This pattern of practice is based primarily on early experience suggesting that uremic bleeding diathesis and hemorrhage were reduced when hemodialysis was initiated before the BUN exceeded 100 mg/dL,[5] the results of small prospective ARF studies in 1975 and 1986,[131] and extrapolation from results of the National Cooperative Dialysis Study in chronic renal failure patients. This relatively prophylactic approach is balanced against potential adverse effects of RRT, including hypotension with worsening renal ischemic acute tubular necrosis, and the renal and systemic inflammatory effects of extracorporeal membrane exposure. Although it seems prudent to start RRT aggressively in critically ill catabolic patients, studies have not shown a significant benefit of prophylactic dialysis, including a recent small study using CRRT by Bouman and colleagues.[132] It is universally accepted that emergent RRT is indicated in the management of ARF when pulmonary edema, hyperkalemia, refractory acidosis, or symptomatic uremia develops. In our opinion, initiation of RRT should also be considered in patients with sustained anuria, persistent oliguria with progressive azotemia and GFR <10 mL/min, and to control fluid balance, rather than waiting for complications of volume overload, electrolyte imbalance, or uremia to develop.

RRT modalities available include intermittent hemodialysis (IHD), peritoneal dialysis (PD), and continuous renal replacement therapy (CRRT). CRRT nomenclature includes elements denoting duration of therapy (C for continuous), vascular access (arteriovenous [AV], or venovenous [VV]), and the solute transport mechanism(s) used (diffusion [dialysis], convection [hemofiltration], or both [hemodiafiltration]). So the different modalities include continuous arteriovenous hemofiltration (CAVH), continuous venovenous hemofiltration (CVVH), continuous arteriovenous and venovenous hemodialysis (CAVHD and CVVHD), and continuous arteriovenous and venovenous hemodiafiltration (CAVHDF and CVVHDF). Solute clearance during RRT occurs either by diffusion or convection. Solute clearance during IHD and continuous dialysis therapies (CAVHD and CVVHD) occurs primarily by diffusion. Solute clearance during CVVH and CAVH is primarily by convection. In CAVHDF and CVVHDF both convective and diffusive solute transport occurs.

CRRT is thought to permit fluid and solute removal with greater hemodynamic stability than intermittent HD for two reasons. The first is the fact that fluid removal is done slowly and continuously, rather than in 1- to 4-L increments over 2- to 4-hour treatment sessions. Rapid diffusive solute clearance by intermittent HD results in loss of intravascular solutes and results in the reduction of plasma osmolality relative to surrounding tissues, which in turn causes transfer of plasma water into tissues. This leads to further depletion of extracellular volume which has been diminished by ultrafiltration.[10] So, in hemodynamically unstable patients CRRT is preferred compared to IHD, as it allows removal of excess fluid in hypotensive patients. CRRT also allows us to better manage fluid status in patients who are receiving TPN. Apart from hypovolemia and plasma hypo-osmolality, there are a variety of other causes of intradialytic hypotension (IDH) (Tables 75-10 and 75-11).[10] Although IDH is common in ICU patients, the complete differential diagnosis of this problem should be considered in every case, particularly when hypotension is profound or refractory to standard measures. Several techniques are used routinely in ICU patients

receiving IHD to improve hemodynamic stability. Intermittent isolated ultrafiltration (also called IUF) sessions, which remove fluid without diffusive solute clearance, are commonly used for acute volume removal with greater hemodynamic stability than intermittent HD. The use of higher dialysate sodium concentrations, called *sodium modeling* (e.g., beginning HD with a 160-mEq/L sodium "bath," decreasing to 140 mEq/L over 4 hours), similarly improves hemodynamic tolerance of intermittent HD, by ameliorating the tendency towards plasma hypo-osmolality. The use of cool dialysate (35.5°C) and increasing dialysate calcium concentration are among the other interventions proven to increase systemic vascular resistance and improve hemodynamic tolerance of HD; increased dialysate calcium also augments cardiac output. Numerous patients hemodynamically intolerant of isolated ultrafiltration, intermittent HD, their sequential combination, and the other modifications mentioned above, have been supported with CRRT. The capacity to alter fluid balance at will, even in hemodynamically unstable patients, is in large part responsible for the attractiveness of CRRT to intensivists.

Although acute therapy of severe hyperkalemia, metabolic acidosis, or intoxications is more efficiently achieved with IHD, lesser abnormalities are corrected relatively quickly and controlled effectively with CRRT**.** Clinical data suggest that CRRT should be strongly considered for patients with severe hyperphosphatemia or elevated intracranial pressure (ICP), and might also be a useful component of therapy for lithium intoxication.[5] Continuous removal prevents the postdialytic rebound elevation of plasma concentration typically seen with IHD in patients with hyperphosphatemia (tumor lysis syndrome or rhabdomyolysis) or lithium intoxication.[5] In patients with cerebral edema complicating acute liver failure, intermittent machine hemofiltration, but not continuous renal replacement therapies (CAVH or CAVHD) raised ICP and decreased cerebral perfusion pressure; similar adverse effects of intermittent HD were previously demonstrated.[5] Raised ICP in this setting is due to acute solute removal and resulting plasma hypo-osmolality, causing a shift of water into the brain along with other tissues. The detrimental effect of this phenomenon on cerebral perfusion pressure may be increased by treatment-induced hypovolemia or hypotension. Despite apparent advantages over intermittent therapies in unstable patients, outcome superiority of CRRT with respect to mortality or recovery of renal function outcomes has not been demonstrated. Data from a U.S. prospective, comparative trial of intermittent HD versus CRRT in ICU ARF did not demonstrate an effect of modality on outcome.[133] In this study, Mehta and colleagues excluded patients with a mean arterial pressure below 70 mm Hg. Randomization did not balance severity of illness between groups; CRRT patients had higher severity of illness and mortality, and there was no difference in mortality between HD and CRRT groups adjusted for Acute Physiology, Age, and Chronic Health Evaluation (APACHE) II scores. Ongoing studies may determine if there is an advantage of any specific modality over others in critically ill patients.

Few RRT dosing guidelines have been established in patients with ARF, but it is clear that dialysis delivery is inadequate in the ICU, even by standards set for stable end-stage renal disease outpatients. Clearance of urea, a low-molecular-weight nitrogenous waste product, is the most commonly studied marker of adequate uremic detoxification by HD. The term Kt/V is a unitless measure of HD dose (based on urea removal): K is the urea clearance of the dialysis membrane used (in milliliters per minute), t is the duration of dialysis (in minutes), and V is the volume of distribution of urea in the patient (in milliliters). Thus, Kt/V is a measure of the volume of plasma cleared of urea during a HD session (Kt) divided by the urea distribution volume (V, assumed to be total body water: 0.5 to 0.6 L/kg), and larger Kt/V values signify greater HD dose. Kt/V measurements of delivered dialysis dose are usually calculated using the ratio of postdialysis to predialysis BUN and a nomogram. In chronic hemodialysis patients the minimum acceptable dialysis dose is a Kt/V of 1.2. Extrapolation of HD data from the chronic HD population to the ARF setting is limited by numerous poorly quantifiable variables, including effects of critical illness on urea kinetic modeling. Furthermore, Kt/V measurements extrapolated from pre- and post-BUN may be very inaccurate in ARF,

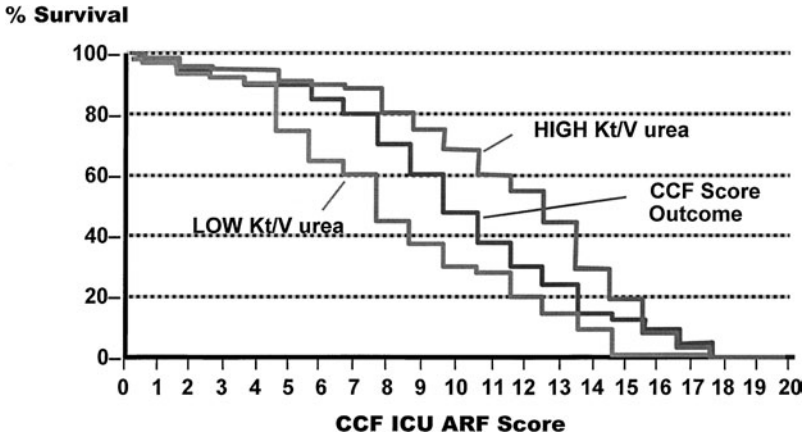

FIGURE 75-6 Relationship between RRT dose and outcome using diffusive solute clearance (hemodialysis). Paganini and colleagues demonstrated by retrospective analysis of a prospectively gathered database that delivered dialysis dose was predictive of mortality in critically ill ARF patients treated with RRT, if they had moderate-range severity of illness. Severity of illness was measured by the Cleveland Clinic Foundation ARF score (higher score predicts increased mortality). Mortality of the most and least severely ill patients was independent of dialysis dose, measured by Kt/V (see text for explanation of Kt/V). ***(Reproduced with permission from Paganini et al.[135])***

because rebound postdialysis increases in BUN from tissue stores hypoperfused during IHD occurs. Furthermore, numerous patient- and technique-related factors impede effective delivery of prescribed dialysis in critically ill patients. In a prospective study which examined the prescribed and delivered dialysis dose in 40 ARF patients found that 68% of ARF treatments failed to deliver the minimum dialysis dose recommended for maintenance HD of chronic renal failure patients, and that for 49% of treatments a minimally adequate dialysis dose was not even prescribed.[134] Failure to adjust dialysis dose and/or achieve adequate dialysis delivery in larger patients was a major source of treatment failure.

In a study done by Paganini and colleagues, improved survival was seen in patients with higher Kt/V, and this survival benefit is particularly evident in patients with moderate-range severity of illness. In patients with least and most severity of illness the mortality was not affected by dialysis dose (Fig. 75-6).[135] Another study done by Schiffl and colleagues found that patients who received daily IHD had a lower mortality compared with patients who received alternate-day IHD (28% vs. 46%), and improved renal recovery.[136] In patients who received alternate-day IHD, time-averaged blood urea nitrogen level was 104 mg/dL, reflecting inadequate dialysis that is below the standard of care for most critically ill patients, so it is not surprising that their outcome was inferior to well-dialyzed patients. Nonetheless, it seems prudent to prescribe more frequent HD for ICU patients treated with intermittent dialysis, to optimize dose delivery, fluid balance, and outcome. There are also outcome data to guide CRRT dosing, provided by the landmark study of Ronco and colleagues, who conducted a large prospective study to determine the impact of hemofiltration dose on survival. In this study, patients were randomly assigned to one of three treatment doses, based on effluent volume (which is equivalent to small solute clearance by continuous hemofiltration, or by low-volume continuous hemodialysis): 20 mL h^{-1} kg^{-1} (group 1), 35 mL h^{-1} kg^{-1} (group 2), or 45 mL h^{-1} kg^{-1} (group 3). Patients assigned to group 1 had higher mortality than those in groups 2 and 3 (Fig. 75-7).[137] Based on this study, we recommend a minimum effluent volume of 35 mL/kg per hour for ICU patients with ARF treated with CRRT. Current and future studies may identify alternative markers of adequate RRT dose, such as clearance of larger molecules, or biomarkers such as leukocyte response to inflammatory stimuli.[59]

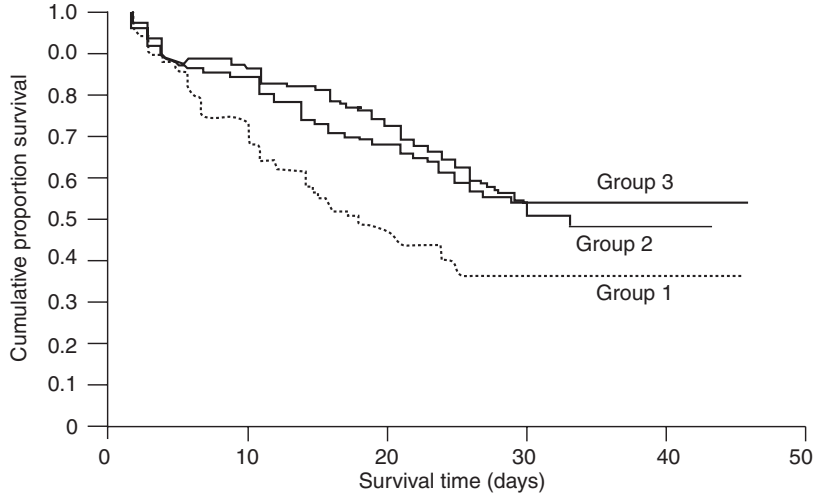

FIGURE 75-7 Relationship between RRT dose and outcome using convective solute clearance (hemofiltration). Kaplan-Meier estimation of survival curves in the three groups of ICU patients with ARF, divided based on dose delivered during CRRT: 20 mL h^{-1} kg^{-1} (group 1), 35 mL h^{-1} kg^{-1} (group 2), or 45 mL h^{-1} kg^{-1}(group 3). Survival in group 1 is significantly lower than in groups 2 and 3. Survival in groups 2 and 3 did not differ significantly. ***(Reproduced with permission from Ronco et al.[137])***

Chapter 76

ELECTROLYTE DISORDERS IN CRITICAL CARE

JOEL MICHELS TOPF
STEVE RANKIN
PATRICK MURRAY

KEY POINTS

- *Measurement of electrolyte free water clearance is extremely useful in understanding the pathophysiology of hyponatremia and hypernatremia.*
- *Treatment of hyponatremia should be guided by the degree of symptomatology, rather than the magnitude of the hyponatremia per se.*
- *Hyperkalemia should be treated emergently if typical electrocardiographic (ECG) changes are present; hence ECG monitoring is indispensable in this setting.*
- *Hypocalcemia need only be treated urgently if it is symptomatic.*
- *Severe hypomagnesemia may have significant consequences itself, including cardiac arrhythmias and muscle weakness; lesser degrees of hypomagnesemia often accompany hypokalemia and hypocalcemia and correction of the magnesium deficit facilitates correction of the other electrolyte abnormalities.*
- *Severe hyperphosphatemia is seen in the setting of renal failure and/or massive cell lysis.*
- *Total body phosphate stores may be significantly reduced and produce organ dysfunction even in the face of normal or minimally decreased serum levels; if suspicion for a depleted state exists, treatment should be given.*

Sodium

METABOLISM

Sodium is the chief extracellular cation and is critical to regulating extracellular and intravascular volume. Total body sodium determines clinical volume status, but sodium concentration does not correlate with volume status. Both hypernatremia and hyponatremia occur in the presence of hypo-, eu-, and hypervolemia. The sodium concentration itself is the single ion that best represents serum osmolality; essentially all of the clinically relevant symptoms of dysnatremia are secondary to alterations in osmolality. Hypernatremia is largely synonymous with hyperosmolality, while hyponatremia is generally indicative of hypoosmolality.

Osmolality and tonicity are related but separate concepts. Osmolality measures all of the solutes in solution, while tonicity only includes particles that are unable to cross from the intracellular to the extracellular compartment. It is these particles which are osmotically active, and by drawing water across compartments they may alter cell volume. Sodium and potassium are the primary determinants of tonicity.

Balancing water intake and excretion is the principal means by which the body regulates sodium concentration. Water balance is maintained by thirst and antidiuretic hormone (ADH). Following a water load, osmolality falls and osmoreceptors in the hypothalamus suppress thirst and ADH release. The latter signals the kidney to produce dilute urine to clear the water load. In states of water deprivation (or a solute load) osmoreceptors detect the rise in osmolality and increase thirst and ADH.

The kidney regulates osmolality and sodium concentration by diluting or concentrating urine. Producing dilute urine allows the kidney to clear a water load, raising plasma osmolality. In order to make dilute urine, multiple criteria must be met:

1. Tubular fluid must be delivered to the diluting segment of the nephron. This can be assured in any patient with adequate effective arterial blood volume (EABV) and a normal or near normal glomerular filtration rate (GFR).
2. There must be intact sodium resorption in the diluting segments of the kidney (i.e., the thick ascending limb of the loop of Henle [TALH]) and the distal convoluted tubule. Loop and thiazide diuretics are the primary causes of inoperative diluting segments.
3. The collecting tubule must be impermeable to water. ADH increases water permeability, so the production of dilute urine requires a lack of ADH.

Concentrating urine allows the kidneys to minimize water loss and compensate for an increase in serum osmolality. In order to produce concentrated urine, the following conditions must be met:

1. A hypertonic medullary interstitium draws water from the medullary collecting ducts. The TALH creates and maintains the high concentration of the interstitium. Any factor that antagonizes the TALH (e.g., loop diuretics, hypercalcemia, or hypokalemia) will disrupt the production of concentrated urine.
2. ADH increases the permeability of the collecting tubules, allowing water to osmotically flow out of the collecting ducts into the medullary interstitium, concentrating the urine.

ANTIDIURETIC HORMONE

ADH plays a crucial role in the concentrating and diluting process. ADH, or vasopressin, is a six-peptide amino acid produced in the hypothalamus and stored in the posterior pituitary gland. Release of ADH follows increases in osmolality or dramatic drops in blood pressure or effective arterial blood volume. An increase in serum osmolality of 1% (2 mOsm/kg) will stimulate ADH, while a similar decrease inhibits release. ADH is less sensitive to changes in blood volume; a loss of 7% to 10% of blood volume is required to release ADH.[1] When osmolality suppresses and volume depletion stimulates ADH release, volume effects predominate and ADH is released. Osmolality is a more sensitive ADH stimulus, while volume is a more potent ADH stimulus. ADH is also released in response to a collection of nonosmotic, nonvolemic stimuli (Table 76-1).

FREE WATER CLEARANCE AND ELECTROLYTE FREE WATER CLEARANCE

The renal excretion or retention of water is central to the regulation of osmolality, so specialized concepts have been developed to model renal water handling. *Clearance* is a generic term used to quantify solute removal (x) by the kidney. Clearance is an artificial construct that represents the volume of blood that is completely cleared of a substance in a set amount of time (Equation 76-1). The clearance formula can be manipulated to calculate the clearance of free water, called the *free water clearance*. Conceptually, urine can be divided into two components: an isotonic and a free water component. The isosmotic component contains all of the excreted solute at the same concentration as that found in plasma; since the solute and water loss occur in the same proportion as found in the body, excretion of this isotonic urine does not affect osmolality. The other component is free water; this is solute-free water and excretion of this compartment raises plasma osmolality. For example: A person makes 1200 mL of urine with an osmolality of 142 mOsm/kg. This urine can be divided into 600 mL of isotonic urine (284 mOsm/kg) and 600 mL of free water. In terms of osmolality, only the 600 mL of free water needs to be considered. The loss of this 600 mL will tend to increase serum osmolality. The case is reversed with concentrated urine. A patient produces 1000 mL of urine with an osmolality of 568 mOsm/kg. This urine can be divided into 2000 mL of isotonic urine (284 mOsm/kg) and a negative 1000 mL of free water. In regards to changes in osmolality only the –1000 mL needs to be considered. The –1000 mL represents water that is added to the body and will decrease serum osmolality. Despite the patient excreting 1000 mL of urine, 1000 mL of fluid have been effectively added to the body by the production of concentrated urine. Equation 76-2 is used to calculate the free water clearance.

$$C_x = \left[\frac{U_x \times V}{P_x}\right]$$

Equation 76-1. Generic clearance formula. Using conventional units, U_x is in milligrams per deciliter of urine, V is in milliliters of urine per minute, and P_x is milligrams per deciliter of blood. After the units cancel, the equation simplifies to milliliters of blood and represents the quantity of blood that is completely cleared of the substance in 1 minute. U_x, urine concentration of x; V, urine volume over a set time period; P_x, plasma concentration of x.

$$V = C_{osm} + C_{H_2O}$$
$$C_{H_2O} = V - C_{osm}$$
$$C_{H_2O} = V - \left[\frac{U_{osm} \times V}{P_{osm}}\right]$$
$$C_{H_2O} = V \times \left[1 - \frac{U_{osm}}{P_{osm}}\right]$$

Equation 76-2. Free water clearance. The derivation of free water clearance begins with the assumption that urine volume is the sum of the solute clearance (C_{osm}) and free water clearance. From there, algebraic manipulation results in the free water clearance equation.

Free water clearance allows one to model changes in osmolality, but as described above, changes in tonicity and associated alterations in cell volume cause the clinical symptoms of dysnatremia. In order to model changes in tonicity (i.e., sodium) rather than osmolality, the free water clearance is further refined to measure electrolyte free water clearance (C_{EFW}). In electrolyte free water clearance, serum osmolality is replaced with serum sodium and urine osmolality is replaced with the sum of urine sodium and potassium (Equation 76-3). To demonstrate the utility of C_{EFW} over C_{H_2O}, consider two patients with identical urine output (800 mL) and urine and plasma osmolality (700 and 270, respectively). One has heart failure and the other has the syndrome of inappropriate secretion of antidiuretic hormone (SIADH). In both patients, the C_{H_2O} is identical at –1274. For every 800 mL of urine they produce, 1274 mL of water is added to the body. When using *electrolyte* free water the two cases look very different. In heart failure (and in all cases of decreased EABV) urine sodium is low, while in SIADH the urine sodium is elevated. Using urine sodium (U_{Na}) = 90, urine potassium (U_K) = 60, and plasma sodium (P_{Na}) = 130 for SIADH, the C_{EFW} is –123 mL. Using U_{Na} = 5, U_K = 60, and P_{Na} = 130 for congestive heart failure (CHF), the C_{EFW} is 400 mL. In the case of CHF the C_{EFW} is positive, so the kidney is appropriately excreting excess water (although it is limited by oliguria), while in SIADH the C_{EFW} is negative, so the production of urine further lowers plasma osmolality.

$$C_{EFW} = V \times \left[1 - \frac{U_{Na+} + U_K}{P_{Na}}\right]$$

Equation 76-3. Electrolyte free water clearance. This formula adapts the free water clearance formula to model changes in tonicity. C_{EFW}, free water clearance; P_{Na}, plasma sodium; U_K, urine potassium; U_{Na}, urine sodium; V, urine volume.

HYPERNATREMIA

Hypernatremia has been reported in 0.2% of hospital admissions and occurs in an additional 0.3% to 1% of patients during their hospital stay.[1a] These numbers likely underrepresent the prevelance of hypernatremia in the ICU, since studies focused on this patient population have shown that 9% of medical ICU patients had a sodium level >150 mmol/L at admission, and an additional 6% developed hypernatremia during the ICU stay.[1b] The body defends against increases in osmolality and serum sodium by increasing water intake and minimizing renal free water excretion (through the creation of a concentrated urine). Though ADH is used to minimize free water losses, drinking water alone is able to maintain a normal sodium and serum osmolality despite a total absence of ADH and the production of large amounts of dilute urine. Because the adequate ingestion of water can prevent and reverse hyperosmolality, persistent hypertonicity (and hypernatremia)

TABLE 76-2 Causes of Hypernatremia

Increased C_{EFW}[a]	Sweat and Insensible Losses	Water Loss into Cells	Increased Intake of Sodium	Central Impairment of Thirst
Central diabetes insipidus	Fever	Severe exercise	Infusions of hypertonic sodium bicarbonate	Reset osmostat

Malabsorption				

[a] Note: Patients with increased electrolyte free water losses that are able to increase water intake will maintain eunatremia. These conditions increase the demand for water, but if that demand is met they will not cause hypernatremia.

only occurs when water ingestion is disabled, as occurs with altered mental status, lack of access to water, or inability to drink water. In a review of hypernatremia 86% of patients lacked access to free water and 94% received less than a liter of electrolyte free water.[1a] In the absence of adequate water intake hypernatremia occurs when C_{EFW} exceeds electrolyte free water intake. Causes of increased electrolyte free water clearance are listed in Table 76-2.

ETIOLOGIES

Loss of Water

Electrolyte free water clearance can exceed water intake either from enhanced renal water loss or extrarenal loss.

Renal Water Loss

Renal water losses occur when the kidney is unable to appropriately concentrate urine. This is generically referred to as diabetes insipidus (DI). Diabetes insipidus can be either central or nephrogenic. In central diabetes insipidus (CDI) there is a complete or partial lack of ADH. In nephrogenic diabetes insipidus (NDI) there is a complete or partial end-organ resistance to ADH. Patients with DI have very high C_{EFW} and present with polyuria, polydipsia, and a normal serum sodium. Hyperosmolality and hypernatremia only occur when the patient fails to drink enough water to compensate for the increased C_{EFW}. Renal water loss plays a role in 90% of hospital-acquired hypernatremia, primarily from diuretics or osmotic diuresis.[1]

Extrarenal Water Losses

The C_{EFW} equation can be modified to look at extrarenal water losses. To do this, change the urinary Na and K to the extrarenal fluid Na and K (see Equation 76-3). When the fluid Na + K is significantly less than serum Na, electrolyte free water is being lost, predisposing the patient to hypernatremia. Sweat, osmotic diarrhea, and insensible water loss all result in significant EFW loss.

Use of Hypertonic Fluids

The addition of any fluid to the body may alter osmolality. The change in osmolality is predictable using an equation that looks at the volume and electrolyte composition of both the infusate and urine. Equation 76-4 calculates the change in sodium following any combination of infusion and urine production.[2a] Figures 76-1 and 76-2 show how the change in sodium formula works to predict hypernatremia in two scenarios, one a hypertonic saline infusion and the other an increase in C_{EFW}. The change in sodium formula is a general model of sodium handling in the body and works equally well in both the etiologies and treatment of dysnatremias.

$$\Delta Na = \left\{ \frac{V_{iv} \times (Na_{iv} + K_{iv}) - V_u \times (Na_u + K_u) - \Delta V \times Na_s}{TBW + \Delta V} \right\}$$

$$\Delta Na = \left\{ \frac{0.4 \times (1000 + 0) - 0.4 \times 140}{42 + 0.4} \right\}$$

$$\Delta Na = 8.1$$

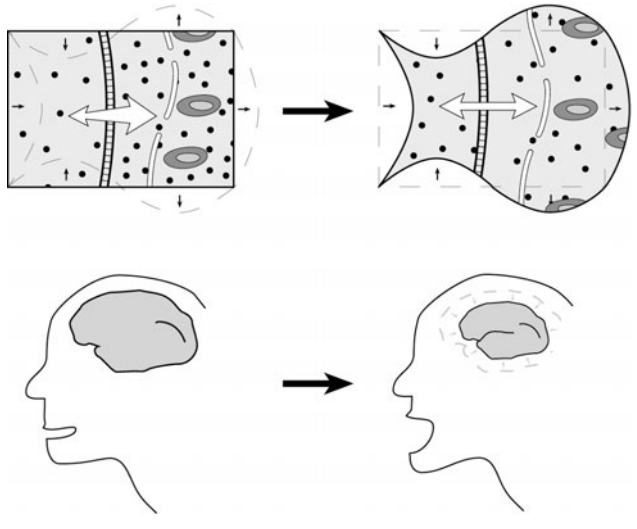
FIGURE 76-1 Change in sodium following a cardiac arrest. This patient was given 4 amps of sodium bicarbonate during a code. Each amp of bicarbonate contains 100 mL and has a concentration of 1 mmol/mL or 1000 mmol/L. The patient is anuric so the urine volume, Na, and K drop out. The patient weighs 70 kg and has 60% body water so TBW = 42. See caption to Equation 76-4 for explanation of variables.

$$\Delta Na = \left\{ \frac{V_{iv} \times (Na_{iv} + K_{iv}) - V_u \times (Na_u + K_u) - \Delta V \times Na_s}{TBW + \Delta V} \right\}$$

$$\Delta Na = \left\{ \frac{8 \times (0+0) - 18 \times (8+15) - (-14) \times 140}{42 + (-14)} \right\}$$

$$\Delta Na = 30.8$$

FIGURE 76-2 Change in sodium in a patient with central diabetes insipidus who stopped his desmopressin and is ingesting an inadequate quantity of water. The patient weighs 70 kg and has 60% body water so TBW = 42. See caption to Equation 76-4 for explanation of variables.



$$\Delta Na = \left\{ \frac{V_{iv} \times (Na_{iv} + K_{iv}) - V_u \times (Na_u + K_u) - \Delta V \times Na_s}{TBW + \Delta V} \right\}$$

Equation 76-4. Change in sodium for any combination of urine and infusate. V_{iv} is the volume of infusate and Na_{iv} is the sodium content of the infusate. Typical values are 0 for 5% dextrose in water, 77 for 0.45% normal saline, 154 for 0.9% normal saline, and 513 for 3% saline; K_{iv} is the potassium content of the infusate; V_u is the volume of urine; Na_u is the sodium content of the urine; K_u is the potassium content of the urine; ΔV is the change in total body volume ($V_{iv} - V_u$); Na_s is the current serum sodium concentration; TBW is the total body water, usually calculated by multiplying weight in kilograms by 0.7 for young men and 0.6 for women and older men.

CLINICAL SEQUELAE

The primary symptoms of hypernatremia are due to loss of cell volume (Fig. 76-3). A decrease in brain volume causes neuromuscular irritability that clinically presents as lethargy, weakness, and headache. These are nonspecific signs and can be particularly occult in the population predisposed to hypernatremia (e.g., altered mental status, dementia, and coma). As sodium rises above 158 mmol/L more severe symptoms may emerge such as seizures and coma, and death may ensue. Interestingly even relatively modest hypernatremia (Na >150 mEq/L) has been associated with increased mortality among ICU patients (RR 1.6) and general inpatients (66% hospital mortality).[1b,1c] Significant decreases in brain volume stretch cerebral bridging veins, rendering them susceptible to rupture and intracerebral hemorrhage.[2,4] Beyond cerebral effects, hypernatremia inhibits insulin release and causes insulin resistance, predisposing patients to hyperglycemia.

FIGURE 76-3 Increased plasma osmolality causes a shift of water out of the intracellular compartment. Decreased cell volume impairs tissue function, particularly in the central nervous system.

In response to increased serum tonicity and volume loss, cells compensate by increasing the number of intracellular osmoles. Initially cells move extracellular electrolytes into the cells, and later they transfer amino acids and other small molecules into the cell. Increased intracellular osmolality restores intracellular volume, and decreases the clinical impact of hypernatremia.

TREATMENT

The goal of treating hypernatremia is to arrest any ongoing cause of hypernatremia, and then to restore serum sodium to normal. Specific therapy should be employed to reduce ongoing water losses, such as correcting hypercalcemia-induced diuresis or administering desmopressin (DDAVP) to patients with CDI. Beyond this, correcting hypernatremia requires giving hypotonic fluid either enterally or parenterally. The enteral route is preferred, as it allows the use of electrolyte free water rather than hypotonic or dextrose-containing fluids. Though the optimum speed of correction has not been rigorously determined, studies on infants and children showed no seizures when sodium was corrected at less than 0.5 mmol/L per hour.[5] The sodium can be safely lowered by 10 mmol in the first day of therapy. Patients with acute increases in sodium (e.g., from hypertonic bicarbonate infusions) can safely be corrected at 1 mmol/L per hour.[5a] The change in serum sodium from a given amount of fluid can be calculated using Equation 76-4. An example of this is shown in Fig. 76-4.

A number of complications from the treatment of hypernatremia can occur. If the sodium is lowered too quickly cerebral edema may occur. Dextrose solutions predispose patients to hyperglycemia, which may cause an osmotic diuresis, worsening the hypernatremia. For this reason enteral fluids are preferred during treatment of hypernatremia.

HYPONATREMIA

Hyponatremia is defined as a serum sodium less than 136 mmol/L. Since serum sodium and its accompanying anions are the principal determinants of serum osmolality, hyponatremic patients are typically hypo-osmolar; however, hyponatremia may also be associated with normal or elevated osmolality. Since the primary morbidity from hyponatremia is due to decreased tonicity, hyponatremia with normal or elevated osmolality does not cause the clinical picture typically associated with hyponatremia.

Pseudohyponatremia is hyponatremia with a normal plasma osmolality. It is an artifact of two popular sodium assays, flame photometry and indirect potentiometry. Serum with elevated triglycerides, proteins (from multiple myeloma or Waldenström's macroglobulinemia, or following intravenous immunoglobulin therapy) or rarely cholesterol, has

Initial Na = 168 mmol/L

$$\Delta Na = \left\{ \frac{V_{iv} \times (Na_{iv} + K_{iv}) - \Delta V \times Na_s}{TBW + \Delta V} \right\}$$

$$\Delta Na = \left\{ \frac{1 \times (0 + 0) - 1 \times 168}{42 + 1} \right\}$$

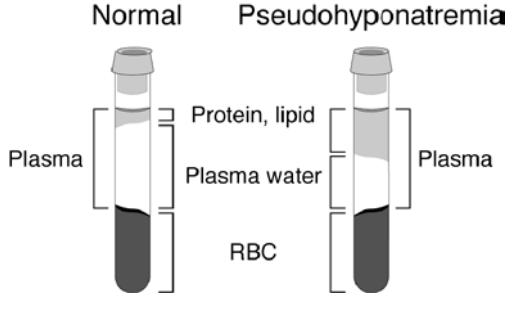
$$\Delta Na = 3.9 \approx 4$$

So: 6 liters free water will decrease Na by 24 to 144 mmol/L

To calculate the rate, limited to 2 mmol/L per hour :

$$\frac{24 \text{ mmol/L}}{2 \text{ mmol/L per hour}} \times 6 \text{ L} = 0.5 \text{ L/h}$$

FIGURE 76-4 Using the change in sodium formula to assist with the treatment of hypernatremia. In this example the patient is assumed to be anuric. During the treatment urine Na and K should be measured along with urine volume to better refine the estimated volume and time needed to correct the hypernatremia. See caption to Equation 76-4 for explanation of variables.



increased solute, and thus a given volume of serum contains less water. This results in a lab error due to overdilution of the sample (Fig. 76-5). Patients suspected of having pseudohyponatremia should have their sodium assessed by direct potentiometry, a technique generally employed by blood gas laboratories that is not susceptible to artifactual hyponatremia. Indirect potentiometry is used in two-thirds of clinical labs, making pseudohyponatremia a real issue.[5b] Since patients with pseudohyponatremia have normal sodium and osmolality, no specific treatment is needed.

With simultaneous hyponatremia and hyperosmolality an additional solute is contributing to the osmolality. Both glucose and mannitol can act as the additional solute. The increased extracellular osmolality draws water from the intracellular space, diluting serum sodium. The measured serum sodium falls by a predictable amount; the common cited adjustment is a decrease in sodium of 1.6 mmol/L for every 100-mg/dL increase in blood glucose.[6] However, the only empiric data that looked at this showed a more complex relationship: The adjustment of 1.6 mmol/L holds until serum glucose exceeds 400 mg/dL, at which point the sodium should fall by 4.0 mmol/L for every 100-mg/dL rise in glucose. For glucose less than 700 mg/dL, using an adjustment of 2.4 worked nearly as well as the more complex biphasic system.[7]

Hyposmotic hyponatremia, also called true hyponatremia, and in the remainder of the chapter simply called hyponatremia, occurs when electrolyte free water intake exceeds electrolyte free water clearance (C_{EFW}). Intact kidneys are able to clear close to 20 L of electrolyte free water, so outside of exceptional water intake, hyponatremia only occurs when there is a defect in the C_{EFW}. This defect in C_{EFW} can alternatively be stated as an inability to produce an adequate volume of dilute urine. This can be due to:

- Decreased delivery of water to the diluting segments of the nephron, namely the thick ascending limb of the loop of Henle (TALH) and distal convoluted tubule (DCT). Decreased delivery of tubular fluid is due to a generalized decrease in glomerular filtration rate (GFR), as seen in renal failure, or increased proximal resorption of water, as seen with decreased EABV.
- Decreased activity in the diluting segments of the nephron due to diuretics. Loop diuretics block solute resorption in the TALH and thiazide-type diuretics block resorption in the DCT.
- ADH activity, which allows water to be resorbed in the collecting tubules, preventing C_{EFW}.

FIGURE 76-5 Pseudohyponatremia occurs when plasma proteins or lipids occupy an unexpectedly high volume. The decreased plasma water is overdiluted while preparing the sodium assay, so the sodium will be falsely reported as low.

ETIOLOGIES

Hypotonic hyponatremia is traditionally broken down by clinical volume status of the patient (Table 76-3). While this may help clinically classify patients, it does not elucidate the pathophysiology of hyponatremia (e.g., CHF and vomiting both cause hyponatremia by inducing a nonosmotic release of ADH, but they are on opposite sides of the classification, as one is hypovolemic and the other hypervolemic). A pathophysiologic approach to hyponatremia categorizes the etiology based on why the patient has compromised C_{EFW}.

Decreased Delivery of Water to the Diluting Segments of the Nephron

Decreases in GFR for any reason reduce C_{EFW}. Patients with renal failure must moderate their intake of fluids or they may develop acute hyponatremia. Decreases in effective arterial blood volume can result from heart failure, cirrhosis, or volume depletion. Even in situations in which the GFR is intact, decreased EABV (due to CHF, liver failure, or nephrotic syndrome) increases resorption of fluid in the proximal tubule, reducing delivery of fluid to the diluting segments. Patients with reduced distal delivery of fluid have positive C_{EFW}, but

TABLE 76-3 Etiologies of Hyponatremia Categorized by Clinical Volume Status

Hypovolemic	Euvolemic	Hypervolemic
Diarrhea	SIADH	CHF
Vomiting	Hypothyroidism	Cirrhosis
Pancreatitis	Glucocorticoid deficiency	Nephrotic syndrome
Burns		Acute renal failure
Diuretic-induced		Chronic renal failure
Mineralocorticoid deficiency		
Salt-wasting nephropathy		
Cerebral salt wasting		

CHF, congestive heart failure; SIADH, the syndrome of inappropriate secretion of antidiuretic hormone.

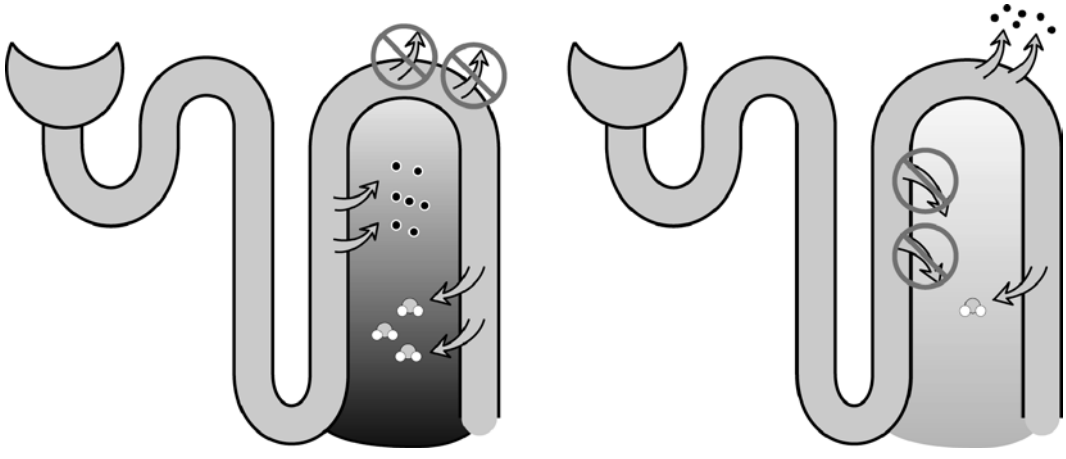
the clearance is less than their intake of free water. The hyponatremia tends to be gradual in onset and of mild severity.

Decreased Activity in the Diluting Segments of the Nephron Due to Diuretics

An intact diluting segment is essential to C_{EFW}. In some patients, severe hyponatremia can follow the initiation of diuretics.[8] Diuretics promote hyponatremia by blocking at least one and possibly all three factors required to produce dilute urine:

1. Thiazide and loop diuretics both directly antagonize the production of dilute urine.
2. Diuretic-induced volume depletion reduces the delivery of water to the diluting segments of the nephron.
3. With more dramatic volume loss, diuretics stimulate a nonosmotic release of ADH, dramatically reducing C_{EFW}.

Despite the fact that thiazide-type diuretics are less potent than loop diuretics, they cause hyponatremia more frequently and hyponatremia that is more severe. The NaK2Cl channel, which is antagonized by loop diuretics, is the engine that produces the hypertonic medullary interstitium. This medullary interstitium is necessary for ADH-stimulated water resorption in the medullary collecting duct. Chronic loop diuretic use attenuates the hypertonicity of the interstitium, so that even in the presence of ADH, little water is resorbed (Fig. 76-6).



Thiazide-induced hyponatremia is classically seen among elderly Caucasian females.[8,9] It should be noted that although these patients are classified as hypovolemic, the volume loss has repeatedly been reported as minor and subtle.[10–12] Although hyponatremia associated with diuretic use normally occurs within the first few days of therapy, hyponatremia due to chronic diuretic use may emerge in a newly sick patient.[11]

ADH Activity

The primary role of ADH is to regulate osmolality, so that it is released in response to increases in osmolality. In the presence of hypoosmolality ADH release is suppressed. However, ADH has a secondary role in maintaining perfusion, and is released in response to large decreases in blood pressure. This nonosmotic release of ADH sacrifices osmoregulation to maintain adequate perfusion. Volume depletion, heart failure, and cirrhosis are all examples in which a nonosmotic release of ADH reduces C_{EFW} and contributes to hyponatremia.

ADH may also be released without an osmotic or perfusion-related stimuli. In these cases the ADH release is considered inappropriate, as it serves no physiologic purpose. The syndrome of inappropriate secretion of ADH (SIADH) is a release of ADH despite decreased osmolality and normal EABV. Causes of SIADH are listed in Table 76-1. Among the elderly

FIGURE 76-6 In the left panel, thiazide diuretics block reabsorption in the DCT, leaving the TALH intact. ADH-induced water resorption is not dissipated. In the right panel, loop diuretics block TALH so that the medullary interstitium loses its concentration gradient. Even in the presence of ADH, little water is resorbed from the collecting tubule due to the loss of the hypertonic interstitium.

no cause of SIADH can be found in up to 10% of patients.[13] The diagnosis of SIADH requires four criteria:

1. Hypotonic (<270 mOsm/kg) hyponatremia (<135 mmol/L)
2. Inappropriately concentrated urine (>100 mOsm/kg)
3. Elevated urine sodium
4. No underlying adrenal, thyroid, pituitary, or renal disease.

UNIQUE CLINICAL SITUATIONS RESULTING IN HYPONATREMIA

Cerebral Salt Wasting

Cerebral salt wasting (CSW) is a rare clinical event that typically follows a subarachnoid hemorrhage. Patients have high urinary flow rates with elevated urine sodium, which ultimately results in severe volume deficiency and hyponatremia. The pathophysiology behind CSW has not been fully elucidated but it is likely that natriuretic proteins are released in response to the CNS injury. Atrial natriuretic peptide, brain natriuretic peptide, and an endogenous oubain-like peptide have all been proposed as possible etiologic agents. The key diagnostic dilemma is differentiating CSW from SIADH, as both can follow CNS insults and are marked by hyponatremia with elevated urine sodium. The principal differences are urine volume (in SIADH it is low, while it is high in CSW) and clinical volume status (it is normal in SIADH, while it is low in CSW). In CSW ADH release is secondary to decreased volume status, and aggressive fluid replacement is required to maintain perfusion and suppress ADH. This differentiates it from SIADH, where isotonic saline will decrease serum sodium. CSW spontaneously resolves after 2 to 3 weeks.[14]

Postoperative Hyponatremia

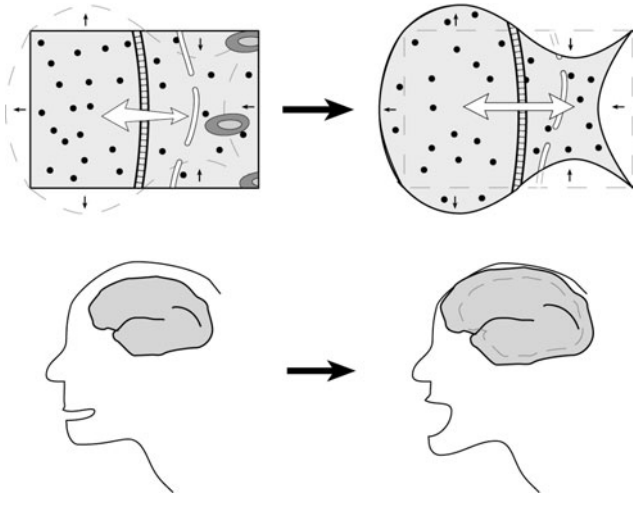
The postoperative period is ripe with factors that stimulate ADH: stress, positive pressure ventilation, pain, nausea, and opioids. It is not surprising that with the addition of generous quantities of IV fluids hyponatremia can occur.[15]

A unique form of postoperative hyponatremia may follow urologic or gynecologic procedures employing large amounts of hypotonic irrigants, typically 1.5% glycine.[16] The hypotonic fluid enters the systemic circulation and patients develop acute neurologic symptoms from either the rapid drop in sodium or from increased ammonia produced from the metabolism of glycine. Patients with hypotonic and neurologic symptoms should be treated for acute hyponatremia. Intact kidneys rapidly clear the irrigant so hyponatremia is only transient. Severe hyponatremia is more common following longer operations, larger resections, and high-pressure irrigation.[17]

Psychogenic Polydipsia

This disorder is most commonly seen in patients suffering from schizophrenia. They overwhelm their urinary diluting capacity by ingesting large volumes of water. Nausea and vomiting from acute hyponatremia is typical and stimulates a nonosmotic release of ADH, worsening the hyponatremia.[18] These patients demonstrate excessive diurnal weight gains, usually in excess of 10% of their body weight.

Adrenal Insufficiency



Adrenal insufficiency reliably causes hyponatremia. There are two mechanisms that cause this: hypovolemic release of ADH and corelease of ADH with adrenocorticotropic hormone (ACTH). Patients with adrenal insufficiency can be hypotensive due to either loss of cortisol, or in the case of primary adrenal insufficiency loss of aldosterone, causing a salt-wasting nephropathy resulting in hypovolemia. The hypotension and hypovolemia reduces water delivery to the diluting segments and stimulates ADH release. The second mechanism is due to enhanced ADH release in response to increased corticotropin-releasing hormone (CRH). CRH is the secretagogue of ACTH, but it also stimulates ADH release.[19,20] In primary and secondary adrenal insufficiency CRH is increased, which will cause increased ADH release, lowering C_{EFW}.

CLINICAL SEQUELAE

Symptoms seen in hyponatremia are largely neurologic and increase in severity with lower sodium and increased rate of development of the hypo-osmolar state. Symptoms are often vague and nonspecific: malaise, nausea, confusion, and lethargy. More dangerous symptoms follow: headache, obtundation, seizures, coma, and death.[10] Unusual symptoms have been reported, including hemiparesis and acute psychosis.[20a] Symptoms are largely due to cerebral edema (Fig. 76-7). With extracellular hypoosmolality the intracellular compartment becomes relatively hypertonic and water osmotically flows into cells, resulting in cell swelling and increased intracranial pressure. Following prolonged hyponatremia (24 to 72 hours) cells compensate for the chronic hyponatremia by ejecting intracellular solutes, lowering intracellular volume. With the restoration of intracellular volume in chronic hyponatremia, the condition becomes essentially asymptomatic.

Hypoxia is repeatedly reported as a common finding among patients with symptomatic hyponatremia. Some authors have attributed this to noncardiogenic pulmonary edema, though central hypoventilation may also be responsible.[20b] The average partial arterial oxygen pressure (Pa_{O_2}) of patients with symptomatic hyponatremia was 63 mm Hg and 68% of the patients in this series were ultimately

FIGURE 76-7 Decreases in extracellular osmolality cause the intracellular compartment to be relatively hypertonic. The hypertonic intracellular compartment attracts water, resulting in cellular swelling and tissue dysfunction. In the brain, cellular swelling causes cerebral edema and elevated intracranial pressure.

Initial Na = 107 mmol/L

$$\Delta Na = \left\{ \frac{V_{iv} \times (Na_{iv} + K_{iv}) - V_u \times (Na_u + K_u) - \Delta V \times Na_s}{TBW + \Delta V} \right\}$$

$$\Delta Na = \left\{ \frac{1 \times (513 + 40) - 1 \times 107}{42 + 1} \right\}$$

$$\Delta Na = 10.4$$

So: 1 liter of 3% saline will increase Na by 10 and 1.2 liters will increase it by 12, the limit for the first day of therapy.

To calculate the rate, divide 1200 mL by 24 hours:

$$\frac{1200 \text{ mL}}{24 \text{ h}} = 50 \text{ mL/h}$$

FIGURE 76-8 Using the change in sodium formula to assist with the treatment of hyponatremia. In this example the patient is assumed to be anuric. During the treatment urine Na and K should be measured along with urine volume to better refine the estimated volume and time needed to correct the hyponatremia.

intubated.[20c] Hypoxia has been shown to delay cellular compensation, resulting in persistent symptoms of acute hyponatremia despite a prolonged clinical course of over 5 days.

TREATMENT

Hyponatremia causes symptoms due to cerebral edema from the osmotic movement of water into cells. Compensation for acute hyponatremia consists of cells ejecting intracellular solutes in order to restore normal cell volume. This compensation complicates treatment decisions because rapidly restoring normal osmolality in the presence of compensated cells can cause the serum to be relatively hypertonic to the cells, resulting in the osmotic movement of water out of the cells. In the CNS this can cause a condition called central pontine myelinolysis (CPM) or osmotic demyelination syndrome (ODS) that results in severe morbidity or death. In determining the treatment plan for hyponatremia one must balance the risk of cerebral edema from the hyponatremia against the risk of ODS from treating compensated hyponatremia. Creating evidence-based guidelines is difficult because of the lack of randomized controlled trials. Recommendations are based on retrospective case series and expert opinion. The following guidelines attempt to balance the risks of these opposing outcomes.

Symptomatic Hyponatremia

In acute hyponatremia little compensation has occurred and the benefits of rapid correction and resolution of cerebral edema outweigh the risks of ODS. While acute hyponatremia has classically been defined as hyponatremia lasting less than 48 hours, a prospective (albeit not randomized) trial has shown active treatment to be superior to fluid restriction for a cohort of patients with CNS symptoms and an average duration of hyponatremia of 5.2 days (all had hyponatremia for longer than 48 hours and a gradual decrease in sodium of 0.5 mmol/L per hour). Given this, patients with symptomatic hyponatremia should be actively treated. Sodium levels should be initially raised rapidly until symptoms abate or the serum sodium has been raised by 4 to 6 mEq/L.[21] Furthermore, the sodium should be raised no more than 12 mEq/L in the first 24 hours.[22–24] The sodium concentration should be assessed frequently to maintain the permitted rate of correction. Aside from volume depletion, hypertonic saline is the best way to raise the sodium concentration to treat acute, symptomatic hyponatremia. When using hypertonic saline to correct hyponatremia Equation 76-4 allows rapid calculation of how much the serum sodium will change in response to 1 L of IV fluid. It should be noted that when using IV fluids to treat hyponatremia, potassium in the IV fluid has the same effect on serum tonicity as sodium, and needs to be added to the sodium.[25,26] Figure 76-8 gives an example of using the change in sodium formula to manage hyponatremia.

Caution should be used when estimating total body water. The common estimate of 0.7 times total body weight for men and 0.6 times total body weight for women assumes a normal hydration status and normal percentage of body fat. This calculation overestimates total body water among patients who are volume depleted or obese. Overestimating TBW leads to exceeding limits on the speed of correction and possibly increased risk of osmotic demyelinization.

In the setting of hyponatremia due to volume depletion, normal saline should be used to restore normal perfusion prior to specific therapy for hypo-osmolality. Restoring normal perfusion will remove the nonosmotic stimulus for ADH release so the kidney will increase free water clearance and auto-correct the hyponatremia. In some situations patients will correct their sodium too fast and require free water infusions to slow the rate of correction.

Asymptomatic Hyponatremia

Whereas acute symptomatic hyponatremia demands aggressive treatment to reverse cerebral edema, chronic asymptomatic hyponatremia is well tolerated and should be treated conservatively. First, any ongoing cause of the hyponatremia (e.g., water intake or diuretics) should be stopped and water restriction initiated. A spot urine sodium and potassium should be checked in order to calculate the C_{EFW}. In most cases this will be positive and can allow one to determine the

degree of fluid restriction required to raise the serum sodium. However, in SIADH the C_{EFW} will be negative, which means that for every milliliter of urine the patient produces, water is added to (rather than cleared from) the body. With a negative C_{EFW} water restriction will rarely be successful at raising serum sodium. In this unique situation a loop diuretic can increase the C_{EFW} by reducing the urine sodium. A negative C_{EFW} only occurs when the urine Na plus urine K is higher than the serum Na, and loop diuretics typically reduce the urine sodium to around 70, which is sufficient to reduce the urine Na plus K to below serum Na. This will make the C_{EFW} positive and allow fluid restriction to increase the serum sodium. (Note: In patients with a positive C_{EFW}, adding a loop diuretic can have the opposite effect by increasing a low urine Na, indicative of good C_{EFW}, to around 70.)

In patients with chronic SIADH, use of the antibiotic demeclocycline acts as an ADH antagonist and so allows more liberal fluid intake. Likewise, increasing the solute load by using a high-protein diet or increased sodium and potassium intake will also allow increased daily fluid intake.

Osmotic Demyelination Syndrome

ODS is the primary complication of therapy for hyponatremia. With rapid or complete restoration of extracellular osmolality, a well adjusted intracellular environment becomes relatively hypotonic. Water then flows from the intracellular to the extracellular compartment, causing cell volume collapse. In the CNS this can cause a demyelinating lesion. Symptoms usually present within a week of the correction of the hyponatremia. Although slowly evolving neurologic symptoms similar to a pseudobulbar palsy and the "locked-in" quadriparesis are classic, findings may be more subtle. Disturbances of movement or behavior or seizures may be the presenting finding.[28] Some patients tend to be more susceptible than others. In a case-control study by Ayus and colleagues, patients with hepatic encephalopathy, hypoxia, or normalization of Na (or an increase greater than 25 mmol/L) in the first 48 hours were found to be susceptible to ODS.[27a] In the event that ODS occurs, some authors advocate relowering the sodium to 120 mEq/L by giving hypotonic fluids and DDAVP, and then allowing the sodium to slowly return to normal. However, there are no randomized trials in the literature to validate this approach, and given the devastating morbidity and mortality of ODS, an attempt to reverse the corrected sodium should be attempted in patients displaying symptoms of ODS.

Potassium

Potassium is the most common cation in the body. The ratio of the intracellular to extracellular potassium concentration is the primary determinant of the resting membrane potential (E_m). Alterations in the E_m disrupt the normal function of neural, cardiac, and muscular tissues. Normal serum potassium ranges from 3.5 to 5.2 mmol/L. The molecular weight of potassium is 39.1, so a daily potassium intake of 80 mmol is roughly equivalent to 3.1 g of potassium.

The normal physiologic handling of potassium can be viewed as a three-step process: ingestion, cellular distribution, and excretion. Irregularities at any of these steps can result in pathologic serum potassium concentrations.

METABOLISM

INTESTINAL ABSORPTION

Normal daily intake is roughly 40 to 80 mmol. Potassium is rapidly and completely absorbed by the small intestine. Net GI absorption (intake minus GI losses) is approximately 90%.[29] Lower GI secretions have high concentrations of potassium, 80 to 90 mmol/L, but due to the limited amount of stool (80 to 120 g/d), daily GI excretion of potassium is only 10 mEq.[30–32] The colonic epithelium is capable of actively excreting potassium, but this is not clinically significant. Patients with chronic renal failure have elevated stool potassium but total potassium excretion is still limited to about 12 mEq/d.[29]

CELL UPTAKE

Following absorption, potassium distributes among the intracellular and extracellular compartments. The intracellular compartment acts as the primary buffer to changes in serum potassium concentration.

The Na-K-ATPase pump, driven by a ubiquitous cell surface enzyme, moves potassium into cells while pumping sodium out of cells. The pump is stimulated by β_2-adrenergic activity, while α-adrenergic activity results in potassium efflux.[33] Insulin also stimulates the activity of this pump and is independent of its hypoglycemic activity.[34]

Extracellular pH can affect the cellular distribution of potassium. Various explanations have been proposed, including a direct effect of pH on the Na-K-ATPase, or a H^+—K^+ exchange to maintain electroneutrality. The effect of pH on potassium distribution varies depending on the nature of the acid-base disturbance. Respiratory acidosis, alkalosis, and organic acidosis all have minimal effect on potassium distribution. Inorganic acidosis can increase serum potassium, while metabolic alkalosis can lower potassium.

RENAL EXCRETION OF POTASSIUM

Renal excretion of potassium can range from 5 to 500 mEq/d.[35,36] Though 500 mmol of potassium is filtered by the glomerulus each day, essentially all of it is resorbed in the proximal tubule and loop of Henle. Any potassium that is ultimately excreted in the urine must be secreted by the distal nephron.[37] Because of this phenomenon, the study of renal potassium handling can focus exclusively on the distal nephron.

The secretion of potassium in the distal tubule is governed by two phenomena: tubular flow and aldosterone activity (Fig. 76-9). Potassium secretion by the principal cells of the collecting duct depends on a favorable electrochemical gradient. Rapid tubular flow provides a continuous supply of potassium-depleted fluid, maintaining a favorable chemical gradient. Additionally, increased tubular flow occurs with high tubular sodium delivery. Resorption of sodium by the principal cells generates a negative charge in the tubular lumen. Some of this negative charge is lost by concurrent resorption of chloride. The luminal electronegativity enhances potassium secretion. Decreased distal chloride delivery, as occurs with metabolic alkalosis, reduces chloride resorption, increasing the tubule electronegativity and enhancing potassium secretion.[38] Aldosterone is a steroid hormone produced in the zona glomerulosa of the adrenal gland. Its principal site of action is the connecting segment and collecting

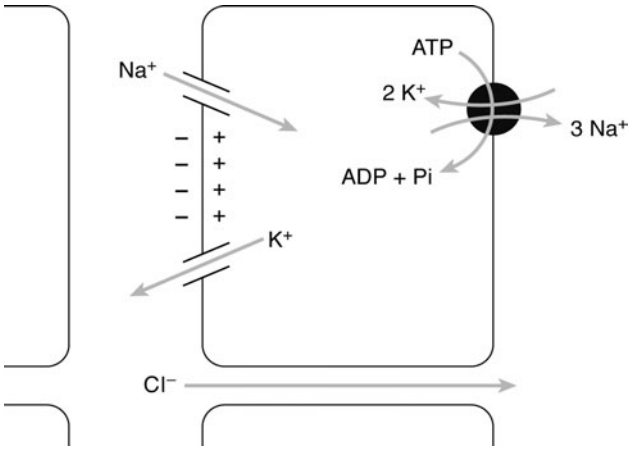


FIGURE 76-9 Potassium handling in the cortical collecting duct. The resorption of sodium creates a negatively charged tubule lumen. This charge helps drive the secretion of potassium. Chloride resorption decreases the negative charge, so increased chloride resorption decreases potassium secretion. ADP, adenosine diphosphate; ATP, adenosine triphosphate; Pi, inorganic phosphate.

tubules of the distal nephron. In the principal cells of the cortical collecting duct (CCD), aldosterone increases the resorption of sodium and hence the secretion of potassium. Aldosterone stimulates the production and activity of Na-K-ATPase, sodium channels, and potassium channels.[39] Aldosterone also has a small but measurable effect on increasing GI potassium excretion.[29] Aldosterone is secreted in response to angiotensin II and elevated serum potassium.

The fact that potassium secretion is dependent on both tubular flow and aldosterone means that renal potassium handling is independent of volume status, despite the fact that both tubular flow and aldosterone are intimately tied to volume status. With volume depletion, increased angiotensin II stimulates the release of aldosterone, which enhances potassium secretion; however, the simultaneous decrease in GFR and increased resorption by the proximal tubule decrease tubular flow, antagonizing potassium secretion. In the opposite case of volume overload, decreased aldosterone suppresses potassium secretion, but increased tubular flow enhances potassium secretion, maintaining potassium balance.

HYPOKALEMIA

Hypokalemia is defined as a serum potassium concentration below 3.5 mmol/L, and is found among 20% of the hospitalized population. However, this high frequency probably does not reflect total body potassium depletion. In a review of 70 hospitalized patients with a potassium less than 2.8 mmol/L, the potassium rose toward normal regardless if they were given potassium or not. The authors suggested that hospitalization for acute illness was associated with increased adrenergic stimulation, resulting in intracellular movement of potassium and transient hypokalemia.[40]

ETIOLOGY

See Table 76-4.

TABLE 76-4 Causes of Hypokalemia

Decreased Potassium Intake	Cellular Shift	Increased Potassium Loss
Anorexia	β-Adrenergic activity	Extrarenal losses
Malnutrition/malabsorption	Endogenous	Chronic diarrhea
Alcoholism	Albuterol	Fistulas and ostomies
Ingestion of grey clay	Dobutamine	Renal losses
	Terbutaline	Loop diuretics
	Fenoterol	Thiazide diuretics
	Insulin	Osmotic diuretics
	Alkalemia	Acetazolamide
	Periodic paralysis	Type I and II renal tubular acidosis
	Thyrotoxicosis	Metabolic alkalosis
	Familial	Bicarbonaturia (vomiting)
	Xanthines	Ketonuria
	Theophylline toxicity	Hypomagnesemia
	Caffeine	Carbenicillin
	Barium toxicity	Bartter's and Gitelman's syndromes
	Treatment of anemia (rapid cell proliferation)	Hyperaldosteronism
		Exogenous steroids
		Adrenal adenoma
		Adrenal hyperplasia (Conn's syndrome)
		Syndrome of apparent mineralocorticoid excess
		Liddle syndrome
		Congenital adrenal hyperplasia
		Renal artery stenosis
		Renin-secreting tumor

Decreased Dietary Intake

Potassium-poor diets usually are merely contributory to hypokalemia. Even among patients with severe malnutrition due to anorexia nervosa and/or bulimia, serum potassium less than 3 mmol/L occurred in less than 2%, and in all of those patients there was enhanced potassium loss from cathartics or vomiting.[41]

Cellular Shifts

Activation of β-adrenergic receptors increases Na-K-ATPase activity. Any physiologic stress that releases epinephrine or norepinephrine can result in a transient decrease in serum potassium. Use of primarily β-adrenergic catecholamines, such as dobutamine, can cause transient hypokalemia.[42] The β-agonists used for bronchodilation or as tocolytic agents can also acutely lower potassium.

Insulin reliably stimulates Na-K-ATPase and lowers serum potassium.[34] Insulin-induced hypokalemia has been documented in the treatment of diabetic ketoacidosis, nonketotic hyperosmolar coma, and with the use of intravenous dextrose solutions.[43] Refeeding syndrome occurs among patients given a carbohydrate-rich diet or parenteral nutrition following periods of starvation. Refeeding syndrome is associated with hypokalemia and hypophosphatemia.[44]

Metabolic alkalosis is associated with the intracellular movement of potassium and increased renal potassium excretion. Increased pH results in movement of hydrogen ions from the intracellular to the extracellular compartment. Potassium shifts into cells to maintain electroneutrality. Simultaneously, increased serum bicarbonate enhances renal potassium excretion. Studies in nephrectomized dogs show a modest but measurable decrease in serum potassium of less than 0.3 mmol/L for each increase in pH of 0.1 (though these data did not account for a significant increase in serum osmolality).[45] The common association of alkalosis and hypokalemia is primarily due to enhanced renal excretion of potassium rather than a transmembrane shift.

Hypokalemic periodic paralysis is an unusual clinical entity in which transcellular shifts in potassium result in paralysis. These patients develop sudden, severe drops in serum potassium associated with skeletal muscle paralysis. Triggers include carbohydrate loads, exercise, and changes in body temperature. Acetazolamide may decrease the frequency and severity of symptoms in some families.[46] Oral potassium can be used to treat acute paralysis but patients often develop rebound hyperkalemia.[47]

Increased Potassium Loss

The cortical collecting duct is the critical site of renal potassium handling. Normally aldosterone activity and sodium delivery to the CCD are balanced so that when one is elevated the other is decreased. Excess renal potassium excretion only occurs when both aldosterone and distal sodium delivery are increased.

Most diuretics increase distal delivery of sodium and increase aldosterone, resulting in hypokalemia. Primary hyperaldosteronism causes hypertension and hypokalemia. The hypokalemia is due to the simultaneous increase in aldosterone activity and sodium delivery to the distal nephron. The increased sodium delivery is due to a spontaneous diuresis in response to the hypertension known as *aldosterone escape*. A full discussion of the causes of increased aldosterone activity is beyond the scope of this text; however, a list of causes is included in Table 76-4.

Normally, the primary anion in the tubular fluid is chloride. Various conditions can result in chloride being replaced by an unresorbable anion. Anions that are not resorbed prevent sodium from being resorbed and increase sodium and tubular fluid delivery to the distal nephron. Additionally, unresorbable anions increase tubule electronegativity, which enhances potassium secretion by the principal cells. The most common example of an unresorbable anion resulting in hypokalemia is bicarbonate. In metabolic alkalosis, increased serum bicarbonate is delivered to the distal nephron, resulting in increased renal potassium loss. Diabetic ketoacidosis increases delivery of the unresorbable anion β-hydroxybutyrate to the distal nephron.

Hypomagnesemia is associated with hypokalemia that is resistant to therapy. Decreased magnesium increases renal potassium losses and needs to be corrected prior to successful treatment of hypokalemia.[48]

Despite a high concentration of potassium in lower GI secretions, 85 to 95 mmol/L, GI potassium losses are typically modest, about 10 mEq/d.[31] Chronic diarrhea can cause hypokalemia, but the mechanism appears to be more complex than simple GI loss of potassium. In cases of experimental diarrhea, daily GI potassium loss was never higher than 24 mEq/d, a level well below average daily potassium intake.[49] In addition, studies on diarrhea show that as stool volume increases, stool potassium concentration falls, ultimately reaching a level similar to that of plasma in cases of severe cholera.[29] Explanations for the commonly seen association of diarrhea and hypokalemia include: secondary hyperaldosteronism, diminished intake of potassium, or transcellular shifts of extracellular potassium.

Gastric secretions have potassium content similar to that of plasma, 5 to 8 mmol/L. Gastric losses result in severe metabolic alkalosis and secondary hyperaldosteronism, both of which enhance *renal* potassium loss.

CLINICAL SEQUELAE

Hypokalemia is a well-known risk factor for cardiac arrhythmia. Increased ectopy with hypokalemia has been documented in ambulatory hypertensive patients, in patients undergoing coronary artery bypass grafting, and during acute myocardial infarction (AMI).[50,51] Following AMI, hypokalemia increases the risk for a number of arrhythmias; patients with hypokalemia are more than twice as likely to develop ventricular fibrillation.[52] Hypokalemia enhances the risk of digitalis toxicity and associated arrhythmias. Digitalis-induced arrhythmias may occur despite normal digitalis levels in the presence of modest hypokalemia.[53]

A drop in extracellular potassium hyperpolarizes the muscle cells, which can prevent myocyte depolarization. Clinically, this can lead to weakness, fatigue, cramping, and myalgia. Severe cases can result in paralysis. Numerous case reports of respiratory muscle weakness and respiratory failure have been reported with hypokalemia due to diabetic ketoacidosis. Severe hypokalemia can cause rhabdomyolysis. Alcoholics may be particularly prone to proximal muscle weakness due to rhabdomyolysis.[54,55]

Hypokalemia can cause polyuria due to increased thirst and by inducing a mild and reversible renal concentrating defect.[56,57] The etiology of the concentrating defect is

multifactorial, but primarily represents decreased renal response to ADH.

Gastrointestinal complications are primarily related to decreased gut motility associated with hypokalemia. Serum potassium of less than 3.0 mmol/L is associated with constipation. Paralytic ileus can occur as potassium falls below 2.5 mmol/L.

Hypokalemia stimulates the proximal tubule to increase ammoniagenesis. Patients predisposed to hepatic encephalopathy can develop encephalopathy from this increased ammonia load.[58]

DIAGNOSIS

Hypokalemia is defined as a serum potassium concentration less than 3.5 mmol/L. Once hypokalemia has been established, the primary diagnostic goal is differentiating renal from extrarenal potassium loss. Urine studies are used to separate extrarenal losses, in which the kidneys are potassium avid, from renal losses, in which the kidney inappropriately wastes potassium. Three studies may be used to differentiate these states: spot urine potassium concentration, 24-hour urine potassium, and the transtubular potassium gradient (TTKG).

The spot urine is the simplest test to use. The urine potassium should be less than 20 mmol/L in the face of hypokalemia. If the spot potassium is greater than 40, renal potassium wasting should be suspected. Urine potassium of 20 to 40 mmol/L is considered nondiagnostic.[59] There are two primary problems with this test; the first is it fails to control for changes in the water content of urine. Since hypokalemia is associated with decreased ADH sensitivity, increased water content will lower the urinary potassium concentration. The second problem is that spot samples provide information for only a single moment in time. Patients with diuretic-induced hypokalemia become potassium avid after the diuretic has cleared. One study on the diagnosis of hypokalemia (mean K = 2.0 mmol/L) found spot urine potassium to have a sensitivity of 40% and specificity of 100% for excess renal potassium loss.[60]

The 24-hour urine potassium test avoids both of the above problems at the expense of increased complexity and a 24-hour delay. Patients with hypokalemia should reduce urinary potassium losses to less than 15 mEq/d. Potassium losses greater than that indicate inappropriate renal losses. The 24-hour urine provides no information on the renal potassium handling prior to the urine collection (e.g., diuretic use that is stopped prior to collection will show an appropriately potassium-avid kidney).

The transtubular potassium gradient calculates the ratio of tubular potassium to venous potassium at the end of the CCD. The CCD is responsible for potassium excretion, so increases in the TTKG indicate renal wasting of potassium, while decreases indicate renal potassium conservation (Fig. 76-10 and Equation 76-5). When serum and renal potassium handling are normal, the TTKG runs from 5 to 8.[61,59] In the face of hypokalemia, the CCD should minimize the potassium excretion, resulting in a reduced TTKG. The TTKG has been validated in patients with decreased dietary potassium, periodic paralysis, diuretic-induced hypokalemia, primary hyperaldosteronism and vomiting.[61–62]

$$\text{TTKG} = \frac{\text{urine K} \div \dfrac{\text{urine Osm}}{\text{plasma Osm}}}{\text{plasma K}}$$

Equation 76-5. The transtubular potassium gradient (TTKG). plasma Osm, plasma osmolality; urine Osm, urine osmolality.

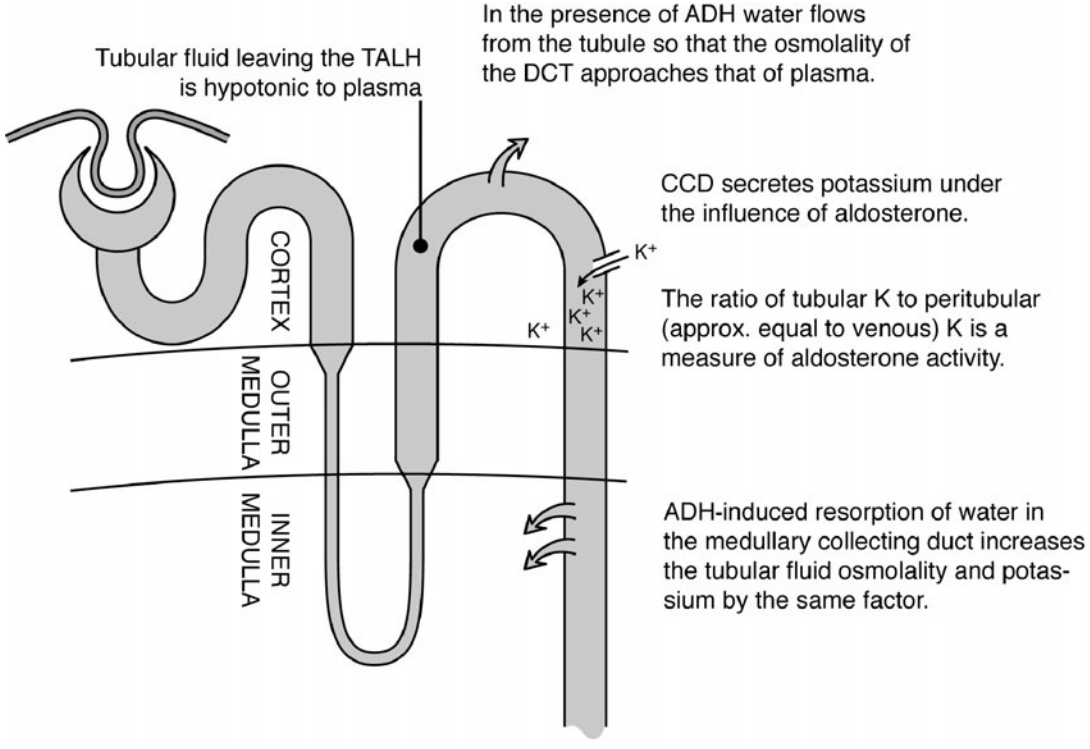

FIGURE 76-10 The transtubular potassium gradient measures the ratio of tubular potassium to interstitial potassium and quantifies the renal excretion of potassium. ADH, antidiuretic hormone; CCD, cortical collecting duct; DCT, distal convoluted tubule; TALH, the thick ascending limb of the loop of Henle.

The TTKG has two assumptions that must be met prior to using this formula:[63]

1. There must be ADH activity to ensure that the osmolality of the tubular fluid approximates the osmolality of blood by the end of the cortical collecting duct. ADH activity is assured by only using the formula when urine osmolality exceeds serum osmolality.
2. There must be adequate tubular sodium to allow the cortical collecting duct to secrete potassium. The test should only be done if the urine sodium concentration is greater than 25 mmol/L.

TREATMENT

The treatment of hypokalemia can be broken down into three questions: when to treat, with which potassium salt, and with what quantity. The National Council on Potassium in Clinical Practice has published clinical practice guidelines on potassium replacement. The guidelines recommend correcting potassium in any patient with potassium below 3.0 mmol/L and select patients with serum potassium below 3.5 mmol/L. They specified the more aggressive treatment regimen for patients with hypertension, congestive heart failure, and increased risk for or history of cardiac arrhythmias or stroke.[64]

Determining the dose of potassium to correct hypokalemia is difficult because there is not a firm relationship between serum potassium and total body potassium. Balance studies have shown that potassium is disproportionately lost from the extracellular compartment rather than total body potassium (e.g., a 25% drop in serum potassium is due to less than a 25% drop in total body potassium). Sterns and colleagues analyzed the results of seven balance studies and found a linear relationship for potassium deficit and serum potassium ($r = 0.893$). The loss of 100 mmol of potassium lowered the serum potassium by 0.27 mmol/L, so a fall from 4 to 3 mmol/L represented a 370-mmol potassium deficit.[65] In Scribner and Burnell's review, they estimated that a drop in potassium from 4 to 3 mmol/L represented a loss of 100 to 200 mmol of potassium, and a drop in serum potassium from 3 to 2 mmol/L represented an additional 200 to 400 mmol deficit.[66] These estimates do not account for altered cellular distribution of potassium. In diabetic ketoacidosis for example, serum potassium overestimates total body potassium, while β-agonist–induced hypokalemia underestimates total body potassium. In most cases of hypokalemia due to cellular redistribution, experts advise against treatment, as the hypokalemia is transient and treatment predisposes the patient to hyperkalemia. One exception to this is symptomatic periodic paralysis in which respiratory arrest due to hypokalemia may occur, so emergent treatment is indicated. Caution should still be used, as rebound hyperkalemia is common.

The form of potassium used in repletion is most often potassium chloride. The chloride anion has some advantages over alternatives such as phosphate, bicarbonate, or citrate. The chloride anion is primarily an extracellular anion, which minimizes the movement of potassium into the cell, maximizing the change in serum potassium. Chloride also does not increase the secretion of potassium at the collecting duct. The use of alternate potassium salts should be reserved for specific clinical scenarios in which there is an indication for the anion (e.g., citrate in metabolic acidosis and phosphate in hypophosphatemia).

In patients who are asymptomatic, oral replacement is sufficient and doses from 40 to 100 mEq of KCl per day are typically sufficient to correct the hypokalemia over several days.[64] Increasing intake of potassium-rich foods is less effective than potassium chloride supplements because the anions associated with dietary potassium are primarily phosphate and citrate.

Potassium chloride can be given as a liquid, powder (often marketed as a salt substitute), or pills with multiple formulations and coatings. The bioavailability of all these formulations is identical, with greater than 70% absorption.[67] The liquid formulation has the fastest absorption and lowest patient compliance of all formulations (due to the bad taste).[68] Wax-matrix extended-release tablets are associated with gastrointestinal tract ulcers and stenotic lesions. The microencapsulated extended-release formulations have the best compliance and low rates of GI side effects.[68,64]

Parenteral potassium should be used to correct symptomatic hypokalemia or when patients are unable to take oral medications. Twenty to forty millimoles of KCl in a liter of isotonic saline or 5% dextrose is a typical solution. Both saline and dextrose solutions can cause problems. Dextrose solutions stimulate insulin release that can result in acute worsening of the hypokalemia.[43,69] The use of saline with dilute concentrations of potassium means that patients must get multiple liters of saline to correct even modest potassium deficits.

The use of concentrated potassium solutions has generated fears about the possibility of precipitating arrhythmias from local, transient hyperkalemia near the infusion site or by causing peripheral vein irritation from caustic potassium solutions. Despite these concerns, the use of concentrated potassium infusions, 200 mmol/L, at a rate of 20 mEq/h in the ICU was shown to be safe and efficacious in both a retrospective study of 495 infusions and a prospective study of 40 patients.[70,71] Twenty milliequivalents of KCl increased the serum potassium by 0.25 mmol/L 1 hour after the infusion finished. The peak rise in serum potassium, 0.48 mmol/L, was at the end of the infusion. ECG monitoring showed no change except for decreased ventricular ectopy. Potassium was infused safely through both peripheral and central sites.

Hypomagnesemia is a common cause of treatment failure. Patients who are resistant to potassium supplementation should have serum magnesium measured, and if low, repleted. Patients with diuretic-induced hypokalemia often benefit from the initiation of a potassium-sparing diuretic. Amiloride has been shown to mitigate magnesium losses associated with loop and thiazide diuretics.

Patients on amphotericin B often become hypokalemic. Both spironolactone (100 mg twice a day) and amiloride (5 mg twice a day) have been shown to increase serum potassium and decrease the use of potassium supplements in randomized prospective trials.[72,73]

In patients with recalcitrant vomiting (i.e., bulimia) and associated hypokalemia, one treatment strategy is to decrease the loss of hydrogen ions with a proton pump inhibitor or H_2-blocker. In one case a bulimic patient was started on lansoprazole and the patient's alkalosis and hypokalemia improved. In addition, the patient remained normokalemic for the following year despite continued vomiting.[74] Proton pump inhibitors may have a similar role in ameliorating hypokalemia associated with gastric suction.

TABLE 76-5 Causes of Hyperkalemia

Increased Potassium Intake	Cellular Shift	Decreased Potassium Excretion
Oral	β-Blockers	Decreased tubular flow
Dietary	Lack of insulin	Renal insufficiency
K supplements	Acidemia (inorganic)	Prerenal azotemia
Salt substitutes	Digitalis toxicity	Volume depletion
Ingestion of red clay	Succinylcholine	Congestive heart failure
Enternal feeding supplements	Periodic paralysis Hyperkalemic	Cirrhosis
Parenteral	Hypertonicity	NSAID use
Medical error	Hyperglycemia	Decreased stimulation of aldosterone
TPN	Mannitol	Type IV RTA (hyporeninism)
CVVH replacement fluid	Cell destruction	ACE inhibitor use
Peritoneal dialysis fluid	Ischemia	Angiotensin-receptor blocker
Old blood transfusions	Necrosis	Decreased synthesis of aldosterone
Treatment of hypokalemia	Hemolysis	Adrenal insufficiency, primary
Penicillin	Rhabdomyolysis	Ketoconazole
(K formulations)	Tumor lysis syndrome	Heparin
	Chemotherapy	Congenital adrenal hyperplasia
	Radiation therapy	Decreased aldosterone activity
	Spontaneous	Spironolactone
		Trimethoprim
		Amiloride
		Triamterene
		Cyclosporine A
		Tacrolimus
		Type I RTA, hyperkalemic variety
		SLE, obstruction, sickle cell
		Decreased GI excretion
		Constipation in ESRD patients

ACE, angiotensin-converting enzyme; CVVH, continuous venovenous filtration; ESRD, endstage renal disease; NSAID, nonsteroidal anti-inflammatory drug; RTA, renal tubular acidosis; SLE, systemic lupus erythematosus; TPN, total parenteral nutrition.

HYPERKALEMIA

ETIOLOGIES

The ability of the kidney to excrete potassium is flexible and adaptable. If dietary ingestion of potassium is increased over a number of days, the kidney increases daily potassium excretion to match. Because of this, dietary loads of potassium do not result in hyperkalemia unless they are sudden, or paired with a defect in renal potassium handling. Likewise, conditions associated with the movement of intracellular potassium to the extracellular space are associated with only transient hyperkalemia because either the kidneys excrete or the cells reuptake the excess potassium. Decreases in the ability of the kidney to excrete potassium increase susceptibility to hyperkalemia from increased potassium intake or transcellular shifts (Table 76-5).

Increased Potassium Intake

Dietary potassium is typically in the range of 40 to 80 mEq/d. Hyperkalemia has been reported to follow the use of potassium chloride salt substitutes, even in the presence of normal renal function.[75] One teaspoon of potassium chloride contains 50 to 65 mEq of potassium. Enteral nutrition supplements may be rich sources of potassium. Ensure Plus at 100 mL/h provides 130 mEq of potassium per day.

Red blood cell transfusions can have extracellular potassium concentrations as high as 70 mmol/L.[76] The risk of hyperkalemia from transfusions rises as the age of the transfusions increases (Table 76-6). Use of "washed" packed red blood cells reduces the risk of transfusion-associated hyperkalemia.[77]

Intracellular Redistribution of Potassium

Increases in plasma osmolality, most often due to hyperglycemia, causes an osmotic movement of water from the intracellular compartment. Potassium moves out of the cell with the water. Using mannitol to increase serum osmolality from 283 to 300 mmol/kg increased potassium from 4.4 to 5.2 mmol/L.[78]

The Na-K-ATPase is critical in preventing intracellular potassium from causing hyperkalemia. Any factor that decreases the activity of this enzyme will cause potassium to leak from cells. A lack of insulin slows the Na-K-ATPase.

TABLE 76-6 Potassium Concentration in Red Blood Cell Transfusions

Age (Days)	Plasma Potassium (mmol/L)[a]	Extracellular Potassium (mmol) per 250 mL of PRBC (Hematocrit 60%)
0	1.6	0.2
7	17	1.7
14	27	2.7
35	44	4.4
42	46	4.6

PRBC, packed red blood cells.
[a] Per Murthy.[255]

In diabetic ketoacidosis hyperkalemia is typical despite total body potassium depletion, and in this setting is largely related to the hyperglycemia.

β-Blockers inhibit the Na-K-ATPase activity and are associated with a mild increase in serum potassium. Uremia reduces Na-K-ATPase activity so that renal failure patients are less able to use the intracellular compartment to buffer potassium loads. Digitalis is a Na-K-ATPase antagonist. Digitalis toxicity can cause severe hyperkalemia. Removing digitalis with binding antibodies allows rapid correction of the hyperkalemia.[79]

Inorganic acids increase serum potassium. Attempts to predict the change in potassium from changes of pH have shown tremendous variability (0.3 to 1.1 mmol/L for a decrease in pH of 0.1) and are considered unreliable.[78] Decreases in pH due to respiratory or organic acidosis have minimal effect on serum potassium.

Cell death results in release of intracellular potassium. Large-scale cell death can cause fatal hyperkalemia. Tissue necrosis and hyperkalemia can be seen with rhabdomyolysis of any etiology. Likewise, tissue ischemia can cause cell death and release large amounts of potassium. Bowel and limb ischemia are occult causes of hyperkalemia. Hemolysis causes hyperkalemia by releasing the intracellular potassium of red blood cells. Tumor destruction with chemotherapy results in release of intracellular contents. Tumor lysis syndrome is hyperphosphatemia, hyperuricemia, hyperkalemia, and hypocalcemia associated with acute renal failure. The prophylactic use of allopurinol has nearly eliminated acute renal failure, which is due to uric acid nephropathy. The syndrome most often occurs with poorly differentiated neoplasms such as Burkitt's lymphoma and acute leukemias, but it has been reported with breast cancer, medulloblastoma, and ovarian and lung cancer. In some rapidly-growing tumors, spontaneous lysis occurs prior to therapy. Hyperkalemia in tumor lysis syndrome is more common in patients with premorbid renal insufficiency.[80]

Succinylcholine is a depolarizing paralytic. It can cause hyperkalemia by two unique mechanisms. The first occurs after muscle damage from burns, trauma, or disuse (often from denervation, prolonged ICU stay, or central nervous system lesion such as stroke or Gullain-Barré syndrome). The muscle damage causes upregulation of the nicotinic acetylcholine receptors so that subsequent exposure to succinylcholine causes massive potassium efflux and hyperkalemia. The second mechanism is a drug-induced rhabdomyolysis. Nearly all of the reported cases of rhabdomyolysis occurred in patients with a preexisting myopathy, often a form of muscular dystrophy (Duchenne's or Becker's).[81]

Renal Dysfunction

Increased intake and cellular redistribution cause transient increases in potassium because the kidneys are so efficient at excreting potassium. Persistent hyperkalemia is almost always associated with a defect in renal potassium clearance. Renal potassium excretion is dependent on adequate tubular flow and adequate aldosterone activity. Besides dramatic decreases in renal function, defects in renal potassium clearance can always be traced back to one of these two problems.

Decreases in GFR from chronic renal insufficiency or prerenal azotemia reduce the flow through the distal tubule and can cause hyperkalemia. Decreases in renal function not associated with oliguria do not typically cause hyperkalemia. Examples of this include aminoglycoside toxicity (usually associated with hypokalemia) and chronic interstitial nephritis.

Inadequate aldosterone activity can be due to pathology at any point in the aldosterone axis. Inadequate renin production causes hypoaldosteronism and subsequently type IV renal tubular acidosis (RTA). Angiotensin-converting enzyme inhibitors and angiotensin-receptor blockers prevent angiotensin II from stimulating the release of aldosterone. Since serum potassium itself can directly stimulate aldosterone release, most patients can maintain potassium homeostasis despite the loss of angiotensin II. However, patients with other defects in potassium handling (e.g., renal insufficiency or decreased insulin) can become hyperkalemic.[82]

Ketoconazole and heparin cause hyperkalemia by blocking aldosterone synthesis. Spironolactone and eplerenone act as competitive inhibitors of aldosterone. Calcineurin inhibitors cause hyperkalemia in a subset of patients, possibly by inducing tubular insensitivity to aldosterone.[83,84] Potassium-sparing diuretics such as amiloride and triamterene and the antibiotic trimethoprim all block collecting tubule sodium channels, decreasing potassium secretion.[85] Distal RTA usually causes hypokalemia; however, one subtype causes hyperkalemia due to a defect in sodium resorption at the cortical collecting duct. This is different from type IV RTA and does not respond to supplemental mineralocorticoids. This defect has been reported in chronic urinary tract obstruction, lupus, and sickle cell anemia. [86,87]

CLINICAL SEQUELAE

The potassium concentrations inside and outside of the cell are the primary determinants of the cellular resting membrane potential (E_m). Changes in the extracellular concentration can have dramatic effects on the resting membrane potential and the cell's ability to depolarize. As extracellular potassium rises, the normally negative E_m increases toward zero; this allows easier depolarization (i.e., increased excitability). However, this excitability is short-lived as chronic hyperkalemia ultimately inactivates the sodium channels critical to producing an action potential. Hyperkalemia shortens the refractory period following depolarization by facilitating faster potassium uptake.

In the myocardium, inactivated sodium channels slow conduction velocity, and high serum potassium speeds repolarization. On ECG, hyperkalemia causes widened QRS complexes (slowed conduction velocity) and shortened ST intervals with tented T waves (rapid repolarization). The slowed conduction associated with rapid repolarization predisposes the myocardium to ventricular fibrillation.

While animal models and experimental protocols document a stepwise progression of ECG changes from peaked T waves to widened QRS to disappearance of P waves, and ultimately a sinusoidal ECG, clinically patients may develop symptomatic arrhythmias without prior ECG changes.[88] Rapid increases in potassium, hyponatremia, hypocalcemia, and metabolic acidosis all increase the likelihood of arrhythmia.[89–92]

Ascending paralysis mimicking Guillain-Barré syndrome has been documented with a serum potassium of 7 mmol/L. In a review of all published cases of hyperkalemic paralysis (excluding hereditary periodic paralysis) the average

TABLE 76-7 Time Course, Expected Decrement of Potassium, and Side Effects of Each Therapy

Treatment	Dose	Onset	Duration	Magnitude	Side Effects
Calcium[a]	1 g (10 mL) of 10% calcium gluconate or calcium chloride; may repeat	Immediate (documented normalization of ECG as early as 15 s)	30–60 min		Caution/contraindicated in hypercalcemia and digoxin toxicity
Insulin and glucose[a]	10 U of regular insulin and 50 g of glucose; can omit the glucose if the patient is hyperglycemic	Significant reduction at 15 min;[a] peak action at 60 min[d]	>6 h (potassium still decreased by 0.76 mmol/L at 6 h)[e]	1 mmol/L	Hypoglycemia and hyperglycemia; hyperglycemia may increase serum potassium through solute drag
Albuterol IV[f]	0.5% mg in 100 mL of 5% dextrose solution infused over 15 min	Onset and peak action at 30 mins	6 h	1–1.5 mEq/L	Tachycardia, variable changes in BP, tremor; rise in blood glucose and insulin; rise in serum potassium in the first minute after MDI spacer use; rise averaged only 0.15 mmol/L, but 59% had a rise of at least 0.1 mmol/L and two had a rise of >0.4 mmol/L
Albuterol nebulized[g]	10–20 mg in 5 mL of normal saline inhaled over 10–15 min	5–10 min with peak action at 30–120 min	3–6 h		
Albuterol MDI with spacer[h]	1200 μg via MDI	3–5 min with potassium falling at end of study	Only one study and test ended at 60 min; K was still trending down	≥0.4 mmol/L	
Sodium bicarbonate	4-mEq/min drip for a total of 400 mEq; note: lower doses, 50–100 mEq have been shown to be ineffective	240 min;[i] note: the prolonged time for onset of hypokalemic effect	Potassium was still falling at end of 6-h study	0.6 at 4 h 0.74 mmol/L at 6 h	May precipitate tetany by decreasing ionized calcium; may antagonize cardioprotective effect of calcium

Data from these references: [a] Campieri et al,[256] [b] Allon et al,[100] [c] Allon et al,[106] [d] Lens et al,[257] [e] Mahajan et al,[110] [f] Montoliu et al,[103] [g] Montoliu et al,[102] [h] Mandelberg et al,[101] and [i] Blumberg et al.[258]

potassium was 9 mmol/L. The use of potassium-sparing diuretics was the etiology of the hyperkalemia in over half of the cases. Electromyograms showed the paralysis to be due to abnormal nerve depolarization rather than muscle pathology.[93]

DIAGNOSIS

The high intracellular potassium content results in frequent misdiagnosis of hyperkalemia. The most common cause is hemolysis following the blood draw. The lab should report this, as it is easy to detect. Increased platelets or white cells can also release potassium, especially if the specimen is allowed to clot. Thrombocytosis greater than 1,000,000 platelets or leukocytosis over 100,000 increase the likelihood of pseudohyperkalemia. Rarely, counts as low as 600,000 platelets or 70,000 leukocytes have been reported to cause the same phenomenon.[94] The other major cause of pseudohyperkalemia is fist pumping prior to phlebotomy. Forearm exercise in the presence of a tourniquet can falsely elevate potassium by 1.4 mmol/L.[95]

In the diagnosis of hyperkalemia, urine chemistries have a limited role since they are primarily useful for differentiating decreased renal excretion from increased potassium loads. Increased potassium loads, whether endogenous or exogenous, rarely are an occult cause of persistent hyperkalemia, and so the urinary chemistries nearly always point to inappropriate renal handling of potassium.

TREATMENT

The decision of when and how to treat hyperkalemia should be based on physical signs, the clinical situation, and serum potassium. Individual tolerances of hyperkalemia can vary dramatically and are influenced by pH, calcium concentration, rate of potassium rise, and underlying heart disease. Patients with rapid increases in serum potassium or hypocalcemia may have arrhythmias at serum potassium levels as low as 7 mmol/L, while newborns regularly tolerate potassium concentrations of that level. Patients with muscle weakness or ECG changes consistent with hyperkalemia should be urgently treated. Modestly elevated potassium in the absence of ECG or muscle weakness can be treated more conservatively (Table 76-7).

First-line therapy for hyperkalemia should be stopping any and all potassium sources. Total parenteral nutrition, potassium supplements, transfusions, and medications containing potassium should be stopped. Patients already on peritoneal dialysis with potassium added to the peritoneal fluid should be switched to potassium-free fluid. Patients on continuous renal replacement therapies need to have the replacement fluid potassium verified and removed.

Calcium

Calcium reverses the ECG changes seen in hyperkalemia and decreases the risk of arrhythmia. Both calcium chloride and calcium gluconate can be used, but the chloride formulation has three times the elemental calcium (0.225 mmol/mL vs. 0.68 mmol/mL of a 10% solution). Since the cardioprotective effect of calcium has been shown to be dose dependent it is presumed that the chloride salt is more effective than the gluconate.[96] The downside of calcium chloride is that it is more irritating to veins. Both compounds cause tissue

necrosis if extravasated. The onset of action is immediate and duration is approximately 1 hour. If, following a dose of IV calcium, hyperkalemic ECG changes persist, the calcium should be repeated. In animal studies, calcium channel blockers ablate the cardioprotective effect of calcium.[96,97]

Calcium may be contraindicated in hyperkalemia due to digitalis toxicity.[98] Digitalis toxicity is associated with intracellular hypercalcemia. Theoretically, additional calcium can worsen the toxicity and precipitate arrhythmias. Clinical data to support this are scant. Bower and Mengle reported two cases of cardiovascular collapse and death following the administration of calcium in digitalized patients, but no information on digitalis levels, serum calcium, or potassium concentrations was provided.[99] Digitalis toxicity with hyperkalemia should be treated with digoxin FAB to rapidly remove the drug (improvement within 2 hours).

Transcellular Redistribution

The fastest method to reduce serum potassium is to induce a transcellular shift. IV insulin with glucose (to prevent hypoglycemia) will reduce potassium within 15 minutes and the lower serum levels persist for up to 6 hours.[100] This treatment can be repeated. The primary side effect is hypoglycemia.

Albuterol has been used to stimulate β_2 receptors and produce a transcellular shift of potassium. Albuterol has been shown to be effective when given IV, by nebulizer, or by metered dose inhaler with spacer.[101–103] One concern is the β-selectivity of albuterol. α-Agonists increase serum potassium. Two studies that looked at potassium immediately after administration of albuterol showed a brief increase in serum potassium.[101,104] A short-lived predominance of α activity immediately following administration of albuterol may account for the increase in serum potassium.

Combining therapies is additive but not synergistic. Combining albuterol and insulin/glucose is particularly appealing, as albuterol decreases the incidence of hypoglycemia.[105] In a well controlled trial the use of insulin and glucose with albuterol was twice as efficacious than either drug alone (1.2 mmol/L at 1 hour vs. 0.6 mmol/L).[106]

Bicarbonate has long been listed as a way to induce an intracellular potassium shift, based primarily on case reports and small trials.[107,108] Recent data have shown bicarbonate to be an ineffective agent for the treatment of hyperkalemia. Blumberg and associates found an increase in potassium of 0.2 mmol/L following bicarbonate infusions, regardless whether isotonic or hypertonic bicarbonate was used.[109] Sodium bicarbonate also was ineffective in patients with low serum bicarbonate. Additionally, increased pH lowers ionized calcium, increasing the risk of arrhythmia with hyperkalemia.

Other strategies to induce a transcellular shift include epinephrine infusions and aminophylline; however, both of these therapies are less effective than insulin and glucose.[109,110]

In patients with cardiac arrest, the ability to induce a transcellular shift is reduced.[111] This may be due to decreased blood flow to skeletal muscle and the liver, which are the primary tissues involved in cellular redistribution.[112]

Enhanced GI Clearance of Potassium

In addition to inducing a transcellular shift of potassium, patients with increases in total body potassium must get specific therapy to remove potassium from the body. Cation exchange resins can enhance intestinal potassium excretion. Sodium polystyrene (SPS) resins bind approximately 1 mEq of potassium per gram of resin. SPS maximally absorbs potassium when given orally, but enemas are effective.[113] When given at doses of 20 to 40 g, SPS resins can be effective at treating acute hyperkalemia after calcium and intracellular shift treatments have been initiated. Two recent studies have questioned the effectiveness of SPS resins, but until larger studies corroborate these findings, SPS resins remain part of the therapy for acute hyperkalemia.[114,98] SPS and sorbitol usage have rarely been associated with intestinal necrosis.[115–117]

Enhanced Renal Clearance of Potassium

In patients with decreased renal excretion of potassium, but adequate GFR, the kidneys may be used to increase potassium excretion. The best way to increase renal potassium excretion is to increase distal delivery of sodium and increase tubular flow by increasing sodium intake and using loop diuretics. Potassium-sparing diuretics should be stopped.

Dialysis

In cases of severe hyperkalemia hemodialysis is the best method to remove potassium from the body. In a study comparing various therapeutic regimens for hyperkalemia, Blumberg and colleagues found hemodialysis to be faster than insulin and glucose, with 1-hour reductions of serum potassium of 1.34 mmol/L.[109] Higher serum potassium concentrations enhance dialytic clearance of potassium. A 4-hour dialysis session with a potassium bath of 1 mmol/L can be expected to remove between 60 and 140 mmol of potassium.[118] Following dialysis the serum concentration rises significantly. Therapies that shift potassium into cells decrease the effectiveness of dialysis and increase the post-rebound serum potassium.[118] There is concern that dialyzing patients prone to cardiac arrhythmias against a low potassium dialysate may precipitate arrhythmias. In a randomized controlled trial, potassium modeling (stepwise lowering of the potassium bath during treatment) reduced premature ventricular contractions (PVCs) and PVC couplets during dialysis.[119] The use of intermittent dialysis has been successful in the face of cardiac arrest. In one case of ventricular fibrillation due to hyperkalemia, CPR provided adequate blood pressure to dialyze the patient. Cardiac function was restored after 25 minutes of dialysis.[120]

Continuous renal replacement therapy (CRRT) is also effective at reducing potassium and is better tolerated than intermittent hemodialysis in unstable patients. CRRT has been used to successfully treat hyperkalemic asystole.[121]

Other Issues in the Treatment of Hypokalemia

An important factor to consider when adopting a treatment strategy for hyperkalemia is whether the source of potassium is transient (e.g., potassium overdose) or continuous (e.g., limb or gut ischemia). In the latter situation the use of intermittent hemodialysis will provide temporary correction followed by recurrent hyperkalemia. CRRT offers a unique advantage in this situation as it prevents rebound hyperkalemia. In cases of severe hyperkalemia from a continuous potassium leak, one should consider mixed modalities: initiating intermittent hemodialysis to rapidly correct the hyperkalemia, followed by CRRT to prevent rebound hyperkalemia.

There are multiple cases in the literature of patients with remarkable neurologic recovery despite prolonged resuscitative efforts.[111,122,123] Patients with hyperkalemic cardiac arrest may have better outcomes than generally associated with

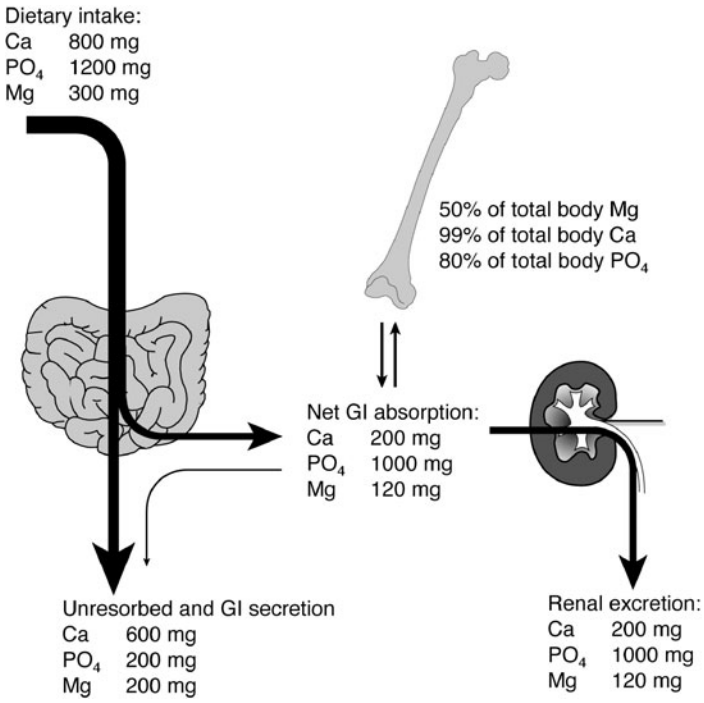

FIGURE 76-11 Calcium, phosphorus, and magnesium have unique patterns of dietary intake, absorption, and degrees of mineralization and renal excretion. Values are typical for adult males on an American diet.

cardiac arrest and deserve aggressive and prolonged resuscitative efforts.

Calcium

Calcium is a divalent cation that regulates cellular movement, hormone release, enzyme activity, and coagulation. Calcium also plays a role in cell injury and death.[124] Ninety-nine percent of total body calcium is located in the bones and teeth. Normally, cytosolic calcium is very low, with a ratio of extracellular to intracellular ionized calcium of 10,000:1.[125]

METABOLISM

MEASURING CALCIUM

Normal serum calcium is 8.8 to 10.3 mg/dL. The molecular weight of calcium is 40; in SI units the normal range is 2.2 to 2.6 mmol/L (4.4 to 5.2 mEq/L). Forty percent of serum calcium is protein bound, primarily to albumin. An additional 10% to 15% is complexed to serum anions, such as bicarbonate, phosphate, and citrate. The remaining 45% is the physiologically active, *ionized* fraction.[126] Normal ionized calcium is 4.0 to 5.2 mg/dL (1.0 to 1.3 mmol/L). Decreases in albumin lower total serum calcium without affecting ionized calcium. Likewise, increases in albumin or globulins cause meaningless increases in total calcium, while the calcium regulatory mechanism maintains a normal ionized calcium.[127,128] Increases in pH enhance calcium binding to albumin, lowering ionized calcium; decreases in pH have the opposite effect. Free fatty acids, either from lipid infusions or endogenous lipolysis, increase calcium binding by albumin, lowering ionized calcium.[129] Despite widespread use of formulas to adjust total calcium for albumin and pH, these have been shown to be poor predictors of ionized calcium. In patients in whom total calcium is borderline or there is suspicion of disordered protein-calcium binding, an ionized calcium level should be measured.[130,131]

CALCIUM REGULATION

Regulation of calcium balance begins with control of dietary absorption. Net calcium absorption is 100 to 200 mg per day (Fig. 76-11). Normally, people are in calcium balance and absorbed calcium is excreted in the urine. Parathyroid hormone (PTH), calcitriol, calcitonin, estrogen, and testosterone regulate calcium balance. The effects of estrogen and testosterone are complex, poorly understood, and will not be discussed here.

PTH is a peptide hormone released from the parathyroid glands in response to ionized hypocalcemia (Fig. 76-12). Elevated calcium, magnesium, and calcitriol all suppress PTH release. PTH minimizes urinary calcium excretion, stimulates the conversion of 25-hydroxyvitamin D to 1,25-dihydroxyvitamin D (calcitriol) by the kidney, and in conjunction with calcitriol, mobilizes calcium from bone.

Vitamin D is ingested or synthesized in the skin. In order for vitamin D to become metabolically active it must be hydroxylated, first in the liver, and then in the kidney, to form calcitriol. Calcitriol increases dietary absorption of both calcium and phosphorus and is active in bone metabolism. Calcitriol inhibits PTH release.

Calcitonin is a 32-amino acid peptide that decreases serum calcium.

RENAL HANDLING OF CALCIUM

Both ionized and complexed calcium, representing 55% to 60% of total calcium, are freely filtered at the glomerulus. Nearly all of this filtered calcium (98%) is resorbed by the tubules (Fig. 76-13). In the proximal tubule, calcium is resorbed with sodium. Increased proximal sodium resorption, as occurs with volume depletion, increases calcium resorption. Typically two-thirds of filtered calcium is resorbed by the proximal tubules. Calcium resorption in the TALH is

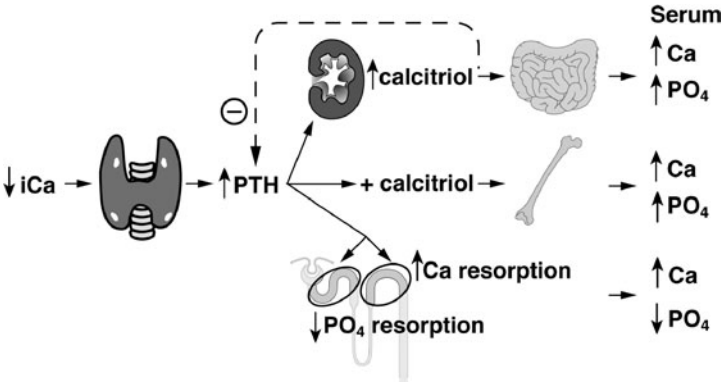

FIGURE 76-12 Decreased ionized calcium stimulates parathyroid hormone release from the parathyroid gland. PTH acts on three targets: it stimulates 1-α-hydroxylase to increase calcitriol synthesis, which increases GI calcium and PO_4 (phosphate) absorption (calcitriol also inhibits PTH secretion); in concert with calcitriol PTH stimulates bone resorption, releasing calcium and PO_4; PTH increases tubular resorption of calcium and decreases tubular resorption of phosphorus, increasing serum calcium and lowering serum phosphorus.

primarily passive, down an electrical gradient created by the Na-K-2Cl carrier and the renal outer medulla potassium (ROMK) channel (Fig. 76-14). The distal convoluted tubule (DCT) is the only area where calcium can be resorbed independent of sodium. PTH increases permeability of the paracellular tight junctions to calcium. PTH and calcitriol both stimulate calcium resorption in the DCT.

HYPOCALCEMIA

Hypocalcemia is common among ICU patients, with prevalence reported to be 20% to 88%.[131–133] Hypocalcemia is more frequent with increased severity of illness and is associated with increased mortality.[132,133]

ETIOLOGIES

Broadly speaking, hypocalcemia occurs when calcium moves out of the vascular space faster than it can be repleted by diet or the mobilization of skeletal calcium. Calcium enters the vascular space via diet or bone resorption. Calcium leaves the vascular space via renal excretion or deposition in bones and soft tissue. In addition, increased pH or chelation by anions can acutely drop the ionized calcium. The etiologies of hypocalcemia are summarized in Table 76-8.

Calcium Deposition

Deposition of calcium in tissues can occur with sudden increases in phosphorus.[134] Tumor lysis syndrome releases a large amount of intracellular phosphorus that binds ionized calcium. Phosphorus overdoses from enemas (especially if mistakenly taken orally) cause hypocalcemia due to the hyperphosphatemia.[134–136] Pancreatitis results in increased serum lipase, resulting in increased free fatty acids that chelate ionized calcium. In addition, pancreatitis is associated with increased calcitonin and decreased PTH, both of which contribute to hypocalcemia.

The citrate used to preserve blood transfusions can bind calcium and causes ionized hypocalcemia. It is normally rapidly metabolized and well tolerated, despite transient decreases in calcium; 10% of patients transiently have ionized calcium levels less than 1 mmol/L.[137] Factors that inhibit citrate metabolism (liver failure, kidney failure, or hypothermia) or rapid or large transfusions predispose patients to

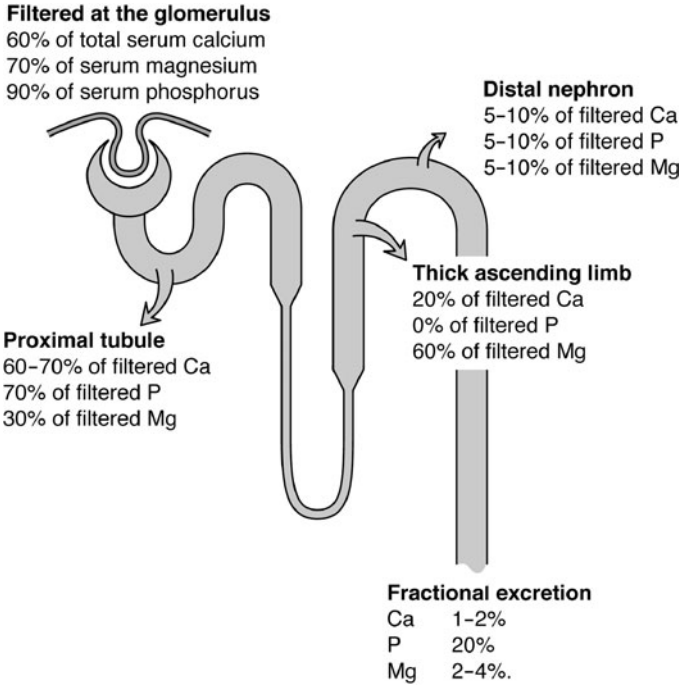

FIGURE 76-13 Renal handling of calcium, phosphorus, and magnesium varies in each segment of the nephron.

TABLE 76-8 Etiologies of Hypocalcemia

Decreased Intestinal Absorption	Increased Renal Excretion	Tissue Deposition/ Serum Complexes
Vitamin D deficiency	Hypoparathyroidism	Citrate
25-D deficiency	Congenital	EDTA
Low sunlight exposure	Mutations of the calciumsensing receptor	Radiocontrast agents (gadolinium causes a pseudohypocalcemia)[d]
Liver disease	DiGeorge syndrome	Pancreatitis
Phenytoin	Pseudohypoparathyroidism	Hyperphosphatemia
Phenobarbital	Acquired	Hungry bone syndrome
Malabsorption	Surgical hypoparathyroidism	Osteoblastic metastatic lesions
Nephrotic syndrome	APECED	Breast cancer
Gastrectomy[a]	Hypermagnesemia	Pancreatic cancer
1,25 D deficiency	Hemochromatosis	Other
Renal failure	Granulomatous diseases	Pentamidine
Ketoconazole	Neoplastic infiltration	Asparaginase
Hydroxychloroquine	Amyloidosis	Doxorubicin
5-Fluorouracil	Wilson's disease	Fluoride
Leucovorin	Hyperthyroidism (thyroid crisis)[b]	
	Cimetidine[c]

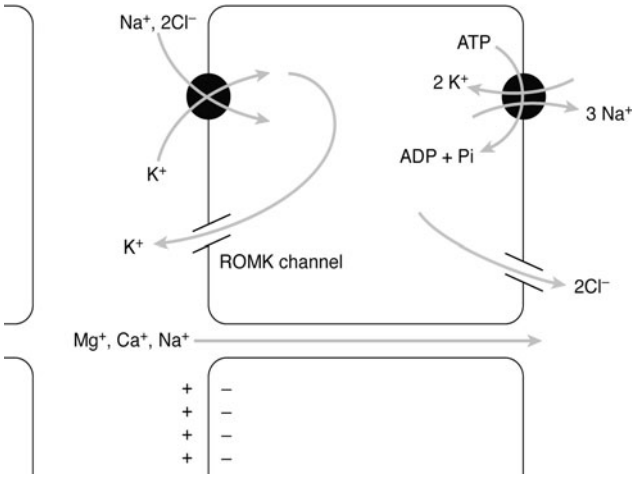
APECED, autoimmune polyendocrinopathy-candidiasis-ectodermal dysplasia syndrome; EDTA ethylenediamine tetraacetic acid.



hypocalcemia. Plasmapheresis can use large amounts of citrate, predisposing patients to ionized hypocalcemia.[138]

Hypoparathyroidism

Hypoparathyroidism increases renal calcium excretion and prevents the mobilization of skeletal calcium. The most common cause of acquired hypoparathyroidism is neck surgery. Following thyroidectomy, the parathyroid gland often stops releasing PTH. This hypoparathyroidism may be temporary or permanent. Hypoparathyroidism can follow radiation therapy, as well as autoimmune, infiltrative, and granulomatous diseases. Following parathyroidectomy for primary or tertiary hyperparathyroidism there may be widespread osteoblastic activity, resulting in hypocalcemia, hypomagnesemia, and hypokalemia. This is termed *hungry bone syndrome* and is due to the rapid mineralization of osteoid. The hypocalcemia can last for months.

Disorders of magnesium can decrease PTH activity. Modest hypomagnesemia decreases end-organ responsiveness to PTH, while more severe hypomagnesemia suppresses PTH release.[139] At high concentrations (>5 mg/dL) magnesium binds the calcium-sensing receptor on the parathyroid gland, imitating hypercalcemia, directly suppressing PTH release.

FIGURE 76-14 The thick ascending limb of the loop of Henle (TALH). Calcium and magnesium are both resorbed through the paracellular space down an electrical gradient. The Na-K-2Cl carrier paired with the apical potassium channel, ROMK, generates the positive potential difference. The Na-K-2Cl carrier itself is not electrogenic because the two cations are balanced by the two chloride anions, but since potassium is recycled through the ROMK channel, the net movement of charge is one anion leaving the tubule, which generates a positive potential difference. Factors that block either the Na-K-2Cl carrier (e.g., furosemide) or the ROMK channel (e.g., hypercalcemia or magnesium depletion) increase renal excretion of calcium and magnesium. ADP, adenosine diphosphate; ATP, adenosine triphosphate; Pi, inorganic phosphate.

Vitamin D Deficiency

Acute hypocalcemia with vitamin D deficiency occurs because of the inability to mobilize skeletal reserves of calcium. Vitamin D deficiency is common among nursing home patients, alcoholics, and malnourished patients. Increased hepatic metabolism of vitamin D occurs in patients on phenytoin and phenobarbital. The nephrotic syndrome is commonly associated with hypocalcemia, though most of this is due to hypoalbuminemia. Ionized hypocalcemia occurs due to the loss of 25-hydroxyvitamin D and its binding protein in the urine. Decreased activation of 25-hydroxyvitamin D occurs with renal failure and hypoparathyroidism.

Critical Illness

Hypocalcemia is a pervasive disorder in the ICU. While hypocalcemia was thought to be limited to patients with sepsis, Zivin and associates have shown hypocalcemia to be common in all patients with severe illness.[133] However, despite careful assessment, a definitive etiology can be found in less

than half of the patients.[132] Some authors believe that ICU-associated hypocalcemia (ICU-H) is an adaptive beneficial response to critical illness, as it may prevent intracellular hypercalcemia and associated tissue damage.[140] While not describing all patients with ICU-H, most patients have elevated levels of PTH and low levels of calcitriol.[141,142] Elevated levels of procalcitonin have also been found in ICU-H, leading some authors to wonder if this supposedly calcium-neutral precursor to calcitonin may exert a hypocalcemic effect.[142]

CLINICAL SEQUELAE

The primary manifestation of hypocalemia is neuromuscular irritability. This can range from perioral numbness and acral paresthesias to severe tetany and seizures. Seizures can occur in the absence of any other neuromuscular irritability. Grand mal, petit mal, and focal seizures have all been reported.

Tetany classically affects the upper extremities followed by the lower extremities. Patients typically demonstrate elbow extension, wrist flexion, and metacarpophalangeal flexion.[135] Tetany can cause laryngospasm or bronchospasm, resulting in respiratory failure. The classic signs of latent tetany are Trousseau's sign (carpal spasm after inflation of a blood pressure cuff on the arm and leaving it in place for 3 minutes) and Chvostek's sign (facial spasm induced by tapping on the facial nerve at the temple). The sensitivity of both is poor and the specificity of Chvostek's is particularly poor (a partial Chvostek's sign is found in 25% of eucalcemic individuals).[143] Tetany may be masked by anticonvulsant therapy.

Acute hypocalcemia can cause heart failure. Even modest hypocalcemia can precipitate heart failure and hypotension in patients with latent cardiac damage. These serious findings can precede tetany.[144] The classic electrocardiogram findings of hypocalcemia are bradycardia, prolonged QT interval, and inversion of the T wave.[138] Heart block and cardiac arrest have also been documented. The electrocardiogram is not a sensitive marker of hypocalcemia and may be normal during life-threatening hypocalcemia.

Hypotension can occur following loss of vascular tone. In one ICU study, decreased ionized calcium correlated with decreased mean arterial pressures. Digitalis acts by increasing intracellular calcium. Hypocalcemia is a cause of digitalis resistance. Patients can sometimes tolerate toxic digitalis levels with concurrent hypocalcemia. Correction of this protective hypocalcemia can precipitate arrhythmias due to digitalis toxicity.

TREATMENT

When to Treat

Unique to calcium among all electrolyte disorders is the theory that hypocalcemia may be an adaptive response to critical illness, and because of this the treatment of ICU-associated hypocalcemia (ICU-H) is controversial.[140] Care must be taken not to extrapolate this controversy to patients in whom the etiology of their hypocalcemia is understood (e.g., acute hypoparathyroidism, tumor lysis syndrome, or acute renal failure). Patients with chronic hypocalcemia and myocardial dysfunction should be given a trial of calcium supplementation. Patients with asymptomatic hypocalcemia secondary to surgical hypoparathyroidism had improved cardiac function with calcium infusions.[145] Calcium should be repleted in cases of seizures, tetany, laryngospasm, and hyperkalemia.[146] Among asymptomatic patients, the risk of significant clinical symptoms rises as the ionized calcium falls below 3 mg/dL, and treatment is warranted in these patients.[125]

The controversy regarding the treatment of ICU-H is due to in vitro data that show intracellular calcium to be a mediator of cell injury in reperfusion and sepsis models. Abbott and colleagues looked at calcium in relation to reperfusion in isolated rat hearts and found that calcium infusion immediately following reperfusion increased mitochondrial damage and decreased cardiac function.[147] In addition, animal studies have repeatedly shown that administering calcium to hypocalcemic septic rats improves blood pressure but *increases mortality*.[148,149] The increased mortality was not reproduced in septic pigs and more recent research has questioned the appropriateness of the rat as an animal model for human sepsis.[150,151]

In critically ill hypocalcemic patients with life-threatening hypotension that is resistant to other therapies (e.g., pressors, volume resuscitation, and inotropes), a trial of IV calcium may be considered. In a study of 12 hypocalcemic patients with bacterial sepsis, seven were hypotensive despite volume resuscitation and dopamine and norepinephrine infusions. Correcting hypocalcemia restored normal blood pressure in all seven patients. Cardiac output, systemic vascular resistance, and urine output all improved following the calcium.[141] However, no studies have been done to assess whether treating ICU-H affects mortality.

It is important to note that all of the negative data on replacing calcium come from studies of sepsis in animals. The applicability to the human population with ICU-H is unclear. The multifactorial etiology of ICU-H is accepted, and it is likely that benefits of treatment vary with the etiology.

How to Treat

Patients with asymptomatic mild hypocalcemia (ionized calcium >3.2 mg/dL) can be treated with increased dietary calcium (Table 76-9). Increases of 1000 mg per day are appropriate. The 25-hydroxyvitamin D level should be checked and patients placed on vitamin D if low. In patients with renal failure, treating the hyperphosphatemia and decreased calcitriol levels will help correct the hypocalcemia.

Severe or symptomatic hypocalcemia should be treated with an infusion of 100 to 200 mg of elemental calcium. This should be given over 10 to 20 minutes to avoid cardiac toxicity. This initial infusion tends to suppress symptoms longer than it maintains a normal calcium level. In order to prevent rebound hypocalcemia a calcium infusion should be started at 0.5 to 1.5 mg elemental calcium/kg per hour (Table 76-10).

TABLE 76-9 Oral Formulations for Hypocalcemia

Agent	Elemental Calcium	How Supplied
Calcium glubionate	64 mg/g	1.8 g/5 mL
Calcium gluconate	90 mg/g	500–1000 mg tab
Calcium lactate	130 mg/g	325–650 mg tab
Calcium citrate	211 mg/g	950 mg tab
Calcium acetate	253 mg/g	667 mg tab
Calcium carbonate	400 mg/g	650–1500 mg tab
Vitamin D requirements	1 μg = 40 IU	
RDA	10 μg	400 IU
For D deficiency	40–50 μg/d	1600 IU/d

RDA, recommended daily allowance.

TABLE 76-10 Parenteral Calcium Formulations

Agent	Supplied	Elemental Ca per mL	Elemental Ca per Gram	
Calcium gluconate	1 g in 10 mL	9 mg/mL	90 mg	4.5 mEq
Calcium chloride	1 g in 10 mL	27.2 mg/mL	272 mg	13.6 mEq
Calcium gluceptate	1 g in 5 mL	18 mg/mL	90 mg	4.5 mEq

Two forms of parenteral calcium are commonly available: calcium gluconate and calcium chloride. Concerns that calcium gluconate requires hepatic metabolism have not been borne out.[152] In a randomized, double-blind trial of the two calcium salts in critically ill children, the chloride salt resulted in a higher and more consistent rise in ionized calcium levels. All of the patients receiving the chloride salt had an increase in ionized calcium versus 65% of the gluconate group.[153] Calcium chloride is caustic to veins and should be reserved for central access. Calcium gluconate can safely be infused peripherally. Both calcium compounds can cause tissue necrosis if extravasated.

Other Treatment Issues

Treatment of hypocalcemia can precipitate arrhythmias, especially in patients on digitalis. Other complications reported from treating hypocalcemia include bradycardia, pancreatitis, and vasospasm.[154]

When hypocalcemia is due to hyperphosphatemia there is concern that providing calcium could accelerate metastatic soft-tissue calcification. The degree to which this occurs is unclear. In the face of hyperphosphatemia, calcium should be limited to reversing acute toxicity (tetany, laryngospasm, and arrhythmias) and full correction of hypocalcemia should be delayed until the phosphorus is normalized.[134]

Hypomagnesemia can contribute to hypocalcemia so patients should have a magnesium level checked and repleted if low.[139] There have been reports of magnesium-responsive hypocalcemia despite normal serum magnesium levels. This is thought to be due to total body magnesium depletion despite normal serum levels (see section on the diagnosis of hypomagnesemia below for details).

The principal therapy for hypocalcemia due to citrate toxicity is metabolism of the citrate. Citrate metabolism occurs via temperature-dependent enzymes so correcting hypothermia improves hepatic metabolism. Steps to improve hypotension and hepatic blood flow should be taken. Saline loading in order to increase renal clearance may speed recovery. Be aware that saline loading will also increase renal calcium excretion. About 20% of citrate is excreted unmetabolized in the urine.

HYPERCALCEMIA

ETIOLOGIES

Hypercalcemia is a relatively common clinical finding. Hypercalcemia occurs when calcium enters the vascular compartment faster than it can be excreted. There are two mechanisms by which calcium enters the vascular space: calcitriol-mediated gut absorption and bone resorption. Likewise, there are two means by which calcium is removed from the vascular space: deposition in tissue and excretion in urine.

The most common cause of hypercalcemia is primary hyperparathyroidism, while malignancy is a distant second. Among hospitalized patients, however, this ratio is reversed, with cancer accounting for 65% of cases and hyperparathyroidism 25%. One series found milk-alkali syndrome to account for up to 12% of patients hospitalized for hypercalcemia.[155] A summary of the etiologies of hypercalcemia are listed in Table 76-11.

Increased Intake

Increased dietary intake alone rarely causes hypercalcemia because the kidney is able to increase calcium excretion dramatically. Increased intake causes hypercalcemia in patients with renal failure or in patients in whom the kidney is prevented from excreting calcium.

Milk-Alkali Syndrome

The milk-alkali syndrome (MAS) is defined by three concurrent findings: hypercalcemia, metabolic alkalosis, and renal insufficiency, and is due to the ingestion of calcium and alkali.[155] In the modern era, patients are typically women being treated for osteoporosis with calcium carbonate, which supplies both the calcium and the alkali. Historically, MAS was characterized by hyperphosphatemia due to the high phosphorus content of milk. In modern MAS, the calcium is a pharmaceutical product without phosphorus and patients tend to be hypophosphatemic, which stimulates calcitriol production, increasing calcium absorption. The hypercalcemia typically responds to stopping alkali and calcium ingestion. Additionally, saline infusions and loop diuretics are effective treatments.[155]

Endogenous Calcitriol Production

Calcitriol synthesis can be increased by chronic granulomatous disorders (e.g., tuberculosis or sarcoidosis), lymphomas, and acromegaly.[156,157] Macrophages found in granulomas convert 25-hydroxyvitamin D to calcitriol despite low PTH levels. Both Hodgkin's disease and non-Hodgkin's lymphoma can cause hypercalcemia by endogenous production of 1,25-dihydroxyvitamin D.

Increased Bone Resorption

Malignancy is the most common cause of inpatient hypercalcemia. Ten to twenty percent of patients with cancer develop hypercalcemia. The most common associated malignancies are breast cancer, lung cancer, and multiple myeloma. There are three primary mechanisms for increased bone resorption in malignancy:

1. Local osteolysis from bone metastasis
2. Tumor secretion of PTH-related peptide (PTH-rP), often called humoral hypercalcemia
3. Tumor-induced hydroxylation of 25-hydroxyvitamin D to calcitriol

PTH-rP is the most common cause of hypercalcemia of malignancy. PTH-rP is a physiologic protein that is normally

TABLE 76-11 Etiologies of Hypercalcemia

Increased Intestinal Intake	Increased Bone Resorption	Decreased Renal Excretion	Miscellaneous
Increased calcium intake	Hyperparathyroidism	Thiazide diuretics	Pheochromocytoma
Renal failure (often with vitamin D supplementation)	Primary	Familial hypocalcuric hypercalcemia	Adrenal insufficiency
Milk-alkali syndrome	Adenoma	Hyperparathyroidism	Rhabdomyolysis
Hypervitaminosis D	Hyperplasia		Theophylline toxicity
Increased intake of vitamin D or metabolites	Tertiary		Coccidioidomycosis[k]
Calcipotriol (topical treatment for psoriasis is structurally similar to 1,25-dihydroxy-vitamin D)[a]	MEN I		Pseudohypercalcemia due to thrombocytosis[l]
Chronic granulomatous disorders	MEN IIA		Human growth hormone[m]
Sarcoidosis	Lithium therapy[g]		Recovery of rhabdomyolysis-induced acute renal failure[n]
Leprosy	Malignancy		
Tuberculosis	PTH-rP (humoral hypercalcemia)		
Berylliosis	Metastasis to the bones		
Histoplasmosis	Breast cancer		
Silicon induced granulomas[b]	Prostate cancer		
Disseminated candidiasis	Langerhans cell histiocytosis[h]		
Wegener's granulomatosis[c]	Hyperthyroidism		
Brucellosis	Immobilization		
Talc granulomatosis[d]	Paget's disease		
Cat-scratch disease[e]	Estrogen and antiestrogens in metastatic breast cancer		
Hodgkin's and non-Hodgkin's lymphoma[f]	Hypervitaminosis A		
Acromegaly	Retinoic acid		
	PTH-rP in pregnancy and lactation[i]		
	Vitamin A toxicity[j]		

Data from these references: [a] Hardman et al,[263] [b] Kozeny et al,[264] [c] Bosch et al,[265] [d] Woywodt et al,[266] [e] Bosch et al,[267] [f] Seymour et al,[157] [g] Bendz et al,[268] [h] McLean et al,[269] [l] Lepre et al,[270] [j] Fishbane et al,[271] [k] Westphal,[272] [l] Howard et al,[273] [m] Knox et al,[274] and [n] Meneghini et al.[275] MEN, multiple endocrine neoplasia; PTH-rP, parathyroid-hormone–related peptide.

involved in the synthesis and development of cartilage. PTH-rP causes hypercalcemia by binding to PTH receptors. Though similar in structure to PTH, PTH-rP is not measured by PTH assays and requires a specific blood test. Hypercalcemia from PTH-rP is most common in nonmetastatic solid tumors, non-Hodgkin's lymphoma, chronic myeloid leukemia (blast phase), and adult T-cell lymphoma.

Hyperparathyroidism

Primary hyperparathyroidism is the most frequent cause of hypercalcemia. Mild hypercalcemia, hypophosphatemia, and elevated PTH are the hallmarks of this condition. Generally patients have three normal parathyroid glands with one large gland containing a functional adenoma. However, in 15% of cases there will be hyperplasia of all four glands. Parathyroid cancer accounts for less than 1% of primary hyperparathyroidism. Surgery to remove the autonomous gland is the preferred treatment, and in cases of diffuse four-gland enlargement, three and a half glands are removed. Rarely, extreme symptomatic hypercalcemia can occur with hyperparathyroidism. This is called *parathyroid crisis* and is characterized by mental status changes, severe hypercalcemia, and very high PTH levels. Surgical removal of the parathyroid tissue is indicated.

Tertiary hyperparathyroidism occurs in chronic renal failure in which chronic PTH stimuli (decreased serum calcium or decreased calcitriol) result in parathyroid glands that autonomously secrete PTH, resulting in hypercalcemia. These patients typically have four-gland hyperplasia and are resistant to medical management and require surgery.

CLINICAL SEQUELAE

Mild hypercalcemia is associated with relatively mild, nonspecific symptoms. Patients with primary hyperparathyroidism are generally asymptomatic, but may complain of weakness, fatigue, anorexia, depression, vague abdominal pain, and constipation. Gastrointestinal side effects become more severe at higher calcium levels. Hypercalcemia has been associated with increased gastrin secretion and may predispose patients to peptic ulcers. Severe hypercalcemia can cause pancreatitis.

Hypercalcemia can cause multiple forms of renal dysfunction. Long-standing hypercalcemia predisposes patients to nephrolithiasis. It also causes volume depletion by reducing sodium resorption in the TALH and decreasing the renal response to ADH. Hypercalcemia can cause acute renal failure by causing volume depletion or by vasoconstriction, reducing renal blood flow. Long-standing hypercalcemia results in irreversible renal insufficiency.

Mental status changes from mild confusion to psychosis or coma can occur in severe cases of hypercalcemia. It is clinically

TABLE 76-12 Treatment of Hypercalcemia

Drug	Dose	Onset	Effectiveness	Duration	Concerns
Saline and furosemide	Infuse saline at a rate high enough to achieve urine output of 250–300 mL/h	24–48 h	0.5–2.0 mg/dL; frequent treatment failures	3 days	Volume overload, electrolyte abnormalities
Calcitonin	4–8 IU/kg SC or IV bid–qid for 1 to 2 d	4 h	2–3 mg/dL	1–4 d	Tachyphylaxis, nausea, rash, flushing, malaise
Hemodialysis	3 h with low-calcium dialysate (0–1 mmol/L)	Significant decrease in calcium after 1 h	4–6 mg/dL in 3 h	Variable; may be repeated as needed	Cardiovascular instability from rapid decrease in calcium
Plicamycin (mithramycin)	25 μg/kg IV over 4–6 h, repeat qd	12–72 h	1–2 mg/dL per dose	2–14 d	Hepatic, renal, bone marrow toxicity; thrombocytopenia
Pamidronate[a]	Single infusion over 2, 4, or 24 h; 30 mg for Ca <12 mg/dL; 60 mg for Ca 12–13.5 mg/dL 90 mg for Ca >13.5 mg/dL	48 h with normocalcemia at 96 h	30 mg lowered Ca by 2.2 mg/dL; 60 mg lowered Ca by 3.3 mg/dL; 90 mg lowered Ca by 3.9 mg/dL	10–30 d; dosing every 2 weeks increased maintenance of normocalcemia	Limit to 30 mg in patients with renal failure; fever in 20%; hypocalcemia (asymptomatic)
Zolendronate[b]	4 mg given over 5 min; 8 mg for relapse or refractory hypercalcemia	96 h; calcium was not assessed prior to 96 h	50% remission at 4 days; 88% at 7 days	32 d for 4 mg; 43 d for 8 mg	Fever; rare (1–2%) renal insufficiency
Chloroquine[c]	250 mg bid	1–3 days	Able to normalize serum calcium in sarcoidosis	Maintenance chloroquine	Only used in patients with increased 1,25 dihydroxyvitamin D; ineffective in hypercalcemia of malignancy
Corticosteroids	Hydrocortisone 200–400 mg/d for 3–5 d	4–7 d	0.5–3 mg/dL	3–4 d	Hyperglycemia, immunosuppression, electrolyte abnormalities

Data from these references: [a] Nussbaum et al,[164] [b] Major et al,[166] and [c] Adams et al.[276]

important to note that mental status impairment can persist for days following correction of hypercalcemia.[158]

TREATMENT

The best treatment for hypercalcemia is to correct the underlying etiology. In situations in which this is not possible or specific hypocalcemic therapy is needed, the treatment should focus on the three legs of calcium physiology: calcium resorption in the kidney, calcium mobilization by the bones, and calcium absorption by the gut. A summary of therapies can be found in Table 76-12.

Calcium resorption, except in the distal convoluted tubule, is paired with sodium resorption so reducing sodium resorption will increase calcium clearance. The most effective way to do this is to infuse saline. Saline also treats the volume depletion found with hypercalcemia. Following volume repletion, loop diuretics can further reduce calcium resorption. The goal of therapy is a brisk diuresis of 250 to 300 mL/h; however, this may be difficult to achieve and poses significant risk to patients.[159] Care should be taken to monitor the patient's volume status and electrolytes. Saline and diuretics are effective short-term therapies, but significant hypercalcemia typically requires additional therapy.

Corticosteroids decrease calcium absorption at the gut and reduce extrarenal formation of calcitriol.[160] Failure of prednisone (20 to 40 mg/d) to correct the granuloma-associated hypercalcemia within 2 weeks should prompt exploration for an alternative diagnosis.[161] Chloroquine and hydroxychloroquine can block peripheral production of calcitriol and are effective treatment for sarcoid-induced hypercalcemia.[162,163] Ketoconazole has also been used in the treatment of calcitriol-induced hypercalcemia.

There are multiple pharmacologic strategies to block bone resorption. The most effective are bisphosphonates. The bisphosphonates are effective at correcting hypercalcemia of malignancy regardless of the etiology.[164] Pamidronate has achieved widespread use and has been shown to be superior in both efficacy and convenience to etidronate and clodronate.[165] Zolendronate, a newer bisphosphonate, has been shown to be superior to the maximum dose of pamidronate in two randomized controlled trials.[166] However, some have questioned the validity of these data due to the poor performance of pamidronate compared to prior trials.

Salmon calcitonin can rapidly lower serum calcium by inhibiting osteoclastic bone resorption. It also increases renal excretion of calcium. It can be given IV or SC and reduces serum calcium by 1 to 2 mg/dL within hours of administra-

tion. Unfortunately, it only works in just over half of patients with hypercalcemia of malignancy, and tachyphylaxis is common after 2 to 3 days.

Dialysis

Dialysis should be considered in patients with severe symptomatic hypercalcemia that is unresponsive to drug therapy. Low-calcium hemodialysis (dialysate calcium of 0 to 0.5 mmol/L) has repeatedly been shown to rapidly correct hypercalcemia. Calcium clearance for hemodialysis ranges from 270 to 680 mg/h. While there is a risk of rebound hypercalcemia, many patients are able to maintain normocalcemia with medical management following a single dialysis session.[167] Continuous renal replacement therapy (CRRT) has been used in cases in which rebound hypercalcemia has been a problem. CRRT can be paired with citrate regional anticoagulation, which chelates free calcium, allowing rapid and durable control of hypercalcemia.[168]

Overview

Treatment of hypercalcemia may utilize multiple modalities. Initially calcium and vitamin D preparations should be stopped. The next action should be to administer saline to restore euvolemia. In cases of endogenous calcitriol excess, steroids are an effective acute treatment and chloroquine/hydroxychloroquine or ketoconazole may be used as long-term therapies. In patients with hyperparathyroidism, surgical treatment is the definitive therapy and seldom is additional therapy required. Using bisphosphonates prior to surgery may result in severe hypocalcemia postoperatively (hungry bone syndrome). In hypercalcemia of malignancy, bisphosphonates are the standard of care, but since onset of action can be delayed up to 48 hours, calcitonin may be used as a bridge. In recalcitrant cases, saline and loop diuretics to create a brisk diuresis may be tried with careful monitoring; however, if patients are severely symptomatic, dialysis should be initiated.

Phosphorus

METABOLISM

In medicine phosphate and phosphorus are often used interchangeably, though using strict nomenclature, phosphorus refers to the element and phosphate to the PO_4^{2-} anion. Inorganic phosphorus exists as a weak acid with three protons that can dissociate: H_3PO_4, $H_2PO_4^-$, HPO_4^{2-}, and PO_4^{3-}. At a pH of 7.4 the ratio of HPO_4^{2-} to $H_2PO_4^-$ is 4:1 and the other forms are essentially nonexistent. Clinical labs report the concentration of elemental inorganic phosphorus which exists almost exclusively as phosphate (e.g., organic phospholipids and phosphorylated proteins, which represent two-thirds of all phosphorus located in the serum, are not measured in the lab assay). The normal range of phosphorus is 3 to 4.5 mg/dL. The molecular weight is 31 so the normal concentration in SI units is 1 to 1.5 mmol/L (1.7 to 2.6 mEq/L). Normal values of phosphorus vary with age (higher levels in younger people). The upper limit of normal in infants is 6.5 mg/dL and adult ranges are not found until late adolescence. The majority (80%) of phosphorus is mineralized in bone with almost all of the remainder in the intracellular compartment. Only 0.1% of total body phosphorus is in the extracellular compartment.

RENAL HANDLING OF PHOSPHORUS

Ninety percent of serum phosphorus is filtered at the glomerulus and 75% to 99% is subsequently resorbed. Na-P co-transporters in the proximal tubule resorb 70% of the filtered phosphorus. PTH and metabolic acidosis both decrease phosphate resorption by the Na-P transporters, increasing the renal excretion of phosphorus.[169] Since phosphorus is resorbed concomitantly with sodium, any factor that decreases sodium resorption will decrease the tubular resorption of phosphorus (see Fig. 76-13).

Normal phosphorus concentrations are maintained by adjusting intestinal absorption and renal excretion. Hypophosphatemia stimulates production of calcitriol, which increases intestinal phosphorus and calcium absorption. The increased calcium suppresses PTH, and decreased PTH will increase resorption of phosphorus in the proximal tubule[170] (see Fig. 76-12).

HYPOPHOSPHATEMIA

Modest degrees of hypophosphatemia are common and of little consequence. Severe hypophosphatemia, however, is rare. In a retrospective review of 55,000 serum phosphorus measurements, persistent phosphorus levels less than 1.5 mg/dL were found in only 0.2%.[171] However, hypophosphatemia was found in 10% to 30% of patients with COPD exacerbations or those admitted to the ICU.[172,173] Because only a tiny proportion of the total body phosphorus is found in the vascular space, the serum phosphorus is not a reliable indicator of total body phosphorus. Isolated hypophosphatemia without intracellular depletion is of little consequence and is usually a transient phenomenon. Severe symptoms from hypophosphatemia are due to total body phosphorus depletion. The causes of hypophosphatemia are listed in Table 76-13.

ETIOLOGIES

Transcellular redistribution is movement of phosphorus into cells. This is usually transient, and in the face of normal total body phosphorus, harmless. However, in the face of preexisting phosphorus depletion, this transcellular movement can provoke serious symptoms including death.[174] The most severe cases of hypophosphatemia due to transcellular distribution are found with refeeding syndrome. Starvation decreases total body phosphorus due to decreased dietary intake. Despite the phosphorus depletion, serum phosphorus typically remains normal as phosphorus leaks out of cells. With refeeding, insulin moves phosphorus into cells where it is consumed. Thirty-four percent of ICU patients experienced refeeding-associated hypophosphatemia after being NPO for as little as 48 hours.[175] Alcoholics admitted to the hospital also commonly suffer from refeeding syndrome. Alcoholics are often poorly nourished and have a renal phosphorus leak resulting in total body phosphorus depletion.

One of the most common causes of intracellular phosphorus redistribution is respiratory alkalosis.[171] The drop in the partial pressure of carbon dioxide results in intracellular alkalemia, which stimulates glycolysis, consuming phosphorus.[176] Metabolic alkalosis rarely causes

TABLE 76-13 Etiologies of Hypophosphatemia

Intracellular Shift of Phosphorus	Decreased Phosphorus Absorption	Increased Renal Excretion
Carbohydrate infusion	Dietary insufficiency	Alcoholism
Fructose	Malabsorption	Volume expansion/natriuretic states
Glucose	Phosphate binders	IV Bicarbonate
Glycerol	Calcium	Bicarbonaturia
Lactate	Magnesium	Glucosuria
Calcitonin	Aluminum	Diuretics
Catecholamines	Sevelamer	Acetazolamide is the most phosphaturic
Epinephrine	Lanthium	Thiazides
Dopamine	Steatorrhea	Loop diuretics[c]
Terbutaline[a]	Vitamin D deficiency	Osmotic diuretics
Albuterol	Glucocorticoids	High salt diet or saline infusion
Insulin[b]	Miscellaneous	Hyperaldosteronism
Respiratory alkalosis	Hungry bone syndrome	SIADH
Rapid cell proliferation	Burns	Fanconi syndrome
Treatment of anemia	Acetaminophen overdose	Multiple myeloma
CML in blast crisis	Bisphosphonates	Aminoglycosides
AML	Gallium nitrate	Heavy metal toxicity
AMML		Chinese herbs
Refeeding syndrome		Congenital
Rewarming hypothermia		Ifosfamide
		Cisplatin
		Cystinosis
		Wilson's disease
		Hereditary fructose intolerance
		Glucocorticoids
		Hyperparathyroidism
		Hypercalcemia
		Metabolic acidosis
		Paraneoplastic syndrome
		PTH-rP
		Tumor-induced osteomalacia
		Renal transplantation
		Acute malaria (falciparum)
		X-linked hypophosphatemic rickets (vitamin D resistant rickets)
		Xanthines

AML, acute myelogenous leukemia; AMML, acute myelomonocytic leukemia; CML, chronic myelogenous leukemia; PTH-rP, parathyroid-hormone–related peptide; SIADH, syndrome of inappropriate secretion of antidiuretic hormone.
Data from these references: [a] Brady et al,[178] [b] Winter et al,[191] and [c] Fiaccadori et al.[172]

hypophosphatemia because it typically fails to induce the intracellular alkalemia essential for the phenomenon.

Dietary insufficiency of phosphorus is rare, as phosphorus is ubiquitous in the diet and the body is efficient at reducing renal losses. Decreased dietary absorption can occur due to corticosteroids, either endogenous or therapeutic. Antacids that contain magnesium, calcium, or aluminum bind dietary phosphorus, preventing its absorption. Vitamin D deficiency decreases intestinal absorption of phosphorus and the lack of calcitriol increases PTH release (Fig. 76-15).

Phosphorus is primarily resorbed in the proximal tubules (see Fig. 76-13). PTH enhances phosphorus excretion. Since phosphate is resorbed in conjunction with sodium, any process that decreases sodium resorption (volume expansion, osmotic diuretics, or glucosuria) decreases phosphorus resorption. Diuretics that act in the proximal tubules, such as osmotic diuretics and carbonic anhydrase inhibitors, have particularly potent phosphaturic effects because they block the primary site of phosphate resorption. Any process that damages the proximal tubule will increase renal excretion of phosphorus. Fanconi's syndrome is characterized by proximal tubule dysfunction and has marked phosphaturia as one of its components. Alcoholics develop a renal leak of phosphorus, which is reversible following weeks of abstinence.[177]

Hypophosphatemia also occurs during therapy for acute bronchospasm. β_2-Agonists, steroids, and IV fluids all

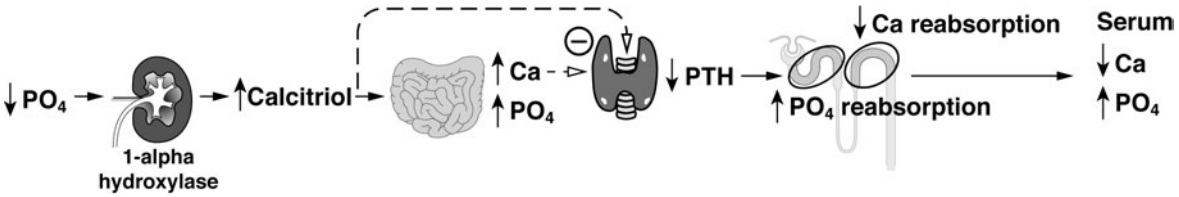


FIGURE 76-15 Decreased phosphorus directly stimulates the production of calcitriol by the kidney. Calcitriol has two principal actions: it increases gut absorption of calcium and phosphate and suppresses PTH release (the increased calcium from gut absorption also suppresses PTH release). The decreased PTH increases renal resorption of phosphorus. Increased serum phosphorus feeds back and inhibits calcitriol production.

increase renal excretion of phosphorus.[178] Since a growing body of evidence indicates that hypophosphatemia weakens muscles and impairs the ability to breathe, monitoring and replacing phosphorus in patients with obstructive pulmonary disease is prudent.[179]

CLINICAL SEQUELAE

Modest hypophosphatemia is devoid of clinical symptoms. Symptomatic hypophosphatemia generally becomes apparent as phosphorus falls below 1.0 mg/dL. Severe hypophosphatemia in the presence of intracellular phosphate depletion can result in significant cellular dysfunction. The oxygen affinity of hemoglobin is regulated by 2,3 diphosphoglycerate (2,3 DPG). Severe hypophosphatemia decreases 2,3 DPG, which increases hemoglobin's affinity for oxygen, decreasing oxygen delivery to tissues. Since phosphate is a substrate for glycolysis, intracellular phosphate depletion can slow glycolysis, decreasing ATP levels. Hypophosphatemia without intracellular phosphate depletion (i.e., transcellular redistribution) is typically benign.[180]

CNS symptoms include weakness, tremors, and paresthesias. Progressive hypophosphatemia can cause delirium, seizures, coma, and death. CNS symptoms are particularly prominent with refeeding syndrome.

Myopathy can occur due to decreased adenosine triphosphate. This can present as proximal muscle weakness, ileus, cardiomyopathy, and respiratory failure.[181] Phosphate repletion has been shown to restore cardiac contractility.[173,182] Patients with decreased total body phosphorus who undergo a superimposed intracellular shift of phosphorus resulting in severe hypophosphatemia can develop rhabdomyolysis. This classically occurs in alcoholics following hospitalization.[183] Since tissue lysis releases phosphorus, the serum phosphorus will normalize following the rhabdomyolysis.

Additionally, arrhythmias and hemolysis can occur with hypophosphatemia.[184,185]

DIAGNOSIS

A few clinical scenarios result in spurious lab results. Mannitol, multiple myeloma, and hyperbilirubinemia (>3 mg/dL) all interfere with some phosphorus assays, resulting in artifactual hypophosphatemia. Patients with very high white blood cell counts can have spurious hypophosphatemia if the specimen is allowed to clot.

Occasionally it is important to separate patients with extrarenal phosphorus losses from those with renal losses. Patients with extrarenal losses and transcellular distribution of phosphorus should have less than 100 mg (3.3 mmol) of phosphorus in a 24-hour collection. Determining the fractional resorption of phosphorus ($FrPO_4$) on a spot urine can give similar information. While $FrPO_4$ normally varies from 75% to 99%, in the face of hypophosphatemia, a $FrPO_4$ less than 95% indicates renal wasting (see Equation 76-6).

$$FrPO_4 = 100 \times \left(1 - \frac{sCr \times uPO_4}{sPO_4 \times uCr}\right)$$

Equation 76-6. The fractional resorption of phosphorus ($FrPO_4$) can be used to determine if hypophosphatemia is due to abnormal renal phosphorus loss or extrarenal phosphorus loss. A $FrPO_4$ less than 95% in the face of hypophosphatemia indicates abnormal renal phosphorus wasting. sCr, serum creatinine; sPO_4, serum phosphorus; uCr, urine creatinine; uPO_4, urine phosphorus.

TREATMENT

Patients with hypophosphatemia and depletion of phosphorus should be treated. Patients with hypophosphatemia due *solely* to a transcellular shift (e.g., respiratory alkalosis) do not need repletion of phosphorus. One should be particularly aggressive about treating hypophosphatemia in patients with septic shock. Hypophosphatemia is common in sepsis and hypophosphatemia is associated with arrhythmias in this population.[184] Animal data suggest that hypophosphatemia decreases response to vasopressors.[186] Human data have shown increased left ventricular function, systolic blood pressure, and pH following normalization of phosphorus.[173,187]

Enteral Replacement

Oral replacement of phosphorus is appropriate for patients with low serum phosphorus in the absence of acute symptoms. Dietary phosphorus can be used but care should be taken not to give phosphorus with an abundance of carbohydrates, which could precipitate an intracellular shift, worsening the hypophosphatemia. In patients with refeeding syndrome and severe hypophosphatemia, in addition to supplementing phosphorus it is important to decrease the delivery of carbohydrates (use lipids and proteins as the primary source of calories). Skim milk has a safe phosphorus:carbohydrate ratio, along with potassium, calcium, and protein needed in malnourished patients (Table 76-14).

Patients should get 1000 to 4000 mg (30 to 130 mmol) of phosphorus per day divided into three or four doses. This should replace most phosphorus deficits over 7 to 10 days. Dividing the daily dose reduces diarrhea. Since it is impossible to know the exact degree of phosphorus depletion, patients should have periodic laboratory monitoring.

Parenteral Replacement

Patients with signs or symptoms consistent with hypophosphatemia should be given IV phosphorus. Various regimens

TABLE 76-14 Phosphorus Supplements

Phosphate Source	Phosphate	Sodium	Potassium
Oral formulations			
Skim cow's milk	1 mg/mL (0.032 mmol/mL)	28 mEq/L	38 mEq/L
Neutra-Phos	250 mg/pkg (8 mmol)	7.1 mEq/pkg	7.1 mEq/pkg
Fleet Phospho-Soda	150 mg/mL (5 mmol/mL)	4800 mEq/L	
Neutra-Phos K	250 mg/cap (8 mmol)		14.25 mEq/cap
K-Phos	150 mg/cap (5 mmol)		3.65 mEq/cap
K-Phos Neutral	250 mg/tab (8 mmol)	13 mEq/tab	1.1 mEq/tab
Parenteral formulations			
Potassium phosphate	93 mg/mL (3 mmol/mL)		4.4 mEq/mL
Sodium phosphate	93 mg/mL (3 mmol/mL)	4.4 mEq/mL	

recommend giving 2.5 to 5 mg/kg over 6 hours.[188] Larger and faster doses (620 mg in an hour or 25 mg/kg in 30 minutes) have been shown to be safe and effective.[173,187] Continued vigilance is important as hypophosphatemia returns in most patients. After IV therapy, patients should be continued on oral phosphates to replenish intracellular stores.

While therapy is generally safe it is not without complications. In a randomized controlled trial of phosphorus replacement in diabetic ketoacidosis, no benefit from treatment was found in terms of speed of recovery, mental status, oxygen-carrying capacity, or 2,3 DPG levels. The only significant finding was decreased ionized calcium in the phosphorus group.[189] Complications due to therapy for hypophosphatemia include hyperphosphatemia with or without associated hypocalcemia; hyperkalemia from potassium preparations; and volume overload or hypernatremia from sodium phosphorus preparations (4.4 mmol of sodium per mL is nine times the concentration of 3% saline).[190]

HYPERPHOSPHATEMIA

The kidney is responsible for excreting excess phosphorus and is so effective at this that it is able to compensate for huge increases in daily phosphate intake. Essentially the study of hyperphosphatemia can be limited to acute phosphorus loads, generalized renal failure, and specific failure in the kidney's ability to excrete phosphorus.

ETIOLOGIES

Increased Intake of Phosphorus

The ability to maintain phosphorus balance in the face of massive phosphorus loads (4000 mg/d) depends on the phosphorus load being spread over time. Sudden loads can overwhelm renal phosphate clearance, resulting in hyperphosphatemia. Phosphorus loads can be exogenous or endogenous (Table 76-15). Exogenous intake can be from diet, phosphate enemas, or parenteral sources. Fleet enemas contain 130 mg (4.15 mmol) of phosphorus per milliliter. Dietary intake of phosphorus can be enhanced by vitamin D toxicity. Calcitriol enhances gut absorption of phosphorus and the associated hypercalcemia, along with the increased calcitriol, suppresses PTH, decreasing renal phosphorus clearance.

Endogenous sources of phosphate are due to release of intracellular phosphorus from cell death or transcellular distribution. Patients who present with diabetic ketoacidosis are usually hyperphosphatemic despite decreased total body phosphorus.[191] This is due to the lack of insulin decreasing the movement of phosphorus into cells and metabolic acidosis slowing phosphorus consuming glycolysis. Tumor lysis syndrome is due to destruction of large bulky tumors with chemotherapy or radiation therapy. The tumor cells release phosphorus, potassium, and purines (metabolized to uric acid). Acute renal failure from urate nephropathy can exacerbate the electrolyte abnormalities. For more

TABLE 76-15 Etiologies of Hyperphosphatemia

Exogenous Phosphorus Intake	Endogenous Phosphorus Loads	Decreased Renal Clearance of Phosphorus
Fleet enemas	Cell death	Renal failure
Oral phosphorus overdose	Tumor lysis syndrome	Hypoparathyroidism
Parenteral phosphate	Rhabdomyolysis	Acquired
Vitamin D intoxication	Tissue infarction	Postsurgical
White phosphorus burns	Malignant hyperthermia	Hypomagnesemia
	Neuroleptic malignant syndrome	Radiation treatment
	Heat stroke	Hemochromatosis
	Transcellular movement	Congenital
	Metabolic acidosis	Pseudohypoparathyroidism
	Ketoacidosis	Hypoparathyroidism
	Lactic acidosis	DiGeorge syndrome
	Respiratory acidosis	Acromegaly
		Growth hormone therapy
		Tumoral calcinosis
		Bisphosphonates

information see the discussion in hyperkalemia section, above.

Decreased Renal Clearance of Phosphorus

Since the kidney is the primary means of excreting phosphorus, renal failure of any etiology is associated with hyperphosphatemia. The kidney maintains phosphorus balance by filtering serum phosphorus and then adjusting the fractional resorption of phosphorus via PTH. In some cases the kidneys fail to excrete phosphorus despite adequate GFR. The primary cause of this is hypoparathyroidism due to removal of the parathyroids or other neck surgery. In the former, the hypoparathyroidism is permanent, while in the latter it is usually a temporary stunning of the gland. Other causes of hypoparathyroidism are discussed under etiologies of hypocalcemia (see Table 76-8).

CLINICAL SEQUELAE

The primary clinical consequence of hyperphosphatemia is hypocalcemia and its metabolic manifestations. Increased serum phosphorus binds ionized calcium, lowering the biologically active fraction of calcium.[192]

Severe hyperphosphatemia can result in metastatic calcification in soft tissues. In rare cases this may contribute to acute renal failure or cardiac arrhythmias.[193] The risk of calcification increases as the calcium-phosphorus product (calcium times phosphorus) rises above 70 mg^2/dL^2. In patients with end-stage renal disease empiric data have shown decreased mortality in patients with a calcium-phosphorus product less than 52. In the same study isolated hyperphosphatemia also predicted increased mortality.[194]

TREATMENT

Hyperphosphatemia in patients with intact renal function is usually transient and self-correcting. Infusing saline to induce natriuresis can enhance renal clearance of phosphorus. Acetazolamide can increase renal clearance by blocking phosphate resorption in the proximal tubule.[195]

If there is decreased renal function or symptomatic hypocalcemia, dialysis is essential. Twenty to thirty millimoles of phosphorus are removed with a 4-hour dialysis session. Continuous renal replacement strategies have been shown to provide better control of hyperphosphatemia and hypocalcemia.[196]

In tumor lysis syndrome the use of sodium bicarbonate to alkalinize the urine can be detrimental. Alkalinization has been used to increase solubility of uric acid in the urine; however, urinary phosphorus solubility decreases with higher urine pH. The use of sodium bicarbonate predisposes to renal calcium deposition. In addition, raising the pH exacerbates the ionized hypocalcemia found in tumor lysis syndrome. The use of allopurinol and uricase prevent hyperuricemia, eliminating the need for alkalinization.

Phosphate binders are regularly used in patients with chronic renal failure to reduce absorption of dietary phosphorus. Though they primarily act to decrease absorption of dietary phosphorus, they have a small but measurable ability to reduce phosphorus in patients not ingesting additional phosphorus.[197] Patients with acute hyperphosphatemia should have a low-phosphorus diet and be started on phosphorus binders (i.e., magnesium, calcium, or aluminum salts, lanthanum carbonate, or sevelamer).

Magnesium

METABOLISM

Magnesium is the second most prevalent intracellular cation. It is a critical cofactor in any reaction powered by ATP, so deficiency of this ion can have dramatic effects on metabolism. Magnesium also acts as a calcium channel antagonist and plays a key role in the modulation of any activity governed by intracellular calcium (e.g., muscle contraction and insulin release).[198] The atomic weight of magnesium is 24.3. Half of total body magnesium is mineralized in bone. Almost all of the remainder is localized in the intracellular compartment with only 1% of total body magnesium in the extracellular space.[199] Normal plasma magnesium concentration is 1.8 to 2.3 mg/dL (0.75 to 0.95 mmol/L; 1.5 to 1.9 mEq/L). Magnesium exists in three states: ionized (60% of total magnesium), protein bound (30%, mostly albumin), and complexed to serum anions (10%).[200,201] Only the ionized magnesium is physiologically active; however, it is not routinely measured. Patients with low serum albumin may have low serum magnesium levels with normal ionized magnesium levels.[202]

MAGNESIUM BALANCE

Net oral magnesium intake is 100 mg (see Fig. 76-11). The kidneys are responsible for excreting this magnesium load. The bulk of magnesium resorption (60% to 70%) occurs in the thick ascending limb of the loop of Henle (TALH) (see Fig. 76-13). The resorption of magnesium in the TALH is inversely related to flow, so that any situation associated with increased tubular flow reduces magnesium resorption. Similarly, any factor that abolishes the positive luminal charge (e.g., loop diuretics or hypercalcemia) opposes magnesium resorption.

Renal resorption of magnesium varies widely to maintain magnesium homeostasis. Fractional resorption of filtered magnesium can decline to nearly zero in the presence of hypermagnesemia or reduced GFR (i.e., all of the filtered magnesium is excreted). In response to magnesium depletion or decreased intake the fractional resorption of Mg^{2+} can rise to 99.5% in order to minimize urinary losses.

HYPOMAGNESEMIA

Hypomagnesemia is common. Among ICU patients, the prevalence of hypomagnesemia ranges from 11% to 65%.[203–205] When present, hypomagnesemia is usually undetected. In a prospective study, 47% of patients undergoing clinical blood testing for electrolyte concentrations had hypomagnesemia, but physicians ordered magnesium levels in only 10% of these patients.[206]

ETIOLOGIES

Hypomagnesemia is nearly always due to increased renal or GI losses (Table 76-16). GI losses or malabsorption of magnesium occur with steatorrhea, diarrhea, and short bowel syndrome (loss of more than 75 cm of bowel).[207–209]

Renal loss of magnesium occurs most prominently in any situation in which there is increased tubular flow. Intravenous fluids or osmotic diuresis from glucosuria will increase tubular flow and magnesium wasting.[210] Loop, thiazide, and osmotic diuretics, recovery from acute tubular necrosis, and relief of urinary tract obstruction have all been documented to

TABLE 76-16 Etiologies of Hyper- and Hypomagnesemia

Hypomagnesemia	Hypermagnesemia
Extrarenal causes	*Decreased renal excretion of magnesium*
Gastrointestinal	Renal insufficiency
Diarrhea	Any etiology with a glomerular filtration rate <10 mL/min
Steatorrhea	Lithium
Congenital malabsorption	Hypocalciuria, hypercalcemia[f]
Protein calorie malnutrition	*Magnesium ingestion*
Alcoholism	Parenteral
Enteral nutrition	Dosing error
Inflammatory bowel disease[a]	Treatment of pre-eclampsia
Gastric suction	Treatment of torsades de pointes or myocardial infarction
Vomiting	Oral
Short bowel syndrome[b]	Damage to the intestinal lining may increase Mg absorption
Sprue	Mg^{2+}-containing antacids
Intestinal bypass for obesity[c]	Gaviscon [$Al(OH)_3$ and $MgCO_3$]
Chronic pancreatitis[d]	Mylanta ($CaCO_3$ and $MgCO_3$)
Skin	Milk of magnesia [$Mg(OH)_2$]
Burns	Maalox [$Al(OH)_3$ and $Mg(OH)_2$]
Toxic epidermal necrolysis	Epsom salts ($MgSO_4$)
Bone	Mg^{2+}-containing cathartics
Hungry bone syndrome	Magnesium citrate
Other	Milk of magnesia [$Mg(OH)_2$]
Pancreatitis	Magnesium-containing enemas
Renal causes	Magnesium citrate
Drugs	Aspiration
Aminoglycoside toxicity	Dead Sea near drowning
Pentamidine toxicity	*Other*
Amphotericin B toxicity	Theophylline toxicity[g]
Thiazide diuretics	
Calcineurin inhibitors	
Foscarnet	
Cisplatin	
Loop of Henle	
Loop diuretics	
Hypercalcemia	
Increased tubular flow	
Osmotic diuresis	
Diabetes types I and II	
Hyperaldosteronism[e]	
Volume expansion	
Diabetic ketoacidosis	
Tubular dysfunction	
Recovery from acute tubular necrosis	
Recovery from obstruction	
Recovery from transplantation	
Congenital renal magnesium wasting	
Bartter's syndrome (one-third of cases)	
Gittelman's syndrome (universal)	

Data from these references: [a] Galland,[277] [b] Hessov et al,[209] [c] Lipner,[278] [d] Papazachariou et al,[279] [e] Massry et al,[210] [f] Sutton et al,[211] and [g] Eshleman et al.[280]

increase magnesium loss.[211–213] Specific magnesium wasting defects can be induced by tubular toxins. Cisplatin, amphotericin B, and the aminoglycosides all cause magnesium wasting independent of any effect on GFR.[214–216] Gitelman's syndrome is a congenital syndrome characterized by hypokalemia, metabolic alkalosis, and normotension. Unlike the similar condition Bartter's syndrome, Gitelman's is often not diagnosed until early adulthood. Hypomagnesemia is a universal finding in Gitelman's, with magnesium levels typically just over 1 mg/dL.[217]

Hypomagnesemia has been reported to occur in 40% of patients with burns.[218] The decreased magnesium is due primarily to exudative skin losses.[219]

CLINICAL SEQUELAE

Hypomagnesemia is usually asymptomatic. In a retrospective review of 1576 consecutive admissions to a geriatric facility in Scotland, 169 patients with hypomagnesemia ($\leq$1.6) showed no difference in duration of stay, survival to discharge, or 6-month survival.[220] However, a prospective study done in an

TABLE 76-17 Clinical Sequelae of Magnesium Disturbances

MAGNESIUM LEVEL			
mg/dL	mEq/L	mmol/L	Manifestation
<1.2	<1	<0.5	Tetany, seizures, arrhythmias
1.2–1.8	1.0–1.5	0.5–0.75	Neuromuscular irritability, hypocalcemia, hypokalemia
1.8–2.5	1.5–2.1	0.75–1.05	Normal magnesium level
2.5–5.0	2.1–4.2	1.05–2.1	Typically asymptomatic
5.0–7.0	4.2–5.8	2.1–2.9	Lethargy, drowsiness, flushing, nausea and vomiting, diminished deep tendon reflexes
7.0–12	5.8–10	2.9–5	Somnolence, loss of deep tendon reflexes, hypotension, electrocardiographic changes
>12	>10	>5	Complete heart block, cardiac arrest, apnea, paralysis, coma

inpatient setting showed a tremendous impact of hypomagnesemia on survival. Though there was no difference in Acute Physiology, Age, and Chronic Health Evaluation (APACHE) II scores at admission, patients with a serum magnesium level <1.5 mg/dL had a dramatically higher mortality rate than patients with normal magnesium (31% vs. 22%).[221]

Determining the clinical consequences of isolated hypomagnesemia is difficult because patients with hypomagnesemia typically also have hypokalemia, hypocalcemia, and hyponatremia. Symptoms due to hypomagnesemia become more common as serum magnesium falls below 1.2 mg/dL[222] (Table 76-17).

Neuromuscular Effects

Neuromuscular irritability is a common sign of magnesium depletion. Patients can develop Trousseau's and Chvostek's signs despite normal ionized calcium. Severe depletion can cause weakness, fatigue, vertical nystagmus, tetany, and seizures.[223] Reversible blindness due to magnesium deficiency has been reported.[224]

Metabolic Effects

Hypokalemia is commonly associated with hypomagnesemia. One series reported it to occur in 40% of patients with hypomagnesemia. The reverse is also true; 60% of patients with hypokalemia are hypomagnesemic.[206] One explanation for this phenomenon is that many of the etiologies of hypomagnesemia (diuretics, alcoholism, and diarrhea, among others) also result in hypokalemia. In addition, hypomagnesemia causes renal potassium wasting. The mechanism for potassium wasting is multifactorial. Decreased intracellular magnesium slows adenosine triphosphate (ATP) production, which decreases Na-K-ATPase activity, resulting in the loss of intracellular potassium. In the TALH and cortical collecting duct the loss of ATP increases the number of potassium channels on the apical membrane.[48] Intracellular potassium flows down its concentration gradient into the tubule and is lost in the urine.

Hypocalcemia has been reported in 12% to 50% of patients with hypomagnesemia.[220,225] Hypomagnesemia suppresses the release of PTH and causes end-organ resistance to PTH. The hypocalcemia is refractory to calcium supplementation until the magnesium deficit is corrected.[139]

Cardiovascular Effects

Hypomagnesemia has been associated with a variety of atrial and ventricular arrhythmias.[226] Zuccala and associates prospectively studied 52 elderly patients undergoing hip surgery. He noted an association of higher rates of arrhythmias with greater perioperative drops in magnesium. The arrhythmogenic association of magnesium depletion was independent of changes in serum calcium and potassium.[227] Torsades de pointes is a unique form of ventricular tachycardia that is refractory to cardioversion, but responds to magnesium repletion. ECG findings with hypomagnesemia include flattened T waves, U waves, prolonged QT interval, and widened QRS complexes. All of these ECG effects are also found with hypokalemia, and may be secondary to changes in potassium.

Since both magnesium depletion and digitalis inhibit the Na-K-ATPase pump, it is not surprising that hypomagnesemia aggravates digitalis toxicity. In fact, hypomagnesemia was the most frequent electrolyte abnormality in a study of digitalis toxicity.[228]

DIAGNOSIS

Hypomagnesemia can be divided into extrarenal and renal causes, which can be readily distinguished by determining if the kidney is magnesium-avid or wasting magnesium. There are two ways to determine renal magnesium avidity: 24-hour urine collection and fractional excretion of magnesium. A 24-hour urine magnesium level less than 20 mg is consistent with an intact renal response to hypomagnesemia and implicates decreased intake or extrarenal losses as the cause of hypomagnesemia. A 24-hour urinary magnesium level greater than 24 mg indicates renal magnesium wasting. The fractional excretion of magnesium (FeMg) allows assessment of the renal handling of magnesium on a single urine specimen. A cutoff of 4% correctly separates patients with renal magnesium wasting (FeMg >4%) from patients with decreased magnesium absorption (FeMg <4%)[229] (Equation 76-7).

$$\text{FeMg} = 100 \times \frac{\text{sCr} \times \text{uMg}}{(0.7 \times \text{sMg}) \times \text{uCr}}$$

Equation 76-7. The fractional resorption of magnesium differentiates between magnesium-avid and magnesium-wasting states. A FeMg greater than 4% in the presence of hypomagnesemia indicates abnormal renal magnesium wasting. sCr, serum creatinine; sMg, serum magnesium; uCr, urine creatinine; uMg, urine magnesium.

Clinical sequelae of altered magnesium content are more dependent on tissue magnesium levels than blood magnesium concentration. One method to infer the tissue

magnesium level in patients with normal serum magnesium is a physiologic test that measures the renal response to a magnesium load. An 800 mg infusion of magnesium is given over 8 hours, and a 24-hour urine is collected starting from the initiation of the infusion. Patients who excrete less than 560 mg (70%) are considered magnesium depleted, while those who excrete more than 640 mg (80%) are said to be magnesium replete.[230] This will only work in patients with normal renal function and normal renal magnesium handling.

TREATMENT

Patients with symptomatic hypomagnesemia should be treated with intravenous magnesium. The most common formulation is magnesium sulfate ($MgSO_4 \cdot 7H_2O$). One gram of $MgSO_4$ contains 0.1 gram of elemental magnesium. Acute symptomatic hypomagnesemia (e.g., seizures, tetany, and arrhythmias) should be treated with 2 g IV over 1 to 5 minutes. In order to restore intracellular magnesium stores the acute bolus should be followed by 8 g over 24 hours and 4 to 6 g a day for 3 or 4 days.[226,231,232]

The American College of Cardiology and the American Heart Association (AHA) recommend 1 to 2 g of magnesium sulfate as an IV bolus over 5 minutes for treatment of torsades de pointes. Because early studies demonstrated a benefit of magnesium in acute myocardial infarction (AMI) the AHA currently recommends administration of 2 g of $MgSO_4$ over 15 minutes, followed by 18 g over 24 hours for AMI in the elderly or patients for whom reperfusion therapy is contraindicated. However, the MAGIC trial failed to show any benefit (or harm) from the use of magnesium in AMI; therefore we expect the AHA to rescind any recommendations for using magnesium in AMI.[233]

Magnesium replacement should be done cautiously in patients with renal insufficiency; doses should be reduced by 50% to 75%. Patients should be monitored during infusions for decreased deep tendon reflexes and magnesium levels should be checked at regular intervals.

Oral supplementation with 360 mg of elemental magnesium per day (divided tid) was effective at treating magnesium depletion.[234] Trials at lower doses were not effective.[235] Patients with significant GI magnesium wasting who fail to raise their magnesium on one formulation of Mg^{2+} may respond to another.[236] Diarrhea frequently complicates oral magnesium repletion.

Potassium-sparing diuretics may be helpful in patients with chronic renal magnesium wasting. Amiloride and triamterene have been shown to be helpful in selected patients.[237,238]

HYPERMAGNESEMIA

Normally the kidney excretes only 2% to 4% of the filtered magnesium, but is capable of increasing fractional excretion to nearly 100% in the face of decreased GFR or increased serum magnesium levels.[211] Because of this renal reserve, hypermagnesemia is rarely seen. In a study that looked for magnesium levels greater than 6 mg/dL, only 8 cases were found among nearly 20,000 nonobstetric patients who had magnesium levels checked.[239]

ETIOLOGIES

The most common cause of hypermagnesemia is renal insufficiency. Patients with progressive renal insufficiency maintain magnesium balance by increasing the fractional excretion of magnesium (FeMg). Patients with severe renal insufficiency have a FeMg of nearly 100%, which allows preservation of magnesium balance despite severe decreases in GFR.[240]

Symptomatic hypermagnesemia (despite normal renal function) has been reported with magnesium infusions. The typical setting is the treatment of preterm labor or preeclampsia/eclampsia. Standard obstetric protocols (4- to 6-g load followed by 1 to 2 g/h) result in serum magnesium levels of 4 to 8 mg/dL.[241] Patients suffering accidental parenteral magnesium overdoses usually have good outcomes, despite significant short-term morbidity and magnesium levels as high as 24 mg/dL.[242,243]

Hypermagnesemia due to ingestion of magnesium is unusual in the absence of renal insufficiency. In one retrospective study of hypermagnesemia, excluding obstetric admissions all cases were due to oral intake and the average creatinine was 4.8. Oral sources of magnesium include antacids and Epsom salts.[244–246] Chronic oral ingestions of magnesium result in severe symptoms, including death. Hypermagnesemia has been repeatedly reported following the use of magnesium-containing enemas.[247–249]

CLINICAL SEQUELAE

Magnesium can block synaptic transmission of nerve impulses. Hypermagnesemia causes loss of deep tendon reflexes, and may lead to flaccid paralysis and apnea.[239,242,250,251] Neuromuscular toxicity also affects smooth muscle, resulting in ileus and urinary retention.[252] In cases of oral intoxication, the development of ileus can slow intestinal transit times, increasing absorption of magnesium.[244] Hypermagnesemia has also been reported to cause parasympathetic blockade, resulting in fixed and dilated pupils, mimicking brain stem herniation.[242] Other neurologic signs include lethargy, confusion, and coma[242,239,251] (see Table 76-17).

Cardiovascular manifestations of hypermagnesemia initially include bradycardia and hypotension.[239,244,251] Higher magnesium levels cause PR interval prolongation, increased QRS duration, and prolonged QT interval.[239] Extreme cases can result in complete heart block or cardiac arrest. One case of ventricular fibrillation has been reported with a Mg^{2+} level of 9.7 mg/dL.[243]

TREATMENT

The first principle of treatment is prevention. Patients with renal insufficiency should not be given magnesium-containing antacids or cathartics. In cases of hypermagnesemia, stopping the infusion or supply of magnesium will allow patients with intact renal function to recover.

Calcium salts can reverse hypotension and respiratory depression.[253] Patients are typically given 100 to 200 mg of elemental calcium intravenously over 5 to 10 minutes.

In patients with severe renal dysfunction, dialysis offers a way to rapidly clear magnesium. Though both peritoneal and hemodialysis can lower magnesium in an acute situation, hemodialysis is the preferred modality.[239,244,254] Continuous renal replacement therapy is also effective at lowering serum magnesium, but is slower than hemodialysis.[251]

Chapter 77

ACID-BASE BALANCE

DAVID KAUFMAN
ANDREW J. KITCHING
JOHN A. KELLUM

KEY POINTS

- *The blood [H^+] and pH are determined by the strong ion difference (SID), the P_{CO_2}, and the total concentration of weak acids, mostly consisting of phosphate and albumin.*
- *Both acidemia and alkalemia have potentially harmful physiologic effects, and the presence of either is related to mortality.*
- *Most acid-base derangements do not benefit from specific correction of the abnormal pH; instead, the intensivist should focus on detecting and treating the underlying condition.*
- *Acid-base disorders are easily characterized using a stepwise approach.*
- *Lactic acidosis is the most important acid-base abnormality in ICU patients. Inadequate tissue oxygenation underlies the lactic acidosis in some patients (acute hemorrhage, critical hypoxemia, cardiogenic shock) but probably does not in others (such as the resuscitated septic patient).*

Acid-base balance and *acid-base disorders* are imperfect terms for the determining factors and disease processes that lead to a particular hydrogen ion concentration [H^+] in the blood. The methodology used routinely to determine an acid-base disorder is accurate in defining the disturbance. This methodology does not, however, reveal the mechanisms that have led to a particular [H^+] in blood. The components of blood that contribute to acid-base balance are

1. Water
2. Strong cations (Na^+, Mg^{2+}, Ca^{2+}, K^+) and strong anions (Cl^-, lactate$^-$)
3. Bicarbonate ion (HCO_3^-)
4. Weak acids and their conjugate bases ($HA + A^- = A_{tot}$) (A_{tot} is the total independent variable, and $HA + A^-$ are dependent variables.)
5. Partial pressure of carbon dioxide (P_{CO_2})
6. Carbonate ion (CO_3^{2-})
7. Hydroxyl ion (OH^-)
8. Hydrogen ion (H^+)

The difference between the strong cations and strong anions (the strong ion difference [SID]), P_{CO_2}, and the total amount of weak acids and their conjugate bases (A_{tot}) are the only independent variables.[1] All the other components are, by definition, dependent, including HCO_3^-, HA, A^-, CO_3^{2-}, OH^-, and H^+. Because the concentrations of each of these six variables are dependent on one or more of the independent variables, we must solve separate equilibrium equations for each. Water itself is minimally dissociated despite the importance of [H^+] and can be considered a constant. The six equations are as follows:

Water dissociation:

$$[H^+] \times [OH^-] = K_1 \times [H_2O] \tag{77-1}$$

Weak acid dissociation:

$$[H^+] \times [A^-] = K_2[HA] \tag{77-2}$$

Weak acid conservation:

$$[HA] + [A^-] = [A_{tot}] \tag{77-3}$$

HCO_3^- formation:

$$[H^+] \times [HCO_3^-] = K_3 \times P_{CO_2} \tag{77-4}$$

CO_3^{2-} formation:

$$[H^+] \times [CO_3^{2-}] + K_4 \times [HCO_3^-] \tag{77-5}$$

Electrical neutrality:

$$SID + [H^+] - [HCO_3^-] - [A^-] - [CO_3^{2-}] - [OH^-] = 0 \tag{77-6}$$

K_1 through K_4 represent constants for the individual reactions. Now that we have six equations and six unknowns, we can arrange any unknown as a fourth-order polynomial and solve the equation. In acid-base balance, the dependent variable in question is [H^+]. Stated less elegantly, there is a unique value for each of the six dependent variables once SID, P_{CO_2}, and A_{tot} are known so that all the equations can be solved simultaneously.

The formula for bicarbonate formation in its most robust form is the familiar Henderson-Hasselbalch equation:

$$pH = pK_a + \log\{[HCO_3^-]/(P_{CO_2} \times 0.03)\} \tag{77-7}$$

Since this equation is no more or less correct than any of the other five equations that must be solved simultaneously, there is nothing wrong with using it to determine an acid-base disorder. Indeed, the fact that all three values are readily available from a standard arterial blood gas determination explains the popularity of this equation.

Metabolic Disturbances

By examining Eq. (77-7) it is possible to determine whether an acid-base disturbance is present and whether it is due to respiratory (P_{CO_2}) or metabolic derangements. One might assume, therefore, that pH is determined by the relationship between P_{CO_2} and [HCO_3^-]. This presumption is false. Likewise, solving Eq. (77-2) for [H^+] does not mean that [H^+] is determined by the HA and A^-. In truth, [H^+] and thus pH are determined by P_{CO_2}, SID, and A_{tot}. Since we define respiratory disorders by alterations in P_{CO_2}, metabolic disturbances are brought about by changes in SID and A_{tot}. They are not caused by changes in [HCO_3^-], but rather, changes in [HCO_3^-] occur as a result of the disturbance.

As SID becomes *less* positive, more [H^+] is released into the solution, and acidemia develops. As SID becomes *more* positive, more [H^+] associates with [OH^-], forming water,

Copyright © 2005, 1998, 1992 by The McGraw-Hill Companies, Inc. Click here for terms of use.

and alkalemia develops. By contrast, A_{tot}, composed of weak acids, is acidifying. As A_{tot} increases, the pH falls, and as A_{tot} decreases, such as with hemodilution, the pH increases.

Respiratory Disorders

By definition, abnormalities in P_{CO_2} are classified as respiratory disorders. SID (and possibly A_{tot}) is manipulated by the human body to compensate for chronic respiratory disorders, thus maintaining pH within the normal range (7.35–7.45). SID decreases to compensate for a chronic respiratory alkalosis, and SID increases to compensate for a chronic respiratory acidosis. The physiologic determinants of P_{CO_2} are straightforward:

$$P_{CO_2} \propto V_{CO_2}/V_A$$

where V_{CO_2} is CO_2 production and V_A is alveolar ventilation. A change in P_{CO_2} must be explained by one of these factors. Hypercarbia and hypocarbia usually can be explained easily at the bedside.

Acidemia and Alkalemia

Even relative extremes of $[H^+]$ are remarkably well tolerated (e.g., pH 7.1–7.7), at least for the short term, in otherwise healthy individuals. However, some authors have even suggested that acidemia itself may be beneficial to critically ill patients.[2] For example, since acidemia shifts the oxyhemoglobin curve to the right, there is better oxygen delivery under acidemic conditions. Unfortunately, this "benefit" is dubious because acidosis also reduces synthesis of 2,3-diphosphoglycerate (2,3-DPG), and thus chronically, acidosis does not appear to improve oxygen delivery. Acidosis may produce other salutary effects on the circulation that could result in benefit in certain clinical scenarios,[2] but acidosis also produces numerous undesirable effects on various systems (Table 77-1), and we caution against "permissive acidosis."

This is not to say that we believe that correcting an acid-base disorder is always appropriate. Indeed, the existing evidence does not support the use of sodium bicarbonate for the purpose of correcting the pH in most conditions of acute acidosis,[3] and some animal experiments even suggest harm.[4] However, supporting respiratory compensation when feasible and avoiding acidosis when possible seems a prudent course of action in most clinical scenarios. Frequently, when treating critically ill patients, it is easy to blur the lines between supportive measures and therapeutic interventions. Common forms of acidemia may be associated with significant mortality because of the disease processes that underlie them, not necessarily because of the actual $[H^+]$. For instance, bowel infarction is lethal, and only surgical resection is curative. Treating the lactic acidosis without addressing the underlying cause of the lactic acidosis in this scenario is certain to fail. Dissecting out the effects of acidosis itself from the causes that underlie it is difficult in patients. However, acidosis itself has been shown to produce harm in animal models[5–8]—especially in models of sepsis, where decreased survival time and hypotension appear to be attributable to exogenous acid loading.[7,8] Nonetheless, it has yet to be demonstrated that treating acidosis improves outcome.

TABLE 77-1 Potential Clinical Effects of Metabolic Acid-Base Disorders

Metabolic Acidosis	Metabolic Alkalosis
Cardiovascular	**Cardiovascular**
Decreased inotropy	Increased inotropy (Ca^{2+} entry)
Conduction defects	Altered coronary blood flow*
Arterial vasodilation	Digoxin toxicity
Venous vasoconstriction	**Oxygen delivery**
Oxygen delivery	Increased oxy-Hb affinity
Decreased oxy-Hb binding	Increased 2,3-DPG (delayed)
Decreased 2,3-DPG (late)	**Neuromuscular**
Neuromuscular	Neuromuscular excitability
Respiratory depression	Encephalopathy
Decreased sensorium	Seizures
Metabolism	**Metabolic effect**
Protein wasting	Hypokalemia
Bone demineralization	Hypocalcemia
Catecholamine, PTH, and aldosterone stimulation	Hypophosphatemia
Insulin resistance	Impaired enzyme function
GI effect	
Emesis	
Electrolytes	
Hyperkalemia	
Hypercalcemia	
Hyperuricemia	

*Animal studies have shown both increased and decreased coronary artery blood flow.

SOURCE: Adapted from Kellum JA: Diagnosis and treatment of acid-base disorders, in Grenvik A, Shoemaker PK, Ayers S, Holbrook (eds): *Textbook of Critical Care*. Philadelphia, Saunders, 1999, Chapter 76, pp 839–853, with permission.

Specific Metabolic Disorders

To diagnose a disorder leading to a change in SID, an actual accounting of strong ions occurs. A decrease in SID may be brought about by the generation of organic strong anions (e.g., lactate and ketones) or the loss of strong cations paired with weak anions to balance charge. If the patient has diarrhea, he or she is losing $[Na^+]$ and $[HCO_3^-]$; therefore, the $[Cl^-]$ will increase relative to the $[Na^+]$, leading to a decrease in SID and, ultimately, acidosis.

The organs of the gastrointestinal tract are underappreciated regulators of acid-base balance. Their ability to manipulate SID complexly is a direct result of the fact that strong ions are handled differently in different portions of the gastrointestinal tract. Cl^- is pumped into the stomach, reducing SID in the stomach and increasing the $[H^+]$ (decreasing the pH) and, at the same time, causing the alkaline tide in the blood (increasing SID) that occurs at the beginning of a meal when gastric acid secretion is maximal. The *alkaline tide* refers to the Cl^--depleted plasma that leaves the stomach. The elevated SID leads to a decrease in $[H^+]$ (increase in pH). Cl^- is reabsorbed in the duodenum, and plasma $[H^+]$ or pH is restored. Given the combination of Cl^- secretion into the stomach and Cl^- reabsorption in the duodenum, a net balance occurs, and plasma $[H^+]$ or pH is not affected. However, if gastric secretions are removed from the patient by nasogastric (NG)

suction or by vomiting, Cl^- cannot be reabsorbed, and SID will increase. Increased SID will lead to a metabolic alkalosis.

The pancreas secretes fluid into the small intestine, which has a SID that is much higher than plasma and very low in $[Cl^-]$. The Cl^--rich plasma leaving the pancreas counteracts the alkaline tide along with Cl^- reabsorption in the duodenum. Large amounts of pancreatic fluid loss will lead to a decrease in plasma SID and an associated acidosis. At the other end of the gastrointestinal (GI) tract, in the large intestine, most of the Cl^- already has been removed in the small intestine, so the only strong ions present are Na^+ and K^+. If large amounts of these strong ions are lost with diarrhea fluid, then the plasma SID will decrease, and acidosis will result. During ischemia to the intestinal tract, significant amounts of lactate can be produced. At physiologic pH, lactate acts as a strong anion and decreases SID, leading to a metabolic acidosis. There is some evidence that the gut may modulate systemic acidosis in experimental endotoxemia by removing anions from the plasma.[9] However, the full capacity of the GI tract to effect acid-base balance is not known. The treatment of metabolic acidosis requires treatment of an underlying disease process and not, strictly speaking, of the acid-base disorder. If the patient developed a lactate acidosis following a seizure, this lactic acidosis would resolve rapidly once the liver metabolized the lactate. Indeed, treatment of acid-base disturbances can lead to severe overshoot alkalosis or acidosis.

Finally, the liver is perhaps the most important abdominal organ involved in the regulation of acid-base balance.[10,11] Hepatic glutaminogenesis is important for systemic acid-base balance and is tightly controlled by mechanisms sensitive to plasma $[H^+]$ and is stimulated by acidosis.[12] Nitrogen metabolism by the liver can produce urea, glutamine, or NH_4^+. Normally, the liver does not release more than a very small amount of NH_4^+ but incorporates this nitrogen into either urea or glutamine. However, the production of urea or glutamine has significantly different effects at the level of the kidney. This is so because glutamine is used by the kidney to generate NH_4^+ and facilitate the excretion of Cl^-. Thus the production of glutamine can be seen as having an alkalinizing effect on plasma pH because of the way in which the kidney uses it. In humans, the liver is also the only organ than synthesizes albumin, the major component of A_{tot}.

Crystalloid Solutions

Manipulating $[H^+]$ in the blood is intellectually easy once one understands the importance of SID but certainly is not of proven benefit. When administered to patients, equimolar concentrations of Na^+ and Cl^- (such as in saline solutions) will increase the $[Cl^-]$ more rapidly than the $[Na^+]$ because $[Na^+]$ is normally much greater than $[Cl^-]$. When this occurs, SID will decrease, and $[H^+]$ will increase. In a test tube, lactated Ringer's solution will behave just like saline because lactate is a strong ion. However, in humans, lactate metabolism is rapid even under conditions of relatively severe hepatic dysfunction. If the liver is functioning and can metabolize lactate, then the unbalanced Na^+ will increase the SID and result in alkalemia. Conversely, if lactate-containing solutions are administered quickly (as in replacement fluid for hemofiltration) and hepatic function is impaired, acidosis will develop, just as in the case of saline loading, because SID is lowered.

Normal saline (0.9% NaCl) is often blamed for causing a "dilutional" acidosis, but all that is occurring is that $[Na^+]$ is relatively unchanged as the $[Cl^-]$ rises, leading to a decreased SID and hyperchloremic acidosis. Adding 75 mEq/L of $[NaHCO_3]$ to 0.45% saline (77 mEq/L $Na^+$and 77 mEq/L Cl^-) will create an isotonic solution that contains half the $[Cl^-]$ (a strong anion) with twice the $[Na^+]$ (strong cation). This solution has a higher SID than normal saline or lactated Ringer's solution and favors alkalemia. Mixing 150 mEq $NaHCO_3$ in 1 L of sterile water increases the SID further and creates an even more potent alkalizing fluid. Again, it is worth emphasizing the need to treat the underlying disorder and not just "correct" the acid-basis disorder.

The Anion Gap and the Strong Ion Gap

The anion gap (AG) was popularized over 30 years ago. Traditionally, it is calculated from the equation $[(Na^+) + (K^+)] - [(Cl^-) + (HCO_3^-)]$ K^+ is often omitted because its plasma concentration is so tightly controlled that there is little variation. However, this is a mistake for two reasons. First, a 2- to 3-mEq difference in the AG may be clinically relevant in some scenarios, and second, techniques used to correct the AG for abnormalities in A_{tot} require a full accounting of other ions. The difference in the gap is made up largely by albumin and, to a lesser extent, phosphate. Other anions, such as sulfate and lactate, normally contribute less than 2 mEq of negative charge, similar in fact to the amount of positive charge contributed by ionized calcium and ionized magnesium. Thus these ions tend to offset each other. Many medical textbooks still report a normal range for the AG of about 12 to 16 mEq (when K^+ is considered). This value, however, is based on older assay methods that were less sensitive for Cl^-; the expected AG using modern analyzers is closer to 8 to 10 mEq. However, many critically ill patients have hypoalbuminemia or hypophosphatemia, and it has been recommended to correct the normal AG for these abnormalities.[10,13] The following formula can be used to estimate the expected "normal" AG for a given patient:

$$\text{AGc} = \text{corrected AG} = 2(\text{albumin g/dL}) + 0.5(\text{phosphate mg/dL}) \quad (77\text{-}8)$$

Thus, for a patient with half the normal albumin and phosphate, the AGc should be approximately 5 mEq/dL. If the measured AG is 10 mEq/dL, then there would be 5 mEq/dL of negative charge still unaccounted for—perhaps attributable to lactate, ketoacid anions, or others.

An alternative to using the traditional AG is to focus on SID. By definition, SID must be equal to and opposite of the negative charges contributed by all the anions, including total CO_2. Normally, the plasma SID is strongly positive (between 40 and 42 mEq/L in healthy humans). Since charge must be balanced in any solution (the principle of electrical neutrality), there must be negative charges to balance this positive charge. Total CO_2 and the weak acids (mainly albumin and phosphate) account for the vast majority of this negative charge. These charges are equal to the "buffer base" first mentioned by Singer and Hastings over half a century ago.[14]

Thus, under normal circumstances, SID should equal buffer base. Although hydroxyl ion concentration [OH^-] is another negative charge, its value is small enough to ignore. Thus total $CO_2 + AG = SID$.[15,16] This estimate of SID, or buffer base, is termed the *effective SID* (SIDe). Alternatively, the apparent SID (SIDa) can be estimated by the equation

$$SIDa = ([Na^+] + [K^+] + [Ca^{2+}] + [Mg^{2+}]) - ([Cl^-] + [lactate^-]) \quad (77\text{-}9)$$

Normally, SIDa = SIDe = SID = buffer base. However, if there are unmeasured strong ions (e.g., sulfates or ketoacid anions), then SIDa will be an inaccurate estimate of true SID, and if there are abnormal weak ions (e.g., proteins), then SIDe will be an inaccurate measure of true SID. When SIDa and SIDe are not equal, their difference (SIDa – SIDe) is termed the *strong ion gap* (SIG). The SIG is positive when unmeasured anions exceed unmeasured cations, and the SIG is negative when unmeasured cations exceed unmeasured anions.

Positive-Anion-Gap (SIG) Acidoses

LACTIC ACIDOSIS

In many forms of critical illness, lactate is the most important cause of a metabolic acidosis.[17] Lactate has been shown to correlate with outcome in patients with hemorrhagic[18] and septic shock.[19] Lactic acid traditionally is viewed as the predominant source of metabolic acidosis occurring in sepsis.[20] In this view, lactic acid is released primarily from the musculature and the gut as a consequence of tissue hypoxia. Moreover, the amount of lactate produced is felt to correlate with the total oxygen debt, the magnitude of the hypoperfusion, and the severity of shock.[17] In recent years this view has been challenged by the observations that during sepsis, even with profound shock, resting muscle does not produce lactate. Indeed, studies by various investigators have shown that the musculature actually may consume lactate during endotoxemia.[21–23] Data concerning the gut are less clear. There is little question that underperfused gut can release lactate; however, it does not appear that the gut releases lactate during sepsis if its perfusion is maintained. Under such conditions, the mesentery is either neutral to or even takes up lactate.[21,22] Perfusion is likely to be a major determinant of mesenteric lactate metabolism. In a canine model of sepsis using endotoxin, gut lactate production could not be shown when flow was maintained with dopexamine hydrochloride.[23]

It is interesting to note that studies in animals as well as humans have shown that the lung may be a prominent source of lactate in the setting of acute lung injury.[21,24–26] While studies such as these do not address the underlying pathophysiologic mechanisms of hyperlactatemia in sepsis, they do suggest that the conventional wisdom regarding lactate as evidence of tissue dysoxia is an oversimplification at best. Indeed, many investigators have begun to offer alternative interpretations of hyperlactatemia in this setting,[25–29] including metabolic dysfunction from mitochondrial to enzymatic derangements, which can and do lead to lactic acidosis. In particular, pyruvate dehydrogenase (PDH), the enzyme responsible for moving pyruvate into the Krebs cycle, is inhibited by endotoxin.[30] Catecholamine use, especially epinephrine, also results in lactic acidosis, presumably by stimulating cellular metabolism (e.g., increased hepatic glycolysis), and may be a common source of lactic acidosis in the ICU.[31,32] Interestingly, this phenomenon does not appear to occur with either dobutamine or norepinephrine[32] and does not appear to be related to decreased tissue perfusion.

Although controversy exists as to the source and interpretation of lactic acidosis in critically ill patients, there is no question about the ability of lactate accumulation to produce acidemia. Lactate is a strong ion by virtue of the fact that at a pH within the physiologic range it is almost completely dissociated (i.e., the pK_a of lactate is 3.9; at a pH of 7.4, 3162 ions are dissociated for every one that is not). Because the body can produce and dispose of lactate rapidly, it functions as one of the most dynamic components of the SID. Lactic acid therefore can produce significant acidemia. Virtually anywhere in the body, pH is above 6.0, and lactate behaves as a strong anion. Its generation decreases the SID and results in increased [H^+].

KETOACIDOSIS

Another common cause of a metabolic acidosis with a positive AG or SIG is ketoacidosis. Ketones are formed by beta-oxidation of fatty acids, a process inhibited by insulin. In insulin-deficient states (e.g., diabetes), ketone formation may increase rapidly. This is so because severely elevated blood glucose concentrations produce an osmotic diuresis, and this may lead to volume contraction. This state is associated with elevated cortisol levels and catecholamine secretion, which further stimulate free fatty acid production.[33] In addition, increased glucagon, relative to insulin, leads to decreased malonyl coenzyme A and increased carnitine palmityl acyl transferase, the combination of which increases ketogenesis.

Ketone bodies include acetone, acetoacetate, and β-hydroxybutyrate. Both acetoacetate and β-hydroxybutyrate are strong anions at physiologic pH (pK_a = 3.8 and 4.8, respectively). Thus, like lactate, their presence decreases the SID and increases the [H^+]. Ketoacidosis may result from diabetes (DKA) or alcohol (AKA). The diagnosis is established by measuring serum ketones. However, it is important to understand that the nitroprusside reaction used for this measurement only measures acetone and acetoacetate, not β-hydroxybutyrate. The state of measured ketosis depends on the ratio of acetoacetate to β-hydroxybutyrate. This ratio is low when lactic acidosis coexists with ketoacidosis because the reduced redox state of lactic acidosis favors production of β-hydroxybutyrate. In such circumstances, the apparent level of ketosis is small relative to the amount of acidosis and the elevation of the AG. There is also a risk of confusion during treatment of ketoacidosis because ketones, as measured by the nitroprusside reaction, may increase despite resolving acidosis. This occurs as a result of the rapid clearance of β-hydroxybutyrate with improvement in acid-base balance and without change in the measured level of ketosis. Furthermore, ketones may even appear to increase as β-hydroxybutyrate is converted to acetoacetate. Hence it is better to monitor success of therapy by pH and AG or SIG than by the assay of serum ketones.

The acidosis seen in AKA is usually less severe. The treatment consists of fluids and glucose rather than insulin.[34]

TABLE 77-2 Causes of an Increased AG (Na^+-Cl^--HCO_3^-)

Renal failure
Ketoacidosis
Diabetic
Alcoholic
Starvation
Change in AG (usually small AG)
Lactic acidosis
Toxins
Methanol
Ethylene glycol
Salicylates
Toluene
Critical illness*
Sodium with weak anions
Decreased cation
Hypomagnesemia
Hypokalemia
Hypocalcemia
Alkalosis

*Unexplained anions have been found in critically ill and injured patients, especially those with sepsis and liver disease. The causative anions have not been identified.

Indeed, insulin is contraindicated because it may cause precipitous hypoglycemia.[35] Thiamine also must be given to avoid precipitating Wernicke's encephalopathy.

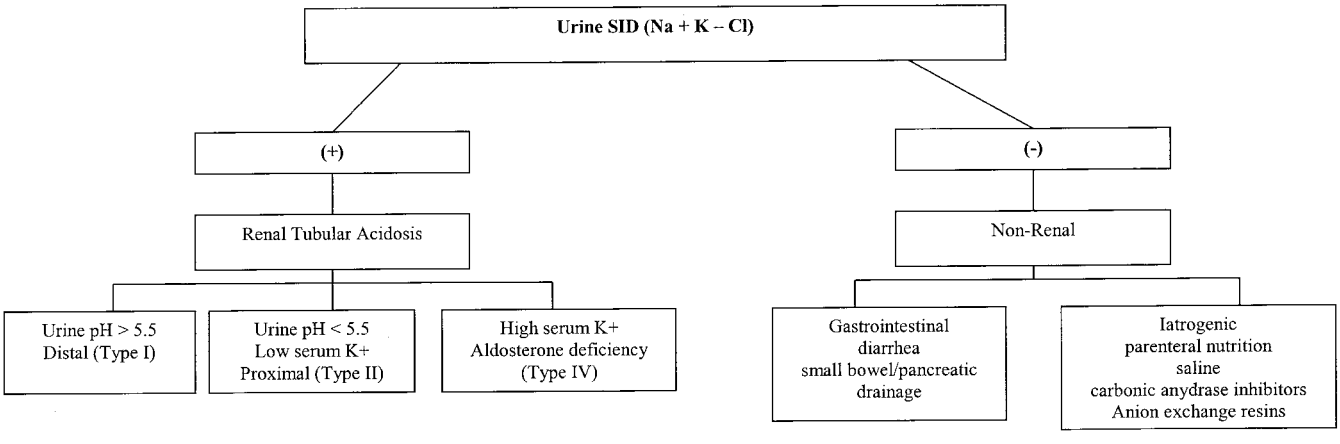
RENAL FAILURE

Although renal failure may produce a hyperchloremic metabolic acidosis, especially when chronic, the increase in sulfate and other acids frequently increases the AG and SIG. However, the increase is usually not large. Similarly, uncomplicated renal failure rarely produces severe acidosis except when it is accompanied by high rates of acid generation, such as from hypermetabolism.[36] In all cases, the SID is decreased and is expected to remain so unless some therapy is provided. Hemodialysis will permit the removal of sulfate and other ions and allow normal Na^+ and Cl^- balance to be restored, thus returning the SID to normal (or near normal). However, patients not yet requiring dialysis and those who are between treatments are often given other therapies to increase the SID.

$NaHCO_3$ is used as long as the plasma [Na^+] is not already elevated. Other options include Ca^{2+}, which usually requires replacement anyway. Ca^{2+} replacement cannot increase the SID much given the rather narrow range of ionized Ca^{2+} (0.975 – 1.125 mmol/L). Even though Ca^{2+} is a divalent cation, it is unreasonable to expect much effect on the SID by administering Ca^{2+}.

POISONS

Metabolic acidosis with an increased AG and SIG is a major feature of various types of drug and substance intoxications (Table 77-2; see also Chap. 102). Again, it is generally more important to recognize these disorders so that specific therapy can be provided than to treat the acid-base disorder itself.



MISCELLANEOUS AND UNKNOWN

Table 77-2 lists several commonly and not so commonly recognized causes of positive AG metabolic acidosis. It is important to recognize that unexplained anions have been found commonly in the plasma of critically ill and injured patients. The etiology or even identity of these anions has not been established, nor has the clinical significance.

Non–Anion-Gap (Hyperchloremic) Acidoses

Hyperchloremic metabolic acidosis occurs as a result of either the increase in Cl^- relative to strong cations, especially Na^+, or the loss of cations with retention of Cl^-. As seen in Fig. 77-1, these disorders can be separated by history and by examination of the urine [Cl^-]. When acidosis occurs, the normal response by the kidney is to increase Cl^- excretion. Failure to do so identifies the kidney as the source of acidosis. Extrarenal hyperchloremic acidoses occur as a result of exogenous Cl^- loads (iatrogenic acidosis) or because strong cations (Na^+ or K^+) are lost from the lower gastrointestinal tract disproportionally to the loss of strong anions (Cl^-).

FIGURE 77-1 Differential diagnosis for a hyperchloremic metabolic acidosis. ***(Used with permission from Kellum JA: Diagnosis and treatment of acid-base disorders, in Grenvik A, Shoemaker PK, Ayers S, et al (eds): Textbook of Critical Care. Philadelphia, Saunders, 1999, Chap 76, p 839.)***

RENAL TUBULAR ACIDOSIS

Examination of the urine and plasma electrolytes and pH and calculation of the urine SIDa allow one to correctly diagnose most cases of renal tubular acidosis (RTA)[37] (see Fig. 77-1). However, caution must be exercised when the plasma pH is greater than 7.35 because this may turn off urine Cl^- excretion. In such circumstances it may be necessary to infuse sodium sulfate or furosemide. These agents stimulate Cl^- and K^+ excretion and may be used to unmask the defect and to probe K^+ secretory capacity.

The mechanisms of RTA are not well established. It is likely that much of the confusion has occurred as a result of attempting to understand the physiology from the point of view of regulating $[H^+]$ and $[HCO_3^-]$. However, as we have discussed, this is simply inconsistent with the principles of physical chemistry. The kidney does not excrete H^+ any more as NH_4^+ than it does as H_2O. The purpose of renal ammoniagenesis is to allow the excretion of Cl^-, which balances the charge of NH_4^+. The defect in all types of RTA is the inability to excrete Cl^- in proportion to Na^+, although the reasons vary by type. Treatment is largely dependent on whether the kidney will respond to mineralocorticoid replacement or there is loss of Na^+ that can be replaced as $NaHCO_3$.

Classic distal (type I) RTA responds to $NaHCO_3$ replacement, and generally 50 to 100 mEq/d is required. K^+ defects are also common in this type of RTA, and K^+ replacement is also required. A variant of the classic distal RTA is a hyperkalemic form, which is actually more common than the classic type. The central defect here appears to be impaired Na^+ transport in the cortical collecting duct. These patients also respond to $NaHCO_3$ replacement. Proximal (type II) RTA is characterized by both Na^+ and K^+ reabsorption defects. The disorder is uncommon and usually part of the Fanconi syndrome, where reabsorption of glucose, phosphate, urate, and amino acids is also impaired. Treatment of this disorder with $NaHCO_3$ is ineffective because increased ion delivery merely results in increased excretion. Thiazide diuretics have been used to treat this disorder with varying success.

Type IV RTA is caused by aldosterone deficiency or resistance. This disorder is diagnosed by the high serum K^+ and low urine pH (< 5.5). Treatment is usually most effective if the cause can be removed. The most common causes are drugs such as nonsteroidal anti-inflammatory agents, heparin, or potassium-sparing diuretics. Occasionally, mineralocorticoid replacement is required.

GASTROINTESTINAL ACIDOSIS

Fluid secreted into the gut lumen contains higher amounts of Na^+ than Cl^-, similar to the differences in plasma. Extremely large losses of these fluids, particularly if volume is replaced with fluids containing equal amounts of Na^+ and Cl^-, will result in a decrease in the plasma $[Na^+]$ relative to $[Cl^-]$ and a decrease in the SID.

IATROGENIC ACIDOSIS

Two of the most common causes of a hyperchloremic metabolic acidosis are iatrogenic, and both are due to administration of chloride. Modern parenteral nutrition formulas contain weak anions such as acetate in addition to Cl^-, and the balance of each anion can be adjusted depending on the acid-base status of the patient. If sufficient amounts of weak anions are not provided, the plasma $[Cl^-]$ will increase, decreasing the SID and resulting in acidosis. As already discussed, administration of normal saline can cause a decrease in the SID and, subsequently, an acidosis.

METABOLIC ALKALOSIS

Metabolic alkalosis occurs as a result of an increased SID. This may occur secondary to losses of anions (e.g., Cl^- from the stomach) or increases in cations (rare). Metabolic alkaloses can be divided into those in which Cl^- losses are temporary and can be effectively replaced (chloride-responsive) and those in which hormonal mechanisms produce ongoing losses that can, at best, be offset temporarily by Cl^- administration (chloride-resistant) (Fig. 77-2). Similar to hyperchloremic acidosis, these disorders can be distinguished by examination of the urine $[Cl^-]$. Although much more investigation has focused on acidosis, alkalosis appears to be associated with poor prognosis as well. In a prospective study, Anderson and Henrich[38] looked at 409 patients with an arterial pH of greater than 7.48. Of these patients, 213 were medical and 196 were surgical. Overall, hospital mortality was 27.9% and increased as pH values rose, reaching 48.5% when the pH was greater than 7.60. While only 2% had pure metabolic alkalosis, patients at greatest risk were those with a mixed respiratory and metabolic alkalosis, having a mortality of 44.2%.

Chloride-Responsive Disorders

These disorders usually occur as a result of Cl^- losses from the stomach, such as from vomiting or gastric drainage. The treatment involves lowering the SID, by giving NaCl (since serum $[Cl^-]$ will rise greater than serum $[Na^+]$), KCl, or even HCl (which is most potent because it contains only strong anions). Saline plus KCl is usually the treatment of choice because volume depletion usually coexists with these disorders. Volume depletion, in turn, stimulates aldosterone secretion, which results in Na^+ reabsorption and the loss of K^+ and Cl^-.

Diuretics and other forms of volume contraction produce metabolic alkalosis predominantly by stimulating aldosterone, as discussed earlier. However, diuretics also induce K^+ and Cl^- excretion directly, further complicating the problem and inducing metabolic alkalosis more rapidly.

Chloride-Resistant Disorders

These disorders (see Fig. 77-2) are characterized by an increased urine $[Cl^-]$ (>20 mmol/L) and are said to be chloride-resistant because of ongoing Cl^- losses. Most commonly, this occurs as a result of increased mineralocorticoid activity. Treatment requires that the underlying disorder be addressed.

Other Causes of Metabolic Alkalosis

Rarely, an increased SID (and therefore metabolic alkalosis) occurs secondary to cation administration rather than anion depletion. Examples of these disorders include milk-alkali syndrome and intravenous administration of strong cations

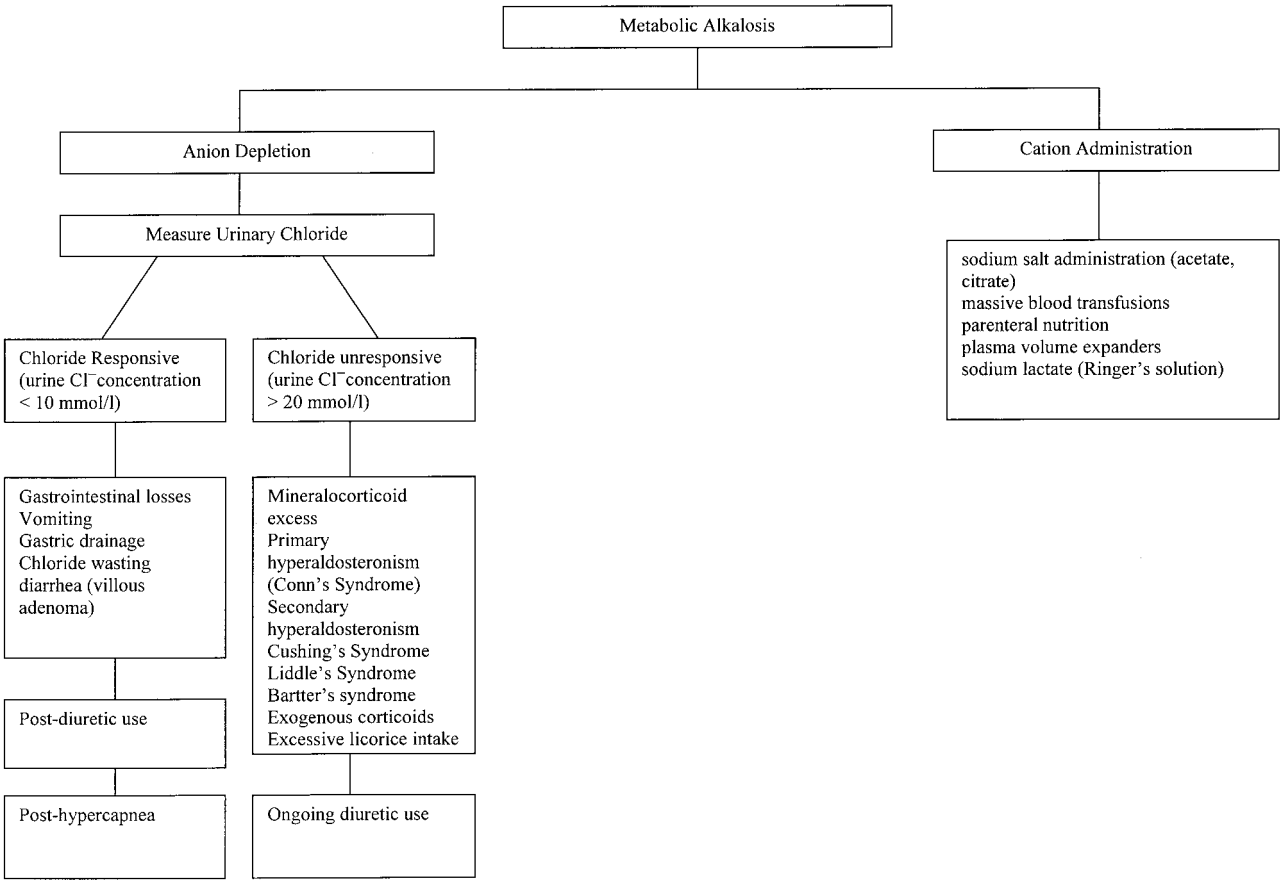


FIGURE 77-2 Differential diagnosis algorithm for metabolic alkalosis (increased SID).

without strong anions. The latter occurs with massive blood transfusion or plasma exchange because Na^+ is given with citrate (a weak anion) instead of Cl^-. Similar results occur when parenteral nutrition formulations contain too much acetate and not enough Cl^- to balance the Na^+ load.

Respiratory Acid-Base Disorders

PATHOPHYSIOLOGY OF RESPIRATORY ACID-BASE DISORDERS

CO_2 production by the body (at 220 mL/min) is equal to 15,000 m*M*/day of carbonic acid.[39] This compares with less than 500 m*M*/day (depending on diet) for all nonrespiratory acids, which are managed by the kidney and gut. Pulmonary ventilation is adjusted by the respiratory center in response to signals from P_{CO_2}, pH and P_{O_2}, as well as some from exercise, anxiety, and wakefulness. The normal P_{CO_2} of 40 mm Hg is attained by a precise match of alveolar ventilation to metabolic CO_2 production. P_{CO_2} changes in a "compensatory" ventilatory response to altered arterial pH produced by metabolic acidosis or alkalosis in predictable ways.

DISEASES OF VENTILATORY IMPAIRMENT

As for virtually all acid-base disorders, treatment begins with addressing the underlying disorder. Acute respiratory acidosis can be caused by CNS suppression, neuromuscular disease or impairment (e.g., myasthenia gravis, hypophosphatemia/hypokalemia), severe mechanical derangements of the chest wall, or airway and parenchymal lung disease (e.g., asthma, acute respiratory distress syndrome [ARDS], etc.). This last category of conditions also produces primary hypoxia, not just alveolar hypoventilation. The two can be distinguished by the alveolar gas equation:

$$P_{A_{O_2}} = P_{I_{O_2}} - P_{CO_2}/R$$

where R is the respiratory exchange coefficient (generally taken as 0.8), $P_{I_{O_2}}$ is the inspired oxygen tension (room air is approximately 150 mm Hg), and $P_{A_{O_2}}$ is the alveolar P_{O_2}. Thus, as P_{CO_2} increases the $P_{A_{O_2}}$ will decrease in a predictable fashion. If the $P_{a_{O_2}}$ is significantly lower than the calculated $P_{A_{O_2}}$, there is a defect in gas exchange.

Chronic respiratory acidosis is caused most often by chronic lung disease (e.g., chronic obstructive pulmonary disease [COPD]) or chest wall disease (e.g., kyphoscoliosis). Rarely, its cause is central hypoventilation or chronic neuromuscular disease.

RESPIRATORY ALKALOSIS

Respiratory alkalosis may be the most frequently encountered acid-base disorder. It occurs in residents at high altitude and in a number of pathologic conditions, the most important of which include salicylate intoxication, early sepsis, hepatic failure, and hypoxic respiratory disorders. Respiratory alkalosis also occurs with pregnancy and with pain or anxiety.

Hypocapnia appears to be a particularly bad prognostic indicator in patients with critical illness.[40] As in acute respiratory acidosis, acute respiratory alkalosis results in a small change in [HCO_3^-], as dictated by the Henderson-Hasselbalch equation. If hypocapnia persists, the SID will begin to decrease as a result of renal Cl^- reabsorption. After 2 to 3 days, the SID will assume a new, lower steady state.[41] Severe alkalemia is unusual in respiratory alkalosis, and management therefore is directed to the underlying cause of the acid-base disorder. Typically, these mild acid-base changes are more important clinically as an alarm than as any threat they pose to the patient.

DIABETIC KETOACIDOSIS, HYPERGLYCEMIC HYPEROSMOLAR NONKETOTIC COMA, AND HYPOGLYCEMIA

JOHN B. BUSE
KENNETH S. POLONSKY

KEY POINTS

- *Diabetic ketoacidosis (DKA), hyperglycemic hyperosmolar nonketotic coma (HHNC), and hypoglycemia are life-threatening disorders of glucose metabolism.*
- *Altered glucose metabolism should be considered in the differential diagnosis of all patients with mental status changes, neurologic deficits, and severe illness.*
- *Therapy of DKA and HHNC requires replacement of deficits of fluids, electrolytes, and insulin.*
- *Mixed-anion-gap acidosis and hyperosmolarity are encountered often in the same patient.*
- *Continuous insulin therapy is essential in DKA.*
- *In DKA and HHNC, careful physical examination and laboratory follow-up with a flow sheet make it possible to prevent the disastrous consequences of aggressive therapy—cerebral edema, pulmonary edema, hypoglycemia, hypokalemia, and hyperchloremic metabolic acidosis.*
- *A search for the underlying cause of metabolic decompensation is required.*
- *Therapy of hypoglycemia requires immediate establishment and maintenance of modest hyperglycemia (glucose concentration above 100 mg/dL or 5.5 mmol/L).*

Diabetes mellitus and its major life-threatening complications—diabetic ketoacidosis (DKA), hyperglycemic hyperosmolar nonketotic coma (HHNC), and hypoglycemia—may precipitate or complicate critical illness. This chapter will focus on the management of DKA because it has been studied more exhaustively and because the same principles are applicable to HHNC. A brief review of the physiology and therapy of hypoglycemia will follow. These conditions have been the subject of other reviews.[1–9a,9b,9c]

Pathophysiology of Diabetic Emergencies

Currently, most patients with diabetes can be classified as having either type 1 diabetes (previously known as *juvenile-onset, ketosis-prone, insulin-dependent,* or *brittle diabetes*) or type 2 diabetes (previously, *adult-onset, non-ketosis-prone, non-insulin-dependent,* or *obesity-related diabetes*). Type 1 diabetes results from the autoimmune destruction of the insulin-secreting β cells in the pancreas, with consequent insulin deficiency. Most persons with type 1 diabetes present in childhood or early adulthood, although well-documented cases also have been described in the geriatric population. Hyperglycemia is usually not present until approximately 90% of insulin secretory capacity is lost. In times of stress (either physiologic or emotional), however, insulin requirements increase and often precipitate metabolic decompensation because of inadequate insulin secretory reserve. Patients with insulin deficiency require insulin therapy for survival. The half-life of insulin in the circulation is 7 minutes, and therapy for insulin deficiency requires continuous delivery of insulin to the circulation by infusion or by diffusion of insulin from depot injections.

The pathophysiology of type 2 diabetes is more heterogeneous. At presentation, persons with type 2 diabetes exhibit both tissue resistance to the action of insulin and a relative deficiency of insulin secretion. Insulin resistance can be overcome only by (1) increasing circulating insulin concentrations, with insulin (often at high doses) or sulfonylureas, (2) imposing calorie restriction, (3) instituting exercise, (4) administering certain antidiabetic medications (metformin and thiazolidine diones), or (5) treating reversible causes of the disease (e.g., obesity; hyperglycemia; sepsis; uremia; catecholamine; excess levels of glucocorticoids, growth hormone, or thyroxine; and antibodies to insulin or to the insulin receptor). Most persons with type 2 diabetes present in middle age and are overweight and sedentary. There is a growing prevalence of the disorder in children and adolescents, as well as a less common familial adolescent form of the disease termed *maturity-onset diabetes of youth* (MODY).

DKA is the life-threatening metabolic consequence of insulin deficiency. Insulin deficiency, in concert with excess secretion of glucagon (primarily), catecholamines, glucocorticoids, and growth hormone, produces hyperglycemia by stimulating glycogenolysis and gluconeogenesis and impairing glucose disposal. As has been elegantly demonstrated by Foster and McGarry,[10] this hormonal milieu also results in lipolysis and unrestrained fatty acid oxidation, producing acetone, β-hydroxybutyrate, and acetoacetate—and thus ketoacidosis.

HHNC is the most severe presentation of a syndrome in which insulin resistance and relative insulin deficiency produce hyperglycemia. The glucose remains largely in the extracellular space and shifts water osmotically from the intracellular compartment. Glucose, water, and salts are filtered at the glomerulus; because the reabsorptive capacity of the renal tubules for glucose has a maximum of approximately 200 mg/min, an osmotic diuresis occurs, with water lost in excess of salts. A vicious cycle of cellular dehydration and diuresis is produced that can only be compensated by adequate fluid intake. With inadequate fluid intake, hyperosmolarity and hypovolemia develop, further increasing insulin resistance and hyperglycemia.

Patients rarely fit purely insulin-deficient or insulin-resistant physiology, particularly when in extremis. Patients with type 1 diabetes whose disease is not well controlled or who are under stress are insulin-resistant. Patients with poorly controlled type 2 diabetes may become insulin-deficient through a process of β-cell exhaustion and present with DKA. In fact, when careful studies of insulin levels,

secretory dynamics, and tissue sensitivity are performed, there is considerable overlap between patients with DKA and patients with HHNC. One of the keys to the management of these patients is recognizing the contributions of insulin deficiency and resistance and optimizing each patient's individual therapy.

DKA, HHNC, and Differential Diagnosis

Early in their course, patients with uncontrolled diabetes present with nonspecific complaints. If the disease follows an indolent course over months to years (more common for type 2 than for type 1 diabetes), patients can present with profound wasting, cachexia, and prostration similar in degree to that of patients with long-standing malignancy or chronic infection. With significant physical or emotional stress, sudden metabolic decompensation can occur.[10a] The cases of DKA and HHNC that are missed usually occur in patients with new-onset diabetes. All patients with nonspecific complaints should be questioned about more specific symptoms of diabetes. Polyuria (or at least nocturia) and weight loss are almost always present, although often not reported by the patient. Any patient with severe illness (acute or chronic) or neurologic changes should have glucose and electrolyte levels measured.

HISTORY AND PHYSICAL EXAMINATION

DKA and HHNC are easily recognized, when considered (Table 78-1). In DKA, metabolic decompensation develops over a period of hours to a few days. Patients with severe DKA classically present with lethargy and a characteristic hyperventilation pattern with deep, slow breaths (Kussmaul respiration) associated with the fruity odor of acetone. They often complain of nausea and vomiting; abdominal pain is somewhat less frequent. The abdominal pain can be quite severe and may be associated with distention, ileus, and tenderness without rebound, but it usually resolves relatively quickly with therapy unless there is underlying abdominal pathology. Most patients are normotensive, tachycardic, and tachypneic, with signs of mild to moderate volume depletion. Hypothermia has been described in DKA, and patients with underlying infection may not manifest fever. Cerebral edema does occur.

Patients with HHNC are usually stuporous, with obvious profound dehydration, and may demonstrate focal neurologic deficits, such as Babinski reflexes, asymmetric reflexes, cranial nerve findings, paresis, fasciculations, and aphasia. The syndrome evolves over days to weeks with a progressive decrease in fluid intake and decline in mental status; usually there is no prior history of diabetes. These patients are hypotensive and exhibit normal to depressed ventilation. Hypothermia, again, is common, although cerebral edema is rare.

LABORATORY TESTS AND DIFFERENTIAL DIAGNOSIS

Once DKA or HHNC is considered, the diagnosis can be made quickly with routine laboratory tests. DKA and HHNC need to be differentiated from each other and from the other causes of ketosis and metabolic acidosis. This is often quite difficult; in fact, these disorders often coexist. Table 78-2 and the following discussion are provided to help in making the distinction. Blood and urine glucose and ketone levels can be obtained in minutes using glucose oxidase–impregnated strips and the nitroprusside reaction, respectively.

TABLE 78-1 Signs and Symptoms of Glucose Metabolism Disorders

Uncontrolled diabetes
Polyuria
Polyphagia
Vaginitis
Nocturia
Weight loss
Skin infection
Thirst
Blurred vision
Fatigue
Polydipsia
Dizziness
Malaise
Diabetic ketoacidosis
Dyspnea
Normotension
Hypo- and hyperthermia
Nausea
Tachycardia
Lethargy to coma
Vomiting
Tachypnea
Fruity breath
Abdominal pain
Abdominal tenderness
Orthostasis
Cerebral edema
Hyperglycemic hyperosmolar nonketotic coma
Dehydration
Hypo- and hyperthermia
Stupor to coma
Dehydration
Focal neurologic signs or seizures
Shallow respiration
Hypotension to shock

The sine qua non of HHNC is hyperosmolarity. The osmolarity can be measured by freezing-point depression, or it can be estimated using the following formula:

$$\text{Osmolarity (mOsm/L)} = 2 \times [\text{sodium}] + [\text{glucose}]/18 + [\text{BUN}]/2.8 + [\text{ethanol}]/4.6 \quad (78\text{-}1)$$

where the concentrations of glucose, blood urea nitrogen (BUN), and ethanol are in milligrams per deciliter, and the concentration of sodium is in milliequivalents per liter. In HHNC, the osmolarity generally is greater than 350 mOsm/L and can exceed 400 mOsm/L. The serum sodium and potassium levels can be high, normal, or low and do not reflect total body levels, which are uniformly depleted. The glucose concentration is usually greater than 600 mg/dL (33.3 mmol/L), and levels over 1000 mg/dL (55.6 mmol/L) are quite common. In pure HHNC, there is usually no significant metabolic acidosis or anion gap. However, severe anion-gap metabolic acidosis of uncertain etiology has been reported in HHNC.[11]

TABLE 78-2 Means of Distinguishing HHNC, DKA, and Other Causes of Metabolic Acidosis

	HHNC	DKA	Lactate	Starvation	Uremia	Rhabdomyolysis	Ethanol	Methanol	Ethylene Glycol	Salicylate
Glucose level	++++	+++	0	0	0	0	−, +	0	0	0, −, +
Ketones	0, +	++++	0	+	0	0	+++	0	0	0, ++
pH	0, −	−−−−	−−−−	−	−−	−−−−	−−−	−−−	−−−	−−−
Anion gap	0, +	++++	++++	+	+	+	+++	++	++	++
Osmolarity	++++	++	0	0	+	++	+	++	++	+

NOTE: 0 = normal levels; + = increased levels; − = decreased levels; scale ranges from mild (+, −) to extreme (++++, −−−−).

The sine qua non of DKA is ketoacidosis. As mentioned earlier, two ketoacids are produced in DKA—β-hydroxybutyrate and acetoacetate—as well as the neutral ketone acetone. The nitroprusside reaction commonly used to detect ketone bodies detects acetoacetate much better than acetone and does not react with β-hydroxybutyrate at all. Particularly in severe DKA, β-hydroxybutyrate is the predominant ketone, and it is possible, though unusual, to have a negative serum nitroprusside reaction in the face of severe ketosis. β-Hydroxybutyrate levels can be measured at many centers and commercially, but this service usually is not readily available. Fortunately, there is a readily available index for unmeasured anions in the blood—namely, the anion gap (normally less than 14 mEq/L):

$$\text{Anion gap} = [\text{sodium}] - [\text{chloride}] - [\text{bicarbonate}] \quad (78\text{-}2)$$

Most persons with DKA present with an anion gap greater than 20 mEq/L, and some have an anion gap greater than 40 mEq/L. However, some patients have a hyperchloremic metabolic acidosis without a significant anion gap.[12] Patients with DKA almost invariably have large amounts of ketones in their urine. The serum glucose level in DKA is usually about 500 mg/dL (27.8 mmol/L). However, an entity known as *euglycemic DKA* has been described, particularly in the presence of decreased oral intake or pregnancy, where the serum glucose level is normal or near normal, but the patient requires insulin therapy for the clearance of ketoacidosis.[13] The arterial pH is commonly less than 7.3 and can be as low as 6.5. There is partial respiratory compensation with hypocapnia. Patients are often mildly hyperosmolar, although osmolalities greater than 330 mOsm/kg are unusual without mental status changes.

Not all patients with hyperglycemia and an anion gap metabolic acidosis will have DKA. Lactic acidosis is the most common cause of metabolic acidosis in hospitalized patients and can be seen in uncomplicated diabetes, as well as in DKA and HHNC. Lactic acidosis usually occurs in the setting of decreased tissue oxygen delivery, resulting in the nonoxidative metabolism of glucose to lactic acid. Lactic acidosis complicates other primary metabolic acidoses as a consequence of dehydration or shock. Thus, assessing its relative contribution can be difficult. The presentation is identical to that seen in DKA. In pure lactic acidosis, the serum glucose and ketone levels should be normal, and the serum lactate concentration should be greater than 5 m*M*. The therapy of lactic acidosis is directed at the underlying cause and at optimizing tissue perfusion.[14]

Starvation ketosis results from inadequate carbohydrate availability, resulting in physiologically appropriate lipolysis and ketone production to provide fuel substrates for muscle. The blood glucose level usually is normal. Although the urine can have large amounts of ketones, the blood rarely does. Usually the arterial pH is normal, and the anion gap is at most mildly elevated.

Alcoholic ketoacidosis is a more severe form of starvation ketosis wherein the appropriate ketogenic response to poor carbohydrate intake is increased through as yet poorly defined effects of alcohol on the liver. Classically, these patients are long-standing alcoholics for whom ethanol has been the main caloric source for days to weeks. The ketoacidosis manifests itself when, for whatever reason, the intake of alcohol and calories decreases. In isolated alcoholic ketoacidosis, the metabolic acidosis is usually mild to moderate in severity. The anion gap is elevated. Serum and urine ketones are always present. However, alcoholic ketoacidosis produces an even higher ratio of β-hydroxybutyrate to acetoacetate than does DKA, and negative or weakly positive serum nitroprusside reactions are common. Respiratory alkalosis associated with delirium tremens, agitation, or pulmonary processes often normalizes the pH but the underlying acidosis should be evident with careful analysis of acid-base status. Usually the patient is normoglycemic or hypoglycemic; sometimes mild hyperglycemia is present. Patients who are significantly hyperglycemic should be treated as if they had DKA. The therapy of alcoholic ketoacidosis consists of administration of thiamine, carbohydrates, fluids, and electrolytes, with special attention to the more severe consequences of alcohol toxicity, alcohol withdrawal, and chronic malnutrition. In more severely ill patients in whom alcoholic ketoacidosis is considered a possibility, there is usually another underlying illness, such as pancreatitis, gastrointestinal bleeding, hepatic encephalopathy, delirium tremens, or infection complicated by coexisting lactic acidosis.[15]

Uremic acidosis is characterized by very large elevations in the BUN level and the creatinine level with normoglycemia. The pH and anion gap are usually only mildly abnormal. The treatment is supportive, with careful attention to fluid and electrolytes until dialysis can be performed. Rhabdomyolysis is a cause of renal failure in which the anion gap can be elevated significantly and acidosis can be severe. There should be marked elevation of creatine phosphokinase (CPK) and myoglobin levels. It should be noted that mild rhabdomyolysis is not uncommon in DKA, but the presence of hyperglycemia and ketonemia leaves no doubt as to the primary etiology of the acidosis.[16]

Toxic ingestions can be differentiated from DKA by history and laboratory investigation. *Salicylate intoxication* can produce an anion-gap metabolic acidosis, usually with a respiratory alkalosis. The plasma glucose level is normal or low and the osmolality normal, and salicylates are detected in

the urine or blood. Salicylate uncouples oxidative phosphorylation; consequently, ketonemia and lactic acidosis develop. It should be noted that salicylates can cause a false-positive glucose determination when the cupric sulfate method is used and a false-negative result when the glucose oxidase reaction is used. *Methanol* and *ethylene glycol* also produce an anion gap metabolic acidosis without hyperglycemia or ketones; they need to be kept in mind primarily because they produce an increase in the measured serum osmolality but not in the calculated serum osmolality—an *osmolar gap.* Their serum levels also can be measured. *Isopropyl alcohol* does not cause a metabolic acidosis, but it needs to be borne in mind because it is metabolized to acetone, which can produce a positive result on the nitroprusside reaction commonly used for the detection of ketoacids. Therapy of these intoxications is discussed elsewhere[17–19] (see Chap. 102). Rare cases of anion gap acidoses have been reported with other ingestions, including toluene, iron, hydrogen sulfide, nalidixic acid, papaverine, paraldehyde, strychnine, and isoniazid.

It should be remembered that patients often present with combinations of the preceding conditions. As already noted, DKA not uncommonly appears with hyperosmolarity and coma. HHNC can have mild to moderate ketonemia and acidosis. Alcoholic ketoacidosis can contribute to either DKA or HHNC, and lactic acidosis is common in severe DKA and HHNC. We believe that any patient with hyperglycemia above 250 mg/dL (13.9 mmol/L) and an anion gap metabolic acidosis should be treated according to the general principles outlined below, with special consideration for possible other contributing metabolic acidoses (see Chaps. 77 and 102).

Therapy

The optimal management of DKA and HHNC has been the object of considerable controversy over the past half century. The guidelines we propose rely heavily on prospective studies of DKA treatment by Kitabchi and coworkers[1] and are readily applicable to HHNC. The general approach (Table 78-3) is (1) to provide necessary fluids to restore the circulation, (2) to treat insulin deficiency with continuous insulin, (3) to treat electrolyte disturbances, (4) to follow the patient closely and carefully, and (5) to search for underlying causes of metabolic decompensation.

TABLE 78-3 Treatment of Severe Disorders of Glucose Metabolism

Diabetic ketoacidosis
Fluids (usual deficit, 5–10 L)
If hypotensive: 1 L normal saline in the first few minutes; repeat as needed to restore the circulation, and consider invasive hemodynamic monitoring
If normotensive: 1 L 0.45% NaCl in first hour
In subsequent hours:
Match urine output with 0.45% NaCl; in addition, provide 100–500 mL/h 0.45% NaCl
Calculate free water deficit and replace 50% over 12 h with 5% dextrose in water
After glucose reaches 250 mg/dL (13.9 mmol/L), add dextrose to IV fluids (~100 g/24 h)
Insulin
10-unit IV bolus
0.1 units/(kg · h), IV or IM
Check glucose hourly, and adjust drip to decrease glucose by 10% or 50 mg/dL (2.8 mmol/L) hourly to a level of 250 mg/dL (13.9 mmol/L)
Potassium (usual deficit, 200–1000 mEq)
Establish that the patient is not oliguric
ECG monitoring for hyperkalemia and hypokalemia
If hyperkalemic, follow hourly
If normokalemic, 10–20 mEq/h
If hypokalemic, 20–40 mEq/h; delay insulin if K < 3.3 mEq/L
Administer two-thirds as chloride and one-third as phosphate salts
Bicarbonate
None is generally indicated
Consider administering $NaHCO_3$ 1 mEq/kg IV for pH < 6.9
May be useful for treatment of hyperkalemia
Search for underlying cause
Monitor:
ECG
Vital signs
Hourly: glucose and electrolyte levels
Every 2–4 h: calcium, magnesium, phosphate
Every 6–24 h: BUN, creatinine, ketones
Hyperglycemic hyperosmolar nonketotic coma (HHNC)
HHNC should be treated like DKA, although patients generally will require more fluids and less insulin

FLUIDS

Volume contraction is one of the hallmarks of DKA and HHNC. It can contribute to acidosis via lactic acid production, as well as decreased renal clearance of organic and inorganic acids. It contributes to hyperglycemia by decreasing renal clearance of glucose. If decreased tissue perfusion is significant, it causes insulin resistance by decreasing the delivery of insulin to the sites of insulin-mediated glucose disposal—muscle and adipose tissue—as well as by stimulating catecholamine and glucocorticoid secretion. Fluid deficits on the order of 5 to 10 L are common in DKA and HHNC. It should be remembered that the urine produced during the osmotic diuresis of hyperglycemia is approximately half normal with respect to sodium content. Therefore, water deficits are in excess of sodium deficits. Historically, large quantities of isotonic intravenous fluids have been administered rapidly to patients in DKA or HHNC. We tend to be more cautious; for patients with a history of congestive heart failure, chronic or acute renal failure, severe hypotension, or significant pulmonary disease, we give early and frequent consideration to the use of invasive hemodynamic montoring.

When there is physical evidence of dehydration—hypotension, decreased skin turgor, or dry mucous membranes—we generally administer 1 L of normal saline solution over the first few minutes and 200 to 500 mL/h in subsequent hours, until hypotension resolves and an adequate circulation is maintained. If hypotension is severe, with clinical evidence of hypoperfusion, and does not respond to crystalloid, then therapy with colloid is considered, often in combination with invasive hemodynamic monitoring. If there is no hypotension and no concern of renal failure, we administer 1 L of half-normal saline solution over the first hour and 100 to 500 mL/h in subsequent hours.

During that first hour, the results of initial laboratory tests usually are obtained and can be quite helpful in planning further therapy. Despite the excess of water losses over sodium,

the measured sodium level is usually low because of the osmotic effects of glucose. These osmotic effects can be corrected using the following simple formula:

$$\text{Corrected sodium concentration} = \text{measured [sodium]} + 0.016\,(\text{[glucose in mg/dL]} - 100) \quad (78\text{-}3)$$

Severe hypertriglyceridemia, which is common in severe diabetes, can cause a false decrease in the serum sodium concentration by approximately 1.0 mEq/L at a serum lipid concentration of 460 mg/dL.[20] An estimated water deficit[21] can be calculated using the corrected sodium concentration:

$$\text{Water deficit in liters} = 0.6 \times (\text{body weight in kg}) \times (\text{corrected [Na+]} - 140) \div 140 \quad (78\text{-}4)$$

Using these formulas, a 70-kg patient with a measured sodium level of 140 mEq/L and a glucose level of 1000 mg/dL would have a calculated water deficit of 4.3 L. If the patient is normotensive after the first liter of fluids, we provide generous maintenance fluids while the patient is NPO, replace urinary losses with one-half normal saline solution, and in addition, provide approximately one-half the calculated water deficit as 5% dextrose over the first 12 to 24 hours (using the preceding example, the amount would be 2 L) and the remainder over the subsequent 24 hours. The plan for fluid therapy should be reevaluated continuously in light of the clinical and laboratory response of the patient. Once the serum glucose level reaches 250 mg/dL (13.9 mmol/L), fluids should contain 5% dextrose, and therapy should be aimed at maintaining the serum glucose concentration in the 150 to 250 mg/dL (8.3–13.9 mmol/L) range for 24 hours to allow slow equilibration of osmotically active substances across cell membranes. At least 100 g of dextrose per 24 hours (at least 80 mL/h of 5% dextrose if the patient is NPO) must be given to prevent ketogenesis. In late pregnancy, approximately 100% more carbohydrate may be needed, so 10% dextrose should be used.

The primary goal of fluid therapy is to maintain adequate circulation, and the secondary goal is to maintain brisk diuresis. Beyond that, pulmonary edema, hyperchloremic metabolic acidosis, and a rapid fall in the serum osmolality should be avoided by frequent monitoring of the patient, the glucose level, and the electrolyte levels. It has been demonstrated that fluid administration and subsequent continued osmotic diuresis are responsible for a large portion of the initial decline in glucose during therapy. In general, persons with HHNC present with more profound dehydration and require more intravenous fluids than persons with DKA.

INSULIN

Insulin is the mainstay of therapy of DKA, which is essentially an insulin-deficient state. In the past, high doses of insulin (upwards of 50 units/h) were favored. In more recent studies, low-dose insulin therapy (0.1 unit/kg per hour) has been shown to be equally effective in producing a decrease in serum glucose concentration and effecting clearance of ketones. Furthermore, low-dose therapy results in a dramatic reduction in the major morbidity of intensive insulin therapy—hypoglycemia and hypokalemia.

Studies have also shown that intravenous (IV) insulin is significantly more effective than intramuscular (IM) or subcutaneous (SC) insulin in lowering ketone body concentration over the first 2 hours of therapy. The SC route is inappropriate for critically ill patients because of the possibility of tissue hypoperfusion and the slower kinetics of absorption. Numerous studies attest to the efficacy of IM therapy in severe DKA. In cases where there is insufficient nursing monitoring or IV access to allow for safe IV administration, hourly IM injections of regular insulin is an acceptable substitute. It is important that a needle of adequate length—at least 1.5 inches for adults—be used.

Last, it has been shown that the administration of a 10-unit IV priming dose of insulin, when a patient is being started on insulin therapy (whether IV or IM), significantly improves the glycemic response to the first hour of therapy. The rationale is to fully saturate insulin receptors before continuous therapy is started and thus to avoid the lag time necessary to achieve steady-state insulin levels. It seems to be possible to mix insulin into normal saline solution without adding albumin to prevent adsorption of insulin onto the infusion set. However, the IV tubing should be flushed with the insulin infusate prior to use.

In those rare instances where the glucose level does not decrease by at least 10%, or 50 mg/dL (2.8 mmol/L), in 1 hour, the insulin infusion rate should be increased, and a second bolus of IV insulin should be administered. As the glucose level decreases, it is usually necessary to decrease the rate of infusion. After the glucose level reaches approximately 250 mg/dL (13.9 mmol/L), it is prudent to decrease the insulin infusion rate and to administer dextrose as described under "Fluids" above. It is a common mistake to discontinue IV insulin in response to a falling glucose level. Because of its short half-life, IV insulin should not be discontinued until after SC insulin is initiated. With resolution of ketosis, the rate of insulin administration approaches the physiologic range of 0.5 to 1.0 units/kg per day.

If the patient is not nauseated, early feeding should be considered because it allows more carbohydrates and insulin to be administered, which accelerates the clearance of ketones. When the decision is made to feed the patient, the patient should be switched from IV or IM therapy to SC therapy. SC insulin should be administered before a meal, and the insulin drip should be discontinued approximately 30 minutes later if regular insulin is used, approximately 15 minutes later if a rapid-acting insulin analogue is used, and in 2 hours if only intermediate or long-acting insulin is used. The glucose level should be checked in 2 hours and at least every 4 hours subsequently, until a relatively stable insulin regimen is determined. Early conversion to oral feeding and SC insulin therapy has been associated with shorter length of hospital stay. A proportion of patients with HHNC do not require therapy for their diabetes after hospitalization, and most do not require insulin.

POTASSIUM

Potassium losses during the development of DKA and HHNC are usually quite high (3 to 10 mEq/kg) and are mediated by protein catabolism compounded by hyperaldosteronism and osmotic diuresis. Most persons with DKA or HHNC have normal or even high serum potassium levels at presentation, but

the initial therapy with fluids and insulin will cause the serum potassium level to fall. Our approach has been to monitor the electrocardiogram (ECG) for signs of hyperkalemia (peaked T wave, QRS widening) initially and to administer potassium if these signs are absent and the serum potassium level is less than 5.5 mEq/L. If the patient is oliguric, we do not administer potassium unless the serum concentration is less than 4 mEq/L or if there are ECG signs of hypokalemia (U wave)—and even then, only with extreme caution. With therapy of DKA, the potassium level always falls, usually reaching a nadir after several hours. We usually replace potassium at 10 to 20 mEq/h, two-thirds as potassium chloride and one-third as potassium phosphate, and monitor serum levels at least every 2 hours initially, as well as following ECG morphology. Some patients with DKA who have had a protracted course including vomiting present with hypokalemia and acidosis; they may require 20 to 40 mEq/h or more by central line to avoid further decreases in the serum potassium concentration; consideration in these rare cases of delaying the initiation of insulin infusion until potassium concentrations are greater than 3.3 mEq/L may be prudent to avoid precipitating a further decline in serum potassium concentration.

PHOSPHATE

Like potassium, phosphate is depleted in patients with DKA and HHNC. Although patients usually present with an elevated serum phosphate level, the serum level declines with therapy. Although no well-documented clinical benefit of phosphate administration has been demonstrated, most authorities recommend phosphate therapy as above and monitoring for its possible complications—hypocalcemia and hypomagnesemia.

BICARBONATE

The serum bicarbonate level is always low in DKA, but no true deficiency is present because the ketoacid and lactate anions are metabolized to bicarbonate during therapy. The use of bicarbonate in the therapy of DKA is highly controversial; no benefit of bicarbonate therapy has been demonstrated in clinical trials. In fact, in two trials, hypokalemia was more common in bicarbonate-treated patients. There are theoretical considerations against the use of bicarbonate. Cellular levels of 2,3-diphosphoglycerate are depleted in DKA, causing a leftward shift in the oxyhemoglobin dissociation curve and thus impairing tissue oxygen extraction. Acidemia has the opposite effect; therefore, acute reversal of acidosis might decrease tissue oxygen extraction. In addition, there are in vitro data to suggest that pH is a regulator of cellular lactate metabolism and that correction of acidosis could increase lactate production. Most important, bicarbonate administration acutely elevates P_{CO_2}, which may lower intracellular pH. We do not administer bicarbonate routinely, but we understand that other authors advocate its use. Bicarbonate therapy should be restricted to (1) patients with severe acidosis (pH below 6.9), (2) patients with hemodynamic instability in whom the pH is less than 7.1, and (3) patients with hyperkalemia and ECG findings. When bicarbonate is used, it should be used sparingly as a temporizing measure while definitive therapy with insulin and fluids are under way. Approximately 1 mEq/kg of bicarbonate is administered as a rapid infusion over 10 to 15 minutes, with further therapy based on repeat measurement of arterial blood gases every 30 to 120 minutes. Potassium therapy should be considered prior to treatment with bicarbonate because transient hypokalemia is a not uncommon complication of the administration of alkali.

MONITORING

It is possible to manage many cases of mild DKA without ICU admission, depending on staff availability. We routinely admit patients with DKA to the ICU if they have a pH below 7.2. If mental status is compromised, then prophylactic intubation is considered, and nasogastric suctioning is always performed because of frequent ileus and danger of aspiration. Only if the patient cannot void at will is bladder catheterization necessary to follow urine output adequately. ECG monitoring is continuous, with hourly documentation of QRS intervals as well as T-wave morphology. Initially, the levels of serum glucose, electrolytes, BUN, creatinine, calcium, magnesium, phosphate, ketone, lactate, and CPK are measured; liver function tests, urinalysis, ECG, upright chest x-ray, and a complete blood count (CBC) are performed; and arterial blood gases are measured. If there is any concern about possible toxic ingestions, toxicology screening is also performed. Subsequently, glucose and electrolyte levels are measured at least hourly; calcium, magnesium, and phosphate levels are measured every 2 hours; and the levels of BUN, creatinine, and ketones are measured every 6 to 24 hours. This frequency of laboratory analysis generally can be tapered as trends in improvement become clear; glucose monitoring using bedside point-of-care systems can be substituted for laboratory analysis of glucose if appropriate quality assurance and documentation programs are in place once glucose levels are in the 400 to 600 mg/dL (22–33 mmol/L) range. The urine ketone concentration is a more sensitive indicator of ongoing or recurrent hepatic ketogenesis than is the level of serum ketones. It is usually not necessary to routinely monitor arterial blood gases because bicarbonate and the anion gap are relatively good indices of the response to therapy. Monitoring venous pH also has been shown to adequately reflect acidemia and response to therapy. In severely ill patients with obvious underlying disease, the course is often more protracted; when venous access is a problem, early consideration should be given to placement of an arterial line. A flow sheet tabulating these findings, as well as mental status, vital signs, insulin dose, fluid and electrolytes administered, and urine output, allows easy analysis of response to therapy. Once the acidosis begins to resolve and the response to therapy becomes predictable, it is reasonable to curtail laboratory use. The goal should be to rapidly achieve hemodynamic stability and to fully correct DKA in 12 to 36 hours.

THE SEARCH FOR UNDERLYING CAUSES

After the patient is stabilized, a careful history and physical examination and a diagnostic strategy should be aimed at determining the precipitating event. In our practice, the most common cause of DKA is poor compliance with insulin therapy or inadequate outpatient insulin regimens; these causes usually are treated easily. The second most common cause is infection, with urinary tract infection, pelvic inflammatory

disease, and respiratory tract infections predominating. It is often difficult to determine initially if the patient is infected. Fever is absent in a significant proportion of patients with diabetic emergencies. The white blood cell count (WBC) is not uncommonly elevated to the range of 20,000/μL or higher, even in the absence of infection.[21] We therefore perform cultures on most patients with DKA or HHNC, and we often treat empirically with antibiotics while awaiting the results of bacterial cultures. Meningitis should be considered in any patient with altered mental status. In this regard, our approach has been to perform lumbar punctures on all patients with meningismus and on patients in whom the change in mental status does not appear to be related to the metabolic insult. The cerebrospinal fluid (CSF) glucose level is not particularly useful in the diagnosis of meningitis in the setting of DKA or HHNC, but a CSF glucose level of less than 100 mg/dL (5.5 mmol/L) is unusual when the serum glucose level is greater than 250 mg/dL (13.9 mmol/L).[22] The relative frequency of sinus infection (the most serious being mucormycosis), foot infection, bacterial arthritis, cholecystitis, cellulitis, and necrotizing fasciitis should be considered. Pneumonia can be difficult to diagnose in patients with dehydration because the alveolar edema fluid, which causes infiltrates on chest x-ray, often is not present but develops along with progressive hypoxia during hydration. To avoid this occurrence, we are particularly judicious with fluid administration in patients we suspect of having pneumonia. Pancreatitis and pregnancy are common precipitants and need to be specially considered in the assessment of abdominal pain, which is extremely common at presentation. Abdominal guarding and tenderness associated with vomiting are seen often. Rebound is present only rarely. These symptoms and findings usually resolve quickly with therapy in the absence of intraabdominal pathology. The serum amylase level is often elevated without pathologic significance, but a high lipase level is usually more specific for a diagnosis of pancreatitis.[23] Acute myocardial infarction and stroke, as well as thromboembolic phenomena, are frequent precipitants and complications of DKA.

Precipitating factors are similar in HHNC, but they are found more commonly and are often more severe. Common associated illnesses are chronic renal insufficiency, pneumonia, gastrointestinal hemorrhage, sepsis (particularly with gram-negative organisms), myocardial infarction, pulmonary embolism, and intracranial events. Burns, hyperalimentation, dialysis, heat stroke, thyrotoxicosis, acromegaly, pancreatitis, and a variety of drugs (mostly diuretics, steroids, and β-blockers) also have been associated.

The more insulin-resistant the patient, the more likely it is that a precipitating cause is present. If a precipitating cause is found, treatment is essential if adequate metabolic control is to be achieved.

COMPLICATIONS AND PROGNOSIS

It should be possible to treat almost all cases of DKA successfully. The most troublesome complication is cerebral edema. It is particularly common in children and can be fatal. In most series, specific causes cannot be assigned, although the use of bicarbonate, more severe DKA, and aggressive hydration, particularly with hypotonic fluids, may contribute.[24] In 50% of patients who subsequently have a respiratory arrest, there are premonitory symptoms; despite early intervention, only half of such patients avoid severe or fatal brain damage. Cerebral edema is much less common in HHNC but may be associated with decreases in plasma glucose concentration below 250 mg/dL (13.9 mmol/L) during the first day of therapy.[25] Other complications of life-threatening severity that have been reported include the acute respiratory distress syndrome (ARDS) and bronchial mucus plugging.[26–28]

The most common complication of HHNC is death. Female gender, lack of prior knowledge of diabetes, and acute infections are risk factors for the development of HHNC. Despite aggressive therapy, mortality is in the range of 20% to 50% in most recent case series. Prognosis is inversely related to serum osmolality, BUN level, and sodium level, although large differences in values are not apparent between survivors and nonsurvivors.[29] The mortality seems to be in large part a function of the underlying illness and the duration of illness before appropriate medical therapy is instituted. Although complete recovery of neurologic function in survivors is the rule, persistent coma is not infrequent. Arterial and venous thromboembolic events are quite common. Standard prophylactic low-dose heparin administration is certainly a reasonable precaution for patients with HHNC, but currently no indication exists for full anticoagulation.

Recurrent admissions for DKA occur in up to one-third of patients. Ensuring adequate and timely outpatient follow-up and diabetes education will reduce relapses. Patients with frequent DKA are rare and require special consideration of neuropsychological contributors.[30]

Hypoglycemia

Although not a complication of diabetes per se, severe hypoglycemia is a not uncommon complication of its therapy. It also may be a major complication of critical illness—particularly hepatic failure, drug overdose, and sepsis. The serum glucose concentration is very strictly regulated in normal persons, being maintained between approximately 60 and 140 mg/dL (3.3–7.8 mmol/L). The differential diagnosis of hypoglycemia can be divided into fasting and postprandial forms (Table 78-4). Fasting hypoglycemia can result from endocrine disorders, hepatic dysfunction, antibodies to insulin or the insulin receptor, or substrate deficiency. The major endocrine causes are excess secretion of insulin or insulin-like growth factor and deficiency of growth hormone or cortisol. Insulin hypersecretion can be from an insulinoma or from normal islet tissue under pharmacologic stimulation. Certain malignancies, particularly sarcomas, hepatomas, and tumors of the biliary tract, can cause elevated levels of free insulin-like growth factors and can present with hypoglycemia, often in the presence of cachexia. Any cause of severe hepatic dysfunction—toxins, viruses, congestive heart failure, or shock—and enzymatic defects causing decreased gluconeogenesis or glycogen storage diseases can cause hypoglycemia. Hypoglycemia can occur with fasting in alcoholism, pregnancy, or uremia due to substrate unavailability, but otherwise, it occurs only with end-stage protein-calorie malnutrition. Postprandial hypoglycemia can be caused by rapid gastric emptying owing to postoperative changes, or it can

TABLE 78-4 Causes of Hypoglycemia

Fasting hypoglycemia
Hypersecretion of insulin or increased levels of insulin-like growth factors
Insulinoma
Nesidioblastosis
Certain carcinomas (sarcoma, hepatoma, others)
Hyposecretion of counterregulatory hormones
Growth hormone deficiency
Cortisol deficiency
Hepatic failure
Toxic (especially alcohol-induced)
Infectious
Congestive
Shock-induced
Caused by an inborn error of metabolism
Starvation
Uremia
Pregnancy
Severe protein-calorie malnutrition
Autoimmune disorder (antibodies to insulin or insulin receptors)
Postprandial hypoglycemia
Idiopathic
Alimentary
Early type 2 diabetes mellitus
Factitious or drug-related hypoglycemia
Insulin
Sulfonylureas and other sulfa compounds
Salicylates
β-Blockers
Pentamidine
Antiarrhythmic agents
Glucose consumption in test tube by leukocytes

TABLE 78-5 Treatment of Hypoglycemia

Consider the diagnosis
Determine capillary glucose concentration
Confirm with measurement of serum glucose (and insulin, C-peptide, and sulfonylurea screen if cause unknown)
Give oral calories if patient is conscious
Reassess; if glucose <100 mg/dL (5.5 mmol/L), *then* administer 50 mL 50% dextrose
Reassess; if glucose <100 mg/dL (5.5 mmol/L), *then* give infusion of 10% dextrose to maintain glucose level > 100 mg/dL (5.5 mmol/L)
Reassess; if glucose <100 mg/dL (5.5 mmol/L), *then* give infusion of 10% glucose + 100 mg/L hydrocortisone + 1 mg glucagon
Reassess; if glucose <100 mg/dL (5.5 mmol/L), *then* add infusion of diazoxide and/or continuous enteral feeding

be idiopathic. It has been associated with early type 2 diabetes. Drugs that can cause hypoglycemia include alcohol, insulin, sulfonylureas, salicylates, β-blockers, pentamidine, some antiarrhythmic agents, akee fruit, and the rat poison Vacor.

The symptoms of hypoglycemia initially result from sympathoadrenal responses and consist of palpitations, anxiety, tremulousness, sweating, and hunger. If hypoglycemia progresses, neuroglycopenic symptoms develop. These include headache, nightmares, fatigue, confusion, bizarre behavior, hallucinations, seizures, coma, and focal neurologic deficits. The absolute glucose concentration at which these symptoms develop is highly variable; in part it depends on the rate of fall in glucose concentration. In critically ill patients, symptoms may be obscured by concurrent problems until profound hypoglycemia, with seizures or coma, evolves.

Patients who present with signs and symptoms compatible with hypoglycemia should have their blood glucose concentration measured and glucose administered—by mouth if conscious, intravenously otherwise. The disappearance of symptoms over a period of minutes suggests that hypoglycemia is the likely etiology. IV administration of 50 mL of 50% dextrose will awaken more than 80% of hypoglycemic patients destined for neurologic recovery.

Patients with hypoglycemia should be fully evaluated to determine etiology. A complete history, physical examination, and routine laboratory tests will result in a likely diagnosis in most cases. The various studies that can be used in less obvious cases should be considered only with the help of a specialist and are beyond the scope of this review. Glucose tolerance testing is usually nondiagnostic. A 72-hour fast will produce a diagnosis in the vast majority of patients with fasting hypoglycemia. At a minimum, glucose, insulin, C-peptide, proinsulin, and urine or serum drug screens for oral hypoglycemic agents should be obtained in both the normal and the hypoglycemic state.

TREATMENT

The most critical step in the therapy of hypoglycemia is recognition of its cause, which indicates its likely duration and severity (Table 78-5). If a patient took his or her insulin, forgot to eat breakfast, and subsequently lost consciousness, an ampule of 50% dextrose administered in the field and followed by breakfast almost certainly would be curative. However, if a patient drank a quart of liquor and then made a suicide gesture by taking long-acting oral hypoglycemic agents, aspirin, and β-blockers, then the hypoglycemia is likely to be severe and long-lasting and will require intensive therapy for days. Similarly, patients with hepatic failure will require continuous therapy with hypertonic glucose once hypoglycemia develops and until hepatic function returns. The goal of therapy is to establish and maintain modest hyperglycemia immediately and to monitor blood glucose concentration intensively using hand-held monitors. Seltzer[9] has described a protocol for use in severe hypoglycemia as follows: In the presence of documented hypoglycemia, whether or not the patient responds to 50 mL of 50% dextrose, a continuous infusion of 10% glucose at a rate sufficient to keep the blood glucose level above 100 mg/dL (5.5 mmol/L) should be started. If more than 200 mL/h is necessary to maintain hyperglycemia, then 100 mg hydrocortisone and 1 mg glucagon are added to each liter of 10% dextrose for as long as necessary. Intravenous diazoxide administration to decrease insulin secretion also can be considered. It is important to remember that much more carbohydrate can be delivered enterally than intravenously, and so in extreme cases, jejunal feeding should be considered early. If the patient awakes, a high-carbohydrate diet should be initiated. Progressive hyperglycemia is the signal that therapy can be tapered. With early aggressive therapy, usually coma is reversed and focal deficits resolve over time.

Chapter 79

ADRENOCORTICAL INSUFFICIENCY

PAUL E. MARIK
GARY P. ZALOGA

KEY POINTS

- *Activation of the hypothalamic-pituitary-adrenal (HPA) axis with increased glucocorticoid activity is an essential component of the general adaptation to stress.*
- *Mediators released in patients with sepsis may either stimulate or impair the synthesis and action of cortisol via actions on the HPA axis and glucocorticoid receptor.*
- *A random cortisol level in a highly stressed ICU patient is currently the most useful test to assess the integrity of the HPA axis.*
- *A stress cortisol level of less than 25 μg/dL in a highly stressed patient (hypotensive, respiratory failure) is highly suggestive of adrenal failure.*
- *The incidence of adrenal failure may be as high as 60% in patients with septic shock.*
- *All patients with suspected HPA axis dysfunction should be treated with stress doses of hydrocortisone (100 mg q 8 IV) pending the results of diagnostic testing.*
- *A random cortisol level of less than 15 μg/dL or a level of less than 20 μg/dL post low-dose corticotrophin stimulation testing (low-dose ACTH test) in a non-hypotensive patient with unexplained fever, eosinophilia or altered mental status warrants a trial of treatment with stress doses of hydrocortisone.*

The maintenance of life depends on the capacity of the organism to sustain its equilibrium via *allostasis*—the ability to achieve stability through change. Allostasis is critical to survival in stress situations.[1] The three major regulatory systems of the body responsible for allostasis include the central nervous system (CNS), the endocrine system, and the immune system. These three regulatory systems are closely interrelated and orchestrate the stress response. Importantly, activation of the hypothalamic-pituitary-adrenal (HPA) axis with the release of cortisol is the cornerstone of the stress response.

The qualitative and quantitative aspects of the stress response depend on the nature and severity of the stressor and are time-dependent. With mild to moderate short-term stress there is general activation of the CNS, the endocrine system, and the immune system in an attempt to restore homeostasis. However, with severe and/or prolonged stress, this coordinated allostatic response may fail with the ultimate demise of the organism. Teleologically, the latter may be viewed as a mechanism to spare society of those overwhelmed by disease. However, these are the very patients who are treated in ICUs and who are trying to "cheat death."

Cortisol, the primary glucocorticoid hormone in humans, is secreted by the adrenal glands. In healthy, unstressed persons, cortisol is secreted in a diurnal pattern under the influence of corticotropin (ACTH) released from the pituitary gland. Corticotropin secretion, in turn, is under the influence of hypothalamic corticotropin-releasing hormone (CRH), and both hormones are subject to negative-feedback control by cortisol. Aldosterone, the primary mineralocorticoid hormone in the body, is also secreted by the adrenal glands. Aldosterone secretion, however, is regulated primarily by the renin-angiotensin system and potassium levels. Circulating cortisol is bound to corticosteroid-binding globulin, with less than 10% in the free bioavailable form. With acute stress in the form of infection, surgery, trauma, burns, or illness, cortisol production increases by a factor that is roughly proportional to the severity of the stress. The increase in cortisol is due to the increased production of CRH and corticotropin and a reduction in the negative feedback from cortisol. Diurnal variation of cortisol secretion is lost. The increased adrenal glucocorticoid production is associated with a shift away from mineralocorticoid and androgen production (i.e., reprioritization).[2] Indeed, while there is activation of the renin-angiotensin system in an attempt to maintain blood pressure, aldosterone secretion is decreased.[3–6] The dissociation between renin-angiotensin and aldosterone may represent an additional adaptive mechanism designed to promote cortisol production in critically ill patients.[3–6] Sustained high levels of ACTH may explain this finding because in normal subjects ACTH causes a biphasic aldosterone response with an initial increase followed by diminished production.[3–5]

Glucocorticoids exert their effects by binding to and activating a 90-kDa intracellular glucocorticoid receptor (GR) protein.[7] All cells appear to have appreciable levels of GR. The GR is localized in the cytoplasm of the cell and translocates into the nucleus on ligand binding. In the absence of hormone, cytoplasmic GR is associated with a large protein complex that includes heat shock protein 90 (hsp-90) and hsp-56.[8] This protein complex functions to maintain the GR in an inactive conformation that is competent for glucocorticoid binding. When activated by a ligand, GRs bind as dimers to glucocorticoid response elements (GREs) in target genes that then activate or repress transcription of the associated genes. Via this mechanism, glucocorticoids regulate gene transcription in every cell in the body. In addition to increased secretion of cortisol, a number of other mechanisms may increase cellular glucocorticoid activity. An acute decline in the concentration of cortisol-binding globulin, as well as decreased cortisol binding to cortisol-binding globulin, results in an increase in the free biologically active fraction of the hormone.[9–13] In addition, the number of GRs may be upregulated acutely during stress. Sun and colleagues[14] demonstrated increased expression of GR mRNA, increased expression of GRs, and increased binding activity of the GRs in skeletal muscle in a murine cecal ligation and perforation model. In this study, pretreatment of the animals with the GR antagonist RU-38486 prevented the increase in GR protein and mRNA levels seen in sepsis and abolished the sepsis-induced increases in GR binding activity. These data suggest that cortisol may increase synthesis of its own receptor directly via a positive-feedback loop. The collective result of adrenocortical adaptation to severe stress is a dramatic increase in cellular glucocorticoid activity. This activation is an essential component of the general adaptation to illness and stress and contributes to the maintenance of cellular and organ homeostasis. For example,

adrenalectomized animals succumb rapidly to hemorrhagic and septic shock, whereas steroid replacement is protective against these challenges.[15,16]

Major Physiologic Actions of Glucocorticoids

In the acutely stressed individual, the metabolic, cardiovascular, and immunologic actions of cortisol play a critical role in mediating the stress response. Glucocorticoids increase blood glucose levels, facilitating the delivery of glucose to cells during acute and chronic stress. Glucocorticoids increase blood glucose concentrations by increasing the rate of hepatic gluconeogenesis and inhibiting adipose tissue glucose uptake.[17] Hepatic gluconeogenesis is stimulated by increasing the activities of phosphoenolpyruvate carboxykinase and glucose-6-phosphatase as a result of binding of glucocorticoids to the GREs of the genes for these enzymes. Glucocorticoids also stimulate free fatty acid release from adipose tissue and amino acid release from body proteins. Proteolysis is activated via glucocorticoid upregulation of the calpain and ubiquitin-proteasome pathways. Major roles of these processes are to supply to the cell energy and substrate that are required for response to stress and repair from injury.

Glucocorticoids are required for normal cardiovascular reactivity to angiotensin II, epinephrine, and norepinephrine, contributing to the maintenance of cardiac contractility, vascular tone, and blood pressure. These effects are mediated partly by the increased transcription and expression of the receptors for these hormones.[18,19] Glucocorticoids are required for the synthesis of N^+,K^+-ATPase and catecholamines. Glucocorticoid effects on the synthesis of catecholamines and catecholamine receptors are partially responsible for the positive inotropic effects of these hormones.[20] Glucocorticoids also decrease the production of nitric oxide and vasodilatory prostaglandins, major vasorelaxants and modulators of vascular permeability.[21–24]

Glucocorticoids possess anti-inflammatory and immunosuppressive effects that are mediated through specific receptor mechanisms.[25–28] Glucocorticoids influence most cells that participate in immune and inflammatory reactions, including lymphocytes, natural killer cells, monocytes, macrophages, eosinophils, neutrophils, mast cells, and basophils. Glucocorticoids decrease the accumulation and function of most of these cells at inflammatory sites. Most of the suppressive effects of glucocorticoids on immune and inflammatory reactions appear to be a consequence of the modulation of production or activity of cytokines (e.g., interleukin 1 [IL-1], IL-2, IL-3, IL-6, interferon-γ [IFN-γ], tumor necrosis factor α [TNF-α]), chemokines, eicosanoids, complement activation, and other inflammatory mediators (e.g., bradykinin, histamine, macrophage migration inhibitory factor). Glucocorticoids control mediator production predominantly through inhibition of transcription factors such as nuclear factor $\kappa\beta$ (NF-$\kappa\beta$).[27,28] This inhibition is mediated by induction of the I-$\kappa\beta\alpha$ inhibitory protein.[29] Glucocorticoids also produce anti-inflammatory effects by enhancing release of anti-inflammatory factors such as IL-1 receptor antagonist, soluble tumor necrosis factor receptor, and IL-10.[30,31] In addition, glucocorticoids block the transcription of mRNA for enzymes required for the synthesis of some mediators (e.g., cyclooxygenase 2, inducible nitric oxide synthase).

Cytokines and the HPA Axis

The HPA axis and the immune response are linked together via a feedback loop in which activated immune cells produce cytokines that signal the brain. Activation of the HPA axis by specific cytokines increases the release of cortisol, which, in turn, feeds back and suppresses the immune reaction (and further cytokine release).[32] IL-1 and IL-6 administered peripherally increase HPA axis activity, increasing levels of CRH, ACTH, and glucocorticoids.[33,34] Cytokines also affect the pituitary and adrenal cortex directly. IL-1, IL-6 and TNF-α stimulate the secretion of ACTH from cultured pituitary preparations, and IL-1 and IL-6 stimulate glucocorticoid production in cultured adrenal preparations.[33,34]

Cytokines, however, also suppress the HPA axis and impair GR function. Whereas acute elevation of IL-6 levels stimulates ACTH release, chronic IL-6 elevation may blunt ACTH release.[35] In addition, TNF-α impairs CRH-stimulated ACTH release,[36,37] and a number of clinical studies have reported inappropriately low ACTH levels in patients with severe sepsis and the systemic inflammatory response syndrome (SIRS).[36,38,39] Indeed, Schroeder and coworkers[40] reported similar circulating levels of ACTH in healthy controls and in patients with severe sepsis. In addition, plasma from patients with septic shock impairs synthesis of corticosteroids by adrenocortical cells.[41–43] TNF-α and corticostatin have been demonstrated to inhibit adrenal gland function.[37,44,45] Corticostatin (defensin) is a peptide produced by immune cells.[46] Concentrations of corticostatin increase over 20-fold in animals with infection but not other forms of stress.[47] TNF-α has been shown to reduce adrenal cortisol synthesis by inhibiting the stimulatory actions of ACTH and angiotensin II on adrenal cells.[44,48,49] Proinflammatory cytokines have been shown to influence the number, expression, and function of GRs. IL-1 has been demonstrated to decrease GR translocation and transcription.[50] The half-life of cortisol has been demonstrated to be prolonged in sepsis; this may reflect a decreased number of GRs or decreased affinity of the receptor for its ligand.[43,51,52] While Sun and colleagues[14] demonstrated increased expression of GRs in skeletal muscle in the early phase of experimental sepsis, Liu and colleagues[53] demonstrated decreased expression of GRs following burn injury. It is particularly noteworthy that in the latter study the decreased expression of GRs was attenuated by treatment with both anti-TNF-α and anti-IL-1 monoclonal antibodies. Ali and colleagues[54] reported a 40% decline in the number of glucocorticoid receptors in the liver of septic rats. The decline in hormone-binding activity was associated with a fall in glucocorticoid receptor mRNA. Decreased affinity of the GR from mononuclear leukocytes of patients with sepsis also has been reported.[55,56] Reduced activity of gluconeogenic enzymes during endotoxemia despite elevated circulating glucocorticoid levels provides further evidence to support impaired intracellular actions of glucocorticoids during sepsis.[57] In total, these data support the idea that mediators released in patients with sepsis may either stimulate or impair the synthesis and action of cortisol via actions on the HPA axis and the GR. The net effect of these opposing actions on the

HPA axis and GR may be time-dependent and in addition depend on the severity of illness and extent of mediator production.

Assessment of Adrenal Function in the Critically Ill

Since there are no clinically useful tests to assess the cellular actions of cortisol (i.e., end-organ effects), the diagnosis of adrenal insufficiency is based on measurement of serum cortisol levels; this has resulted in much confusion and misunderstanding.[39,58–69] Traditionally, the "integrity" of the HPA axis has been assessed by the short corticotropin stimulation test (also known as the *Cosyntropin stimulation test*). This test is usually performed by administering 250 μg of synthetic corticotropin intravenously and obtaining a serum cortisol determination before and 30 and 60 minutes following administration.[58,70] A 30- to 60-minute serum cortisol level below 18 μg/dL or an increase in the cortisol concentration of less than 9 μg/dL has been regarded by many as diagnostic of adrenal insufficiency.[58] However, these criteria were developed to assess adrenal reserve in patients with destructive diseases of the adrenal glands and are based on responses in normal, nonstressed, healthy controls.[58,70] We believe that the standard corticotropin stimulation test lacks sensitivity for the diagnosis of adrenal insufficiency[58,71–74] (Table 79-1).

High doses of corticotropin (e.g., 250 μg) are supraphysiologic (over 1000-fold higher than normal maximal stress ACTH levels).[39,62–65] The very high levels of corticotropin obtained with 250 μg can override adrenal resistance to ACTH and result in a normal cortisol response. Patients with normal responses to high-dose corticotropin may fail to respond normally to stress[61,71] (Fig. 79-1). Owing to the decreased sensitivity of the high-dose ACTH stimulation test (HD-ACTH) for the diagnosis of adrenal insufficiency, many investigators evaluated the use of lower doses of ACTH that approximate stress levels of ACTH (i.e., 1 to 2 μg) for the diagnosis of adrenal insufficiency. A number of studies have demonstrated that a 1-μg dose (LD-ACTH) of corticotropin is more sensitive and specific for diagnosing primary and secondary adrenal insufficiency than the 250-μg dose.[38,71,73,75–79]

The change in cortisol level following corticotropin stimulation (Δ_{max}) is used by some clinicians to diagnose adrenal insufficiency.[59,63,64,80] However, the Δ_{max} is a measure of adrenal reserve and not adrenal function. The increase in cortisol following administration of corticotropin should not be used as a criterion for the diagnosis of adrenal insufficiency. A maximally stressed patient may be secreting all the cortisol that his or her adrenal glands can synthesize. This patient may have an appropriately high serum cortisol level but be unable to respond further following corticotropin injection (no reserve). For example, a critically ill patient with a basal stress cortisol level of 54 μg/dL that increases to 57 μg/dL with corticotropin does not have adrenal insufficiency. It is the absolute level that is of importance rather than the Δ_{max}. On the other hand, it is clear from a number of studies that impaired response to ACTH (i.e., small Δ_{max}) has prognostic value and generally indicates a poor prognosis. The exact reasons for this are unclear but may relate to high levels of circulating factors that impair adrenal response to maximal stress.

Most important, the administration of exogenous ACTH bypasses the CNS-hypothalamic-pituitary axis and tests the integrity of the adrenal glands directly. It is essential that one evaluate the entire axis because defects in the hypothalamic-pituitary components frequently cause adrenal insufficiency. Endogenous stresses such as hypotension, hypoxemia, fever, and hypoglycemia are superior stimuli for testing the integrity of the HPA axis than is ACTH testing. These endogenous stressors test the function of the entire HPA axis and therefore should be regarded as the "gold standard" for adrenal testing. In other words, the HPA axis evolved to respond to stress and is best evaluated using stress that tests all components of the axis. Many inappropriately assume that the ACTH stimulation test is capable of detecting the presence of adrenal insufficiency because they assume that significant adrenal atrophy has occurred and results in diminished ACTH responsiveness. This concept is flawed for a variety of reasons. First, it takes 1 to 2 weeks for the adrenal gland to atrophy following pituitary removal when all ACTH secretion from the pituitary is lost. Thus the ACTH stimulation test may easily miss acute adrenal insufficiency (the most common form of adrenal insufficiency in critically ill patients). Second, adrenal atrophy may take longer in patients with partial adrenal insufficiency (common in critically ill patients). Third, the response to ACTH may be normal in patients with partial secondary adrenal insufficiency or ACTH resistance. ACTH testing is not required to diagnose adrenal insufficiency in severely stressed patients because the CNS-HPA axis already should be maximally activated. In such patients, a random stress cortisol level provides adequate information on the integrity of the entire HPA axis. In patients in whom the level of stress is less intense (not hypotensive, hypoxemic, or in pain), the LD-ACTH simulation test should be used to assess adrenal reserve (Fig. 79-2). One also may evaluate the pituitary-adrenal axis by administering CRH.[40] This test bypasses the hypothalamus but does require the integrity of the pituitary and adrenal glands. However, the sensitivity and specificity of the test for detecting adrenal insufficiency in critically ill patients have not been determined.

There is much controversy regarding levels of circulating cortisol that are considered to be an adequate response to stress.[58] Many textbooks and published manuscripts state that the normal circulating cortisol response to stress is a level greater than 15 to 20 μg/dL. However, the choice of 15 to 20 μg/dL is based primarily on the response to exogenous high-dose ACTH (250 μg) and the response to insulin-induced hypoglycemia in nonstressed, non-critically ill patients.[70] During surgical procedures such as laparotomy, serum corticotropin and cortisol concentrations rise rapidly,

TABLE 79-1 Causes for Lack of Sensitivity of High-Dose ACTH Stimulation Test for the Diagnosis of Adrenal Insufficiency

Bypasses CNS-hypothalamic-pituitary components of HPA axis
Uses supraphysiologic levels of ACTH
Overrides ACTH resistance
Insensitive for diagnosis of acute adrenal insufficiency; better for detection of chronic adrenal insufficiency
Short-term stimulation may not reflect response to chronic ACTH elevation
May be normal in patients with partial secondary adrenal insufficiency who fail to respond to stress

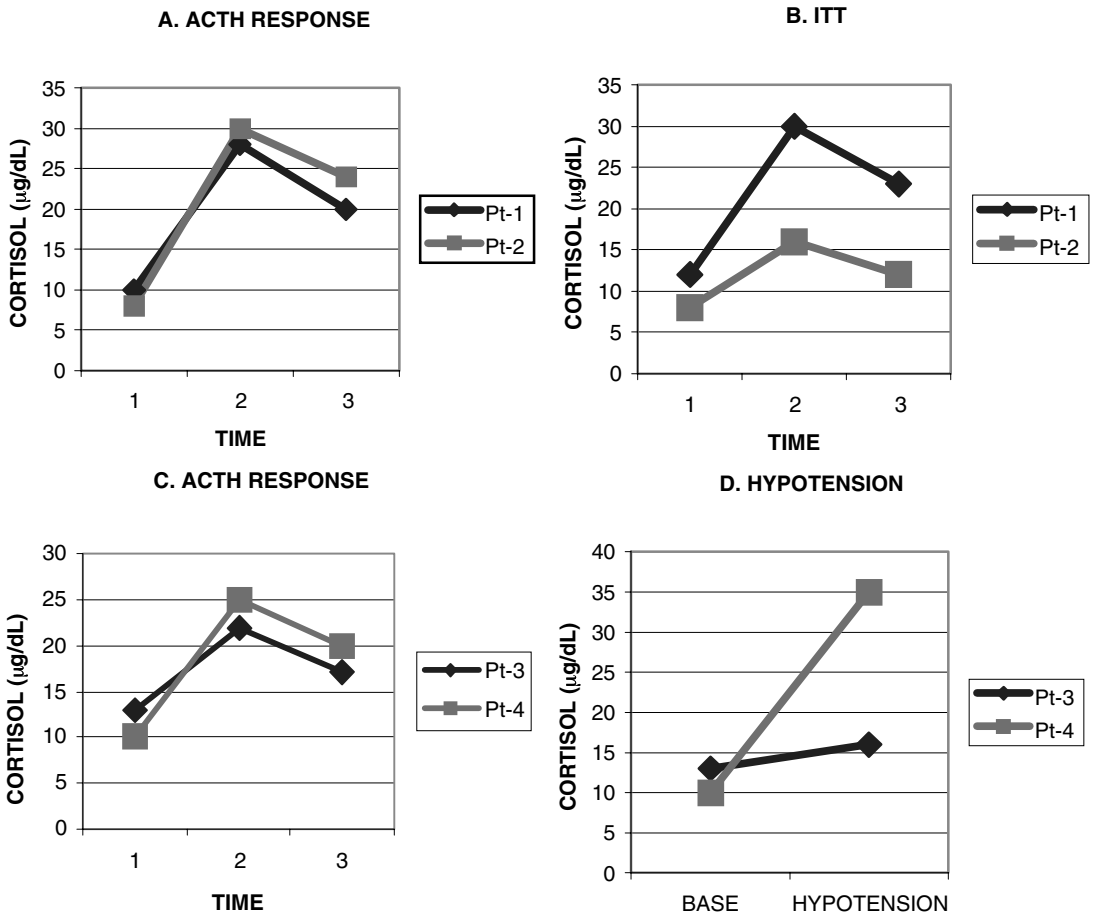

FIGURE 79-1 Discordant cortisol response to ACTH stimulation test and insulin tolerance test (ITT) (*A*, *B*) and ACTH stimulation test and hypotension (*C*, *D*). Patients 1 and 2 responded similarly to ACTH, but patient 2 failed to respond adequately to hypoglycemia induced by insulin. Patients 3 and 4 responded similarly to ACTH, but patient 4 failed to respond adequately when he became hypotensive.

peaking in the immediate postoperative period, and then decline to baseline levels over the next 72 hours.[81] The magnitude of the postoperative increase in serum cortisol concentration is correlated with the extent of the surgery, with a peak between 30 and 45 μg/dL in patients undergoing major surgery.[82–87] During severe illness, serum cortisol concentrations tend to be higher than those of patients undergoing major surgery.[81] In patients with multiple trauma, the serum cortisol level remains greater than 30 μg/dL for at least a week, with peak values between 40 and 50 μg/dL.[88] Cortisol levels are increased in critically ill ICU patients, with the highest values being reported in patients with the highest illness severity scores and those with the highest mortality.[89,90] We have found cortisol levels to be elevated in all forms of shock (Fig. 79-3). Interestingly, cortisol levels are significantly lower in patients with septic shock compared with patients with hypovolemic and cardiogenic shock, suggesting the presence of mediators that impair HPA axis function. Overall, the available data suggest that the degree of activation of the HPA axis and elevation in serum cortisol level is related to the severity and duration of the stressor. Animal and human studies demonstrate increasing serum levels of epinephrine and cortisol with increasing severity of stress, with hypotension and sepsis being two of the most intense stressors.[91,92] Based on the available data,[74] we believe that a random cortisol level in severely stressed patients (e.g., those with hypotension, hypoxemia, burn, high fever, multiple trauma) should be above 25 μg/dL. Higher levels may be appropriate in patients with septic shock due to "tissue cortisol resistance."

The cortisol threshold of 25 μg/dL for an adequate adrenal response to severe stress is supported by two clinical studies that evaluated the hemodynamic response of replacement doses of hydrocortisone in vasopressor-dependent patients. While the hemodynamic response to steroids may be a crude marker of acute adrenal insufficieny, we have no other end-organ or biochemical marker of cellular glucocorticoid activity at this time. Furthermore, this end point has been used in other studies evaluating the role of corticosteroids in vasopressor-dependent patients with sepsis and may serve as a surrogate marker of inadequate glucocorticoid activity during severe illness.[93–96] Rivers and colleagues[97] studied the HPA axis in a group of vasopressor-dependent surgical patients. In a subgroup of patients treated with corticosteroids, the basal serum cortisol concentration was 49 μg/dL in the steroid nonresponders and 20 μg/dL in patients who were weaned from vasopressors within 24 hours of the initiation of steroid treatment. Only one patient in the steroid-responsive group had a baseline serum cortisol level of greater than 25 μg/dL, and only 2 nonresponders had a baseline level of less than 25 μg/dL. In this study, the diagnostic sensitivity

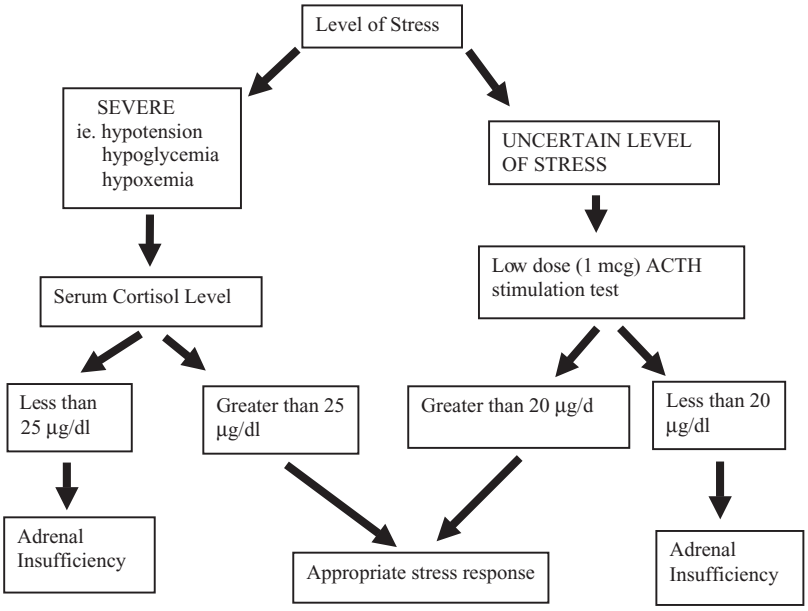

FIGURE 79-2 Evaluation of HPA axis function.

of a threshold of 25 μg/dL was 90%, with a specificity of 92%, a positive predictive value of 60%, and a negative predictive value of 66%. Similarly, we investigated the hemodynamic response following treatment with replacement doses of hydrocortisone in 59 medical patients in septic shock.[71] The baseline serum cortisol level was 14.1 $\pm$ 5.2 μg/dL in the steroid-responsive patients compared with 33.3 $\pm$ 18 μg/dL in the steroid-nonresponsive patients. The sensitivity of a baseline cortisol level of less than 25 μg/dL in predicting steroid responsiveness was 96%, this compared with 22% for the standard HD-ACTH stimulation test. The area under the receiver operating characteristic (ROC) curve of the stress (baseline) cortisol level was 0.84; a stress cortisol level of 23.7 μg/dL had the best discriminating power, with a sensitivity of 86%, a specificity of 66%, a likelihood ratio of 2.6, a positive predictive value of 62%, and a negative predictive value of 88%. Clearly, there is no absolute serum cortisol level that distinguishes an adequate from an insufficient adrenal response.

Based on current evidence, we believe that a random cortisol level should be interpreted in conjunction with the severity of illness, and 25 μg/dL is a useful threshold value for an appropriate response to severe stress (see Fig. 79-2). We believe that a random cortisol level should be above 25 μg/dL in severely stressed ICU patients with normal adrenal function. It is not necessary to obtain cortisol levels at a specific time of the day because critically ill patients lose the diurnal variation in their cortisol levels.[82] In nonhypotensive critically ill patients, the normal cortisol response (30 to 60 minutes) after 1 to 2 μg corticotropin (LD-ACTH) should be a level greater than 20 μg/dL. We do not recommend performing the unphysiologic high-dose corticotropin stimulation test. Importantly, a random cortisol level of less than 15 μg/dL or a level less than 20 μg/dL post LD-ACTH test in a nonhypotensive critically ill patient with unexplained fever, eosinophilia or, metal status changes may warrant a trial of replacement doses of corticosteroids.

Incidence of Adrenal Insufficiency

The incidence of adrenal insufficiency in critically ill patients is variable and depends on the underlying disease and severity of the illness. The reported incidence varies widely (0% to 77%) depending on the population of patients

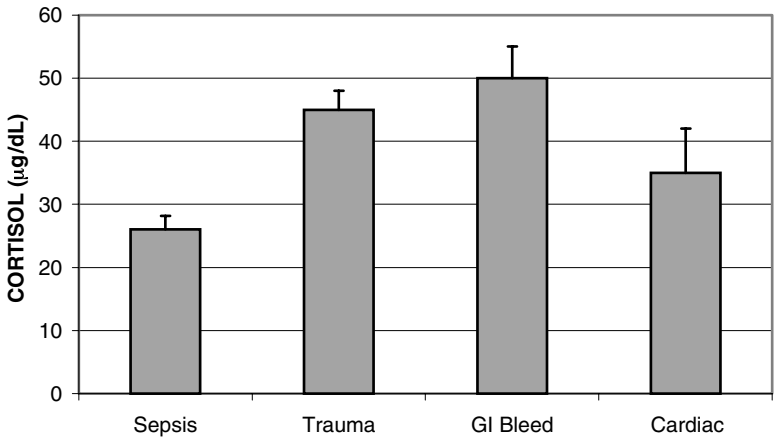

FIGURE 79-3 Cortisol (mean $\pm$ SEM) response to shock in critically ill patients.

studied and the diagnostic criteria used to diagnose adrenal insufficiency.[39,51,62–65,71,97–101] However, the overall incidence of adrenal insufficiency in critically ill patients approximates 30%, with an incidence as high as 50% to 60% in patients with septic shock.[72] The following incidences of adrenal insufficiency apply to patient groups with no previous history suggestive of adrenal insufficiency (e.g., previous use of glucocorticoids). For example, using the criteria cited earlier (stress cortisol level <25 μg/dL), we diagnosed adrenal insufficiency in 36 of 59 (61%) patients with septic shock.[71] Only 5 (9%) of these patients met the "classic criteria" (cortisol level <18 μg/dL 60 minutes after 250 μg corticotropin) for adrenal insufficiency. Rydvall and colleagues[102] reported a 47% incidence of adrenal insufficiency in a general ICU population (using a stress cortisol threshold of 25 μg/dL). Briegel and colleagues[99] reported 13 of 20 (65%) patients with septic shock having a stress cortisol level of less than 25 μg/dL. Sibbald and colleagues[65] reported 20 of 26 (77%) septic patients with stress cortisol levels of less than 25 μg/dL. Moran and colleagues[103] reported a 49% incidence of adrenal insufficiency in patients with septic shock. We reported a 50% to 75% incidence of adrenal insufficiency in critically ill HIV-infected patients.[73]. Interestingly, we found a 0% incidence of adrenal insufficiency in nonhypotensive septic patients, which contrasted with a 61% incidence in septic patients with hypotension.[71] Patients with closed head injury have an incidence of adrenal insufficiency of approximately 15%, whereas patients with cardiogenic shock following myocardial infarction have an incidence of adrenal insufficiency of approximately 5% to 10%. In a subset of patients with acute gastrointestinal hemorrhage and hypotension, we found an incidence of adrenal insufficiency of only 2% to 4%. Unfortunately, the incidence of adrenal insufficiency has not been evaluated reliably in all groups of critically ill patients and clearly varies with the underlying disease.

Clinical Features of Acute HPA Axis Failure

Patients with chronic adrenal insufficiency usually present with a history of weakness, weight loss, anorexia, lethargy, slowed mentation, and general failure to thrive. Some patients complain of nausea, vomiting, abdominal pain, and diarrhea. Clinical signs include orthostatic hypotension and, rarely, hyperpigmentation (primary adrenal insufficiency). Laboratory testing may demonstrate hyponatremia, hyperkalemia, hypoglycemia, and a normocytic anemia.[74,104] This presentation contrasts with the features of acute adrenal insufficiency (Table 79-2). Hypotension refractory to fluids and requiring vasopressors is the most common feature of acute adrenal insufficiency in critically ill patients.[71,74,104] Patients usually have a hyperdynamic circulation, which may compound the hyperdynamic profile of septic patients.[71] However, the systemic vascular resistance, cardiac output, and pulmonary capillary wedge pressure can be low, normal, or high.[72] The variability in hemodynamics reflects the combination of adrenal insufficiency and the underlying disease. Importantly, acute adrenal insufficiency always should be excluded in critically ill patients requiring vasopressor support. CNS dysfunction is common, frequently compounded by the underlying disease. However, adrenal failure may present with altered mental status, particularly unexplained confusion, as the major clinical finding. Lethargy, weakness, anorexia, and abdominal complaints are common. Furthermore, in critically ill patients with unexplained fever, adrenal failure should be excluded. Laboratory assessment may demonstrate eosinophilia and hypoglycemia. Hyponatremia and hyperkalemia are uncommon. Many patients have a mild metabolic acidosis.

TABLE 79-2 Symptoms and Signs Suggestive of Hypoadrenalism in Critically Ill Patients

Specific features
Hypotensive septic patients
Vasopressor-dependent patients
Eosinophilia (usually mild)
Hyponatremia and hyperkalemia
Hypoglycemia (rare)
Pituitary deficiencies (gonadotrophin, thyroid, diabetes insipidus)
Hyperpigmentation (rare)
Vitiligo (rare)
Nonspecific features
Weakness, fatigue
Anorexia, weight loss
Nausea, vomiting
Diarrhea
Anemia
Metabolic acidosis
Unexplained fever
Unexplained mental status changes
Hyperdynamic circulation

Causes of Acute Adrenal Insufficiency in the Critically Ill

Acute adrenal insufficiency (Table 79-3) occurs in patients who are unable to increase their production of cortisol in the face of acute stress. This includes patients with hypothalamic and pituitary disorders (secondary adrenal insufficiency) and patients with destructive diseases of the adrenal glands (primary adrenal insufficiency). Secondary adrenal insufficiency is common in patients who have been treated with exogenous corticosteroids within the past year. Other causes of secondary adrenal insufficiency include pituitary infarction, hypothalamic disease, and sepsis.

Synthetic glucocorticoids are commonly used drugs. The use of these drugs is associated with suppression of the HPA axis. The degree of suppression depends on many factors, including the glucocorticoid potency, the dose, the dosing schedule, and the duration of use. The degree of suppression, however, generally is not predictable in any individual patient.[105] The use of inhaled corticosteroids in asthmatics also has been associated with varying degrees of adrenal suppression.[75,106] Systemic glucocorticoids probably do not cause significant HPA axis suppression when used for less than 5 days. When these drugs are used for between 5 and 30 days, the HPA axis will recover in most patients within 14 days of stopping treatment.[107] However, when used for longer than 30 days, it may take up to a year for the HPA axis to recover. The recovery of the HPA axis can be assessed most reliably by measurement of a random cortisol level in a stressed patient. The degree of adrenal recovery in the

Phenytoin (increased metabolism)

unstressed patient can be determined by the response to 1 μg corticotropin.[115] However, it is important to note that supraphysiologic doses of glucocorticoids suppress both CRH production in the hypothalamus and ACTH production in the pituitary gland. This suppression can outlast the duration of adrenal suppression.[108] Therefore, a normal cortisol response to high-dose corticotropin does not predict conclusively a normal response to stress (which involves the hypothalamic-pituitary components of the axis).[109] The properties of the corticosteroids in common use are listed in Table 79-4.

The most common cause of chronic primary adrenal insufficiency (Addison's disease) in the past was tuberculosis, followed by autoimmune disease. However, human immunodeficiency virus (HIV) infection and other infections in immunosuppressed patients (e.g., tuberculosis, CMV, fungal) are currently the most important causes of primary adrenal insufficiency. The adrenal gland is the endocrine organ most commonly involved in patients with the acquired immunodeficiency syndrome (AIDS).[110–114] Human CMV has been demonstrated in the adrenal glands of 33 to 88 percent of patients who died of AIDS. Less commonly, tubercle bacilli, *Cryptococcus neoformans*, *Toxoplasma gondii*, *Histoplasma capsulatum*, lymphoma, hemorrhage, or Kaposi's sarcoma may involve the adrenal gland.[113] In addition, a number of drugs used in patients with HIV infection, most notably ketoconazole and megestrol acetate, can impair adrenal function.[115,116] Although the adrenal gland is commonly affected by opportunistic infections and tumor infiltration in AIDS, adrenal insufficiency in the outpatient setting is uncommon.[113,117] However, these patients may be unable to increase the synthesis of cortisol in the face of stress. Using the revised diagnostic criteria (i.e., stress cortisol level <25 μg/dL), we reported adrenal insufficiency in 75% of critically ill HIV-infected patients who had not been treated with corticosteroids.[73]

Sepsis and the systemic inflammatory response syndrome (SIRS) are the most common causes of adrenal failure in the critically ill. There is increasing evidence of HPA axis insufficiency in critically ill septic patients, which appears to result from circulating suppressive factors released during systemic inflammation.[39,62–65,71,80] It should be emphasized that in most cases adrenal failure results from suppression of the HPA axis and GR expression and is completely reversible, with restoration of normal adrenal function once the patient has recovered from the septic episode.[99] In addition to sepsis, we have noted a high incidence of HPA axis failure in patients with liver failure. The exact cause remains unclear. However, we recommend screening all critically ill cirrhotic patients for adrenal failure.

We have reported three patterns of adrenal insufficiency in patients with septic shock based on their response to low-dose (LD) and high-dose (HD) corticotropin.[71] Forty-two percent of patients failed to respond to both LD and HD corticotropin and most likely represent patients with primary adrenal gland failure. Twenty-eight percent of patients had low stress cortisol levels but responded to both LD and HD corticotropin; we postulate that these patients lacked adequate secretion of CRH or ACTH and represent patients with secondary adrenal insufficiency. In a previous study we demonstrated that 85% of the patients with adrenal insufficiency (baseline cortisol of less than 25 μg/dL) had inappropriately low (<40 pg/mL) ACTH levels.[118] A third group of patients (30%) failed to respond to LD corticotropin but responded normally to HD corticotropin. Due to the ability of pharmacologic doses of corticotropin to produce a normal

TABLE 79-4 Properties of Commonly Used Corticosteroids

Agent	Equivalent Dose, mg	Glucocorticoid Potency	Mineralocorticoid Potency	Duration of Action, h
Dexamethasone	0.75	25	0	72
Methylprednisolone	4	5	0.5	36
Prednisolone	5	4	0.8	24
Prednisone	5	4	0.8	24
Hydrocortisone	25	1	1	8

response, when physiologic stress levels of corticotropin were ineffective, we postulate that this group represents patients with corticotropin resistance. It is possible that these various patterns of HPA axis failure during critical illness represent the differential effects of inhibitory mediators at various levels of the HPA axis.

Adrenal Exhaustion Syndrome

Patients with chronic critical illness may develop adrenal insufficiency while in the ICU. Although not evaluated in prospective trials, we have observed patients who had normal adrenal function when admitted to the ICU but who later developed adrenal insufficiency (e.g., long term ventilated patient with ARDS) (Fig. 79-4). The only apparent cause was a prolonged systemic inflammatory response. The adrenal insufficiency may have resulted from chronic secretion of systemic cytokines and other HPA axis suppressive substances.[119] These patients have a higher mortality compared with patients who maintain adequate cortisol levels (see Fig. 79-4) and illustrate the importance of serial follow-up of adrenal function in long-term critically ill patients.

Prognosis

We believe that there is a bimodal distribution of mortality in relationship to the random cortisol level during sepsis. Patients with low cortisol levels (i.e., <25 μg/dL) who are not treated with corticosteroids and patients with very high levels (i.e., >45 μg/dL) have the highest mortality. This hypothesis may explain the apparent contradictory reports in the literature. Annane and colleagues[59] reported a mean random cortisol level of 34 μg/dL in 189 patients with septic shock, with the nonsurvivors having higher levels than survivors (39 versus 28 μg/dL, respectively). However, in the study by Schroeder and colleagues,[40] the mean random cortisol level was only 19 μg/dL, with nonsurvivors having a lower cortisol level than survivors (10 versus 17 μg/dL). Most of the patients included in the study by Schroeder and colleagues would have met our criteria for adrenal insufficiency. However, none of the patients was treated with corticosteroids.

Impaired responses to corticotropin and CRH are also associated with increased mortality.[40,103] However, it remains unclear as to whether the impaired response is a direct contributor to the increased mortality or is secondary to hypothalamic-pituitary dysfunction or suppression (i.e., from circulating mediators or elevated cortisol levels).

Treatment of Acute Adrenal Insufficiency

Deficiency of cortisol is associated with increased morbidity and mortality during critical illness. Mckee[68] randomized 18 critically ill patients with adrenal insufficiency to glucocorticoid treatment or placebo. One of eight (13%) steroid-treated patients died compared with 9 of 10 (90%) placebo patients. Evidence for high mortality from adrenal insufficiency in critically ill patients also comes from the report of Ledingham and Watt,[120] who noted increased mortality from use of etomidate (a sedative agent that causes adrenal insufficiency) in multiple-trauma patients (44% etomidate versus 27% other sedatives). The report by Ledingham and Watt emphasizes that even slight impairment of the adrenal response during severe illness can be lethal. Rivers and colleagues[97] reported faster weaning from vasopressors and improved survival in hydrocortisone-treated critically ill patients (79% versus 55%). We found that patients with septic shock and inappropriately low cortisol levels had improved survival when treated with hydrocortisone (65% versus 35%).

Further evidence to support the benefit of glucocorticoid treatment of acute adrenal insufficiency in patients with septic shock comes from the studies of Bollaert and colleagues[94] and Briegel and coworkers.[93] Bollaert and colleagues[94]

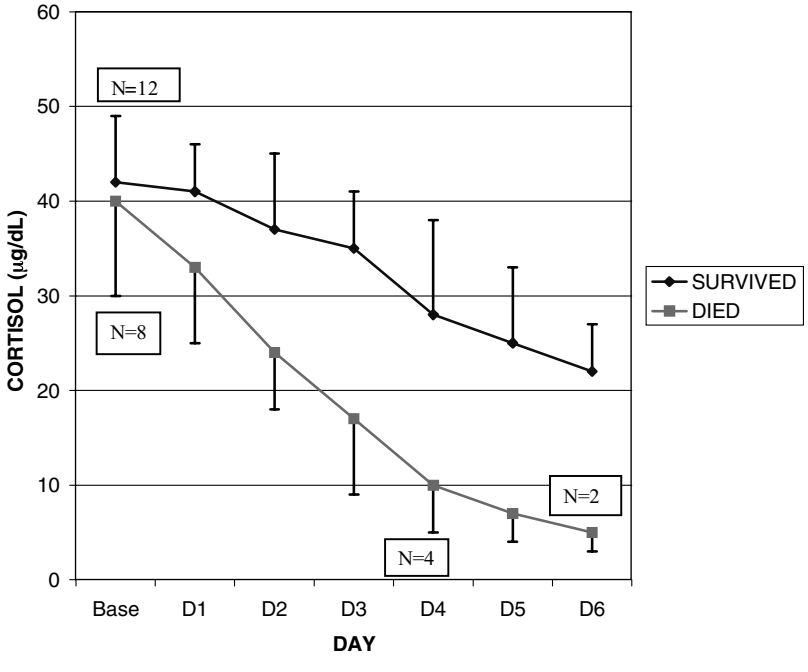

FIGURE 79-4 Adrenal exhaustion syndrome. Daily cortisol levels in a group of patients with sepsis who survived versus died. Cortisol fell to very low levels, which are consistent with adrenal insufficiency in the patients who died.

randomized 41 patients with septic shock to hydrocortisone (100 mg IV every 8 hours) or placebo. Although random cortisol levels were obtained, treatment with hydrocortisone was not stratified based on the levels. However, the glucocorticoid-treated patients had a significantly greater reversal of shock at 7 and 28 days and reduced 28-day mortality (30% versus 70%, $p = 0.09$) compared with the placebo group. Similarly, Briegel and colleagues[93] randomized 40 critically ill septic shock patients to intravenous hydrocortisone or placebo. Hydrocortisone treatment was associated with improved shock reversal and decreased days of vasopressor support. There also was earlier resolution of organ dysfunction, shorter ventilator time, and shorter ICU stay. Annane and colleagues[80,96] randomized 200 septic shock patients to steroid replacement or placebo. There was a significant 30% decrease in death in a subset of the steroid-treated patients. Oppert and colleagues[95] treated 20 septic shock patients with hydrocortisone (10 mg/h for 7 days). Patients with "inadequate" steroid production were weaned from vasopressors significantly faster than patients with "adequate" steroid production. These studies of physiologic stress doses of glucocorticoids administered for many days contrast with earlier studies of high-dose glucocorticoids (i.e., 30 mg/kg methylprednisolone) administered for one to two doses. The short-term pharmacologic dose studies of glucocorticoids failed to report benefit in patients with septic shock.[121,122]

Interestingly, Schelling and colleagues[123] evaluated the effect of hydrocortisone treatment during septic shock on the incidence of posttraumatic stress disorder. The administration of hydrocortisone at stress levels during septic shock reduced the incidence of posttraumatic stress disorder and improved emotional well-being in survivors.

Perioperative Steroid Coverage

The stress of major surgery may precipitate acute adrenal insufficiency in patients with inadequate adrenal reserve (i.e., adrenal crisis). This is especially true in patients with secondary adrenal insufficiency maintained on exogenous glucocorticoids. Prospective, randomized trials have failed to adequately evaluate the dose of glucocorticoid required in various perioperative settings. Thus recommendations for glucocorticoid coverage are based on a risk-benefit evaluation, published studies in the literature, and clinical experience. Importantly, patients with adrenal insufficiency undergoing surgery should receive appropriate stress doses of glucocorticoids before and after surgery. If surgery is prolonged (i.e., >4 to 6 hours), we recommend an additional dose of glucocorticoid during surgery. Patients with a high likelihood of impaired gastric emptying or impaired gut absorption should receive glucocorticoid repletion via the intravenous route until gut function has returned to relatively normal levels. We caution against the use of intramuscular glucocorticoid preparations in patients in whom hypoperfusion of muscle is likely. Patients also should receive sufficient steroid to control their underlying disease (e.g., asthma, autoimmune disease). Minimal doses of glucocorticoid for treatment of patients with suspected adrenal insufficiency based on type of surgery are as follows: First, patients undergoing minor surgery (e.g., hernia repair, laparoscopic cholecystectomy, knee surgery) should receive a minimal dose of 25 mg hydrocortisone equivalent prior to and 8 hours following surgery. This dose may be given orally if gut function is intact or intravenously. If patients demonstrate normal recovery, they may be weaned quickly from steroids or returned to maintenance levels. Second, patients undergoing moderate surgical stress (e.g., open cholecystectomy, partial colon resection, uncomplicated back surgery, hip replacement) should receive 25 to 50 mg hydrocortisone equivalent every 8 hours intravenously for 1 to 2 days. The dose then may be tapered to baseline levels based on clinical response. Third, patients undergoing major surgical stress (e.g., pancreatoduodenectomy, esophagectomy, total colectomy, repair for perforated bowel, cardiopulmonary bypass, ileofemoral bypass) should receive 50 to 100 mg hydrocortisone equivalent every 8 hours intravenously for 2 to 3 days. The dose then can be tapered to baseline doses based on clinical response. Importantly, the dose should be increased to maximal stress doses (100 mg hydrocortisone equivalent every 8 hours intravenously) in patients who remain hypotensive or deteriorate during recovery from surgery.[124]

Therapeutic Approach to Patients with Presumed Adrenal Insufficiency

In patients with severe stress (e.g., hypotension, hypoxemia, pain), a random (stress) serum cortisol level should be obtained (see Fig. 79-2). The patient should be started empirically on hydrocortisone (100 mg IV every 8 hours) pending results of testing. If the serum cortisol level returns less than 25 μg/dL, the hydrocortisone should be continued. In addition, if the patient has improved clinically with hydrocortisone and the cortisol level is greater than 25 μg/dL, we favor continuing the hydrocortisone for a few days (unless there is a specific contraindication). The dose of hydrocortisone should be tapered down toward maintenance doses as the patient's clinical status improves. If the level of stress is uncertain and adrenal insufficiency is suspected, we favor adrenal testing with the low-dose (1 μg) corticotropin stimulation test (see Fig. 79-2). If the corticotropin stimulation test cannot be performed immediately, administer dexamethasone (2 mg) and perform the test within the next 12 hours. Dexamethasone does not significantly crossreact with cortisol in the assay for cortisol and can be given to patients pending adrenal testing.

The currently recommended dosage schedule in adults includes 100 mg hydrocortisone intravenously every 8 hours or 50 mg intravenously every 6 hours.[69,71,80,94,97] While a continuous infusion of hydrocortisone has been recommended, there are no data at this time to suggest that this dosing regimen is more efficacious than intermittent doing. In the study reported by Annane and colleagues,[80] patients were treated with hydrocortisone (50 mg every 6 hours) and fludrocortisone (50 mg daily). However, as demonstrated previously, it appears that low aldosterone levels are part of the "normal" stress response, and there are no data to suggest that fludrocortisone provides any additional benefits over hydrocortisone alone. Furthermore, as illustrated in Table 79-4, hydrocortisone possesses mineralocorticoid activity. When given at high doses (e.g., 200 to 300 mg daily), hydrocortisone has adequate mineralocorticoid activity to treat primary adrenal failure.

Conclusion

HPA axis dysfunction is common in severely ill patients. Even slight impairment of the adrenal response to severe illness can increase morbidity and mortality, and we believe that low serum cortisol levels may be the cause rather than the consequence of poor outcome in these patients. Therefore, a high index of suspicion for adrenal insufficiency is required in all critically ill patients, particularly those with refractory hypotension. All patients with suspected HPA axis dysfunction should be treated with stress doses of corticosteroids pending the results of diagnostic testing.

Chapter 80
THYROID DISEASE

ROY E. WEISS
SAMUEL REFETOFF

KEY POINTS

- *Virtually all patients admitted to an ICU have low levels of serum triiodothyronine (T_3), and 30% to 50% have low levels of thyroxine (T_4) with normal or low levels of serum thyrotropin (TSH).*
- *Patients who have a T_4 level of less than 3.0 μg/dL despite normal levels of T_4-binding proteins have a 68% to 84% mortality rate.*
- *T_3 is the logical choice for critically ill patients requiring thyroid hormone replacement.*
- *Early intubation and mechanical ventilation are crucial for successful treatment of myxedema coma.*
- *Management of myxedema coma should include administration of glucocorticoids while the adrenal status is being assessed.*
- *Alterations in thyroid function change the metabolism of almost all drugs, and the doses need careful adjustment to prevent drug toxicity or decreased efficacy.*
- *Autonomous hypersecretion and exogenous overdose of thyroid hormone are the most common causes of severe thyrotoxicosis.*
- *Hyperpyrexia and altered mental status are the hallmarks of thyroid storm.*
- *Medical treatment of severe hyperthyroidism usually normalizes circulating thyroid hormone levels in 2 to 3 weeks, except under circumstances of iodine overload, in which case hyperthyroxinemia may persist for months.*
- *Blockade of hormonal secretion is best accomplished by the addition of stable iodine to an antithyroid drug regimen.*
- *In severe thyrotoxicosis, treatment with iopanoic acid (TELEPAQUE) can be lifesaving.*
- *βBlockers prevent thyroid storm in the thyrotoxic patient undergoing surgery, and they may ameliorate cardiovascular dysfunction in thyroid storm, but their side effects often interfere with therapy in the elderly, in patients with asthma, and in patients with cardiomyopathy.*
- *Amiodarone-induced thyrotoxicosis in a critically ill patient should be managed with methimazole (30 to 50 mg/d), potassium perchlorate (500 mg twice a day), and prednisone (30 to 40 mg/d).*
- *After gastric aspiration and lavage, only symptomatic and supportive treatment is needed in cases of levothyroxine overdose.*
- *Neonatal thyrotoxicosis can be life threatening; it is usually caused by transplacental transfer of thyroid-stimulating antibodies. It is transient and requires only short-term treatment.*

Hypothyroidism, Nonthyroidal Illness, and Myxedema Coma

Hypothyroidism is a state of tissue deprivation of thyroid hormone. It is manifested by general reduction of the metabolic rate accompanied by specific symptoms and signs. Usually, hypothyroidism is caused by a decreased supply of thyroid hormone due to one of the following: (1) failure of the gland to synthesize and secrete thyroid hormone, (2) failure of the pituitary to secrete thyrotropin (thyroid-stimulating hormone [TSH]), or (3) hypothalamic disease resulting in a deficiency of thyrotropin-releasing hormone (TRH).

Perhaps the most controversial, if not the most challenging, aspects of thyroidology for the intensivist are how to interpret thyroid function tests in critically ill patients and what to do when the test results are abnormal. Clinically important hypothyroidism in its most severe form usually is seen in patients with primary hypothyroidism who then develop some intercurrent illness; it develops over several weeks and culminates in myxedema coma. Equally challenging are the thyroid function abnormalities seen in patients with concurrent severe illness and the assessment of the thyroid hormone status at the tissue level.

Evaluation of Thyroid Function in Patients with Severe Nonthyroidal Illness Syndrome (NTIS)

DEFINITION OF NONTHYROIDAL ILLNESS SYNDROME

Virtually all critically ill patients have reduced serum levels of triiodothyronine (T_3), and approximately 30% to 50% also have low levels of thyroxine (T_4), both associated with normal or low serum TSH values.[1] This phenomenon has been termed *low T_3 syndrome*, *nonthyroidal illness* (NTI), or *euthyroid sick syndrome*. Each of these descriptive terms assumes a priori that such patients are euthyroid despite reduced thyroid hormone levels. The condition is not limited to acute illness. Patients with chronic hepatic or renal failure, calorie deprivation, and a variety of other illnesses present similar thyroid hormone profiles.[2] Serum concentrations of both T_3 and T_4 also are decreased following nonthyroid surgical procedures.[3] In patients with a T_4 value of less than 3.0 μg/dL, the mortality rate is 68% to 84%,[4] indicating that a low T_4 concentration without a corresponding increase in TSH is a marker for a high risk of death in the critically ill population. To understand this phenomenon and develop a rational basis for treatment, it is useful to review the thyroid physiology, with emphasis on processes occurring in NTI.

THYROID HORMONE PHYSIOLOGY IN CRITICAL ILLNESS (FIG. 80-1)

METABOLISM OF THYROID HORMONE IN PERIPHERAL TISSUES

Ninety percent of the hormone secreted by the thyroid gland is T_4, the remainder being T_3. Thyroid hormone is metabolized in peripheral tissues by stepwise monodeiodination until the molecule is completely stripped of iodine. This

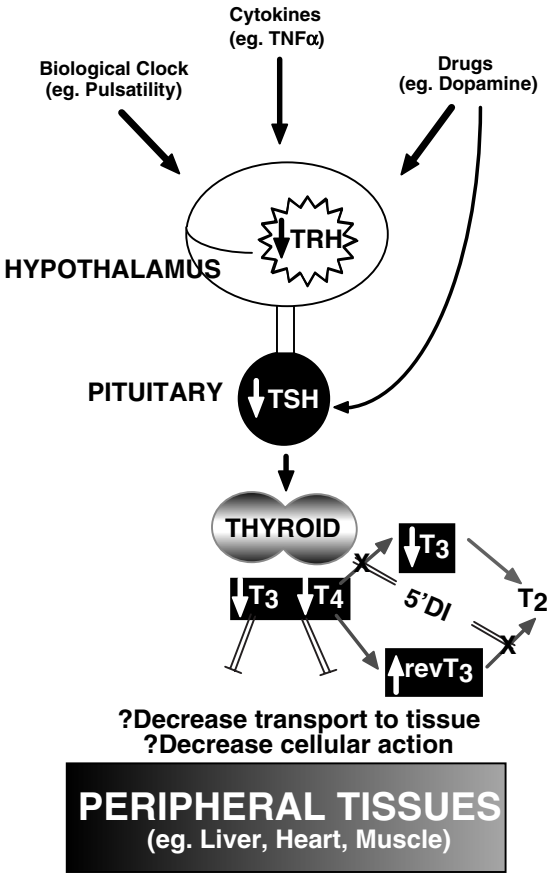

FIGURE 80-1 Physiologic basis for nonthyroidal illness syndrome (NTIS). Diagrammatic representation of the events that may contribute to NTIS, including the effects on the hypothalamus and pituitary and site of thyroid hormone action at the peripheral tissue level. Bold white arrows indicate changes in serum concentrations.

process uses specific enzymes called *deiodinases*. The deiodination of T_4 can take one of two pathways—removal of the iodine from the outer or phenolic ring (5′ position), resulting in 3,3′, 5-triiodothyronine (T_3) or removal of the iodine from the inner or tyrosyl ring (5 position), yielding 3,3′, 5′-triiodothyronine (reverse T_3 [rT_3]). T_3 is the active form of the hormone, whereas rT_3 has no biologic activity. The same enzyme that removes iodine from the 5′ position of the T_4 molecule also is responsible for deiodination of the 5′ iodine from rT_3. Therefore, reduction in the 5′-deiodinase activity, which is invariably associated with severe illness and malnutrition, not only reduces the serum T_3 level but also increases that of rT_3.

THYROID PHYSIOLOGY IN THE BRAIN IN NTIS

The nature of perturbations of the hypothalamic-pituitary-thyroid axis in critically ill patients is beginning to be understood. The basal TSH values in serum of humans with NTIS can be normal or low, but the response of TSH to TRH usually is attenuated.[2] Stress and malnutrition may be partly responsible. In rats, starvation reduces hypothalamic messenger ribonucleic acid (mRNA) for TRH, reduces portal serum TRH, and lowers pituitary TSH content.[5] Furthermore, low TRH mRNA has been documented in the paraventricular nuclei of patients with NTIS.[6] One therefore would predict that if diminished TRH is, at least in part, contributing to NTIS and the low thyroid hormone levels, then treatment with TRH should increase the TSH and therefore increase the thyroid hormone levels. In fact, Van den Berghe and colleagues[7] have demonstrated that administration of TRH to patients with NTIS leads to increase in serum TSH, T_3, and T_4 levels. Critically ill patients who eventually will recover from their illness have, as a rule, less impairment of the TSH response to TRH. The mechanism for the reduced TRH production in NTIS is unknown but may be related to cytokines or glucocorticoids. These factors probably are responsible for suppression not only of TRH but also of other hypothalamic factors that may be decreased in NTIS, such as corticotropin-releasing hormone and gonadotropin-releasing hormone.

The preceding, however, does not rule out an effect of NTIS directly on the pituitary. For example, why is serum TSH not elevated when the thyroid hormone levels are low? There is experimental evidence that the pituitary may be "euthyroid" owing to increased pituitary conversion of T_4 to T_3, unlike other tissues.[8]

In addition, drugs commonly administered to ICU patients have inhibitory effects on the hypothalamic and pituitary function. Dopamine is one such drug; it inhibits TSH even when infused at low doses.[9,10]

OTHER ACTIONS OF THYROID HORMONE ON PHYSIOLOGY IN NTIS

Type II pneumocytes, which have been shown to be involved in regulation of lung function, express thyroid hormone receptors on their surfaces.[11] Furthermore, T_3 has been shown to modulate surfactant function during sepsis.[12–14]

Sepsis and multisystem organ failure often are associated with disseminated intravascular coagulation (DIC) and consumption of coagulation inhibitiors such as antithrombin III. Treatment of rats with experimentally induced NTIS with T_3 reduced the sepsis-induced decrease in antithrombin III levels.[15]

INTERPRETATION OF THYROID FUNCTION STUDIES (TABLE 80-1)

The levels of thyroid hormone and TSH are measured in many critically ill patients at some point during the course of hospitalization. Low concentrations of thyroid hormone without an appropriate increase in serum TSH level would, under normal conditions, raise the suspicion of pituitary (secondary) or hypothalamic (tertiary) hypothyroidism. However, in a critically ill patient, the diagnosis of primary hypothyroidism with inadequate pituitary response needs consideration. A modest elevation of serum TSH level without an increase in rT_3 concentration is a strong indicator of primary hypothyroidism. Except in the presence of renal failure, a decreased rT_3 level raises the possibility of hypothyroidism and should prompt a search for the etiology. While these possible diagnoses are being investigated, thyroid hormone replacement and glucocorticoid treatment are indicated. Since results of rT_3 measurement often are not obtained readily, this test is useful in retrospect for ruling out primary endocrine dysfunction and adds little to the decision of initial management of patients. Since only severe primary hypothyroidism requires emergency treatment, its recognition is

TABLE 80-1 Interpretation of Thyroid Function Tests

Diagnosis	T_4 Level	T_3 Level	TSH Level	rT_3 Level
Primary hypothyroidism	↓	↓ or N	↑	↓ or N
Central hypothyroidism	↓	↓	N	↓
NTI	↓ or N	↓	N or ↓	↑ or N

ABBREVIATIONS: ↓, decreased; ↑, increased; N, normal; NTI, nonthyroidal illness.

usually simple because of persistent TSH elevation, a prior history of thyroid disease, and physical findings compatible with hypothyroidism.

TO TREAT OR NOT TO TREAT

Should patients with low serum levels of thyroid hormone in the face of catastrophic NTIS receive hormonal replacement? In order to answer this question, several issues need to be determined: (1) Is the serum TSH level an accurate reflection of the thyroid status of all body tissues, or does it only reflect the status of the pituitary? (2) Are the tissues of the body functionally hypothyroid? and (3) Is the low serum T_3 level an adaptive mechanism for conservation of energy during critical illness? Unfortunately, these questions remain relatively unanswered. In a randomized, prospective study to determine the effect of T_4 treatment in NTIS, 11 patients admitted to an ICU with reduced thyroid hormone levels were treated with intravenous T_4, and 12 served as controls.[16] The study indicated an earlier mortality in the treated group, although the number of survivors was not significantly different between the groups. It was concluded that T_4 therapy was not beneficial, and inhibition of TSH secretion by the administration of T_4 may be detrimental to the recovery of thyroid function. These results have been confirmed in a similar study carried out in an ICU setting.[17] Nevertheless, many physicians understandably find it difficult to withhold treatment in a dying patient with virtually undetectable thyroid hormone levels.

Not only are data on the benefit of thyroid hormone treatment limited, but it is unlikely that an answer regarding the efficacy of this treatment will be forthcoming, given multiple-organ involvement in serious illness and the difficulty of interpreting the effect of thyroid hormone replacement in individuals receiving multiple drugs. Thus the argument centers not only on the question of whether such patients are truly hypothyroid (hence the bias of the term *euthyroid sick*) but also on whether this temporary hypothyroidism may not, in fact, be beneficial. Inhibition of the type I 5′-deiodinase is the principal mechanism that reduces the supply of biologically active thyroid hormone, T_3, to peripheral tissues in the severely ill. Experimental work in a rat model indicates that peripheral tissue hypothyroidism is maintained by an inhibition of the usual compensatory increase in TSH level. This inhibition occurs because normal levels of T_3 are generated in the pituitary gland, which uses a different form of 5′-deiodinase, the type II enzyme, that is actually more active in severe illness.[8,18] Teleologists argue that this mechanism to reduce the delivery of thyroid hormone to peripheral tissues is not accidental and, therefore, that reduced metabolic activity may be beneficial in the face of the increased catabolism characteristic of severe illness. The question is, Does the physician or nature know best? At our institution there is no consensus on this subject.

Recent studies have shown decreased serum T_3 concentrations in patients undergoing cardiopulmonary bypass surgery. T_3 treatment can normalize the serum levels and may increase cardiac output and lower systemic vascular resistance[19]; however, these effects may be negligible.[20]

Table 80-2 may serve as a bedside guide to the intensivist for the selection of patients for thyroid hormone treatment.

WHAT TO TREAT WITH

If the decision is made to treat a sick patient who has reduced thyroid hormone levels, the logical choice is T_3. Administration of T_4 does not change the serum T_3 concentration significantly—it only increases the level of the biologically inactive rT_3. The problem with T_3 treatment is its potential cardiac "toxicity." One possible problem is the proarrhythmogenic effect of T_3 in anesthetized patients; another possible problem is that T_3 may increase the oxygen demand of a myocardium with a fixed coronary artery lesion. T_3 is now available as the product TRIOSTAT; however, the cost of a single day's treatment for myxedema would be in excess of US$3500! Alternatively, a solution of T_3 for intravenous use can be prepared by the hospital pharmacist by dissolving L-T_3 in 0.1 N NaOH, followed by a 10-fold dilution in normal saline containing 2% albumin to a final concentration of 25 μg T_3 per milliliter. The solution is sterilized by a single passage through a 0.22-μm Millipore filter and is stored, for no longer than 1 week, at 4° C, protected from light. The materials for this preparation cost about US$1.

Myxedema Coma

DIAGNOSIS

Myxedema coma is caused by marked and prolonged depletion of thyroid hormone. The cardinal features of myxedema coma are (1) defective thermoregulation to the point of

hypothermia, (2) altered mental status to the point of coma, (3) a history or sign (such as a neck scar) of ablative thyroid treatment, and (4) an identifiable precipitating event. The condition is a medical emergency because it is fatal in approximately one-half of cases.[21] This rare entity occurs typically in elderly women with long-standing hypothyroidism who develop an intercurrent illness and lapse into coma or in hypothyroid persons exposed to cold or given tranquilizers, narcotics, or sedatives sufficient to push them to the brink of myxedema coma. Table 80-3 lists events likely to precipitate myxedema coma. The usual features of severe hypothyroidism (myxedema) include dry, coarse skin, scaly elbows and knees, yellowness in the skin without scleral icterus, coarse hair, thinning of the lateral aspect of eyebrows, macroglossia and hoarseness, obtundation, delayed deep tendon reflexes, and hypothermia. When a markedly reduced serum T_4 level and an elevated TSH concentration accompany these signs, the diagnosis is obvious. However, as for thyrotoxic crisis, initiation of treatment should not be delayed until the results of the thyroid function studies are available. Furthermore, because of intercurrent illness, TSH values may not be elevated in proportion to the severity of hypothyroidism. A high index of suspicion in a patient presenting as just described should prompt immediate treatment after a blood sample is taken for laboratory confirmation of the diagnosis.

PULMONARY AND CARDIOVASCULAR COMPLICATIONS

Alveolar hypoventilation is known to occur in myxedema.[22] It is thus not surprising that patients with underlying lung pathology experience worsening of gas exchange. It has been demonstrated that the hypoxic ventilatory drive is depressed in patients with myxedema and that it responds to hormone replacement.[23] The hypercapnic ventilatory response is also significantly depressed, but it does not change with replacement of thyroid hormone. Therefore, a reduced central nervous system (CNS) drive to breathe and decreased respiratory muscle activity are the main reasons for respiratory depression in myxedema coma. Secondary aspiration pneumonia, laryngeal obstruction, and reduced surfactant contribute to lung dysfunction. It is important to be alert to the potential for subtle but progressive aspiration and ventilatory failure.

The cardiovascular complications in myxedema coma are caused by the combination of hypothyroid cardiomyopathy, hypothermia, and hypoxia. Pericardial effusion is almost a constant finding, but it rarely leads to tamponade. It is best demonstrated by echocardiography. In patients with long-standing hypothyroidism, hypercholesterolemia may accelerate the progress of atherosclerosis, leading to ischemic heart disease. The reader is referred to the discussion of hypothermia and its cardiovascular complications (see Chap. 110).

The intercurrent illness and decreased food intake caused by the mental obtundation of myxedema may reduce the serum levels of cholesterol and TSH, diminishing their value as indicators of the severity of the myxedema. Patients presenting with a more profound hypothermia have a poor prognosis. The laboratory findings in patients with myxedema coma are listed in Table 80-4.

TREATMENT

THYROID HORMONE

Although severe hypothyroidism, especially in elderly patients, should be treated cautiously, with gradual increments of small doses of thyroid hormone, myxedema coma is an exception to this rule. The immediate threat to life takes precedence over the risks of rapid hormone replacement. The advantage of treating critically ill patients with T_3 as opposed to T_4 was discussed earlier. In hypothyroid patients without major intercurrent illness, T_4 therapy alone may be sufficient to increase the serum T_3 level to normal in 2 to 3 days. This is unlikely to be true in ICU patients with multiple-organ-system failure. The principle of hormonal treatment is to rapidly replenish the extrathyroid pool of thyroid hormone, which consists mainly of hormone bound to serum proteins, and to provide the tissues with their daily requirement of the biologically active hormone. Replenishment is best achieved by the immediate administration of T_4, a hormone with a considerably longer half-life (7 days) and higher affinity for serum proteins than T_3.[22–24] The active form of the hormone, T_3, then can be provided because it is readily available to tissues and carries a smaller risk of accumulating to excessive amounts (owing to a half-life of approximately 1 day).

The average size of the extrathyroid T_4 pool is approximately 800 μg/1.73 m^2.[24–27] On the basis of this estimate and the normal turnover rate of 10% per day, the daily T_4 requirement can be calculated to be, on average, 80 μg (possibly 50 μg in hypothyroidism, owing to a reduced rate of hormone degradation). Intensivists using only T_4 for treatment should give initially 500 μg L-T_4, followed by 50 to 100 μg daily. The serum T_4 concentration should be in the normal range within 24 to 48 hours. Daily electrocardiographic (ECG) monitoring for ischemic changes and continuous monitoring of rhythm are essential.

We prefer a regimen that uses both T_4 and T_3. Following the intravenous loading dose of 500 μg T_4, 25 μg T_3 is given every 6 hours through a nasogastric tube until improvement is noted, and provided the diagnosis has been confirmed by laboratory tests. The dose is then reduced to maintenance level, and the agent is changed to T_4 only after recovery from intercurrent illness.

USE OF STEROIDS

The rate of metabolism of most drugs and natural compounds is markedly reduced in patients with myxedema coma. Therefore, the absolute requirement for steroids is reduced. However, because of the 5% to 10% incidence of associated primary hypoadrenalism, glucocorticoids should be given until evidence for intact adrenal function is secured by the cortisol measurement on the blood sample obtained on admission. The usual dose of hydrocortisone is 50 mg intravenously every 6 hours. The steroid dose then can be tapered rapidly after confirmation of a normal pituitary-adrenal axis. Alternatively, the initial dose can be 2 mg dexamethasone, and a 1-hour adrenocorticotropin hormone (ACTH, cosyntropin) stimulation test can be done on the spot to assess adrenocortical function[26] (see Chap. 79).

SUPPORTIVE CARE

Early intubation and mechanical ventilation are believed to be central for the successful treatment of myxedema coma. Severe hemodynamic collapse in the presence of a large pericardial effusion may necessitate immediate pericardiocentesis. Because hypothyroidism can cause an elevation of the serum creatine phosphokinase (CPK) level, obtaining a baseline value is helpful for follow-up, particularly if a myocardial infarction is later suspected. Moderate elevations of the blood urea nitrogen (BUN) and creatinine levels are not uncommon and are not necessarily indicative of chronic renal failure.

Hypothermia is treated with blankets, letting internal heat generation slowly warm the body.[21] External warming runs the risk of initiating shock by producing peripheral vasodilation in a patient with already reduced cardiac output. Measurement of central venous pressure is useful to guide therapy. Patients with myxedema are rarely volume overloaded, and the use of diuretics runs the risk of further reducing cardiac output. Hyponatremia is best treated by water restriction because the total body sodium content is increased owing to the storage of sodium in glycosaminoglycan, forming the myxedematous accumulation that becomes mobilized with thyroid hormone treatment. Antiulcer prophylaxis is recommended. More important, it should be remembered that hypothyroidism reduces the metabolism of all drugs, and their dosing needs careful adjustment to prevent drug toxicity. Diligent investigation into the precipitating causes should include blood, urine, and sputum cultures, and empirical treatment with antibiotics should be given.

If severe anemia is present, it should be corrected with blood transfusion to increase the oxygen-carrying capacity of the blood. Use of α-adrenergic agents should be avoided because patients are already vasoconstricted.

EFFICACY OF TREATMENT

Assuming that an accurate diagnosis has been made and that proper therapeutic measures have been carried out, how are the patient's progress and the efficacy of treatment followed? The physician is committed to treat the patient for several days or as long as the serum TSH concentration remains elevated. Reduction of the TSH level is the earliest indicator of a response to thyroid hormone therapy. Irreversible damage to the respiratory centers has been observed, with failure of spontaneous respiration, despite full repletion of thyroid hormone. No laboratory measurements are helpful in assessing the peripheral tissue responses to thyroid hormone in the critical care setting. The ultimate gauge of successful treatment is complete clinical recovery.

Goiter and Acute Airway Obstruction

Large goiters, weighing 150 g or more, can cause some degree of tracheal obstruction, especially if they are substernal in location. In a series of 2908 goiters, only 58 (2.0%) caused tracheal obstruction at presentation. Tracheal compression obstructing up to 75% of the tracheal lumen often remains asymptomatic.[28] Although dyspnea on exertion has been attributed to goiter, the symptoms are often only nocturnal, manifesting as stridor or, when more severe, as sleep apnea. This problem can be confirmed by x-ray views of the trachea at rest and during a reverse Valsalva maneuver and by sleep studies.[29]

Growth of the goiter would have to be extensive to cause direct tracheal compression. In Riedel's struma, there is tracheal cartilage destruction by fibrous invasion, which also can cause bilateral vocal cord paralysis. Several case reports have been published describing the acute presentation of tracheal obstruction associated with goiter.[30,31] Management of these patients is somewhat difficult because emergency tracheostomy may be difficult to perform owing to interference by the thyroid gland. The use of small endotracheal tubes and immediate subtotal thyroidectomy should reduce the need for tracheostomy. It should be noted that subtotal thyroidectomy may not be successful in the presence of tracheomalacia, which may necessitate prosthetic supports.[32] In some instances, a simple division of the thyroid isthmus may be sufficient to relieve the symptoms. Although not particularly useful in the acute care setting, ^{131}I therapy can be effective in the long term in elderly patients with large, compressive goiters.[33]

Thyrotoxicosis

Thyrotoxicosis occurs when the supply of thyroid hormone exceeds the amount needed for normal tissue function. The source of thyroid hormone may be (1) excessive synthesis and secretion of hormone from the thyroid gland in response to either TSH or abnormal thyroid-stimulating substances (usually immunoglobulins), (2) autonomous hormone hypersecretion or abnormal release of preformed hormone, or (3) production of the hormone by an exogenous or ectopic source.[34] Manifestations can be mild or severe depending on the degree of hormone excess and its duration, as well as the presence of intercurrent illness. Aspects related to thyrotoxicosis in the severely ill patient will be the focus of this section.

A few basic facts about thyroid physiology are important for understanding the therapeutic approach to thyroid disorders. Iodine is actively transported into the thyroid gland, where it is covalently bound to tyrosines within the

thyroglobulin molecule. The iodinated tyrosines are coupled to form mainly T_4 as well as some T_3. It is in the form of thyroglobulin that the hormone is stored in the colloid of the thyroid follicles. In response to TSH or an abnormal stimulator, thyroglobulin is digested by proteolysis, and the liberated hormone—predominantly T_4—is secreted into the circulation. In the blood, T_4 is transported bound to specific serum proteins. In virtually all peripheral tissues, T_4 derived from blood is converted into the active hormone, T_3, by removal of a single iodine atom from the 5′ position in the outer ring of the molecule. This reaction is mediated by a tissue-specific 5′-deiodinase. Removal of iodine from the inner ring yields the inactive form rT_3. Intracellular T_3 binds to nuclear receptors, through which it exerts its effects.

DIAGNOSIS IN THE ICU

Thyrotoxicosis may be manifested by adverse changes in every organ system. Pyrexia, tachycardia, congestive heart failure, oxyhemoglobin desaturation, and hypertension are the hallmarks of thyrotoxic crisis.[35] There also may be involvement of the CNS, ranging from tremulousness to seizures and coma, or involvement of the respiratory system, with tachypnea and respiratory muscle fatigue. Goiter and exophthalmos are as likely to be absent as present. Unfortunately, at the time of presentation in the ICU, most patients with these characteristics have only modest elevations of thyroid hormone concentration in serum (see above). Failure to recognize these symptoms as manifestations of thyrotoxicosis may result in nonspecific treatment, with a resulting risk of morbidity or even death. On the other hand, failure to treat pyrexia as a sign of sepsis or tachycardia as a sign of ischemia or hypoxia could be equally devastating. Stat laboratory measurement of thyroid hormone levels is not always available to provide firm laboratory support for the diagnosis. A 2-hour radioiodine uptake test conceivably could be done at the bedside using a portable gamma counter probe, but it is not practical. Therefore, the preliminary diagnosis of thyrotoxicosis usually is based on a careful history and physical examination. Useful findings are (1) a previous diagnosis and treatment of thyrotoxicosis, (2) presence of exophthalmos, (3) goiter, (4) a history of thyroid hormone ingestion, (5) evidence of previous thyroid surgery, including an anterior neck surgical scar, and (6) recent use of iodine-containing radiologic contrast agents. Such information only supports the possibility that suggestive physical signs may be due to thyrotoxicosis.

PHYSIOLOGIC CONSEQUENCES AND CARDIOVASCULAR COMPLICATIONS

Thyroid hormone exerts its tissue effect both directly by interaction with specific nuclear receptors and indirectly through activation of the sympathoadrenal system. Each of these actions causes unique effects on various tissues. The physiologic basis of the sympathomimetic effect of thyroid hormone is unknown. Table 80-5 summarizes the cardiopulmonary complications of thyrotoxicosis.

Perhaps the most detrimental effect of thyrotoxicosis, which clearly is evident in the more severe state of thyroid storm (see below), is pyrexia. Increased body temperature may be secondary to the increased basal metabolic rate or to actual resetting of hypothalamic thermoregulation. Pyrexia further increases cardiovascular stress; therefore, reduction of body temperature is an important goal of therapy.

TABLE 80-5 Cardiopulmonary Complications of Thyrotoxicosis

Increased metabolic demand with increased O_2 consumption and CO_2 production
Respiratory muscle weakness
Increased work of breathing
Hyperdynamic circulation
Potential for high-output heart failure
Potential for myocardial ischemia
Arrhythmias

Neurologic complications of severe thyrotoxicosis include neuromuscular disorders of myopathy (present in over 50% of all hyperthyroid patients and classified as severe in 4%),[36] exophthalmic ophthalmoplegia, aggravation of myasthenia gravis, and thyrotoxic periodic paralysis (primarily in Asian men). Except for irritability and tremulousness, the delirium, stupor, coma, and convulsions may be related to the direct action of thyroid hormone on the brain.[37] Thyroid hormone can affect the concentrations and distributions of various neurotransmitters.[38] Hematologic manifestations of thyrotoxicosis[39] are rarely life threatening. It is useful for the intensivist to be aware that hyperthyroidism can cause slight anemia. Anemia may be secondary to hemodilution caused by increased blood volume, but true reduction of red blood cell mass may be caused by reduced iron absorption and vitamin B_{12} deficiency associated with autoimmune reduction of gastric acidity and intrinsic factor. Minimal thrombocytopenia, with rare instances of idiopathic thrombocytopenic purpura, has been reported.[40] Moderate eosinophilia may occur and has been attributed to relative or absolute hypoadrenalism. A variable relative or absolute lymphocytosis may be associated with hyperthyroidism. These manifestations may cloud the picture of a critically ill patient who may have other hematologic perturbations for different reasons.

Hypercalcemia is the most common life-threatening electrolyte abnormality seen in thyrotoxicosis.[39] Severe hypercalcemia (11.8 to 19.2 mg/dL) has been reported in several patients with thyrotoxicosis.[41]

The most notable effect of thyrotoxicosis on the gastrointestinal system is hypermotility with malabsorption.[42] The myopathy of hyperthyroidism may cause weakness of the striated muscles of the pharynx and, perhaps, the smooth muscle of the esophagus. Such patients could have dysphagia and then could aspirate and develop pneumonia.[43] Patients with hyperthyroidism appear to have a higher incidence of gastritis.[44] This association is consistent with the hypergastrinemia seen in thyrotoxic patients.[45] Treatment with H_2 blockers or proton pump inhibitors is indicated.

Rarely, fulminant hepatic necrosis or less severe hepatic injury occurs. Although thyroid hormone has no direct toxic effect on the liver, hyperthermia can result in hepatic failure. In patients receiving propylthiouracil (PTU), drug toxicity is more likely the cause of fulminant hepatic necrosis.[46] Any thyrotoxic patient who presents with jaundice or other signs of hepatic injury should have a thorough evaluation for possible alternative causes of liver damage.

Thyroid Storm

Thyroid storm, or *thyrotoxic crisis*, is a life-threatening though rare complication of severe thyrotoxicosis. The diagnosis is clinical, bearing no direct relation to the absolute levels of thyroid hormones in serum. The cardinal features of thyroid storm are marked tachycardia, hypertension, and widened pulse pressure; hyperpyrexia (usually greater than 38.5° C [101° F]); and altered mental status. In extreme cases, cardiovascular collapse and shock may be seen. Some investigators contend that abnormal mentation is the most important diagnostic component of thyroid storm.[26] Of course, these clinical features can occur with a multitude of illnesses in the absence of thyrotoxicosis. Some authors propose a "point system" for determining whether a patient's condition represents true storm or severe thyrotoxicosis, but the distinction between these two entities is not useful clinically.[47] A blood sample for measurement of the levels of T_4 or free T_4, or the free T_4 index (FT_4I), and TSH, by a sensitive method, should be obtained immediately in all individuals suspected of having this disorder. Empirical treatment then should begin. It is prudent to obtain a blood sample for cortisol determination before "stress doses" of steroids are administered for use later in deciding later whether long-term therapy is necessary. Laboratory findings in thyroid storm are listed in Table 80-6.

PRECIPITATING FACTORS

Patients who develop thyroid storm usually have poorly controlled thyrotoxicosis; often there is an identifiable precipitating factor[26,48] (Table 80-7). In many cases it is difficult to determine whether the intercurrent illness is the cause or the consequence of the thyroid storm.

TREATMENT

To prevent irreversible cardiovascular collapse, the treatment of thyroid storm should take a four-pronged approach: (1) therapy to reduce the serum thyroid hormone levels, (2) therapy to reduce the action of the thyroid hormones on peripheral tissues, (3) therapy to prevent cardiovascular decompensation and to maintain normal homeostasis, and (4) treatment of the precipitating event(s).

THERAPY TO REDUCE THYROID HORMONE LEVELS

An antithyroid drug, either PTU or methimazole (MMI), is given to prevent further synthesis of thyroid hormone. These drugs are not available in parenteral form; they can only be given orally or by nasogastric tube. Instances may arise in which these drugs cannot be given even by nasogastric tube—such as, for example, in patients with infarcted bowel. PTU offers a slight advantage over MMI in that, in addition to its inhibitory effect on hormone synthesis, it decreases the conversion of T_4 to T_3 in peripheral tissue. PTU should be given in a dose of 200 to 250 mg every 6 hours, and MMI should be given in a dose of 25 mg every 6 hours. Some authors recommend giving an initial PTU loading dose of 600 to 1000 mg, but this strategy has not been proved to be advantageous. Another regimen that has been reported consists of one 600-mg loading dose of PTU (12 tablets suspended in 90 mL of water) given as a retention enema, followed by 250 mg of PTU every 4 hours plus potassium iodide, 1 g diluted in 60 mL of water, given after the second PTU dose.[49] PTU has an immediate onset of action for blocking the synthesis of thyroid hormone, but serum levels of thyroid hormone may take several weeks to normalize because of continuing secretion of stored hormone. In severe thyrotoxicosis with a decreased glandular content of hormone, a significant decline in serum levels may be observed in a matter of a few days. We usually repeat thyroid function tests every other day while the patient is acutely ill to help guide management.

Blockade of hormonal secretion usually is best accomplished by the addition of stable iodine to the antithyroid drug regimen. Iodine can be administered as Lugol's solution or as a saturated solution of potassium iodide (ssKI) (2 drops every 12 hours) or given by intravenous drip as sodium iodide (0.5 mg every 12 hours). It is important not to give iodide prior to antithyroid drug blockade because new hormone synthesis may occur and result in delayed release of hormone. There have been several cases where the use of iodine alone triggered thyroid storm. Administration of antithyroid drugs 1 hour before iodine is given is sufficient to establish blockade of hormone synthesis. A combination of antithyroid drugs and ssKI should decrease the serum T_3 level to the normal range in 1 to 5 days; however, the metabolic response may lag behind by 2 to 3 days.[50] Corticosteroids and propranolol, which also decrease the peripheral conversion of T_4 to T_3, can be used to further reduce the serum T_3 concentration (Tables 80-8 and 80-9).

In the event that antithyroid drugs cannot be used because of a previous history of reactions, such as agranulocytosis or hepatotoxicity, iodine and oral cholecystographic agents may

ABBREVIATIONS: +, minor effect; ++, moderate effect; + + +, strong and principal effect; PTU, propylthiouracil; MMI, methimazole; $LiCO_3$, lithium carbonate; $KClO_4$, potassium perchlorate; ssKI, saturated solution of potassium iodide; IOP, iopanoic acid; TBG, thyroxine-binding globulin.

have to be used alone—the latter in the form of ipodate or iopanoate (iopanoic acid). These agents are strong inhibitors of the 5′ deiodination of thyroid hormones; thus they decrease serum levels of T_3 and increase those of rT_3.[51] They also bind to the thyroid hormone receptor, but it is unclear whether this results in competitive inhibition of T_3 action.[52] These agents have a high iodine content (approximately 60% by weight) and thus also act by releasing iodine in the course of their degradation. As in the case of iodine treatment, their administration in the absence of antithyroid drugs requires careful monitoring of the clinical status. Iopanoic acid (TELEPAQUE) may be given in amounts of 1 to 3 g daily. We have found that 3 g/d often causes diarrhea; this effect can be prevented with no reduction of the drug's therapeutic efficacy by giving 0.5 g three times a day. Alternatively, sodium ipodate (ORAGRAFIN) may be used at a dose of 0.5 mg/d, which can reduce serum T_3 by 62% in 1 day.[53,54]

For the rare patient with allergic reactions to both antithyroid drugs and to iodine-containing contrast media, lithium carbonate and perchlorate are alternative drugs. Lithium carbonate can be given in doses of 300 mg every 6 hours, with subsequent adjustments to maintain a serum lithium level of 0.7 to 1.4 mEq/L. Caution should be exercised in patients over 60 years of age. This drug acts by blocking iodide uptake and hormone release by the thyroid gland. Sodium or potassium perchlorate (ClO_4) competes with iodide for uptake by the thyroid gland, ultimately reducing the production of T_4. These compounds are not readily available in the United States. Serious side effects, including aplastic anemia and nephrotic syndrome, occur rarely.

Successful reduction of the serum concentration of thyroid hormones by means of plasma exchange has been reported in three patients (two of whom were pregnant).[55,56] Filtration through a resin bed that removes T_3 and T_4 has been used occasionally.[57] Intravenous administration of thyroxine-binding globulin has been shown experimentally to decrease the transfer of thyroid hormone from blood to tissues.[58]

PREVENTION OF SYSTEMIC DECOMPENSATION

Reduction of the body temperature decreases the demands on the cardiovascular system. Body temperature can be reduced by cooling and by pharmacologic blockade of the thermoregulatory centers. Use of a cooling blanket and ice packs alone will induce shivering; treatment with chlorpromazine, 25 to 50 mg, and meperidine, 25 to 50 mg, intravenously every 4 to 6 hours will decrease the severe shivering and limit further heat generation.[21]

Patients in thyroid storm lose excessive amounts of fluid because of (1) increased insensible water loss associated with hyperthermia and tachypnea, (2) decreased levels of antidiuretic hormone, and (3) vomiting and diarrhea associated with increased intestinal motility. Thus patients may present

TABLE 80-9 Drugs Used in the Treatment of Thyrotoxicosis

Drug	Dose	How Supplied	Adverse Effects
Propylthiouracil	200–250 mg q6h PO	50-mg tablet	Rash, agranulocytosis, hepatic toxicity
Methimazole	25 mg q6h PO	5- and 50-mg tablet	Rash, agranulocytosis, hepatic toxicity
Lithium carbonate	300 mg q6h PO	150-, 300-, and 600-mg tablets	Nausea, vomiting, arrhythmias, pseudotumor cerebri
Lugol's solution	2 drops q12h PO	8-mg iodine drop	Hypersensitivity
ssKI	1 drop q12h PO	50-mg iodide drop	Hypersensitivity
Iopanoic acid	0.5 g tid PO	0.5-g tablet	Abdominal cramps, diarrhea, hypersensitivity, nephrotoxicity
Perchlorate	1.0 g qd	0.5-g tablet (66.7% organically bound)	Aplastic anemia
Propranolol	40 mg q6h PO1 mg slow IVP	10-, 20-, 40-, 60-, and 80-mg tablets; 1-mg/mL vials	Asthma, heart block
Hydrocortisone	100 mg IV piggyback q8h	100-mg vials	Immunosuppression

ABBREVIATIONS: ssKI, saturated solution of potassium iodide.

with either high- or low-output failure, and fluid management may necessitate central venous catheterization to determine filling pressures and guide management. Solutions containing crystalloid (for volume replacement) and dextrose (to replenish hepatic glycogen stores and minimize the breakdown of body protein) are used. Treatment with high doses of propranolol, as discussed below, can make it necessary to use 5% to 10% dextrose solutions. Multivitamins often are administered to replenish the B-complex vitamins.

Treatment of congestive heart failure usually is supportive. While reduction of the high body temperature should be attempted before specific treatment is instituted, the judicious use of inotropic agents and diuretics also should be considered. Since patients are often volume depleted, diuretics should be used carefully and always with meticulous monitoring of intravascular volume. Impending shock should be treated with rapid correction of volume and with inotropic agents, as indicated. Atrial fibrillation is a known complication of thyrotoxicosis. Control of ventricular response can be achieved with β blockers, but conversion to sinus rhythm can be achieved only after the patient is made euthyroid.

Since relative hypoadrenalism is thought to occur in thyroid storm because of accelerated metabolism of glucocorticoids, it is prudent to give 300 mg hydrocortisone intravenously, followed by 100 mg every 8 hours to provide adequate stress levels. In addition, glucocorticoids can be beneficial for their effect in reducing the conversion of T_4 to T_3 in peripheral tissue. Use of parenteral H_2 blockers is indicated to reduce the likelihood of ulcer formation. In thyrotoxicosis, there is rapid clearance of drugs. Therefore, doses of digitalis, insulin, and antibiotics need to be increased to be effective. Two exceptions are adrenergic drugs and anticoagulants.[59] It is necessary to remember to reduce drug doses as the thyrotoxicosis resolves.

REDUCTION OF THYROID HORMONE ACTION ON BODY TISSUES

The effects of thyroid hormone can be reduced by (1) decreasing its conversion to the active form, T_3, (2) counteracting its sympathomimetic effects, (3) displacing it from its receptor, and (4) reducing its transport to tissues.

The oral cholecystographic agents, as discussed earlier, may act in part by displacing T_3 from its site of action at the receptor in cell nuclei. Other analogs of thyroid hormone with reduced thyromimetic activity, which nevertheless compete with thyroid hormone at its site of action, deserve theoretical consideration.[60] The activity of 5′-deiodinase is regulated by the concentration of T_4, as well as by catecholamines and other factors. PTU, glucocorticoids, propranolol, oral cholecystographic agents, and amiodarone also reduce the activity of this enzyme and thus decrease the generation of T_3, resulting in reduction of serum T_3 concentration. Severe acute or chronic nonthyroidal illness also suppresses T_3 generation in peripheral tissues.

β Blockers, which are useful in the preparation of thyrotoxic patients for surgery, should be used with caution in thyroid storm. Whereas surgical stress clearly is related to increased catecholamine levels, and thyroid storm can be prevented by the use of propranolol, it is unclear whether thyroid storm induced by other mechanisms is equally responsive to β blockers. However, when there is evidence of increased adrenergic activity short of thyroid storm (i.e., no evidence of hyperpyrexia or mental status changes), 1 mg propranolol can be administered by slow intravenous push every 5 minutes until an effect on pulse rate is seen. Usually a total daily dose of 300 to 400 mg oral propranolol is required to achieve effective β blockade in the severely thyrotoxic patient. It appears that younger patients are more susceptible to hyperadrenergic states with more labile courses and do better with β blockers.[21] By contrast, elderly patients may present with "apathetic" thyrotoxicosis without elevation in body temperature and without severe tachycardia. These elderly patients more often experience cardiotoxic effects in response to β blockers. Therefore, β blockers should be used with caution in thyroid storm and in severe thyrotoxicosis, except in the elderly, in asthmatics, and in patients with evidence of dilated cardiomyopathy. When surgery is indicated in such patients, careful titration of the adverse adrenergic cardiovascular effects (tachycardia, large pulse pressure) can be implemented with shorter-duration β blockers (esmolol) preceded by maximal bronchodilator therapy in asthmatic patients or right-sided heart catheterization in elderly patients and those with prior heart failure.

TREATMENT OF PRECIPITATING EVENTS

Without an antecedent history of surgery, any patient with thyroid storm should be suspected of being septic until proven otherwise. Blood, urine, and other body secretions (i.e., ascites or pleural fluid and sputum) should be Gram stained and cultured. Empirical use of broad-spectrum antibiotics is recommended.

In a seriously ill patient in whom an infection or other precipitating cause, such as diabetic ketoacidosis, cannot be identified, pulmonary thromboembolism[61,62] or bowel infarction should be considered.

THYROID STORM IN PREGNANCY

The approach to treatment of thyroid storm in pregnant patients is similar to that outlined earlier. Thyroid storm is clearly a life-threatening condition for the mother. The basic approach to prevent decompensation is aggressive fluid replacement along with treatment of the precipitating event and antithyroid therapy. Because β blockers may have deleterious effects on the fetus at all stages of fetal development, their use must be weighed against maternal safety. While administration of iodide often results in the development of massive fetal goiter, PTU can be given to the toxic pregnant patient with only a small likelihood of adverse effects on the fetus.

Anesthesia and Surgery: Risks and Management in Thyrotoxic Patients

The Swiss surgeon Emil Theodor Kocher (1841–1917), who was the first to operate on hyperthyroid patients, was also among the first to recognize that thyroidectomy carried a high rate of mortality in "unprepared" thyrotoxic patients. The stress of any form of surgery or anesthesia alone could push a mildly decompensated thyrotoxic patient into a thyroid crisis, a life-threatening condition (see above). Therefore, it is important to control thyrotoxicosis prior to surgery. Ideally, the FT_4I should be below the upper limit of normal.

Unfortunately, even in the presence of a rapid turnover rate, thyroxine has a half-life of at least 72 hours, and frequently it takes more than 1 week to achieve a normal FT_4I—an unacceptable wait, especially when the need for surgery is urgent. In such instances, the preoperative therapeutic goal is to prevent the occurrence of thyroid storm. Blocking the effect of thyroid hormone on the sympathetic nervous system, particularly on the heart, is an alternative (if not an ideal) approach to therapy.[63] An arbitrary goal of maintaining a heart rate below 90 beats per minute may not always be achieved in patients who have a pulse rate of 200 beats per minute at the outset. In fact, there are no strict criteria for the response to therapy prior to surgery. Propranolol is the most widely used drug[64–66]; other parenteral preparations are now available, but there is no clear evidence that any of them has advantages over any other. Propranolol, however, has the added effect of decreasing the conversion of T_4 to T_3 in peripheral tissues. This effect may not be shared by other β blockers, such as atenolol. By and large, β blockers have little effect on the serum concentration of T_4 or on the metabolic status of the patient. The combined use of an antithyroid drug (PTU or MMI) and iodide provides the most rapid means of reducing the serum level of thyroid hormone; the antithyroid drug blocks the synthesis of the hormone, and iodide blocks its release. Although the results of determinations of serum thyroid hormone concentrations may not be available on a stat basis, it is important to obtain a blood sample before treatment is initiated.

We would like to discuss three scenarios for the preoperative treatment of thyrotoxic patients. First, consider an ICU patient who is in a septic condition with severe cholecystitis. The presence of thyrotoxicosis has been confirmed by an FT_4I of 21 (normal range = 6 to 10.5) and a TSH level below 0.01 mU/L. A cholecystectomy is planned as the definitive treatment, to take place in approximately 1 week. In this instance, the physician has time to institute therapy aimed at reducing the thyroid hormone concentration and to follow serum hormone levels as guides of therapeutic response. Initiation of PTU, 200 mg every 8 hours given orally or by nasogastric tube, followed by 1 or 2 drops of ssKI twice daily, is the suggested treatment for this patient's thyrotoxicosis. The reason for starting PTU before iodide is to prevent the gland from being flooded with iodide, which has been shown to produce, on occasion, a later exacerbation of thyrotoxicosis. A full discussion of these drugs appears under Thyroid Storm above and in Table 80-4. Thyroid function tests should be performed every 2 days.

Second, consider a 65-year-old woman admitted for semiemergent aortic valvuloplasty for severe aortic stenosis due to rheumatic carditis. She has been noted to be thyrotoxic; recent thyroid function tests revealed an FT_4I of 19 and a TSH level of less than 0.01 mU/L. The valvuloplasty is scheduled for the next morning. While antithyroid drugs and ssKI should be given at the onset, in this case there is little chance for this treatment to reduce the thyroid hormone levels in 24 hours. Propranolol can provide a rapid and effective preparation for surgery.[66] An initial dose of 40 mg every 6 hours is appropriate, to be followed by increments of 20 mg every 6 hours, depending on the response, as judged by the heart rate. Although the usual dose is approximately 40 mg every 6 hours, doses of up to 320 mg/d may be required. Symptoms of tachycardia, anxiety, and sweating should be relieved within 12 hours. Intraoperative propranolol may be administered for tachycardia as needed. Propranolol treatment should be resumed within 4 to 6 hours after surgery and maintained for 48 hours. If the patient is unable to take oral medications perioperatively, then propranolol can be administered as a 1.0- to 2.0-mg slow intravenous bolus. On postoperative day 3, the dose of propranolol can be halved; it can be halved again on day 4, and the drug can be discontinued completely on day 5, 6, or 7 depending on the symptoms and the response to continuing antithyroid drug therapy. Propranolol is not indicated in patients with bronchial asthma, advanced grades of heart block, or unstable insulin-dependent diabetes nor in patients taking quinidine or psychotropic drugs that augment adrenergic activity. β Blockers generally are safe and effective in congestive heart failure, when administered with caution, and are useful in correcting the high-output failure of thyrotoxicosis. Three cases have been reported in which thyroid storm followed surgery for which the patient had been prepared with propranolol alone.[67–69]

Third, consider a 25-year-old 38-week primigravida who must undergo emergent cesarean section for fetal distress. The patient is known to have active Graves' disease. She has not been compliant in taking the prescribed PTU and is febrile, tachycardic, and hallucinating. Appropriate preparation for this patient prior to general anesthesia and emergency cesarean section would be intravenous propranolol, 1.0 to 2.0 mg as a slow intravenous bolus. Then 10 to 15 mg propranolol can be added to 500 mL 5% dextrose and infused while the patient's and fetus's heart rates are monitored. Continuation of the propranolol after surgery would be indicated, as discussed earlier. The use of atropine to control bronchial secretions during surgery should be avoided in thyrotoxic patients because of possible exacerbation of the sympathomimetic activity. There are reports of the use of plasma exchange in severe thyrotoxicosis of pregnancy.[54] In summary, euthyroidism can be rapidly accomplished with iopanoic acid and dexamethasone, β-blockers, and, when possible, antithyroid drugs.[69a]

Amiodarone-Induced Thyrotoxicosis

Amiodarone is an iodine-rich antiarrhythmic (37% of its weight is organic iodine). Because of its efficacy, it has become widely used. This has resulted in a significant increase in side effects associated with the drug, such as thyrotoxicosis. Given the patient's underlying cardiac problem that necessitated the use of this drug, the thyrotoxicosis, when it occurs, results in a worsening of the problem. The incidence of amiodarone-induced thyrotoxicosis (AIT) is thought to be higher in individuals with low dietary iodine. Amiodarone also can cause hypothyroidism but usually in populations with relatively high dietary iodine.

The mechanism of AIT is unknown but undoubtedly involves thyroid iodine dysautoregulation and destruction and/or inflammation of the thyroid gland. AIT is classified as types I and II. Type I occurs in structurally abnormal thyroid glands (such as a nodular goiter), and type II occurs in a structurally normal gland.[70] Type I is caused by iodine-induced thyroid hormone synthesis, and type II is believed to be due to a destructive thyroiditis. Treatment of type I

and type II AIT in critically ill patients can be a challenge, and often the type of AIT is not apparent at the time of presentation.

The diagnosis is made in a patient who presents with the typical laboratory findings of thyrotoxicosis and a history of being on or recently having been on amiodarone. Owing to accumulation of the drug in fat tissue, it has a long half-life in the body. Laboratory tests such as an elevated spot urinary iodine determination and an ^{123}I uptake test (although the latter is rarely practical in the ICU setting) can be helpful to confirm the diagnosis in a patient who is thyrotoxic and on amiodarone.

The most appropriate treatment of AIT is still to be determined. All agree that amiodarone should be discontinued immediately in all patients, where possible. Two recent investigations have demonstrated that treatment with prednisone or prednisolone was advantageous in resolution of the hyperthyroidism.[71,72] The mechanism of how steroids help may be related to their anti-inflammatory effect during a destructive type II AIT or to the effect on reduction of conversion of T_4 to T_3. A protocol for the treatment of AIT in the ICU is outlined in Fig. 80-2. Briefly, the critically ill patient should be placed on prednisone 30 mg daily, along with an antithyroid drug, PTU 200 mg three times daily or MMI 20 mg twice daily, and potassium perchlorate, 500 mg twice daily. This regimen should continue for 2 weeks, at which time repeat serum FT_4I and FT_3I and urine iodine level should be measured. If the FT_4I and FT_3I both are normal, a rapid taper of the steroid and discontinuation of the potassium perchlorate (because of its poor gastrointestinal tolerance) should be initiated, and management of the antithyroid drug should be as in anyone with hyperthyroidism. If the FT_4I and/or FT_3I are elevated, then the same course of medications should be continued for 2 more weeks, and then remeasurement of the serum thyroid hormone and urine iodine levels would be indicated. In circumstances where medication is not an option and the severity of the thyrotoxicosis is causing cardiovascular collapse, patients should be stabilized as much as possible, and emergent thyroidectomy should be considered. Radioactive iodine ablation is rarely an option given the low thyroidal uptake of the isotope.

Levothyroxine Overdose

Levothyroxine (L-T_4) is dispensed commonly and, in the United States, is the fourth most frequently prescribed drug in the 3.05 billion prescriptions written in 2002 (*http://www.rxlist.com/top200.htm*). This wide availability leads to frequent overdoses, with reports of 2000 to 5000 acute toxic exposures annually in this country.[73–75] Despite the high frequency of overdosage, with documented blood levels of T_4 up to 16 times normal, there have been no reported deaths from L-T_4 ingestion.[74] Clearly, patients do become symptomatic, with tachycardia, nervousness, diarrhea, and even seizures, but these symptoms generally are self-limited. In patients suspected (but denying) of having ingested thyroid hormone, the finding of a suppressed serum thyroglobulin level in the presence of a high serum T_4 and/or T_3 level is diagnostic.[76]

The most commonly used thyroid preparation today is synthetic L-T_4, which contains no T_3, in contrast to the thyroid preparations of 20 years ago, which consisted of thyroid gland extracts containing 20% to 30% T_3. Therefore, ingestion of a large quantity of L-T_4 does not cause immediate toxic effects. Symptoms occur after a significant amount of T_4 has been converted to T_3, usually about 24 hours after ingestion. After gastrointestinal decontamination, by induction of vomiting

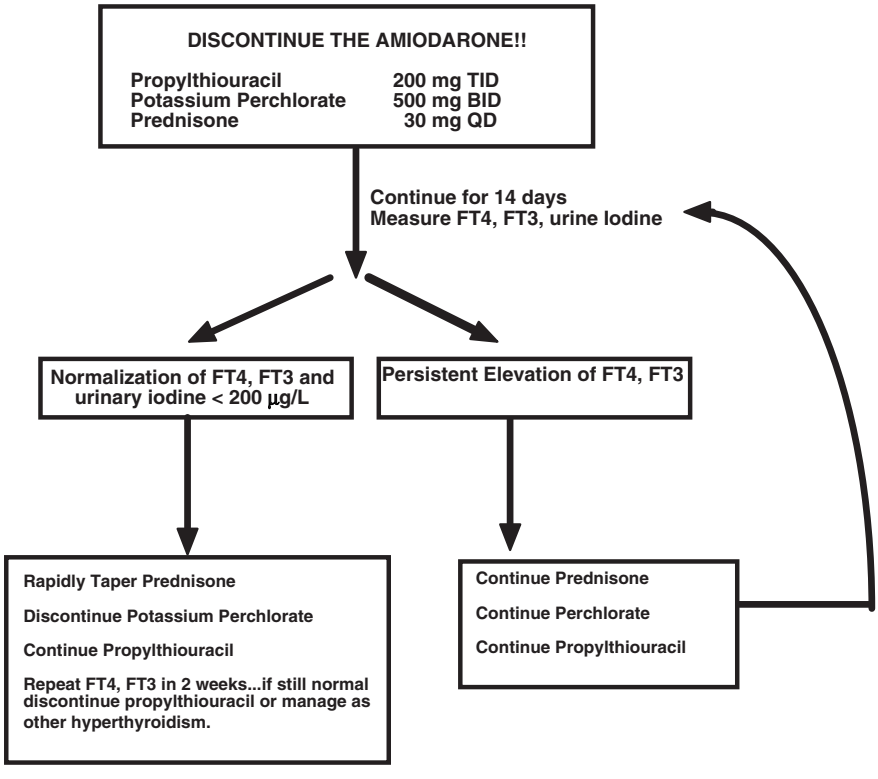

FIGURE 80-2 Proposed protocol for the treatment of critically ill patients with amiodarone-induced hyperthyroidism.

with syrup of ipecac and gastric lavage using charcoal, only symptomatic and supportive treatment is indicated. Recommendations by Lehrner and Weir,[77] based on experience with two patients and review of the literature, are aggressive treatment with (1) gastrointestinal decontamination, (2) cholestyramine to increase fecal elimination of the hormone, (3) prednisone and propylthiouracil, and (4) propranolol. Recently, Gorman and colleagues[74] recommended only gastrointestinal decontamination and propranolol if the patient is markedly symptomatic. They suggested home gastrointestinal decontamination when 0.5 mg L-T_4 has been ingested and determination of the serum T_4 level for ingestions of roughly 2.0 to 4.0 mg. When we give 1 mg T_4 for an absorption test, the serum T_4 level increases by only about 2 μg/dL in 8 hours. Therefore, the former guidelines are a bit conservative, and we would recommend that ingestion of over 10 mg in an adult is cause for aggressive treatment. Elderly patients and persons with underlying cardiac disease should be hospitalized for observation if the serum T_4 level is high or the patient is symptomatic. Cholestyramine has been used in treating iatrogenic thyrotoxicosis and may shorten the time it takes for the thyroid hormone concentration to normalize.[78] The use of other medical therapy should await the onset of symptoms.

Neonatal Thyrotoxicosis

Neonatal thyrotoxicosis is a rare emergency that is treatable but nevertheless is associated with a 12% to 16% mortality.[79,80] A neonate can present signs of thyrotoxicosis within the first 24 hours of life but usually later if the mother was receiving thyroid-suppressive therapy and when blocking as well as stimulating antibodies are present. Physical findings are goiter, tachypnea, tachycardia, cardiomegaly, hyperkinesis, restlessness, diarrhea, and poor weight gain. Flushing, periorbital edema, and exophthalmos also may be present.

Most infants with neonatal thyrotoxicosis are born to mothers with hyperthyroidism. Neonatal thyrotoxicosis also can occur with no documented maternal thyroid disease and even in the presence of maternal hypothyroidism. In most cases, this disease is caused by transplacental transfer of thyroid-stimulating immunoglobulin.[81] In others, where such a substance cannot be demonstrated in the mother's serum, there may be de novo formation of thyroid-stimulating immunoglobulins in the fetus due to neonatal Graves' disease or autonomous hyperfunction due to an activating mutation in the TSH receptor.[82]

Treatment of neonatal thyrotoxicosis is short term until the placentally transferred immunoglobulins have disappeared. PTU is given at doses of 5 to 10 mg/kg per day in three divided daily doses. Iodide solutions (10% potassium iodide, 76.6 mg/mL) may be given in a dose of 1 drop, or about 4 mg, every 8 hours. High-output congestive heart failure and other sympathomimetic effects can be treated with propranolol, 2 mg/kg per day in two or three divided doses. Caution should be exercised in the use of propranolol because severe bradycardia and hypoglycemia may result.[83] Surgery and radioiodine treatment are required after the initial drug control of thyrotoxicosis in infants with nonautoimmune hyperthyroidism.

Iodide-Induced Thyrotoxicosis (Jodbasedow)

Iodide, in the form of dietary supplements or medication (e.g., antitussive agents, amiodarone, or contrast agents), can induce thyrotoxicosis, especially in patients who are relatively iodide deficient. Treatment requires special considerations because antithyroid drugs alone are slow to act because of a flooded iodine pool. To deplete the gland of iodine, perchlorate must be added to the therapeutic regimen—particularly in amiodarone-induced thyrotoxicosis.[84] Naturally, iodide treatment is not indicated.

Chapter 81

GUT AND HEPATOBILIARY DYSFUNCTION

ELI D. EHRENPREIS
THOMAS D. SCHIANO

KEY POINTS

- *Alterations in gastrointestinal motility occur commonly in critically ill patients.*
- *The small intestine is the site of obstruction in 90% of cases of mechanical bowel obstruction. Pelvic adhesions are the most common cause. Thirty percent of cases require surgery.*
- *Intestinal pseudo-obstruction (nonmechanical bowel obstruction) may present with clinical symptoms that are similar to mechanical obstruction. Treatment includes nasogastric suction, rehydration, and correction of causative factors.*
- *Ogilvie's syndrome (colonic pseudo-obstruction) is characterized by abdominal distension and marked dilation of the cecum and right colon on abdominal x-rays. Treatment with colonoscopic decompression of the right colon is successful in about 60% of patients. Intravenous neostigmine is also effective.*
- *The incidence of diarrhea in the critically ill is greater than 40% and is up to 60% in patients receiving enteral feedings.*
- Clostridium difficile *infections are generally acquired in the hospital in patients receiving broad-spectrum antibiotics. Measurement of* C. difficile *toxin A or B in the stool by rapid enzyme-linked immunosorbent assay (ELISA) is the most practical method for diagnosis. Treatment consists of metronidazole or vancomycin for 7 to 14 days.*
- *Hyperbilirubinemia is frequently seen in patients with sepsis; cytokines along with bacterial endotoxins impair transport of bile acids at the sinusoidal and canalicular membranes, resulting in cholestasis.*
- *The etiology of total parenteral nutrition (TPN)-associated liver dysfunction appears to be multifactorial. The diagnosis is often made after the exclusion of other causes such as the concurrent use of potentially hepatotoxic medications, biliary obstruction, infections, and underlying intrinsic liver disease.*
- *Critically ill patients have multiple risk factors that predispose to acalculous cholecystitis. Patients often present atypically; unexplained fever and evidence of occult infection may frequently be the only manifestations. Ultrasonography alone is of limited value in diagnosis.*
- *Strong clinical suspicion and early recognition of acalculous cholecystitis are essential. Because of delays in diagnosis, more than 40% of patients develop complicated disease with gangrene, abscess, or perforation of the gallbladder.*

Gastrointestinal (GI) and hepatic dysfunction are common in the critically ill patient, particularly in the setting of multiple organ system failure (MOSF) and the systemic inflammatory response syndrome (SIRS). Many factors are responsible for the pathophysiologic derangements of the GI tract and liver in critically ill patients. Disordered function may be directly related to the precipitating illness of the patient, which can lead to additive morbidity, thus perpetuating a vicious cycle. Management of disordered GI and hepatic function often necessitates aggressive and sometimes invasive diagnostic and therapeutic maneuvers, placing critically ill patients at risk for iatrogenic complications. These conditions may create vexing problems in the ongoing care of patients in the intensive care unit. It is therefore imperative for the clinician to develop a thorough understanding of the pathophysiology of GI and hepatic dysfunction in the critical care patient. This knowledge will permit identification of these conditions and allow for management decisions that are appropriate and timely.

In this chapter, we review the physiology of intestinal motility, and the pathophysiology and clinical features of intestinal obstruction and pseudo-obstruction. We also review the various causes of diarrhea in the critically ill patient, as well as the pathophysiology of bacterial translocation. In addition, the relationship between hepatic dysfunction in the critically ill patient as related to infection and parenteral nutrition will be discussed. The diagnosis and management of acalculous cholecystitis will also be reviewed.

Intestinal Motility

Alterations of intestinal motility are common in the critically ill patient. The following discussion will be restricted to small intestinal and colonic motility, since these are the GI organs most subject to dysfunction in the intensive care setting.

NORMAL FUNCTION OF THE SMALL INTESTINE AND COLON

The contents of the small intestine and colon are subject to complex processing prior to their excretion from the rectum. As GI contents are moved through the stomach and small intestine, mixing and churning result in the reduction in size of individual particles. These smaller particles allow increased exposure of nutrients to the small intestinal mucosa. The contents of the small intestine subsequently undergo nutrient and electrolyte absorption with a net secretion of fluid. The normal transit time of a liquid bolus from the mouth to the ileocecal valve is less than 2 hours, whereas solid substances take up to 8 hours to reach the cecum.[1] The colon functions as a storage organ, with solid contents remaining within the colon for an average of 35 hours prior to excretion.[2] Intraluminal contents undergo solidification as they move from the proximal to distal colon as marked reabsorption of water, sodium, and chloride, and net secretion of potassium, takes place. These processes occur through highly coordinated events with regional differences within portions of the small and large intestine. The control of luminal fluid and electrolyte balance, as well as motility of the small intestine and colon, requires the integration of neuronal, muscular, and endocrine components of these organs.

NEUROANATOMY OF THE SMALL INTESTINE AND COLON

The complexity of intestinal neuroanatomy can be appreciated by the fact that the neuronal density of the gut is

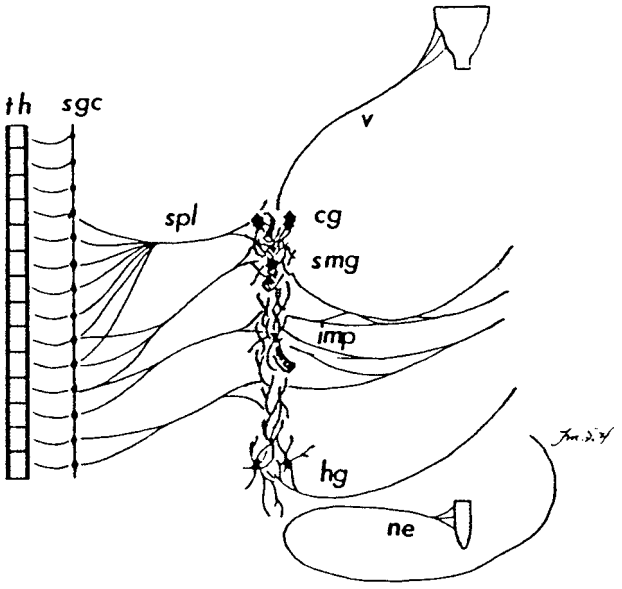

FIGURE 81-2 Diagrammatic representation of autonomic innervation of the colon. Sympathetic preganglionic fibers from the thoracic region of the spinal cord (th) travel to the sympathetic ganglionic chain (sgc). Splanchnic neurons are formed (spl) which travel to prevertebral ganglia (cg, celiac ganglia; smg, superior mesenteric ganglia; imp, intermesenteric plexus; hg, hypogastric ganglia). Postganglionic fibers from these plexuses then travel to submucosal and intramuscular plexuses of the colon. Parasympathetic fibers originate form the medulla and coalesce as the vagus nerve (v) and the pelvic and hypogastric plexuses called the nervi erigentes (ne). (*Reprinted with permission from Berk JE:* Gastroenterology. *Philadelphia, Saunders, 1985.*)

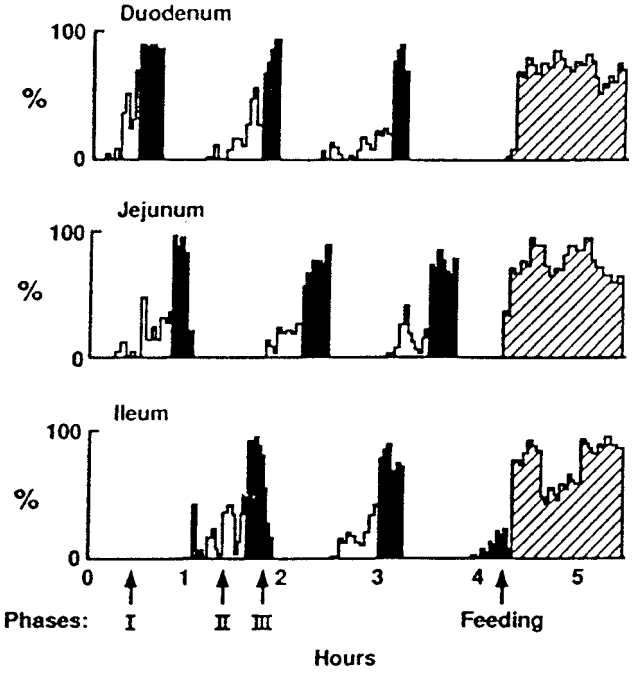
approximately equivalent to that of the spinal cord. This network of neuronal pathways has been described as the "brain of the gut."[3] The small and large intestine have both intrinsic and extrinsic neuronal components. The intrinsic neurons of the small intestine and colon consist of cell bodies which are located in either the submucosa (Meissner's plexus) or the intermuscular region between the circular and longitudinal muscles of the gut wall (Auerbach's plexus) (Fig. 81-1). Submucosal nerve cell bodies are most prominent in the duodenum and decrease in density in a caudal direction; intermuscular nerve cell bodies are more evenly distributed throughout the GI tract.

The extrinsic intestinal nervous system makes up a significant portion of the autonomic nervous system and consists of parasympathetic and sympathetic branches. The distributions of these pathways are markedly different.[4,5] Parasympathetic motor fibers originating from the medulla coalesce along the vagus nerve. Additional parasympathetic motor axons arise from the sacral portion of the spinal cord and join as the pelvic nerves and hypogastric plexus. The axons of these vagal and sacral parasympathetic plexuses advance directly to the GI tract, where they synapse with cell bodies in the submucosa or intermuscular areas as previously described. Sensory fibers arising from the GI tract that synapse with central nervous system (CNS) ganglia are also present in these plexuses.

Adrenergic pathways start at the thoracolumbar region of the spinal cord. These neurons synapse with ganglia which are located outside the GI tract called the *paravertebral ganglia.* Sympathetic neurons synapse within or pass beyond these ganglia and then form several nerve bundles termed the *splanchnic nerves.* The splanchnic nerves advance to prevertebral ganglia and plexuses located on the aorta and its branches. The prevertebral ganglia include the celiac, superior mesenteric, inferior mesenteric, intermesenteric, and hypogastric plexuses. Postganglionic axons from these ganglia then travel along the blood vessels to the submucosal and intermuscular plexuses as previously described. Sensory fibers arising from the GI tract are also found within the thoracolumbar sympathetic system (Fig. 81-2). Cholinergic neurons result in stimulation of gut motility by a direct effect on the enteric smooth muscle. Adrenergic neurons cause gut relaxation, primarily by inhibition of cholinergic neurons.[6] Other important enteric neurotransmitters include serotonin, somatostatin, and vasoactive intestinal peptide. For example, stimulation of 5-HT_4 (serotonin) receptors promotes intestinal motility and decreases noxious sensations from the gastrointestinal tract.[7] Opioid receptor inhibition also stimulates small intestinal motility and decreases oral-cecal transit time.[8]

MUSCULAR ANATOMY OF THE SMALL INTESTINE AND COLON

Small intestinal and colonic motility are accomplished by contraction of the smooth muscles that make up a portion of the walls of these organs. The muscular portion of the small intestine is divided into an inner circular layer and outer longitudinal layer. In the small intestine and rectum, the longitudinal muscular layer consists of a thick coat which surrounds the entire circumference of these organs. In the colon, the longitudinal muscles are arranged in three bundles, called *teniae coli,* which traverse the colon and then fan out in the rectum. The presence of circular and longitudinal muscle layers in



the small and large intestines allows for shortening of intestinal segments when the longitudinal musculature contracts, and narrowing of the intestinal lumen when circular muscles contract.

CLASSIFICATION OF MUSCULAR CONTRACTIONS OF THE GUT

Two main forms of contractions occur in the small intestine. These are called *ring contractions* and *sleeve contractions*. Ring contractions are contractions of circular muscle and result in narrowing of the small intestine lumen. These occur continuously in the fed state, but are intermittent in the fasted state and result in the caudad movement of the intestinal contents. Sleeve contractions are caused by longitudinal muscle contraction. Their primary function is the mixing of small intestinal contents.[5]

Normal motor activity in the small intestine is highly organized. In the fed state, ring contractions moving from the proximal to distal small intestine result in the caudad movement of its contents. Motility in the fasted state is quite complex.[9] The fasted motility pattern occurs 4 to 6 hours after completion of a meal. This pattern consists of three phases (Fig. 81-3). Phase I is a rest phase which makes up about 80% of the entire cycle. Phase II is the beginning of rhythmic ring contractions, which may be solitary or clustered. Phase III consists of maximum ring contractions, also called the *migrating motor complex* (MMC), which begin in the proximal portion of the intestine and move in a distal direction. It is evident that the MMC causes a wave of contractions that sweep along the small intestine.[10] The function of the MMC is the emptying of food particles that remain in the small intestine after completion of the fed pattern of motility.

FIGURE 81-3 Normal small intestinal motility. Resting phase I and active phases II (*open bars*) and III (*solid bars*) are shown. After feeding, motility stops periodically, and the fed pattern of motility occurs (*hatched bars*). (*Reprinted with permission from Sleisenger MH, Fordtran JS:* Gastrointestinal Disease. *Philadelphia, Saunders, 1998, p 1443.*)

Ring contractions also occur in the colon; sleeve contractions do not. Colonic ring contractions are subdivided into tonic ring contractions and rhythmic ring contractions. Tonic ring contractions are sustained contractions of the circular musculature which form the haustral markings of the colon. The haustra, which divide the colon into individual segments, are stable for long periods. They disappear when mass movement of feces occurs on a periodic basis, then subsequently reappear. Rhythmic ring contractions cause mass movements of fecal material every few hours, as well as continuous caudad and cephalad motion of fecal material. Rhythmic ring contractions cause mixing of the colonic contents.[5]

Unlike the detailed information available on small intestinal motility, the motility patterns of the colon in the fed and fasted state have not been fully elucidated.

Disordered Motility

One of the most common GI abnormalities encountered in the critical care setting is the disruption of normal intestinal motility. Loss of motor function may occur in the small intestine as well as the colon. A variety of terminologies have been used to describe disrupted intestinal motility. *Ileus* is a physiologic term referring to the complete discontinuation of neuromuscular function in the small and large intestine. The term *acute intestinal pseudo-obstruction* refers to nonmechanical causes of small intestinal and colonic dysfunction. *Intestinal obstruction* describes a mechanical blockade of the small or large intestine. *Postoperative ileus* is a term for the normal gut response that occurs for up to 72 hours following abdominal and other types of surgery. Often the clinician will be faced with a diagnostic dilemma in differentiating between mechanical intestinal obstruction, which may require surgical intervention, and pseudo-obstruction, which generally responds to medical therapy.

ACUTE INTESTINAL OBSTRUCTION IN THE CRITICALLY ILL

More than 90% of all cases of mechanical obstruction of the intestine involve the small intestine alone. Intestinal obstruction is generally caused by adhesions within the abdominal and pelvic cavities; hernias, carcinoma, and intestinal volvulus are other less common causes. Intestinal obstruction may also occur as a consequence of congenital anomalies such as intestinal malrotation; inflammatory bowel disease, especially Crohn's disease; intestinal ischemia; or impaction of the intestinal lumen by foreign bodies such as gallstones.[11]

Adhesions develop after abdominal surgery and following prior intra-abdominal sepsis.[12] Intestinal obstruction secondary to adhesions may occur as early as 3 days after the original surgery. However, delayed effects of adhesive small bowel disease are common, with some patients having recurrent bouts of small intestinal obstruction up to 20 years after their initial surgery.[13]

The pathophysiologic consequence of a mechanical small intestinal obstruction is distention of the region of the small intestine proximal to the blockade. High pressures develop within the intestinal lumen that may ultimately compromise

the blood flow to affected areas. Bowel edema with fluid secretion into the small intestinal lumen occurs as well. This phenomenon, in conjunction with fluid losses secondary to vomiting, causes fluid and electrolyte derangements. As luminal pressure increases, strangulation of the bowel may occur. Bacterial translocation into the circulatory system with resulting bacteremia as well as perforation, peritonitis, and shock are the sources of mortality associated with this condition.

The clinical presentation of patients with acute intestinal obstruction includes intermittent abdominal pain, nausea, and vomiting. Fever, leukocytosis, and electrolyte disturbances commonly occur. Colicky abdominal pain, distension, and abnormal bowel sounds in a patient with previous abdominal surgery are highly sensitive and specific for the presence of mechanical small intestinal obstruction.[14]

Radiographs of the abdomen with supine and upright views as well as an upright chest x-ray are commonly used to confirm the diagnosis of small intestinal obstruction. Whereas dilated loops of small intestine and colon with the presence of air in the rectum are seen in acute intestinal pseudo-obstruction, mechanical intestinal obstruction is characterized by small intestinal dilation alone without much air in the colon or rectum. Air-fluid levels may be present and represent separation of gas and fluid within fluid-filled, static portions of the small intestine (Fig. 81-4). Absence of air beyond a dilated segment of the small intestine is seen in a complete small intestinal obstruction. Air under the diaphragm on the upright chest x-ray is indicative of an intestinal perforation.

FIGURE 81-4 Radiograph of an acute mechanical small intestinal obstruction showing multiple dilated loops of small intestine. (*Courtesy of Dr. Arunas Gasparaitis.*)

Computed tomography (CT) scanning with oral contrast has been demonstrated to have better sensitivity in diagnosing complete small intestinal obstruction than plain abdominal radiography.[15] CT with contrast may also be used to pinpoint the location of a mechanical small intestinal obstruction by identifying decompressed bowel that is distal to the obstruction and may be used to diagnose the presence of intestinal ischemia.[16] CT scanning is also used to identify the source of obstruction such as an intra-abdominal or pelvic mass. Small intestinal radiography with contrast may be used to differentiate intestinal obstruction from pseudo-obstruction and for cases not resolving with conservative management. Caution is advised with the use of contrast studies, since barium entering the abdominal cavity through a perforated organ may cause a chemical peritonitis, whereas aspirated water-soluble contrast can result in pneumonitis. The therapeutic role of water-soluble contrast agents for the relief of intestinal obstruction has been investigated and remains controversial.[17]

Partial small intestinal obstruction is initially treated conservatively with nasogastric suction, administration of intravenous fluids, and correction of electrolyte abnormalities. Nasogastric suction is used for bowel decompression. Serial abdominal examinations and x-rays are vital in the ongoing management of partial intestinal obstruction. The development of sepsis, complete obstruction, or clinical signs of perforation are indications for immediate surgery. Nonresolution of partial mechanical small bowel obstruction is another indication for surgery.[18]

Conservative management for partial small intestinal obstruction is effective in about 70% of patients. Patients failing conservative management require laparotomy and lysis of adhesions with resection of nonviable intestine. Hospital mortality for small intestinal obstruction is about 10%. Recurrences are common, and more than 50% of patients undergoing surgery for intestinal obstruction can expect a recurrence during their lifetime.[13]

INTESTINAL PSEUDO-OBSTRUCTION

Intestinal pseudo-obstruction results from disruption of the extrinsic or intrinsic neuronal pathways of the intestine. The mechanism for the development of this disruption varies. In some patients, such as those who have recently undergone abdominal surgery, sympathetic overdrive is present, thus diminishing cholinergic output to the intestine. In others, the direct anticholinergic activity of drugs and neurohumoral mediators inhibits gut function.[19] A variety of conditions may result in acute intestinal pseudo-obstruction (Table 81-1). Small intestinal motility in patients with acute idiopathic intestinal pseudo-obstruction is markedly reduced. For example, manometric studies performed in patients with these disorders show marked abnormalities of the fasted motility pattern, including the MMC.[20]

The clinical symptoms of acute intestinal pseudo-obstruction closely resemble those of mechanical small intestinal obstruction. Most patients have abdominal distention and absence of bowel sounds. Abdominal pain is usual but may not be recognized in the patient who is sedated, delirious,

TABLE 81-1 Common Causes of Acute Intestinal Pseudo-Obstruction

Intra-abdominal
Surgery (especially abdominal)
Acute pancreatitis
Peritonitis
Retroperitoneal hemorrhage
Intestinal ischemia
Drugs
Narcotics
Anticholinergics
Cyclic antidepressants

Hypercalcemia
Hypermagnesemia
Miscellaneous
Myocardial infarction
Sepsis
Shock of any cause
Bone fractures
Surgery (postoperative—nonabdominal)
Vasculitis
Chronic intestinal motility disorders

or encephalopathic. Vomiting may also be present, placing patients with this condition at risk for aspiration pneumonia.

Treatment consists of correction of electrolyte abnormalities and administration of intravenous fluid. Pharmacologic agents that may be causing or aggravating the condition should be discontinued. Nasogastric suctioning may result in symptomatic improvement and may alter the pathophysiologic consequences of bowel distention in these patients. Limited therapeutic trials of pharmacologic agents for acute intestinal pseudo-obstruction or prolonged postoperative ileus with metoclopramide and erythromycin have shown few beneficial effects.[20] Recent studies of opiate antagonists including methylnaltrexone and alvimopan[21,22] have shown promise as potential therapies for postoperative ileus. Movement of the patient and ambulation when possible are encouraged.

OGILVIE'S SYNDROME: ACUTE COLONIC PSEUDO-OBSTRUCTION

This syndrome, first described by Sir Heneag Ogilvie in 1948, is generally seen in the ICU or in postoperative patients. It is characterized by abdominal distention accompanied by colonic dilation, particularly involving the cecum and right colon. A variety of medical conditions are associated with the development of Ogilvie's syndrome. It is generally accepted that this disorder results from decreased parasympathetic tone to the distal colon from the sacral nerves with normal vagal impulses to the right side of the colon resulting in a pseudo-obstruction of the distal colon with associated proximal colonic dilation.[23] Sympathetic hyperactivity of the right colon has also been postulated as a potential mechanism for the development of this disorder.

The most common medical conditions associated with Ogilvie's syndrome include sepsis, respiratory failure, organic brain disorders, and malignancy. Trauma to the spine, retroperitoneum, and pelvis, as well as burns, may also result in the development of Oglivie's syndrome.[24,25] Electrolyte disturbances, including hyponatremia, hypernatremia, hypokalemia, and hypocalcemia, are seen in the majority of patients.[26] A variety of medications have been implicated as potential etiologic agents in Ogilvie's syndrome, including narcotics, phenothiazines, calcium channel blockers, and cyclic antidepressants. For example, in one review of Ogilvie's syndrome, 56% of patients had received opiates on the day of diagnosis, 42% had received phenothiazines, and 15% ingested cyclic antidepressants.[27] Other medications associated with the development of Ogilvie's syndrome include clonidine and anticholinergic agents. Ogilvie's syndrome may also occur in the postoperative period, most commonly after cesarean sections, orthopedic surgery, and urologic procedures.[24]

Physical examination of patients with Ogilvie's syndrome always reveals abdominal distention. Bowel sounds remain present in most patients, but may be hypoactive or high pitched. Leukocytosis may be seen in up to 30% of patients, even prior to the development of associated bowel ischemia or perforation. Abdominal x-rays are the diagnostic test of choice, showing dilation of the cecum, usually with associated dilation of the right colon (Fig. 81-5). A decrease in the gas pattern of the left colon is often seen. At the time of diagnosis of colonic pseudo-obstruction, the transverse diameter of the cecum often measures 9 cm or greater on an unmagnified abdominal film.[28]

FIGURE 81-5 Plain radiograph of a patient with Ogilvie's syndrome showing massive cecal and transverse colon dilation. (*Courtesy of Dr. Geraldine Newmark.*)

Ogilvie's syndrome may be complicated by ischemia and perforation of the distended cecum. As the colon becomes increasingly enlarged (and its radius of curvature increases), less additional pressure is needed to further distend it, and its wall tension rises dangerously (as described by the law of Laplace).[28] Case series have shown that the spontaneous cecal perforation rate in Ogilvie's syndrome is approximately 13%, and mortality from this occurrence is 43%. However, the absolute cecal diameter does not correlate specifically with the risk of perforation. The duration of cecal dilation and the rate at which it dilates appear to be the most important factors related to perforation.[29]

The goal of therapy for Ogilvie's syndrome is decompression of the colon. Some have advocated an initial conservative approach, including nasogastric suction, intravenous hydration, correction of electrolyte abnormalities, discontinuation of offending medications, and treatment of predisposing medical or surgical conditions.[27] Others suggest early colonoscopic decompression of the cecum and right colon as an effective and safe therapy for the disorder.[26] The colonoscope is advanced to the cecum or the right colon, an often technically challenging procedure because no colonic cleansing preparation is used. Minimal air is insufflated during the procedure to prevent iatrogenic cecal perforation. The reported success rate for initial colonoscopic decompression ranges from 61% to 76%.[23,26] The success rate increases after repeat colonoscopic decompression which is required in 20% to 50% of cases. Complication rates for colonoscopic decompression in Ogilvie's syndrome are modest and range from 0% to 3% in published series. Overall the condition carries a mortality rate of approximately 15% in uncomplicated cases, with patients generally dying from their underlying condition. If bowel becomes ischemic or perforates, mortality increases to about 40% as previously described.[27]

A variety of pharmacologic treatments have been attempted for Ogilvie's syndrome, including cisapride and erythromycin.[30,31] These treatments have been reported as case studies only. Neostigmine, a cholinesterase inhibitor, stimulates neuromuscular activity. Several case studies involving a total of 58 patients have demonstrated the efficacy of neostigmine administered slowly by the intravenous route.[32–34] Most recently, Trevisani and associates treated 28 patients with 2.5 mg neostigmine administered over 3 minutes. Twenty-six patients (93%) had resolution of the condition with therapy.[34] Abdominal cramping, nausea, and diaphoresis were common side effects, although no patients experienced severe bradycardia or cardiovascular collapse, complications that have been described with the use of neostigmine.

Colonoscopic decompression fails in approximately 15% to 20% of patients, even after multiple attempts. These patients require surgical decompression, generally accomplished with a cecostomy and placement of a catheter. A 50% morbidity and 15% mortality is anticipated following cecostomy placement for Ogilvie's syndrome.[29] Complications include pericatheter leakage, superficial wound infections, catheter herniation, catheter dislodgment, and prolonged cecal-cutaneous fistula. Nonetheless, this procedure is reportedly successful in 96% of patients. Occasionally patients will require a colonic resection for treatment of this disorder, with an expected 30% surgical mortality.[27]

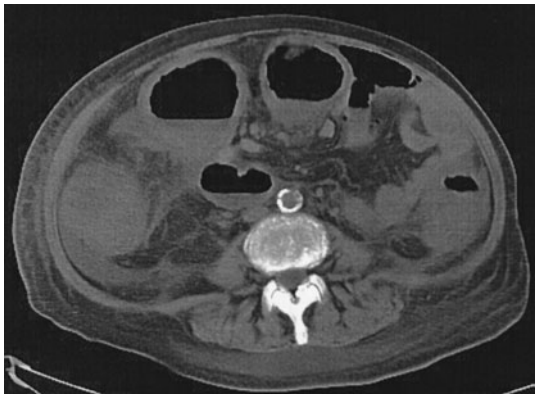
Miscellaneous conditions
Endocrinopathies (i.e., hyperthyroidism)
Vasculitis
Ischemia
Irritable bowel syndrome
Graft-vs-host disease

Diarrhea in the Critically Ill Patient

The incidence of diarrhea in critically ill patients is greater than 40%.[35] Differentiating between potential causes of diarrhea in these patients is necessary for optimal management of these disorders (Table 81-2). The following discussion will focus on the most common of these conditions.

CLOSTRIDIUM DIFFICILE COLITIS

Clostridium difficile is a fastidious gram-positive spore-forming anaerobe that is toxin-producing. *C. difficile* is found in the colonic flora in up to 3% of the general population. The organism is readily acquired from the environment, and studies have shown that bathrooms, sinks, and floors of hospitals and chronic care facilities often harbor colonies of *C. difficile*.[36] It may persist in the rooms of infected individuals for up to 40 days.[37] Patients are at high risk of developing *C. difficile* colitis after receiving broad-spectrum antibiotics, particularly those with activity against anaerobic organisms. Clindamycin and broad-spectrum cephalosporins are often implicated, but symptomatic *C. difficile* colitis has been described following the administration of almost all currently used antibiotics. Broad-spectrum antibiotics eliminate the normal colonic flora, the majority of which are anaerobic organisms. Preexisting carriage, or more commonly, exposure to environmentally-acquired *C. difficile* results in subsequent colonization, overgrowth, and infection with the toxin-producing organism. Immunosuppressed patients are at particular risk for the development of severe toxic colitis secondary to *C. difficile*. Such patients may develop diffuse colonic involvement with bowel ischemia and perforation.



Symptoms of *C. difficile* colitis include abdominal pain, diarrhea, and fever. Some patients may have neither abdominal pain nor diarrhea, so *C. difficile* colitis should always be considered in the differential diagnosis of patients with occult

sepsis.[38] Leukocytosis, electrolyte abnormalities, and hypoalbuminemia may also be present.[39] *C. difficile* is diagnosed by stool examination. Fecal leukocytes are often present. Culturing of *C. difficile* is the gold standard for diagnosing this disorder, but is technically difficult to perform. Measurement for the presence of *C. difficile* toxin A or B by rapid ELISA is the most common method of diagnosis. It has a sensitivity of 86% and specificity of 100%. The cytotoxic assay for toxin B is more sensitive (94% to 100%), but requires a tissue culture laboratory to perform and takes up to 48 hours.[37] Plain radiography or CT imaging may provide clues to the diagnosis (Fig. 81-6A and B). A bedside sigmoidoscopy is useful for identifying the presence of colitis. If the patient is infected with *C. difficile,* typical pseudomembranes will be seen about 60% of the time (Fig. 81-7).

Treatment for *C. difficile* colitis should be initiated in all patients in whom the toxin has been identified or in whom endoscopic findings suggest this disorder. Broad-spectrum antibiotics should be discontinued if possible. Metronidazole 250 to 500 mg PO qid for 7 to 14 days or vancomycin 125 to 250 mg PO tid for 7 to 14 days is used to eradicate the organism. A high response rate is expected with oral antibiotic therapy, although relapse rates of 15% to 20% following treatment can be expected.[40] Intravenous metronidazole 500 to 750 mg q6h may be used in those patients who cannot tolerate oral antibiotic therapy, but this may not be as effective as oral therapy. For patients who are critically ill due to *C. difficile* colitis, combined therapy with intravenous metronidazole and oral vancomycin may be indicated.[41]

MISCELLANEOUS CAUSES OF DIARRHEA

Patients receiving enteral tube feedings commonly develop diarrhea; the published incidence ranges from 5% to greater than 60%.[31] Diarrhea in these patients can often be attributed to the osmolarity of the feeding solutions. When the rate of administration of enteral feeding is high, the normal mechanisms for fluid and electrolyte reabsorption in the small intestine and colon may be overwhelmed. In other critically ill patients, intestinal wall edema and villous atrophy may be present, resulting in nutrient malabsorption and increased osmotic load to the colon. A number of studies have shown that patients with low serum albumin levels, particularly levels below 2.6 g/dL, are at risk for diarrhea.[42] Finally, altered colonic flora following the administration of broad-spectrum antibiotics results in decreased colonic reabsorption of

carbohydrates, which produces an osmotic type of diarrhea as well.

A variety of methods have been suggested to lessen the diarrhea associated with enteral feeding, but these have met with variable success.[43] Current recommendations include decreasing the infusion rate of enteral feedings, adding fiber to enteral formulas, decreasing the osmolality of the feeding solution by diluting it with water, and adding dipeptides and predigested proteins to standard enteral formulas.[44] Lactose-free or reduced-fat-content formulas may benefit occasional patients.

Sorbitol, a common additive in medications that are administered in a liquid or syrup form, may also cause diarrhea. Since sorbitol, a sugar alcohol, is not absorbed in the small intestine, it functions as an osmotic agent in the colon, increasing intraluminal fluid and electrolytes. The sorbitol content of administered medications should be checked in all patients with unexplained diarrhea who are receiving medications in a suspension or syrup form.[45] Magnesium, a common ingredient in antacid preparations, also causes diarrhea. It should also be remembered that many different medications may cause diarrhea in individual patients by a variety of mechanisms. Medications should therefore always be included in the differential diagnosis of diarrhea.

Patients in the ICU may also have diarrhea owing to the presence of preexisting GI illnesses, such as intestinal ischemia, inflammatory bowel disease, small intestinal diseases, and pancreatic insufficiency. Following gastric or small intestinal resections, patients commonly develop diarrhea due to stasis of bowel contents and subsequent bacterial overgrowth, as well as to malabsorption occurring as a direct result of the surgery. Bacterial overgrowth may also occur following prolonged ileus and loss of the MMC, combined with a loss of local immunoglobulin production in the small intestine.

Bacterial Translocation

The gut normally functions as an effective barrier against bacteria and endotoxin present in the intestinal lumen. Some migration of bacteria across the GI mucosa occurs in health, likely contributing to the regulation of local and systemic immunity against the innumerable antigens that contact the intestinal epithelium.[46] In the critically ill patient, however, abnormal intestinal barrier function results in greater transmucosal passage of bacteria and endotoxin. In addition to being a potential source of infection, this bacterial translocation appears to serve as a trigger for the release of cytokines and other cellular mediators that may in turn activate or further perpetuate the inflammatory and hypermetabolic responses to injury. Thus gut dysfunction may play a major role in the initiation and propagation of MOSF.[47]

Components of the physiologic gut barrier include the normal microbial flora, bile salts within the intestinal lumen, the epithelial mucous layer, peristalsis, and an intact local and systemic immune system.[46,48] Normal microbial flora occupy the space closest to the intestinal epithelial cells, thereby limiting attachment to the enterocytes of potentially pathogenic gram-negative enteric bacteria. Oral antibiotics eliminate indigenous microflora and increase the risk of bacterial translocation, an effect which may be seen for prolonged periods following cessation of antibiotic therapy. *Enterococcus faecalis, Pseudomonas aeruginosa,* and the Enterobacteriaceae appear to translocate in the greatest numbers. H_2 blockers and proton pump inhibitors facilitate upper GI tract bacterial colonization, which may also predispose to translocation. Finally, ileus, hyperosmolar enteral feeding, and TPN all disrupt the normal intestinal microbial flora.[49]

Small amounts of endotoxin normally enter the circulation and appear to play a role in maintaining the reticuloendothelial system in a primed state.[50] Bile salts within the intestinal lumen normally limit endotoxemia by binding intraluminal endotoxin. Loss of bile salts associated with critical illness may allow more endotoxin to reach the portal circulation. In animal models of obstructive jaundice, bacterial overgrowth, which occurs as a consequence of the absence of enteric bile salts, appears to promote bacterial translocation.

Further defense against translocation is provided by the normal mucus layer, which contains immunoglobulin A and other protective substances, as well as normal gut peristalsis, which impedes bacterial penetration of the protective layer of mucus. Translocation appears to become clinically relevant only with failure of local and systemic immunity. Immunosuppressive drugs increase bacterial translocation in animals, indirect evidence that intact systemic immunity may itself limit translocation.[51]

Mucosal atrophy, particularly when it occurs as a consequence of luminal nutrient deprivation, is another predisposing factor. TPN is associated with thinning of the gut mucosa and increased translocation, a consequence that can be prevented by providing nutrition via an enteral rather than intravenous route. Bacterial translocation also more readily occurs in a gut mucosal barrier compromised by ischemia.[52] Hypotension and shock may significantly decrease splanchnic perfusion, resulting in reduced oxygen delivery to the intestinal mucosa and accelerated free radical generation.[46] Lipid peroxidation and cell membrane injury result, leading to ischemia and increased mucosal permeability. Even short periods of hypotension can result in splanchnic ischemia, since splanchnic blood flow is reduced out of proportion to systemic blood flow in models of hypovolemia. This splanchnic ischemia has recently been shown to contribute to the hepatic dysfunction that ultimately occurs over time in critically ill patients. A mismatch between hepatic metabolic demand that appears to be significantly increased in MOSF, and hepatic blood flow may be at the root of this problem.[53]

Protein malnutrition, burns, pancreatitis, inflammatory bowel disease, hemorrhage, systemic infection, any form of shock, abdominal surgery, radiation, trauma, intestinal obstruction, advanced liver disease, and obstructive jaundice all promote bacterial translocation.[52,54–58] Several of these features may interact in critically ill patients to cause infection remote from the GI tract, enteric bacteremia without an identified infectious source, or propagation of systemic inflammation. The presence of two predisposing factors (e.g., treatment with antibiotics in combination with immunosuppressive drugs) appears to synergistically promote systemic spread of translocating bacteria. Intestinal barrier dysfunction and bacterial translocation may thus play a central role in MOSF.[47]

Although it seems clear that the critically ill are predisposed to bacterial translocation, preventive therapy has not been

particularly beneficial. Aggressive resuscitation from shock may decrease the chances for translocation. Although TPN has not been proven to predispose to bacterial translocation in humans, enteral feeding is more physiologic and could offset gut barrier failure and thus is always preferred over TPN[56] (see Chap. 11). In rats, use of glutamine in TPN has been shown to minimize intestinal permeability and bacterial translocation caused by trauma and endotoxemia.[59] Selective decontamination of the digestive tract with nonabsorbable antibiotics may decrease bacterial translocation by suppressing potentially pathogenic microorganisms in the oropharynx and upper GI tract. Whereas selective gut decontamination appears to reduce nosocomial colonization, it may or may not have a significant effect on mortality and length of ICU stay.[60–62] In addition, selective gut decontamination may predispose to the development of resistant organisms (see Chap. 43). Improved delineation of the role of bacterial translocation in human critical illness is anticipated.

Hepatobiliary Dysfunction

Patients in the intensive care unit present a difficult challenge when diagnosing and treating complications related to the biliary tract.[63] Laboratory data are often nonspecific in diagnosing biliary tract complications. Gallbladder abnormalities are frequently seen on imaging studies in intensive care patients; therefore their presence does not necessarily indicate acute disease.[64] Because there is often a delay in diagnosing biliary tract disease in these patients, intervention is associated with high morbidity and mortality when compared to the ambulatory setting. Hepatic dysfunction significantly prolongs length of hospital stay and increases mortality in critically ill patients.[65]

CHOLESTASIS OF SEPSIS

Cholestasis results from impaired bile formation or obstruction to bile flow. Biochemically, cholestasis is characterized by a disproportionate increase in serum alkaline phosphatase or bilirubin concentrations relative to aminotransferase elevations. Cholestasis is classified as *intrahepatic* when there is a defect in bile formation at the level of the hepatocyte or *extrahepatic* when there is structural or mechanical impairment to bile flow[66] (Table 81-3).

TABLE 81-3 Differential Diagnosis of Cholestasis

Extrahepatic Causes	Intrahepatic Causes
Cholangitis	Medications
Bacterial	Allopurinol
Viral	Amoxicillin/clavulanic acid
Autoimmune	Captopril
Sclerosing cholangitis	Chlorpromazine
Biliary strictures	Estrogens
Choledochal cysts	Erythromycin
Pancreatitis	Flutamide
Neoplasms	Haloperidol
Pancreatic	Hydralazine
Ampullary	Ketoconazole
Bile duct	Phenytoin
Metastatic	Quinidine
Acalculous cholecystitis	Sulfonamides
	Sepsis
	Infiltrative disease
	Sarcoidosis
	Lymphoma/Hodgkin's disease
	Amyloidosis
	Infection
	Mycobacterium avium-intracellulare
	Tuberculosis
	Postoperative jaundice
	Primary biliary cirrhosis
	Sclerosing cholangitis
	Post–liver transplant
	Chronic rejection
	Fibrosing cholestatic hepatitis
	Total parenteral nutrition
	Alcoholic liver disease
	Cholestasis of pregnancy
	Pediatric
	Alagille's syndrome
	Cystic fibrosis
	Biliary atresia

In the critically ill, cholestasis is at times a manifestation of underlying hepatobiliary disease. Most cholestasis seen in the ICU, however, occurs in the absence of any intrinsic liver disease. Cholestatic jaundice occurring in infected and bacteremic patients, termed the *cholestasis of sepsis,* has been a well-recognized clinical syndrome for two decades.[67,68] Bilirubin levels range typically from 5 to 10 mg/dL, with the conjugated fraction predominating. This suggests that the hyperbilirubinemia seen in sepsis results from impaired bile canalicular secretion.[69,70] Liver biopsy characteristically shows retained bile concretions within bile ductules (Fig. 81-8A and 8B). This histology differs from that seen in patients with biliary obstruction in whom cholestasis is present within both hepatocytes and bile ductules; bile ductular proliferation also occurs in obstructive jaundice (Fig. 81-8C).

Bile formation depends in large part on the ability of hepatocytes to transport bile acids from sinusoidal blood into bile canaliculi against a steep concentration gradient. The initial step is mediated in part by an active, sodium-driven bile acid uptake system across the sinusoid. An hepatocyte sodium-taurocholate-transporting polypeptide appears to be the major sinusoidal sodium-bile acid cotransporter. Efflux across the canalicular membrane represents the rate-limiting step in the overall transport of bile acids and depends both on a negative membrane potential and on adenosine triphosphate (ATP) hydrolysis.[71] There also appear to be ATP-dependent canalicular transport proteins; endotoxin and certain cytokines released in response to endotoxin may selectively impair these bile acid transporters. Endotoxemia severely impairs the transport of certain bile acids and organic anions at both the sinusoidal and canalicular membranes. As a result of this impaired hepatic bile acid and organic anion transport, bile flow is decreased.[72]

Cholestasis is not restricted to gram-negative sepsis alone, suggesting that nonendotoxin mediators may also impair bile secretion. Tumor necrosis factor-α (TNF-α) inhibits bile acid transport at both the sinusoidal and canalicular membranes. In vivo administration of anti-TNF-α antibody has been shown to prevent endotoxin-induced cholestasis. The end result of this inhibition of bile acid and organic anion transport is that sinusoidal transport may exceed canalicular transport, and potentially toxic compounds may accumulate

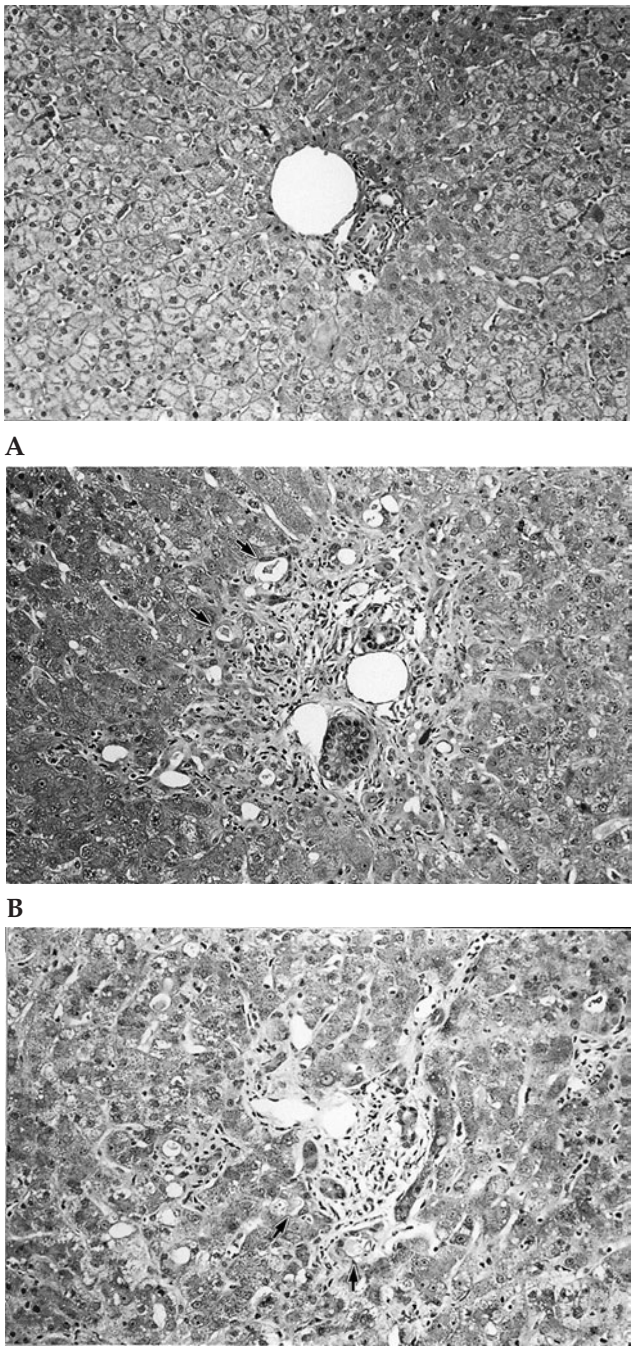

FIGURE 81-8 ***A.*** **Photomicrograph of a normal liver demonstrating a central vein and an adjacent portal tract. The liver architecture is well preserved.** ***B.*** **In sepsis the portal tract is expanded by a proliferation of bile ductules accompanied by polymorphonuclear leukocytes (*small arrows*). Ductular cholestasis is present (*large arrow*).** ***C.*** **In the presence of bile duct obstruction, similar portal tract and bile ductular proliferation occur, but brownish pigment denoting cholestasis is seen in both bile ductules and individual hepatocytes (*arrows*). (*Courtesy of M.I. Fiel, MD.*)**

intracellularly.[73] Impaired canalicular bile formation and resulting bile stasis, along with decreased intestinal luminal bile acid concentration, appear to perpetuate a vicious cycle by predisposing to bacterial translocation and further endotoxin absorption.[70,74,75]

When critically ill patients develop elevated serum bilirubin levels, biliary obstruction, viral hepatitis, and drug toxicity[66] should be excluded. As with cases of postoperative jaundice,[76] the etiology of cholestasis is often multifactorial. Hematologic causes of unconjugated hyperbilirubinemia such as hemolysis, multiple blood transfusions, and hematoma resorption should also be sought. Gilbert's syndrome affects approximately 10% of the general population and can present with an isolated unconjugated hyperbilirubinemia.[77] If all these conditions are excluded, infection, whether documented or occult, should be suspected as the cause of hyperbilirubinemia.

HEPATOBILIARY COMPLICATIONS OF TOTAL PARENTERAL NUTRITION

Total parenteral nutrition (TPN) is associated with various catheter-related and metabolic complications (see Chap. 11). In addition, hepatic dysfunction is a common occurrence in many patients.[78] This may result in abnormal liver chemistry tests, and less frequently, in hepatomegaly or jaundice. It is often unclear to what extent other factors such as infection, malnutrition, the concurrent use of potentially hepatotoxic medications, alcoholism, or underlying intrinsic liver disease may contribute to the liver dysfunction.[79]

In adults, modest elevation of serum aminotransferase levels occurs within the first 2 to 3 weeks of initiating TPN. These abnormalities are usually mild and reverse within 10 to 14 days of cessation of TPN. Elevations of serum alkaline phosphatase and bilirubin can occur with more prolonged parenteral nutrition. Since these abnormalities may normalize despite continuance of TPN, they should not be interpreted as evidence of permanent hepatic dysfunction or histologic damage. The early predominant histologic abnormality of the liver is steatosis, which is almost always clinically asymptomatic (Fig. 81-9). Long-term administration of TPN in infants may be accompanied by the development of cirrhosis and chronic liver disease.[78–80] In these infants, chronic liver disease appears to be a direct consequence of prolonged cholestasis. Though once thought to be a rare occurrence, recent studies have shown more adults developing advanced

FIGURE 81-9 Photomicrograph of a liver biopsy specimen from a patient who was given nothing by mouth, after receiving TPN for 1 month. Note the widespread distribution of clear fat vesicles characteristic of hepatic steatosis. (*Courtesy of M.I. Fiel, MD.*)

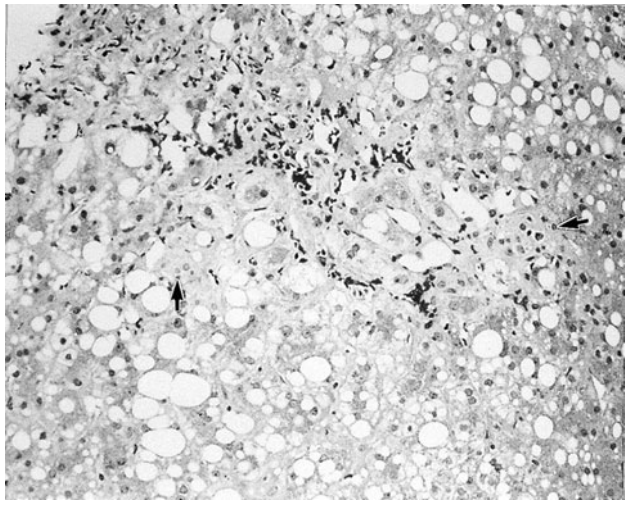

TABLE 81-4 Possible Interrelated Factors Contributing to TPN Hepatotoxicity

Composition of TPN
Excess glucose (maximal rate of utilization is 4–5 g/kg, beyond which fat synthesis occurs)
Excess fat calories (hepatic deposition of exogenous fatty acids occurs)
Imbalance between amino acids and glucose (may impair the hepatic secretion of triglycerides)
Hypercaloric feeding (may stimulate insulin release which in turn promotes lipogenesis and the synthesis of acylglycerol from glucose)
Possible deficiency states
Selenium
Carnitine
Essential fatty acids (impaired lipoprotein formation)
Glutamine
Choline
Vitamin E
Taurine
Increased bacterial translocation and portal endotoxemia
Toxic amino acid metabolites or bile acids (especially lithocholic acid)
Altered gastrointestinal hormonal milieu
Immaturity of biliary secretory system (pediatric population)
Prolonged fasting
Intestinal stasis and perturbation of the enterohepatic circulation of bile salts (promotes intraluminal bile salt deconjugation, leading to increased lithocholic acid production)

liver disease from long-term TPN use.[81] Thus once significant cholestasis has developed, even in adults, TPN should generally be discontinued.

The exact mechanism of TPN-induced liver dysfunction remains unknown but is probably multifactorial in nature. Possible contributing factors are listed in Table 81-4.[78–80] The development of steatosis during TPN appears primarily to be related to the combined effects of excess glucose calories and impaired hepatic triglyceride secretion.[79,82] In addition, lipoprotein synthesis may become impaired and hepatic triglyceride secretion limited when amino acid supplementation is inadequate. Although essential fatty acid deficiency may similarly cause hepatic steatosis, most standard TPN solutions contain all essential amino acids, vitamins, and trace elements, so deficiency states are unlikely to be major contributors to TPN-associated hepatic dysfunction. Bacterial translocation and prolonged fasting may contribute to cholestasis by upsetting the enterohepatic bile salt circulation and affecting biliary secretory capacity. The cholestasis resulting from sepsis itself may be an additive or complicating factor.[72] Patients with TPN-related hepatic dysfunction appear predisposed to infection.

The development of biliary sludge, cholelithiasis, and calculous and acalculous cholecystitis are all increased in patients receiving TPN. Gallbladder sludge is detected in half of patients receiving TPN for a total of 4 to 6 weeks, and in almost 100% of patients after 8 to 13 weeks. TPN-induced gallstones are pigmented and composed primarily of calcium bilirubinate. Gallstone formation may partly relate to prolonged fasting; reduced gallbladder contractility and impaired bile flow result from prolonged use of TPN and may contribute to stone formation. Loss of normal enteral stimulation by oral nutrients also plays a role. Disease or resection of the terminal ileum further promotes the development of cholelithiasis in some patients.[78–80]

Proving TPN-induced hepatobiliary disease is challenging, since this is usually a diagnosis of exclusion. Evaluation in the ICU should include assessment of hepatitis viral serologies; radiologic studies looking for signs of biliary obstruction, liver abscess, or cholecystitis; and a search for systemic infection or hepatotoxic medications. There may be a high incidence of false-positive (nonvisualization) hepatoiminodiacetic acid (HIDA) or diisopropyl iminodiacetic acid (DISIDA) scans related to impaired gallbladder emptying in patients receiving TPN.[78] Liver biopsy may be useful to delineate any intrinsic liver disease contributing to hepatic dysfunction in the critically ill patient, but generally is not required.

If TPN-related liver chemistry abnormalities occur, they will usually normalize with discontinuation of TPN.[78–80] Physicians should avoid using an excess of glucose (>4 to 5 g/kg body weight) or an excess of total calories in TPN. Concurrent use of oral or enteral feeding or discontinuation of TPN may improve gallbladder contractility and decrease the risk of gallstone formation or cholecystitis. Cholecystokinin has been administered periodically to promote gallbladder contractility, though this has not been shown to reliably decrease the formation of gallstones.[78–80] Studies are currently examining the efficacy of ursodiol in preventing the cholestasis associated with prolonged TPN use.[83]

ACALCULOUS CHOLECYSTITIS

Acute cholecystitis may occur at any time in a patient with gallstones but is especially dangerous in patients with chronic debilitating conditions or intercurrent critical illness. Though acalculous cholecystitis comprises only 2% to 15% of all cases of acute cholecystitis, the critically ill appear to be at much greater risk. More than 50% of postoperative cases of acute cholecystitis are of the acalculous form. Risk factors are prevalent in ICU patients and include mechanical ventilation, TPN use, dehydration, use of narcotics, hypotension, chronic renal failure, and massive blood transfusion. Diabetes mellitus, human immunodeficiency virus infection, abdominal vasculitis (such as polyarteritis nodosa), and cardiac surgery are also associated with acalculous cholecystitis. This condition may also occur in trauma and burn patients and following bone marrow transplantation.[63,84–86]

Most patients developing acalculous cholecystitis have no previous history of gallbladder disease and present with atypical clinical manifestations. Abdominal examination is often unreliable owing to the presence of altered mental status, concomitant systemic illness, or recent abdominal surgery. Leukocytosis and hyperbilirubinemia occur commonly but are nonspecific in the setting of critical illness. Unexplained fever or evidence of infection may frequently be the only manifestations of acalculous cholecystitis. Because of the extremely high morbidity and mortality associated with acute acalculous cholecystitis, a high index of suspicion as well as early recognition are of paramount importance. Acalculous cholecystitis occurs commonly enough in critically ill patients that it should be in the differential diagnosis in any septic patient without a clear focus of infection.[63,84]

The etiology of acalculous cholecystitis is not completely understood; one major predisposing factor appears to be biliary stasis. Stasis and gallbladder dysmotility can be precipitated by prolonged fasting, general anesthesia, dehydration, and the use of narcotics. The resultant increase in bile viscosity has been postulated to produce functional cystic duct obstruction, increasing intraluminal gallbladder pressure; it may also render the gallbladder mucosa more susceptible to local injury. Gallbladder ischemia has also been implicated in the development of acalculous cholecystitis. This is supported by the high incidence of gallbladder mucosal necrosis, endothelial dissection, arteriolar thrombosis, gangrene, and perforation noted in autopsy studies. Gallbladder ischemia may occur as a result of low flow states in shock, systemic infection, dehydration, and hypercoagulable disorders. Prolonged mechanical ventilation with positive end-expiratory pressure may result in ischemia by decreasing portal perfusion and by raising hepatic venous and common bile duct pressures.[63,86]

Bedside abdominal ultrasonography is an unreliable routine screening tool for acute acalculous cholecystitis.[87] When present, characteristic findings include pericholecystic fluid, a gallbladder wall thickness greater than 4 mm, subserosal edema, and intramural gas. However, there can be a high false-positive rate in patients receiving TPN and in those with ascites or hypoalbuminemia. HIDA and DISIDA scanning may fail to visualize the gallbladder, implying cystic duct obstruction (Fig. 81-10). False-negative gallbladder scintigraphy is unusual. Neither scintigraphy nor ultrasound can differentiate between calculous and acalculous cholecystitis. Morphine cholescintigraphy is superior to ultrasonography in making a diagnosis. Mariat and associates performed bedside ultrasonography and morphine cholescintigraphy in 28 patients suspected of having acalculous cholecystitis. Sensitivity of ultrasound and scintigraphy was 50% and 67%, specificity was 94% and 100%, positive predictive value was 86% and 100%, and negative predictive value was 71% and 80%, respectively. The probability of disease was 100% with a positive scintiscan regardless of ultrasound results. A positive ultrasound finding was associated with an 86% probability of disease, but with a probability of only 66% with negative scintigraphy results.[88] Diagnostic laparoscopy or laparotomy is a more definitive method of diagnosing cholecystitis but has obvious attendant risks.[89] In some centers, percutaneous cholecystostomy performed by an interventional radiologist provides a less risky means for obtaining bile fluid cultures and decompressing the biliary system,[90] but these microbiologic studies may not be sensitive or specific (see Chaps. 89 and 101).

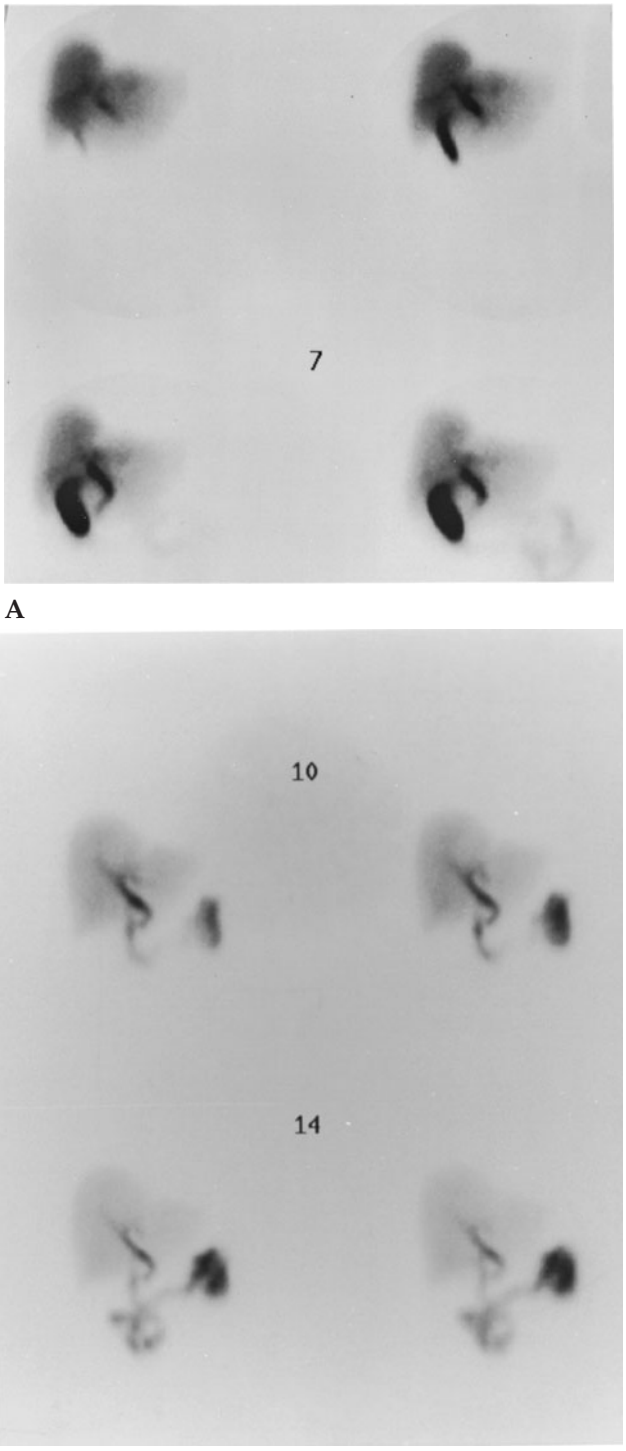

FIGURE 81-10 *A.* **A normal HIDA scan. Note the appearance (*arrows*) of isotope within the gallbladder within 15 minutes of injection of tracer.** *B.* **HIDA scan of a 73-year-old man with acalculous cholecystitis. Note the appearance of tracer in the duodenum (*arrows*) and the absence of gallbladder visualization up to 60 minutes after injection of the isotope. (*Courtesy of Richard Gunderman, MD.*)**

Because of delays in making a diagnosis, more than 40% of patients with acalculous cholecystitis develop complicated

disease characterized by gangrene, pericholecystic abscess, or gallbladder perforation. In one series, 40% of patients with acalculous cholecystitis who underwent surgery more than 48 hours after symptom onset developed gallbladder perforation.[63,84–85] The mortality in complicated acalculous cholecystitis may be as high as 75%, with death usually due to MOSF. Once acalculous cholecystitis is recognized, cholecystectomy is the mainstay of treatment. The high incidence of gangrene and perforation makes inspection of the entire gallbladder very important. Cholecystostomy is an option in the critically ill, but this approach risks missing complicated disease and fails to adequately drain the common bile duct in cases of concomitant cholangitis. A cholecystostomy drainage catheter should remain in place for 10 to 14 days to allow maturation of the tract between the gallbladder and the abdominal wall.[90] If rapid clinical improvement does not ensue, open cholecystectomy is indicated. Laparoscopic cholecystostomy and transpapillary endoscopic cholecystostomy have proved to be effective treatment options in some patients.[89,91]

Chapter 82

GASTROINTESTINAL HEMORRHAGE

RAM SUBRAMANIAN
TIMOTHY McCASHLAND

KEY POINTS

- *Aggressive intravenous resuscitation with fluids and blood, and airway protection are crucial in the management of the acutely bleeding patient.*
- *Endoscopy should be performed with therapeutic intent for both upper and lower gastrointestinal bleeding.*
- *Pharmacologic therapy should be used as an adjunct to endoscopic therapy.*
- *An early team approach, involving medical, radiologic, and surgical personnel, should be implemented.*
- *In the setting of severe bleeding or bleeding refractory to endoscopic therapy, angiographic and surgical therapies should be instituted promptly.*

Gastrointestinal (GI) hemorrhage continues to be a frequent indication for intensive care management, with over 300,000 hospitalizations reported annually in the United States.[1] Upper GI (UGI) bleeding has continued to predominate, with lower GI (LGI) bleeding constituting approximately 25% of all GI bleeding.[2] Despite improved diagnostic and therapeutic modalities in the last two decades, the mortality rates for upper and lower GI hemorrhage have demonstrated different trends. Mortality from UGI bleeding has remained stable at 10%,[3] and this could be explained by an aging population with a significantly higher GI bleeding mortality due to comorbid conditions.[4] In contrast, the mortality from LGI bleeding has decreased dramatically despite an aging population, and this is probably due to more aggressive diagnostic and therapeutic endoscopic intervention.

The management of GI hemorrhage in the ICU is multidisciplinary, involving the intensivist, gastroenterologist, radiologist, and surgeon. A successful outcome relies on effective fluid resuscitation, maintenance of adequate perfusion pressure, prompt hemostasis, monitoring of end-organ function, and prevention of multiple-organ failure.

Clinical Considerations

PROGNOSTIC FACTORS

Multiple studies focusing primarily on nonvariceal UGI bleeding have been designed to define prognostic factors for GI bleeding and to identify high-risk patients.[5–7] A common and pivotal feature of these studies is the combined use of clinical variables and endoscopic findings to guide risk stratification, thereby stressing the importance of integrating clinical and endoscopic information for optimal decision making. Table 82-1 outlines the clinical and endoscopic indicators associated with an increased risk of rebleeding and higher mortality. A recent study has identified similar prognostic indicators for LGI bleeding.[8]

INITIAL PRESENTATION

GI bleeding is divided into UGI and LGI bleeding based on its location proximal or distal to the ligament of Treitz at the junction of the duodenum and jejunum. UGI bleeding commonly presents with hematemesis and/or melena, and a nasogastric (NG) lavage that yields blood or coffee-ground material supports the diagnosis. However, it is important to note that a negative or bile-stained NG aspirate (indicating an open pylorus) does not exclude a UGI source because the bleeding may be intermittent.[9] In comparison, hematochezia is usually the presenting sign of an LGI source. These distinctions based on presenting signs are not absolute because melena can be seen with proximal LGI bleeding and hematochezia can be present with massive, brisk UGI bleeding.

INITIAL EVALUATION AND MANAGEMENT

Table 82-2 outlines the initial evaluation and management for GI hemorrhage.

HEMODYNAMIC

Regardless of the etiology and site of GI hemorrhage, the initial management should be directed at maintaining hemodynamic stability by restoring intravascular volume. Intravenous access with two large-bore IV catheters should be maintained at all times. In the presence of hypotension or hypovolemic shock, prompt fluid resuscitation with crystalloids and packed red blood cells is essential. Monitoring end-organ perfusion and preventing ischemic organ injury improves survival. In particular, coronary and renal perfusion should be assessed. An electrocardiogram should be obtained in patients at risk for myocardial ischemia, and renal laboratory parameters and urine output should be followed to assess for possible prerenal azotemia, acute renal failure, and (in cirrhotics) hepatorenal syndrome. In the subset of patients with suspected variceal hemorrhage, central venous pressure (CVP) monitoring may be useful to prevent sustained portal hypertension and recurrent bleeding following fluid replacement; a CVP of less than 10 mm Hg may prevent recurrent variceal bleeding. When left-sided heart failure coexists,

TABLE 82-1 Adverse Clinical and Endoscopic Prognostic Indicators

Clinical indicators
Age > 60 years
Severe comorbidities
Onset of bleeding during hospitalization
Emergency surgery
Clinical shock
Red blood emesis or NG aspirate
Requiring > 5 U PRBCs
Endoscopic indicators
Major stigmata: active bleeding, visible vessel, adherent clot
Ulcer location: posterior duodenal bulb, higher lesser gastric curvature
Ulcer size > 2 cm in diameter
High-risk lesions: varices, aortoenteric fistula, malignancy

TABLE 82-2 Initial Management of Gastrointestinal Hemorrhage

Maintain two large-bore IV catheters (14- or 16-gauge peripheral IV/central line)
Fluid resuscitate with crystalloids to maintain hemodynamic stability
Transfuse packed red cells to maintain hematocrit > 30%
Urgent endoscopy with therapeutic intention for refractory hypotension/shock
Acid-suppression therapy with IV H_2RAs or PPIs after endoscopic treatment
Platelet transfusion and fresh frozen plasma/recombinant factor VIIa to correct thrombocytopenia and coagulopathy
ECG in patients at risk for myocardial ischemia
A nasogastric tube should be inserted if patient has hematemesis
CVP or Ppw monitoring may be helpful if variceal bleeding is suspected. A CVP < 10 mm Hg may help prevent recurrent variceal bleeding
Splanchnic vasoconstrictors (octreotide/terlipressin) in variceal bleeding
Empirical antibiotics in variceal bleeding
Consultation with interventional radiology and surgery

monitoring of pulmonary artery wedge pressure (Ppw) may facilitate aggressive fluid resuscitation while reducing the risk of cardiogenic pulmonary edema.

GASTROINTESTINAL/ENDOSCOPIC

Prompt identification and hemostasis of the source of GI hemorrhage are essential in improving patient outcome. In the event that initial fluid resuscitation establishes hemodynamic stability, endoscopy may be performed under stable conditions within the first 24 hours of the bleed. However, emergent endoscopy with therapeutic hemostatic intent should be performed for patients with UGI and LGI hemorrhage who cannot be stabilized hemodynamically with intravascular volume resuscitation and continue to bleed. Multiple studies in UGI bleeding[10,11] and more recent studies in LGI bleeding[12,13] have demonstrated that therapeutic esophagogastroduodenoscopy (EGD) and colonoscopy using hemostatic interventions such as epinephrine injection and electrocautery facilitate early control of bleeding, reduce rebleeding rates, and improve short-term morbidity and mortality. Based on these observations, the 2001 American Society for Gastrointestinal Endoscopy (ASGE) recommendations emphasize the importance of emergent endoscopy with therapeutic intent in the setting of persistent hemodynamic instability.[14,15] Absolute contraindications to endoscopy include suspected GI perforation, acute uncontrolled unstable angina, severe coagulopathy, untreated respiratory decompensation, and severe patient agitation. Apart from perforation, other conditions contraindicating endoscopy can be corrected, following which endoscopy should be performed. In the face of massive exsanguination, emergent surgical intervention (perhaps facilitated by intraoperative endoscopy) should be considered instead of endoscopy.

A potential caveat to emergent endoscopy is the marginally increased risk of complications compared to elective endoscopy, although the development of smaller and more flexible scopes is likely to reduce this risk. A specific risk is perforation, and with regard to upper endoscopy, the anatomically susceptible regions are the cricopharyngeal region at the site of esophageal intubation and the pylorus-duodenum junction during a blind duodenal intubation. The risk of perforation during emergency EGD can be lowered with pre-endoscopic NG lavage, which facilitates visualization. Recent studies have suggested that the prokinetic agent erythromycin, given as a single intravenous dose of 250 mg prior to EGD, improves visualization and diagnosis.[16]

In the setting of nonvariceal UGI bleeding, acid suppression with histamine receptor antagonists and proton pump inhibitors has shown short-term efficacy only after hemostasis has been achieved using some form of therapeutic endoscopic intervention.[17,18] Therefore, acid suppression may be beneficial in the short-term management of UGI bleeding following endoscopic intervention. In the setting of variceal bleeding, pharmacologic therapy with a splanchnic vasoconstrictor such as octreotide and empiric antibiotic therapy should be initiated.

HEMATOLOGIC

In order to ensure adequate oxygen-carrying capacity in the circulation and to prevent end-organ ischemia, the hematocrit should be maintained above 30%. It should be noted that the initial hematocrit after an acute GI bleed can be misleading because acute hemorrhage produces loss of whole blood, and the hematocrit does not change initially because the initial loss of plasma and erythrocytes is equivalent. Within 24 to 72 hours of the initial bleed, plasma is redistributed from the extravascular to the intravascular space, thus resulting in a dilution of the red cell mass and a fall in the measured hematocrit. Intravenous hydration with crystalloids compounds this dilutional anemia so that red cells should be replaced promptly. In most instances, there is sufficient time to allow typing and cross-matching of red cells; however, in the setting of massive exsanguination, the transfusion of non–cross-matched type-specific blood may be necessary. In the presence of thrombocytopenia, platelets must be transfused to maintain the count above 60,000/μL. Any existing coagulopathy should be corrected with fresh frozen plasma to lower the prothrombin time to within 2 seconds of the normal range. Recent studies have demonstrated the ability of recombinant activated factor VIIa (rFVIIa) to rapidly correct severe coagulopathy in hepatic failure,[19,20] and this agent may assume an important role in the treatment of coagulopathy in the future. During the process of aggressive intravascular volume resuscitation, fluids and blood products should be warmed to prevent the development of a cold coagulopathy, and the core body temperature should be maintained above 35°C (see Chaps. 68 and 69).

PULMONARY

In the presence of active hematemesis, an NG tube should be placed to decrease the risk of aspiration. Endotracheal intubation should be performed for airway protection and to decrease the risk of aspiration in the following situations: (1) in the presence of active hematemesis and decreased mental status, (2) prior to an emergent EGD for active hematemesis, and (3) prior to insertion of an esophageal tamponade tube. In the setting of shock, intubation and full mechanical ventilatory support are indicated to decrease the oxygen consumption of the respiratory apparatus. During the performance of an EGD, significant hypoxemia may occur, especially in elderly patients and in those with moderate to severe obstructive pulmonary disease (defined as a FEV_1/FVC ratio of less

than 0.6).[21] Probable causes include hypoventilation due to sedative agents, the partial airway obstruction produced by the endoscope, and aspiration of gastric contents, resulting in bronchospasm and ventilation-perfusion mismatch.

CONSULTATION

Radiology and surgery should be consulted early in the course of management. In the setting of nondiagnostic upper or lower endoscopy, radiologic modalities offer diagnostic and therapeutic options to achieve hemostasis. Emergent surgical intervention is indicated in the exsanguinating patient who may not be stable enough for endoscopic or radiologic evaluation.

When endoscopic evaluation is unable to identify the cause of bleeding, the two diagnostic radiologic modalities available are angiography and radionuclide scans. As outlined later, angiography with embolotherapy or selective infusion of vasoconstrictors offers therapeutic options as well (see Chap. 101).

The angiographic diagnosis of acute arterial hemorrhage is based on visualization of extravasated contrast material in the gastrointestinal lumen. Therefore, it only identifies the bleeding site if active bleeding is occurring when the study is performed. In addition, the rate of bleeding must be brisk, in the range of 0.5 to 1 mL/min. In the case of brisk UGI bleeding, angiography may demonstrate a bleeding site in 75% of patients, with most bleeding episodes originating from a branch of the left gastric artery. In the setting of LGI bleeding, the average diagnostic yield is decreased to about 60%, with diverticular disease and vascular ectasia being the most common findings.

Radionuclide studies occasionally aid in the detection of the bleeding site. The current radionuclide scan of choice is the ^{99m}Tc-pertechnetate-labeled red blood cell scan. The radionuclide scan offers the ability to detect rates of bleeding of less than 0.5mL/min, and the 48-hour stability of the tagged red blood cells allows repeated nuclear imaging for 1 to 2 days following administration of the radionuclide in the setting of intermittent bleeding. However, a positive radionuclide study localizes the bleeding only to an area of the abdomen and cannot define the mucosal location of the bleeding site precisely. Therefore, a positive result should prompt a repeat endoscopy or angiography to localize the bleeding site precisely.

REBLEEDING

In most instances, the presentation of rebleeding is similar to that of the initial episode, and the source is identical to the site of the initial bleed. After hemostasis of the initial bleed following spontaneous cessation or therapeutic intervention, the patient should be monitored closely for rebleeding, especially in the presence of clinical and endoscopic indicators associated with an increased risk of rebleeding (see Table 82-1). Apart from the obvious signs of gastrointestinal blood loss characterized by melena, hematemesis, or hematochezia, more subtle signs of rebleeding may include tachycardia and hypotension owing to a decreasing intravascular volume. Therefore, continuous hemodynamic monitoring should be performed following initial hemostasis, and invasive monitoring with a central venous catheter or an arterial line may be considered for the patient at high risk for rebleeding. A falling serum hemoglobin concentration on serial measurements may suggest a recurrent bleed. The management of rebleeding should include immediate repeat endoscopic intervention targeted at the initial lesion, followed by radiologic or surgical intervention, if necessary. Specific pharmacologic and endoscopic interventions for long-term secondary prophylaxis against rebleeding will be discussed in the sections that follow.

Upper Gastrointestinal Hemorrhage

With regard to prognosis and treatment, UGI hemorrhage can be divided into (1) variceal hemorrhage and (2) nonvariceal hemorrhage.

Variceal Hemorrhage

Variceal hemorrhage presents as a symptom of decompensated cirrhosis in as many as 50% of patients and accounts for about one-third of all deaths related to cirrhosis. Mortality is related to hepatic disease severity, as defined by the Childs-Pugh classification (Table 82-3), with an overall mortality estimated at 50%. There are two distinct phases in the course of variceal hemorrhage. In the first phase, defined by the initial episode of active hemorrhage, only 50% of patients stop bleeding spontaneously (in contrast to nonvariceal hemorrhage, in which 90% cease spontaneously). The initial bleed is followed by a second phase of an approximately 6-week duration, defined by a high risk of recurrent hemorrhage, with the greatest risk of rebleeding being within the first 48 to 72 hours.

MANAGEMENT

The management of variceal bleeding is outlined in Fig. 82-1. In addition to multiorgan ischemic injury from hypoperfusion, variceal hemorrhage in the setting of cirrhosis predisposes the patient to specific derangements, including hepatic encephalopathy, type 1 hepatorenal syndrome, and systemic infection. These processes contribute to the high mortality associated with variceal bleeding, and therefore,

TABLE 82-3 Childs-Pugh Classification of Hepatic Disease Severity

	POINTS ASSIGNED		
Parameter	1	2	3
Ascites	Absent	Slight	Moderate
Bilirubin (mg/dL)	<2	2–3	>3
Albumin (g/dL)	>3.5	2.8–3.5	<2.8
INR	<1.7	1.8–2.3	>2.3
Encephalopathy	None	Grade 1–2	Grade 3–4

Total Score (Five Parameters)	Childs-Pugh Stage
5–6	A
7–9	B
10–15	C

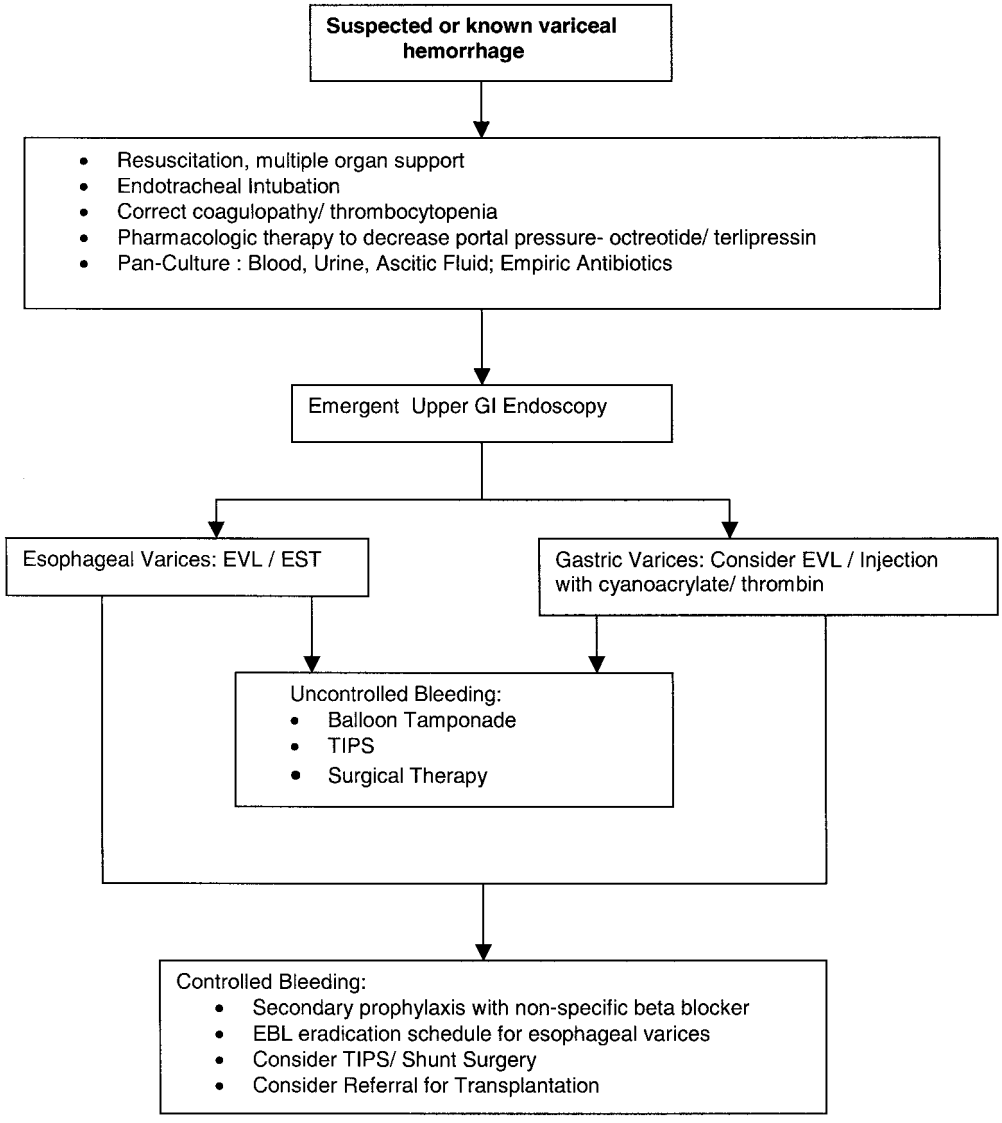

FIGURE 82-1 Management of variceal hemorrhage. EVL, endoscopic variceal band ligation; EST, endoscopic sclerotherapy.

the management should address these issues in addition to achieving hemostasis and hemodynamic stability.

CARDIOPULMONARY

Fluid resuscitation should be aimed at achieving an isovolemic status because this approach prevents persistent portal hypertension and recurrent variceal bleeding.[22] To this end, invasive hemodynamic monitoring with a central venous catheter can be used to guide fluid therapy. In the setting of hypotension that is refractory to fluid resuscitation, a peripheral vasoconstrictor such as norepinephrine should be the vasoactive agent of choice. Agents that have β_2-agonist activity, such as dopamine, should be avoided because they potentially could cause splanchnic vasodilation and therefore worsen the variceal bleed. Splanchnic vasoconstrictors such as octreotide and terlipressin (discussed later) can have a beneficial effect on systemic blood pressure by diverting blood away from the splanchnic circulation. Endotracheal intubation for airway protection is critical, especially in the setting of encephalopathy, active hematemesis, or emergency endoscopy.

INFECTION

Bacterial infections are common after acute variceal hemorrhage, with the common sites being respiratory, ascitic, and urinary. The presence of infection has been associated with failure to control the initial bleed and an increase in the recurrence of rebleeding, likely owing to the induction of a hyperdynamic circulation and increased portal pressure.[23,24] A meta-analysis of studies regarding the use of prophylactic antibiotics in variceal bleeding suggests that this intervention significantly increases the number of variceal bleeders who do not acquire an infection and improves short-term mortality.[25] Although most of the pertinent studies include a quinolone, the optimal choice and duration of antibiotic therapy have not been defined, and therefore, the choice of empirical antibiotic therapy should be institution-specific. An important consideration is the potential for quinolone resistance in cirrhotic

patients who have been on norfloxacin for the prevention of spontaneous bacterial peritonitis (SBP). Prior to initiating antibiotic therapy, blood, urine, and (if indicated) ascitic fluid cultures should be obtained.

HEMATOLOGIC

In addition to fresh frozen plasma, recombinant activated factor VIIa (rFVIIa) is emerging as a procoagulant that can rapidly correct severe coagulopathy associated with decompensated liver disease and promote hemostasis in variceal hemorrhage.[19,20] In a small uncontrolled study of 10 patients,[20] a single dose of 80 μg/kg normalized the prothrombin time in all patients within 30 minutes, and immediate hemostasis was obtained in all patients. Although larger studies are needed to confirm these observations, these initial studies suggest that rFVIIa may assume an important role in the management of acute variceal hemorrhage.

NEUROLOGIC

In the setting of decompensated liver disease, variceal bleeding could induce or exacerbate hepatic encephalopathy (HE). Therefore, in the presence of decreased mental status during variceal bleeding, HE should be considered as a potential etiology in addition to cerebral hypoperfusion, and empirical lactulose therapy via an NG tube or as an enema should be considered (see Chap. 84). Elevated serum ammonia levels may be useful in supporting the diagnosis of HE.

HEMOSTATIC THERAPY

Specific therapies aimed at arresting active bleeding include pharmacotherapy and endoscopic therapy. Multiple studies have proven the increased hemostatic efficacy of combined pharmacotherapy and endoscopic therapy over either treatment alone.

PHARMACOTHERAPY

In the setting of variceal bleeding, pharmacologic agents are aimed at causing splanchnic vasoconstriction and reducing portal hypertension. Empiric pharmacotherapy should be initiated in suspected variceal hemorrhage prior to endoscopic diagnosis and intervention. Selective splanchnic vasoconstriction has the added advantage of diverting blood flow from the splanchnic circulation to the systemic circulation, thereby improving systemic blood pressure. In particular, improved renal perfusion could prevent or ameliorate the hepatorenal syndrome.

The current agent of choice in the United States is the somatostatin analog octreotide. Somatostatin and its analogs inhibit the release of vasodilator hormones such as glucagon, thereby indirectly causing splanchnic vasoconstriction and decreased portal inflow. Although octreotide has a longer half-life than somatostatin, its therapeutic efficacy is obtained only with a continuous infusion; the recommended dose is a 50-μg IV bolus, followed by an infusion of 50 μg/h for 5 days. A recent meta-analysis of trials of octreotide has demonstrated improved control of bleeding compared with other therapies, including the previous agent of choice, vasopressin.[26] Furthermore, the adverse extrasplanchnic vasoconstrictive effects observed with vasopressin, such as myocardial and cerebral ischemia, are not observed with octreotide.

More recently, the long-acting vasopressin analog terlipressin has received a favorable recommendation based on European studies, which report fewer side effects than vasopressin and an efficacy similar to that of octreotide and endoscopic sclerotherapy.[27] In addition, a systematic review comparing trials of terlipressin with other pharmacotherapies identified terlipressin as the only pharmacologic agent that reduced mortality, therefore suggesting that terlipressin may be the future vasoactive agent of choice in acute variceal bleeding.[28] Larger prospective trials are awaited to confirm these encouraging preliminary studies. Terlipressin is currently not available in the United States.

ENDOSCOPIC THERAPY

Following the administration of pharmacotherapy, emergent endoscopy with therapeutic hemostatic intent is imperative. As outlined in Fig. 82-1, endoscopic evaluation can localize the source of the variceal bleed to an esophageal or gastric varix. This is an important distinction because, while esophageal variceal bleeding is amenable to endoscopic therapy, gastric variceal bleeding may require more aggressive salvage measures, as outlined below.

Endoscopic therapy is based on the interruption of blood flow through the venous collateral system lining the distal esophagus and gastric cardia using either stimulation of thrombosis (e.g., sclerotherapy) or immediate occlusion (e.g., band ligation). The two established forms of endoscopic therapy are endoscopic sclerotherapy (EST) and endoscopic variceal band ligation (EVL). While sclerotherapy involves the intravariceal or paravariceal injection of a sclerosant (e.g., sodium morrhuate), band ligation involves the placement of small bands around varices in the distal 5 cm of the esophagus (Fig. 82-2). A meta-analysis has shown that EVL is superior to EST in initial hemostasis, obliteration of varices, rates of recurrent bleeding, complications, and mortality,[29] and EVL is now the endoscopic treatment of choice for acute variceal hemorrhage. However, a technical challenge during use of the band ligator apparatus is the decreased endoscopic field of view in a setting already complicated by active hemorrhage. Therefore, EST may be indicated in the setting of poor initial visualization, followed later by definitive EVL treatment.

GASTRIC VARICES

While the preceding endoscopic interventions are effective in esophageal variceal bleeding, gastric variceal bleeding presents a technical challenge. Gastric varices are located deeper in the submucosa, where EVL and EST are not successful in obtaining sustained hemostasis. Initial studies reporting successful hemostasis with intravariceal injection of cyanoacrylate tissue glue[30] and thrombin[31] suggest novel approaches to endoscopic intervention in gastric variceal bleeding. However, these therapies need further validation. In the setting of gastric variceal bleeding, EVL may be attempted to obtain initial hemostasis. However, given the limited success of endoscopic hemostasis, the emergent application of nonendoscopic interventions should be anticipated, which may include balloon tamponade, transjugular intrahepatic portosystemic shunt (TIPS), and surgery.

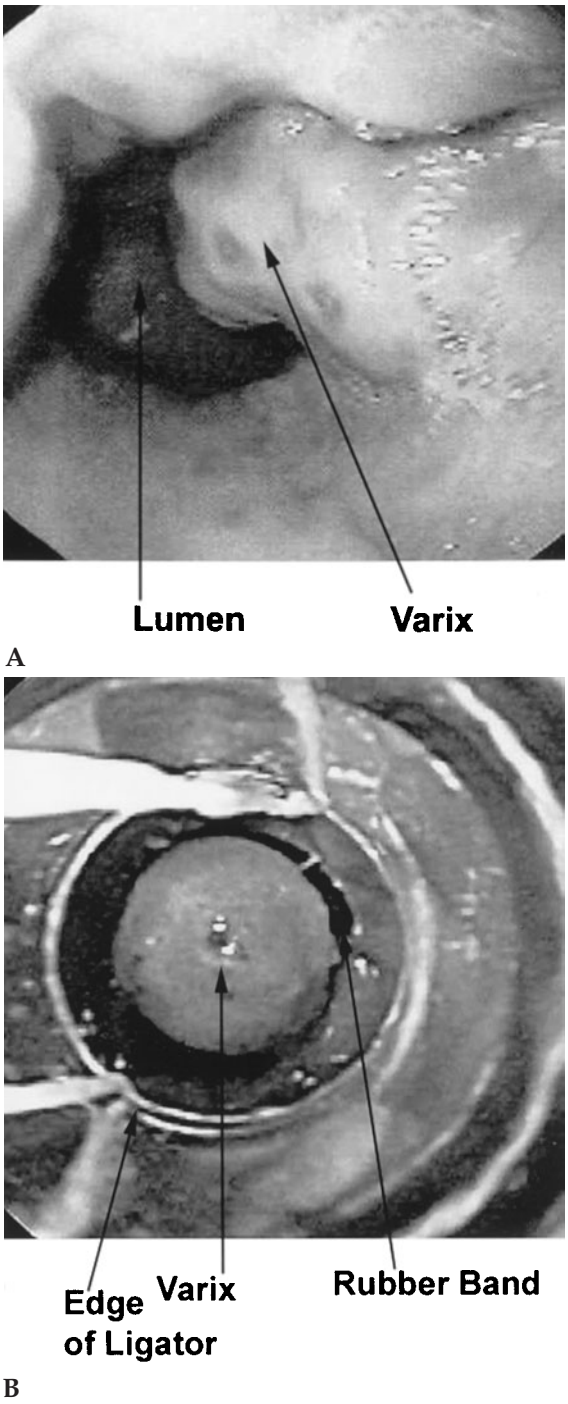

FIGURE 82-2 ***A*****. Esophageal varix before banding.** ***B*****. Variceal banding viewed through endoscope.**

COMPLICATIONS OF ENDOSCOPY

Most complications have been associated with EST, and the advent of variceal band ligation (EVL) has decreased the incidence of complications significantly after therapeutic endoscopy. Following endoscopic intervention, local complications include ulceration, dysmotility, and stricture formation, and regional complications include esophageal perforation and mediastinitis. In addition, both EST and EVL increase the risk of developing portal hypertensive gastropathy (PHG) and its bleeding sequelae because blood is shunted away from the venous system of the gastroesophageal junction to that of the gastric mucosa. Bleeding from PHG is characterized by a diffuse, slow bleed from the gastric mucosa that typically is not amenable to localized endoscopic therapy.

SALVAGE THERAPY FOR ENDOSCOPICALLY UNCONTROLLED BLEEDING

In the event that hemostasis cannot be achieved by initial endoscopic therapy or there is evidence of rebleeding after initial hemostasis, a repeat trial of endoscopic therapy may be attempted. However, following a second failed endoscopic trial, nonendoscopic interventions need to be implemented emergently. These interventions may include balloon tamponade, TIPS, and surgical therapy.

BALLOON TAMPONADE

Esophageal tamponade tubes (such as the Sengstaken-Blakemore tube) effectively achieve short-term hemostasis by compressing the gastric and distal esophageal mucosa. In most cases, tamponade is effective after inflating only the gastric balloon. Endotracheal intubation is imperative prior to insertion of tamponade tubes to decrease the risk of aspiration. Once the airway is secured, the tube can be passed either nasally or orally to the stomach. The gastric balloon should be inflated only partially (with approximately 30 mL of air) pending radiographic confirmation of correct placement because inadvertent inflation of the balloon in the esophagus can lead to esophageal perforation. Once adequate positioning is ensured, the gastric balloon can be inflated fully according to the manufacturer's recommendations (gastric balloons are inflated to predetermined volumes, whereas the esophageal balloon component is inflated according to pressure). If hemostasis is not achieved by isolated inflation of the gastric balloon, the esophageal balloon can be inflated to 35 mm Hg, a pressure exceeding the intravariceal pressure. Following inflation, traction should be applied to the apparatus at the insertion site to maintain proper positioning. A maximum duration of 48 hours is recommended for variceal compression because prolonged tamponade can lead to esophageal wall ischemia. An NG tube inserted above the esophageal balloon is mandatory to prevent aspiration of oropharyngeal secretions that collect above the inflated apparatus, unless the tube has its own lumen for esophageal suction. A major limitation of tamponade therapy is the high risk of rebleeding following deflation of the balloon. Furthermore, given the serious complications of pulmonary aspiration and esophageal ulceration and perforation, this mode of therapy should be performed by skilled personnel and generally as a temporizing step while planning definitive treatment.

TRANSJUGULAR INTRAHEPATIC PORTOSYSTEMIC SHUNT (TIPS)

Following temporary stabilization with balloon tamponade, further definitive treatment to achieve hemostasis involves the creation of an artificial vascular shunt between the systemic and portal circulation in order to decompress the variceal vasculature. This can be accomplished surgically (discussed below) or via TIPS, which offers a less invasive method for obtaining a vascular shunt. The TIPS consists of an expandable metallic stent placed intrahepatically between portal and hepatic veins using radiologically guided access

(see Chap. 101). Traditionally, TIPS has been recommended as secondary prophylactic therapy for variceal bleeding in the setting of mild to moderate liver disease, and advanced cirrhosis has been regarded as a contraindication to TIPS therapy due to increased mortality after TIPS in this setting. However, recent studies with favorable hemostasis and mortality data have supported the use of emergent TIPS as salvage therapy for refractory variceal hemorrhage, even in advanced cirrhosis.[32] Therefore, when variceal hemorrhage is refractory to pharmacologic and endoscopic therapy, urgent TIPS therapy should be considered irrespective of the severity of hepatic disease. The hemodynamic benefits of TIPS therapy can be attributed not only to portal decompression and variceal hemostasis but also to increased venous return due to intravascular mobilization of any existing ascites. Additional beneficial effects of TIPS therapy include treatment of refractory ascites and the hepatorenal syndrome.

SURGICAL THERAPY

Since the advent of TIPS as salvage therapy for refractory variceal hemorrhage, there has been a reduction in the need for surgical intervention. However, shunt surgery for portal decompression is indicated for variceal hemostasis in patients with preserved hepatic synthetic function (i.e., Childs-Pugh A disease).[33] Esophageal transection with or without devascularization may be another surgical option in massive exsanguination refractory to other interventions.

Shunt operations can be divided into (1) nonselective shunts (e.g., portacaval shunts) that decompress the entire portal system and divert all blood flow away from the portal vein and (2) selective shunts (e.g., distal splenorenal shunt) that compartmentalize the portal tree into a decompressed variceal system and a hypertensive superior mesenteric vein that maintains sinusoidal perfusion. A selective shunt is the preferred operation because portacaval shunts significantly alter vascular anatomy and therefore complicate future liver transplant surgery. In addition, emergency portacaval shunts are associated with a higher rate of thrombosis and shunt failure.

Distal esophageal transection in the setting of massive variceal exsanguination may control bleeding, but mortality remains above 80%. Since the transection does not address the underlying portal hypertension, varices recur after a variable period, and rebleeding should be anticipated. Esophageal transection with devascularization of the gastroesophageal junction (Sugiura procedure) may be considered in patients who have an absolute contraindication to shunt surgery, such as extensive thrombosis in the portal venous circulation involving the splenic, superior mesenteric, and portal veins.

Variceal hemorrhage may occur in noncirrhotic patients. Patients with extrahepatic portal hypertension are better operative shunt candidates than cirrhotics. When large gastric varices accompanied by small or absent esophageal varices are identified, splenic or portal vein thrombosis should be considered as a possible etiology rather than cirrhosis. Splenic and portal vein thrombosis may occur in the setting of acute pancreatitis, pancreatic cancer, abdominal trauma, and hypercoaguable states. It is essential to identify this subset of patients with variceal hemorrhage because splenectomy rather than a portosystemic shunt may be curative. Celiac angiography is diagnostic.

SECONDARY PROPHYLAXIS

If successful hemostasis is achieved by any of the interventions just discussed, it is essential that secondary prophylaxis to prevent variceal rebleeding is initiated in the ICU. Once the hemodynamic status is stabilized, nonspecific β-blocker therapy (nadolol 20 to 40 mg/d) should be initiated to decrease portal hypertension. This pharmacologic intervention should be coupled with an endoscopic variceal band ligation schedule as defined by the gastroenterologist because the combination of these therapeutic modalities decreases the risk of variceal recurrence and rebleeding.[34] In addition, the patient should be evaluated for vascular shunt procedures, including TIPS and surgical shunts. Most important, early referral to a transplant center should be initiated to evaluate the patient for liver transplantation.

Nonvariceal Hemorrhage

In contrast to variceal hemorrhage, nonvariceal hemorrhage presents a favorable prognosis. The improved outcome can be attributed to a greater than 90% spontaneous cessation rate of bleeding and to the absence of a predisposition to multiorgan dysfunction that exists in decompensated cirrhosis. As outlined in Table 82-1, multiple studies pertaining to nonvariceal hemorrhage have identified clinical and endoscopic indicators that increase the risk for continued or recurrent bleeding, and therefore predict an adverse prognosis. The remaining mortality rate of 10% is largely due to rebleeding in patients with these factors. The important role of early therapeutic upper endoscopy in achieving hemostasis, reducing rebleeding, and improving short-term morbidity and mortality has been established[10,11] and reiterated in a recent consensus statement addressing the management of nonvariceal bleeding.[11a] Furthermore, with regard to peptic ulcer disease, endoscopic characterization of high-risk ulcer lesions has led to the development of specific endoscopic therapies that have improved hemostatic efficacy and outcome compared with prior medical therapy.[35]

The evaluation and management of nonvariceal hemorrhage are outlined in Fig. 82-3. Following initial hemodynamic, pulmonary, and hematologic management, early upper endoscopic evaluation with therapeutic intent should be conducted. Emergent endoscopy should be pursued in the setting of hemodynamic instability that is refractory to fluid resuscitation. Acid-suppression therapy has demonstrated short-term efficacy only after endoscopic hemostasis has been achieved[17,18] and therefore should be used as an adjunct to endoscopy. Since peptic ulcer disease accounts for the majority of nonvariceal bleeds and has been the focus of therapeutic developments, the different treatment modalities will be discussed in this context. The management of some nonulcer lesions, including stress-related mucosal damage (SRMD), will follow.

PEPTIC ULCER DISEASE (PUD)

ENDOSCOPIC THERAPY

Progress in endoscopic diagnosis and therapy has been due largely to major improvements in endoscopic techniques and equipment. A number of hemostatic endoscopic methods have been developed,[36] but the two used most commonly

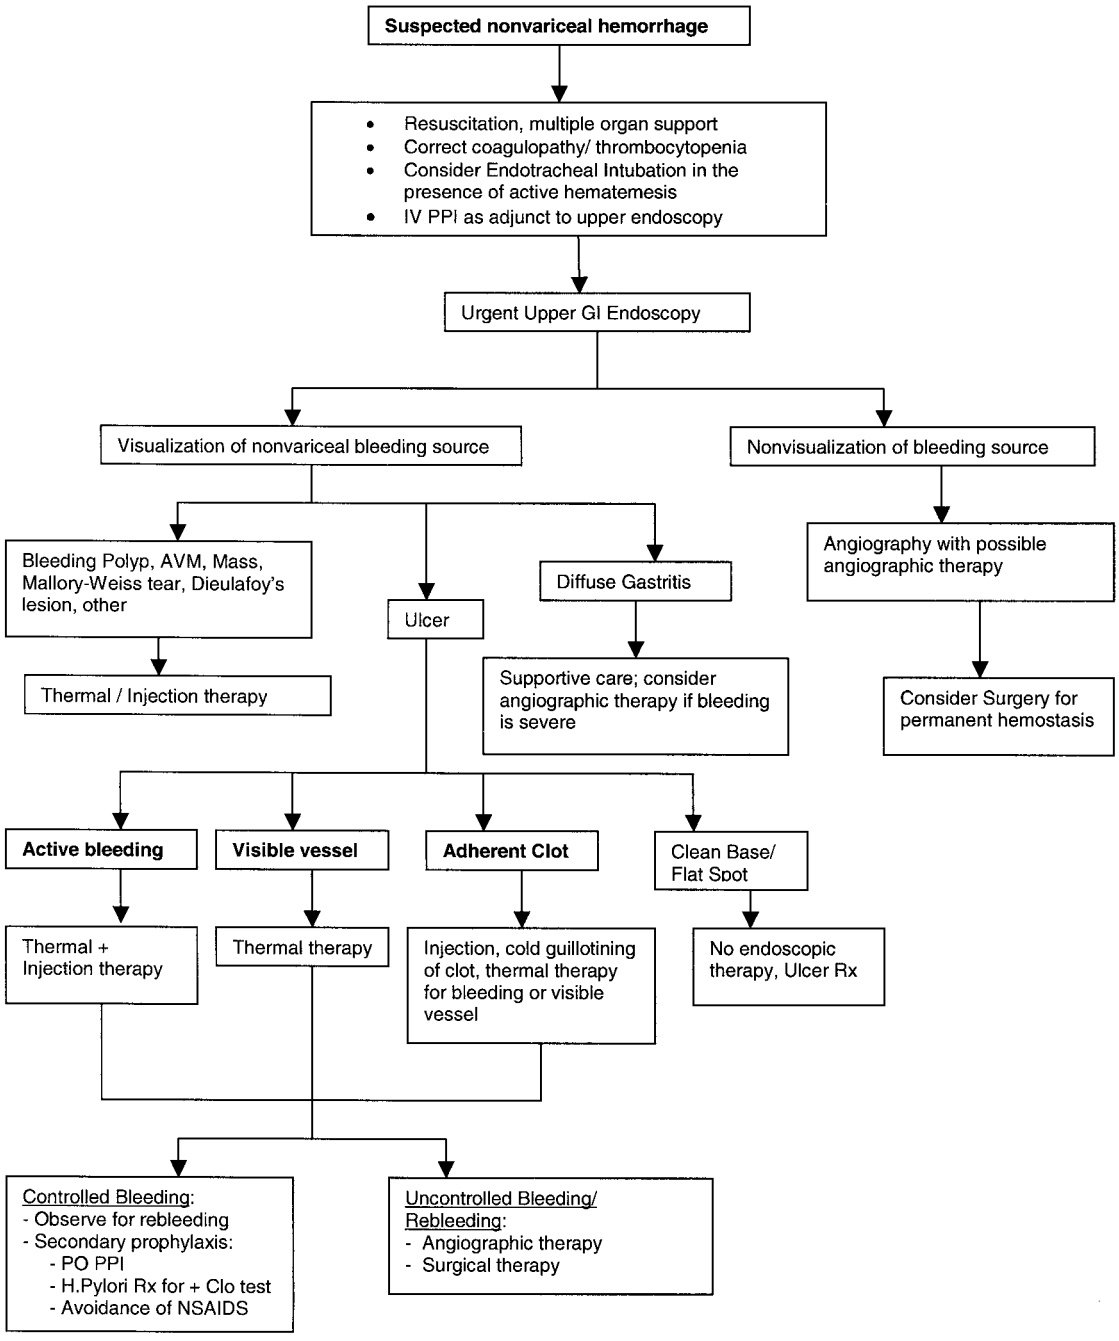

FIGURE 82-3 Management of nonvariceal hemorrhage. Bold entries indicate high-risk lesions

in the United States are contact thermal devices and injection therapy with epinephrine.

Contact Thermal Devices

Thermal therapy is designed to produce coagulation and dehydration in the ulcer base surrounding the bleeding vessel, and this results in constriction and destruction of the submucosal feeding vessels supplying the surface artery. The two types of thermal therapy that have gained popularity are the bipolar probe and the heater probe. Bipolar probes heat contacted tissue by passing electricity via tissue water between positive and negative electrodes located at the tip of the probe. Once the contact tissue is fully desiccated, electrical conduction ceases, and deeper tissue coagulation is restricted. On the other hand, the heater probe uses a thermocouple at the end of the probe to generate heat, and this process does not depend on tissue water. Therefore, deeper tissue coagulation is achievable despite desiccation, although this increases the risk of perforation.

Injection Therapy

Injection therapy is aimed at causing vasoconstriction and necrosis of the bleeding vessel and surrounding tissue. Injection with epinephrine (1:10,000 dilution in saline) or absolute

alcohol has been shown to be effective in achieving acute hemostasis.[37] While epinephrine exerts a vasoconstrictive effect on the vessel, pure ethanol causes dehydration, contraction, and necrosis of the vessel and surrounding tissue. It should be noted that the rebleeding rate is high if epinephrine injection therapy is performed in isolation, and therefore, it should be combined with thermal coagulation therapy. The technique used in injection therapy involves the injection of the agent via an injector catheter in four quadrants within 2 to 3 mm of the active bleeding point in the ulcer base. While the volume of total epinephrine administered can range from 5 to 10 mL, the total volume of ethanol should not exceed 1 mL because extensive ulceration may occur.

Endoscopic Evaluation and Treatment in PUD

As outlined in Fig. 82-3, the endoscopic management of PUD is guided by the characteristics of the ulcer, which defines the lesion as exhibiting "major" or "minor" stigmata of ulcer hemorrhage. The major stigmata consist of (1) active bleeding, (2) a visible, nonbleeding vessel, and (3) an adherent clot, and these three lesions are associated with a high risk of rebleeding and therefore increased short-term mortality. The stigmata associated with a low risk of rebleeding include (1) a clean base and (2) a flat/pigmented spot, and these lesions have a favorable prognosis. Specific endoscopic treatment guidelines have been developed by the ASGE for each of these lesions[14] based on multiple studies addressing the response of these lesions to thermal and injection therapy. These guidelines and subsequent studies have led to the following endoscopic treatment recommendations: (1) combination therapy with injection and thermal coagulation is superior to monotherapy either in active bleeding[38,39] (Fig. 82-4) or for an adherent clot,[40] (2) monotherapy with thermal coagulation is indicated for a nonbleeding visible vessel, and (3) no endoscopic therapy is required for low-risk lesions, which include a clean base and a flat/pigmented spot.

In anticipation of initiating secondary prophylaxis for PUD, the visualization of a duodenal or gastric ulcer should prompt the endoscopist to obtain a gastric antral mucosal biopsy to test for *Helicobacter pylori*. The gastric biopsy may be difficult to perform during the acute phase of the bleeding, and the presence of blood or antiulcer medications may interfere with a biopsy urease test. In the absence of a gastric biopsy, a venous blood sample should be tested for *H. pylori* serology, or stool or breath testing should be performed. Furthermore, a negative gastric antral mucosal biopsy should be confirmed with a serologic test, especially if antiulcer therapy has been initiated prior to the biopsy.

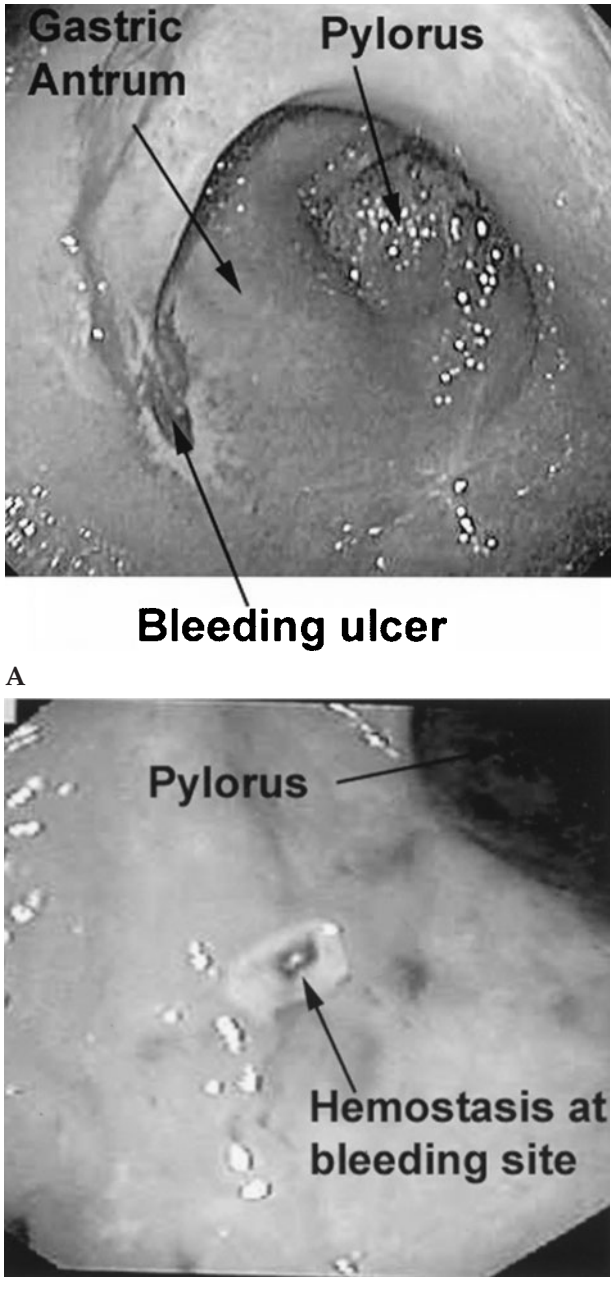

FIGURE 82-4 ***A.*** **Bleeding gastric ulcer prior to therapy.** ***B.*** **Successful hemostasis following thermal and injection therapy.**

PHARMACOTHERAPY

While intravenous histamine receptor antagonists (H_2RAs) are used commonly in the initial management of PUD bleeding, there is no evidence that this intervention improves short-term outcomes, such as rebleeding rates or transfusion requirements.[41] The concept that more profound acid suppression with proton pump inhibitors (PPIs) will improve short-term outcomes has been investigated, and most studies have shown short-term efficacy of PPIs when administered after successful endoscopic hemostasis.[42,43] Therefore, acid-suppressive therapy in the form of PPIs should be administered as an adjunct to endoscopic therapy and should not be used in lieu of an endoscopic evaluation. Studies comparing intravenous and oral PPI therapy are awaited; however, intravenous PPI therapy may ensure improved bioavailability in the setting of a bleeding gastrointestinal tract. The improved hemostatic efficacy of PPI over H_2RA therapy may be due to the superior ability of PPI therapy to maintain a gastric pH above 6.0 and therefore protect an ulcer clot from fibrinolysis.[44]

Several studies have evaluated the efficacy of the splanchnic vasoconstrictors somatostatin and octreotide in the treatment of acute nonvariceal hemorrhage. A meta-analysis of

these studies suggests that somatostatin and octreotide are associated with a reduced risk of continued bleeding and rebleeding in PUD.[45] Therefore, in addition to acid-suppressive therapy, these agents also may be considered as pharmacologic adjuncts to endoscopic therapy.

ANGIOGRAPHY

In most cases of nonvariceal hemorrhage, endoscopic evaluation is able to visualize the bleeding lesion and deliver effective hemostatic therapy. However, in a minority of patients, the bleeding source is not visualized by endoscopy, thereby necessitating angiographic localization. Also, angiography offers the option of hemostatic therapy using arterial vasoconstrictors or embolization; however, this generally is reserved for patients who are poor surgical candidates or for the control of bleeding in an unstable patient awaiting surgery.

Localization

As mentioned previously, angiography can successfully localize brisk UGI bleeding (rate > 0.5 mL/min) in 75% of cases,[46] with most bleeding episodes (85%) originating from a branch of the left gastric artery. The right gastric and short gastric arteries account for the remainder of the sources.

Hemostatic Therapy

UGI arterial bleeding can be controlled by the selective arterial infusion of vasoconstrictors such as vasopressin or embolization of particulate matter. Most studies indicate that selective intraarterial vasopressin is more effective than a peripheral intravenous infusion in achieving hemostasis.[47] Since the vasoconstrictive action of vasopressin is more pronounced on terminal blood vessels such as arterioles, venules, and capillaries, this therapy is more effective in controlling bleeding from such vessels, as in diffuse hemorrhagic gastritis, rather than a duodenal ulcer bleed originating from a large gastroduodenal artery. In the setting of gastric bleeding, therapy appears to be equally effective when administered via the left gastric or celiac artery.[48] A usual therapeutic vasopressin dose is 0.2 unit/min, with a recommended maximum dose of 0.4 unit/min. If hemostasis is achieved, the infusion is continued in the ICU for 24 to 36 hours and then tapered over 24 hours. Rebleeding after cessation of the infusion is a concern[48] and can be treated with repeat vasopressin treatment or embolization.

Embolization therapy uses various substances, most frequently a gelatin sponge (Gelfoam), to selectively embolize the bleeding vessel. Since this technique carries the risk of causing bowel wall ischemia and infarction due to nonspecific embolization, a target vessel must be accessible for selective catheterization of the bleeding site. Necrosis of the stomach, duodenum, gallbladder, liver, and spleen has been documented following nonspecific embolotherapy. Since the duodenum has a dual blood supply from the celiac artery and the superior mesenteric artery, spontaneous infarction of the duodenum is rare. The patient with advanced atherosclerotic vascular disease or with prior gastric surgery involving ligation of collateral vessels is at greater risk of infarction due to a compromised collateral circulation. In view of the higher morbidity associated with embolization therapy, it should be used only after unsuccessful intraarterial vasopressin therapy. Furthermore, embolization therapy should not be followed immediately by vasopressin therapy because this may compromise the collateral circulation, resulting in tissue infarction.

SURGICAL THERAPY

Surgical intervention for bleeding peptic ulcers should be considered in two situations. First, surgery is used to control life-threatening hemorrhage that is refractory to medical and endoscopic intervention. In fact, in patients who have a low operative risk and who have been stabilized effectively to allow surgery, angiographic therapy should not be attempted. Second, surgery should be considered in the patient in whom medical management has failed to heal or prevent recurrence of peptic ulceration, particularly if there have been previous complications attributable to PUD, such as bleeding. The patient who has recurrent hemorrhage owing to noncompliance with maintenance ulcer therapy should be considered for elective surgical therapy once bleeding has stopped. It should be emphasized that surgical morbidity and mortality are greatly reduced when the surgeon operates electively in the nonbleeding patient. Therefore, successful initial hemostasis using endoscopic and pharmacologic therapy is preferable prior to surgical intervention. In the setting of hemorrhage refractory to nonsurgical intervention, stabilization of cardiopulmonary status and optimization of hematologic parameters prepares the patient for emergent surgery and improves postoperative outcome.

The choice of surgical procedure depends on the location of the ulcer and on the stability of the patient. In the patient with an actively bleeding duodenal ulcer undergoing an emergent operation, the bleeding point of the ulcer will be oversewn and truncal vagotomy and pyloroplasty performed. Vagotomy and antrectomy may be considered if the patient has been stabilized adequately. In the setting of exsanguinating hemorrhage, gastric resection may be considered, but this procedure carries a high mortality of approximately 50%.[49] Selective vagotomy with either pyloroplasty or antrectomy, an option in the elective situation, is not advisable in an unstable patient.

Gastric ulcer bleeding is treated with the same approach as a bleeding duodenal ulcer, except that resection is recommended if the situation permits. Partial gastrectomy carries a slightly lower mortality in the setting of gastric ulcer bleeding than when performed for a bleeding duodenal ulcer.[50] Resection for an actively bleeding gastric carcinoma is recommended only when performed electively because it is a prolonged procedure that may be unsuitable for an unstable patient.

Following surgical intervention for bleeding peptic ulcers, mortality approaches 30%, with postoperative wound infection being the major complication.

SECONDARY PROPHYLAXIS

Once successful hemostasis is achieved, secondary prophylaxis is initiated to prevent recurrent ulcer bleeding, especially following nonsurgical hemostatic therapy. If histologic or nonhistologic evaluation for *H. pylori* is positive, appropriate treatment should be initiated because this reduces the long-term (1-year) rate of rebleeding from gastric or duodenal ulcers.[51] In addition, long-term acid suppressive therapy with oral H_2RAs or PPIs is indicated, and nonsteroidal anti-inflammatory drugs (NSAIDs) should be avoided.

MALLORY-WEISS TEAR

Mallory-Weiss tear generally is a self-limited cause of nonvariceal bleeding, rarely requiring more than supportive intervention. However, patients with portal hypertension are at increased risk of massive bleeding from Mallory-Weiss tears compared with those with normal portal pressures.[52] In the rare instance of continued bleeding from a Mallory-Weiss tear in a patient without portal hypertension, endoscopic therapy with either thermal coagulation or injection therapy should be attempted prior to surgical oversewing of the lesion. In the presence of portal hypertension, thermal coagulation may worsen the bleeding; therefore, band ligation or sclerotherapy should be performed. Following hemostasis, acid-suppression therapy with H_2RAs or PPIs may be given as adjunctive therapy to accelerate healing.

DIEULAFOY'S LESION

A Dieulafoy's lesion is a dilated aberrant submucosal vessel of unclear etiology that erodes the overlying epithelium in the absence of a primary ulcer. It is usually located along the high lesser curvature of the stomach near the gastroesophageal junction, although it has been found in all areas of the GI tract, including the esophagus and duodenum. Massive bleeding can occur when the eroding submucosal vessel is an artery. The endoscopic treatment of choice is a combination of epinephrine injection therapy and thermal coagulation.[53] Also, endoscopic band ligation has been used successfully to achieve hemostasis in bleeding Dieulafoy's lesions.[54] The risk of rebleeding after endoscopic therapy remains high (up to 40% in some reports) owing to the usually large size of the underlying artery. In the event of rebleeding, repeat endoscopic intervention may be attempted, following which surgical wedge resection of the lesion should be performed to achieve permanent hemostasis.

STRESS-RELATED MUCOSAL DAMAGE (SRMD)

SRMD, also referred to as *stress ulcers* or *stress-related erosive syndrome* (SRES), is the result of multiple-organ-system failure in the critically ill patient. The incidence of hemorrhage due to SRMD appears to be decreasing, probably as a result of significant advances in the intensive care management of the critically ill patient, including optimization of hemodynamic status and tissue oxygenation,[55] and the early initiation of stress ulcer prophylaxis. However, in the event of SRMD-induced hemorrhage, the mortality rate is greater than 30% owing to the difficulty in controlling such bleeding and the poor prognosis of the underlying disease. With regard to etiology, gastric mucosal ischemia secondary to systemic (and splanchnic) hypoperfusion is considered to be the major inciting factor, with acid and pepsin assuming minor roles. Of note, acid and pepsin secretion are normal to low in most critically ill patients, and increased gastric acidity is observed only in patients exhibiting Cushing's ulcers related to central nervous system (CNS) trauma or infection.

Bleeding from SRMD may be *overt* and significant, resulting in hemorrhage and hemodynamic compromise, or *occult* and minimal, detectable only by Gastroccult testing of the gastric contents. Although occult bleeding due to SRMD may occur frequently in critically ill patients, it is of little clinical significance because few of these patients progress to overt bleeding. Multiple studies have attempted to assess the relative importance of the underlying disease processes and biochemical abnormalities in inducing SRMD.[56,57] Two major risk factors identified are coagulopathy and mechanical ventilation for greater than 48 hours.[56] Other suggested risk factors include sepsis, hypotensive shock, acidosis, peritonitis, extensive burns, hepatic failure, and renal failure, with multiple risk factors having an additive effect on the probability of SRMD.

Endoscopically, SRMD may appear as multiple shallow erosions or submucosal hemorrhage during the early stages. After the first several days of the ICU course, SRMD lesions are characterized by multiple, deeper, acute ulcerations, predominantly in the gastric lesser curvature or fundus, and these lesions can erode into the submucosa, causing massive hemorrhage. Bleeding usually manifests as oozing of blood from the margins of these lesions. However, submucosal penetration can cause hemorrhage from a major artery, with the typical endoscopic appearance of an ulcer with a visible vessel.

THERAPY

The mainstay of therapy for SRMD is supportive, with an attempt to reverse the underlying precipitating factors. Acid suppression in the form of intravenous H_2RAs or PPIs may be used as adjunctive therapy to endoscopic or angiographic intervention. The role of endoscopic therapy in SRMD may be limited because the lesions usually are diffuse and not amenable to directed therapy. However, in the setting of a single dominant lesion or a few bleeding lesions, endoscopic therapy may achieve successful hemostasis in 90% of such cases.[58] Therapeutic angiography is recommended for bleeding that is refractory to endoscopic therapy. Both intraarterial vasopressin therapy[59] and embolotherapy[60] are equally successful at controlling hemorrhage without major ischemic complications owing to the rich collateral blood supply of the gastric mucosa. Since the left gastric artery is the source in most cases of SRMD-induced bleeding, this vessel is a convenient target for embolization therapy.

Surgery usually should be avoided because a near-total gastrectomy is required in most instances, and mortality exceeds 50%. Gastrectomy should be undertaken only when massive hemorrhage persists despite nonsurgical therapy in a viable patient with treatable medical problems.

PROPHYLAXIS

Since hemorrhage from SRMD presents a therapeutic challenge and carries a high mortality, much attention has been given to prophylactic therapy. Despite the existence of SRMD in the setting of low or normal acid secretion, prophylaxis has been directed toward acid suppression or neutralization. The superior efficacy of intravenous H_2RAs compared with sucralfate in preventing SRMD has been demonstrated,[61] and therefore, H_2RAs are preferred. Furthermore, prior concerns regarding the increased incidence of nosocomial pneumonia with acid-suppressive therapy has not been observed in subsequent studies. More recently, oral and intravenous PPIs have been added to the regimen of acid-suppressive therapy in the ICU and should assume increasing importance in the prophylaxis of SRMD.

In addition to pharmacologic therapy, adequate nutritional support and, in particular, enteral nutrition have been shown to decrease the incidence of SRMD.[62,63] The prophylactic effect of enteral nutrition is not mediated by an increase in gastric pH and instead may involve an increase in gastric epithelial energy stores, which, in turn, maintain epithelial integrity and prevent necrosis and ulceration. Therefore, the initiation of adequate nutrition support in the critically ill patient, preferably via the enteral route, may play a prophylactic role against SRMD. In the absence of a functional gastrointestinal tract, total parenteral nutrition (TPN), which has demonstrated a protective effect against SRMD, can be considered, although the net effect may be harmful[62] (see Chap. 11).

Lower Gastrointestinal Hemorrhage

LGI bleeding is defined as bleeding originating from a source distal to the ligament of Treitz. Hematochezia is the common presenting sign of LGI bleeding, and the two frequent LGI sources are diverticulosis and angiodysplasia. However, in the patient with hematochezia and hemodynamic compromise, a briskly bleeding UGI source should be included in the differential diagnosis. Studies have indicated that as many as 10% of patients suspected initially to have LGI bleeding ultimately are found to have a UGI source.[64]

In the past decade, technologic advances in endoscopy have greatly improved the diagnostic and therapeutic utility of colonoscopy in LGI bleeding. Traditionally, colonoscopic evaluation in the setting of LGI bleeding was delayed owing to the need for bowel cleansing, the lack of proven diagnostic and therapeutic efficacy, and the fear of increased procedural risks. However, in recent years, several studies have suggested that emergency therapeutic colonoscopy for acute LGI hemorrhage facilitates early control of bleeding, reduces rebleeding and surgical intervention rates, and improves short-term morbidity and mortality.[12,13] Based on these studies, the practice guidelines of the ASGE have emphasized the diagnostic and therapeutic utility of colonoscopy in the early management of LGI bleeding.[15]

The evaluation and management of LGI hemorrhage is outlined in Fig. 82-5. Most patients who experience severe LGI bleeding are elderly, with an average age of 65, and have comorbidities, including cardiac and respiratory disease. Therefore, prompt resuscitative measures aimed at multiple-organ support should be initiated. As mentioned previously, in the setting of hematochezia and hypotension, a UGI source should be considered in the differential diagnosis. The presence of a positive NG aspirate or historical risk factors for UGI bleeding should prompt an emergent EGD. A negative NG aspirate and a clinical suspicion for an LGI source should lead to a diagnostic and potentially therapeutic colonoscopy following a rapid oral purge with polyethene glycol (PEG). In the presence of massive LGI bleeding, immediate angiographic or surgical intervention without endoscopic evaluation is indicated.

The different diagnostic and treatment modalities used in the management of LGI hemorrhage (see Fig. 82-5) are outlined below. In contrast to UGI hemorrhage, a role for adjunctive pharmacotherapy has not been established in LGI bleeding.

COLONOSCOPY

Following the exclusion of a UGI source, an emergent colonoscopy after a rapid oral purge is the initial examination of choice for diagnosis and treatment. Studies have indicated that following colonic cleansing, colonoscopy offers a higher diagnostic yield and a lower complication rate than the traditional angiographic approach.[64,65] An accepted bowel cleansing protocol is 4 L polyethylene glycol (GOLYTELY) given orally or via an NG tube over 2 hours.[64] Metoclopramide (10 mg) is administered at the start of the purge to facilitate intestinal transit and to minimize the risk of emesis. This bowel preparation regimen has not been associated with an increase in the rate of bleeding or rebleeding.[64]

The overall diagnostic yield of emergent colonoscopy in LGI bleeding is 69% to 80%.[64,66] Diverticular bleeding and angiodysplasia are the most common findings in the majority of large series, with colitis (ischemic, inflammatory, or radiation-induced), neoplasia, and anorectal disease being some of the minor etiologies. If an adequate colonoscopic evaluation does not reveal a bleeding source, and an upper endoscopy is negative, a small intestinal etiology should be considered. Intubation of the terminal ileum at the time of colonoscopy may be useful because fresh blood emanating from the ileum may be indicative of small intestinal bleeding. Small bowel evaluation with push enteroscopy, capsule endoscopy, or enteroclysis can be initiated once hemostasis is achieved spontaneously or with nonendoscopic methods. A further discussion regarding the evaluation of small intestinal bleeding will follow.

ENDOSCOPIC THERAPY

The hemostatic techniques used in therapeutic colonoscopy are similar to those used in therapeutic upper endoscopy. Both thermal coagulation and injection therapy with epinephrine have been used successfully to obtain hemostasis in acute LGI bleeding. With further expertise and advances in endoscopic technology, this relatively new field of therapeutic colonoscopy is expected to evolve.

DIVERTICULAR BLEEDING

The endoscopic visualization of a visible vessel or pigmented protuberance within a diverticular segment identifies patients who are at high risk for persistent or recurrent diverticular bleeding.[67] In this setting, thermal coagulation or injection therapy with epinephrine may be used individually or together to achieve successful hemostasis (Fig. 82-6). Studies have suggested that endoscopic hemostasis may prevent recurrent diverticular bleeding and the need for hemicolectomy.[12,15] Therefore, endoscopic therapy offers a viable long-term alternative to surgical therapy for diverticular bleeding in the elderly patient, who may not be an ideal candidate for surgical intervention. However, massive diverticular bleeding may not be amenable to endoscopic therapy because of poor endoscopic visualization or failed endoscopic therapy, thereby necessitating angiographic or surgical therapy.

ANGIODYSPLASIA

Bleeding from angiodysplastic lesions frequently is responsive to endoscopic therapy. These lesions often are located in the cecum and right colon and represent acquired arteriovenous malformations. Successful hemostasis can be achieved

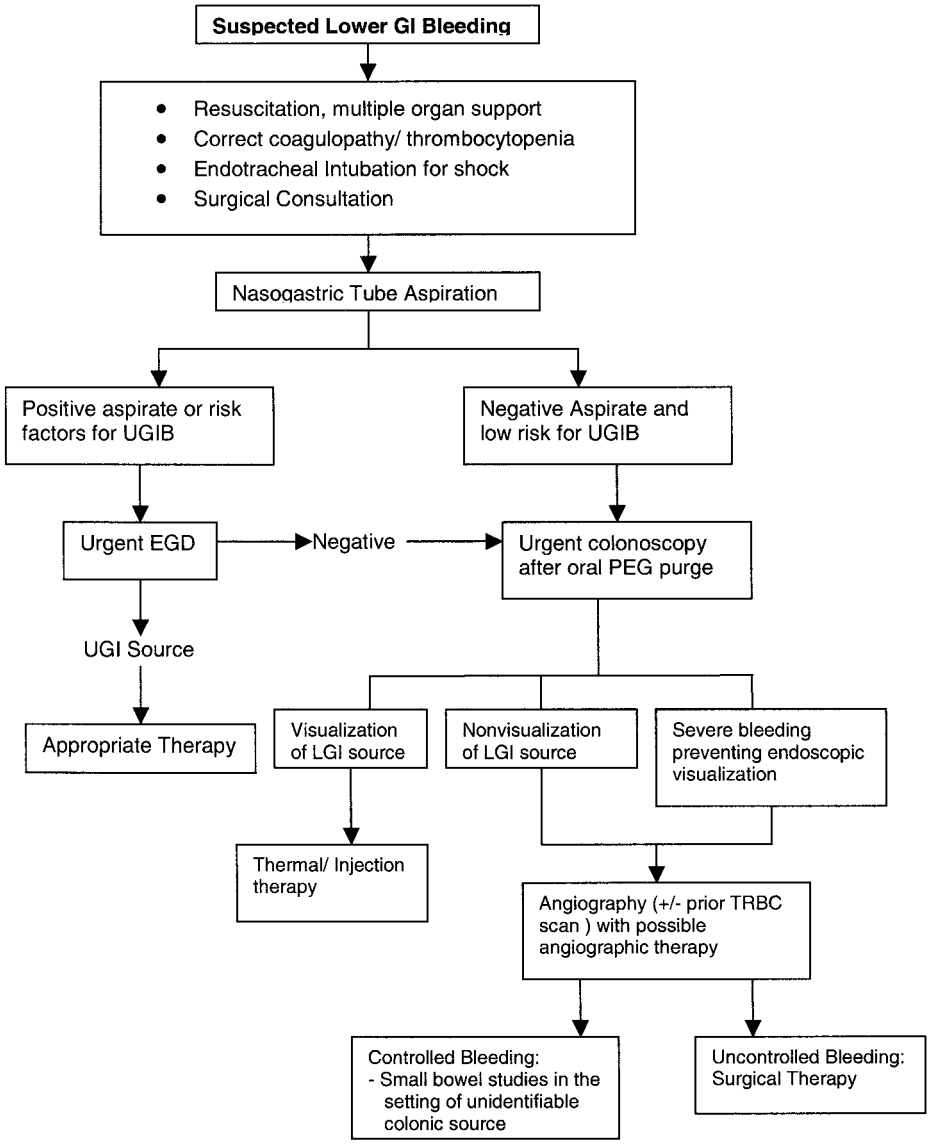

FIGURE 82-5 Management of lower GI hemorrhage. TRBC, tagged RBC; PEG, polyethylene glycol.

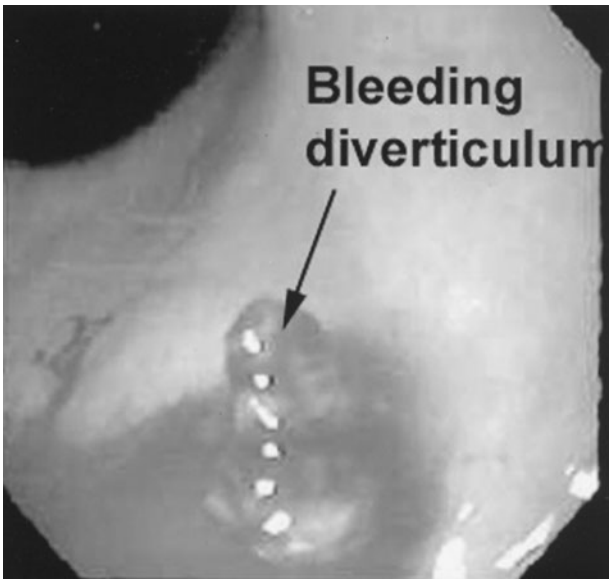
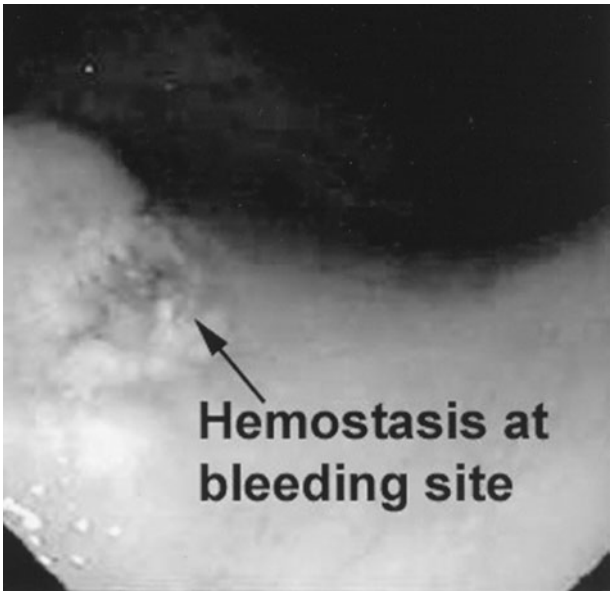
with both injection therapy and thermal coagulation.[68] The periphery of the lesion should be treated before the center in order to obliterate the feeder vessels. With respect to thermal coagulation, the recommended power settings are lower than those used for a bleeding peptic ulcer owing to the increased risk of perforation in the right colon.



Additional lesions responsive to thermal and injection therapy include postpolypectomy sites, radiation colitis, and anorectal sources. Noncontact modalities such as the argon-plasma coagulator (APC) have been used effectively in the management of radiation colitis and postpolypectomy bleeding. In addition, a band ligation technique similar to esophageal variceal band ligation can be used to treat bleeding internal hemorrhoids.[69]

RADIONUCLIDE STUDIES



In the event of a negative colonoscopy, a radionuclide scan using ^{99m}Tc-pertechnetate-labeled red blood cells is used frequently to localize the LGI bleeding site prior to subsequent angiographic evaluation. The nuclear scan offers the ability to detect rates of bleeding as low as 0.1 mL/min, and the 48-hour stability of the tagged red blood cells allows repeated imaging during this time period. However, the high sensitivity of radionuclide imaging is offset by its low specificity compared with a positive endoscopic or angiographic examination.[70] A positive radionuclide study localizes the bleeding only to an area of the abdomen and cannot define precisely the mucosal location of the bleeding site. Therefore, a positive scan should be used to direct attention to specific sites of the GI tract that can be examined subsequently by angiography or a repeat endoscopy. Furthermore, surgical intervention should not be based on the results of a radionuclide scan alone but should be guided by accurate angiographic or endoscopic evaluation.

ANGIOGRAPHIC THERAPY

Angiography with therapeutic intent is the appropriate treatment modality in the setting of massive bleeding that precludes colonoscopy or after a nondiagnostic colonoscopy. The overall diagnostic yield of angiography ranges from 40% to 78%, with diverticular disease and angiodysplasia being the

A

B

FIGURE 82-6 ***A*****. Bleeding colonic diverticulum prior to therapy.** ***B*****. Successful hemostasis after thermal and injection therapy.**

most common findings.[71] In a stable patient, a radionuclide scan is performed often for initial localization prior to angiographic evaluation because the nuclear scan is a more sensitive examination and detects slower rates of bleeding. In the absence of localization via nuclear imaging, the superior mesenteric artery (SMA) is examined first because most diverticular and angiodysplastic bleeds occur in bowel supplied by this artery.[72] If the evaluation of the SMA is negative, the inferior mesenteric and celiac vessels are studied.

The intermittent nature of LGI bleeding in many cases presents a problem for angiographic evaluation and treatment because active bleeding at the time of dye injection is required for a positive examination. Initial angiographic hemostasis using intraarterial vasopressin or embolization ranges from 60% to 100%, although recurrent bleeding may be as high as 50%, especially following vasopressin therapy.[73] Intraarterial vasoconstrictive therapy with vasopressin is used predominantly in diverticular bleeding and angiodysplasia and is associated with a major complication rate of 10% to 20%, including arrhythmias, ischemia, and pulmonary edema. Transcatheter embolization therapy with various agents, including gelatin sponge and microcoils, may be a more definitive means of controlling hemorrhage but is associated with a risk of intestinal infarction as high as 20%. Attempts to reduce this risk have included the application of a highly selective catheterization technique and the use of a relatively distal site for embolization with temporary occluding agents.[74]

In the event that therapeutic angiography does not achieve permanent hemostasis, emergent surgical therapy is indicated. However, initial angiographic therapy in the actively bleeding patient may achieve temporary hemostasis and hemodynamic stability and thereby allow surgical intervention in a controlled setting with an improved operative mortality.[73]

SURGICAL THERAPY

In the patient presenting with exsanguinating LGI hemorrhage, colonoscopy and angiography should be deferred, and an emergent subtotal colectomy should be performed. In all other cases, surgical therapy should be reserved for hemorrhage that is refractory to nonsurgical interventions. Furthermore, preoperative localization of bleeding is crucial to avoid extensive surgical resection and to ensure that the bleeding is truly arising from the LGI tract.

PREOPERATIVE LOCALIZATION

The role of angiography and colonoscopy in identifying the bleeding site was outlined previously. In addition to angiography and colonoscopy, exploratory laparotomy with intraoperative endoscopy can be used to localize the bleeding source, especially in the small intestine. Intraoperative endoscopy can be performed with oral, rectal, or enterotomy introduction of the endoscope. Following incision of the abdominal wall and exposure of small bowel, the endoscope can be introduced orally. The endoscope, generally a pediatric colonoscope, can be advanced easily to the ligament of Treitz. Subsequently, the entire small bowel is examined by pleating the small bowel over the colonoscope. The endoscopist must limit the amount of air insufflation because excessive distention of the bowel will result in prolonged postoperative ileus. Following inspection of the small bowel to the ileocecal valve, a second inspection is performed as the colonoscope is withdrawn slowly. The surgeon assists the examination by carefully inspecting the serosal side of the bowel for abnormalities, such as a transilluminated angiodysplastic lesion. Alternatively, a sterilized colonoscope may be placed through an enterotomy site in the small bowel and then can be passed proximally and distally into the small bowel to facilitate examination. This approach carries a risk of contamination of the exposed peritoneum. A collaborative effort between the endoscopist and the surgeon is essential for the efficient and safe performance of intraoperative endoscopy.

Once the source of bleeding is localized, a segmental colectomy involving the bleeding lesion can be performed. In a

patient with extensive diverticular disease and a localized diverticular bleeding site, a segmental resection eradicating the bleeding site is adequate without the need to resect segments involving nonbleeding diverticula.[73] With respect to angiodysplasia, the presence of cecal angiodysplasia should alert the surgeon to the possibility of angiodysplasia in the distal terminal ileum. It should be noted that angiography that demonstrates cecal angiodysplasia may fail to identify a similar small bowel lesion, and therefore, intraoperative small bowel endoscopy should be used. In addition, when a right hemicolectomy for suspected angiodysplasia is undertaken, resection of the distal 30 to 60 cm of the terminal ileum should be considered.

A subtotal colectomy is indicated for exsanguinating hemorrhage or persistent hemorrhage without an identifiable site of bleeding and involves colonic resection from the cecum to proximal rectum with an ileoproctostomy. This procedure is associated with a high morbidity and mortality, but rebleeding rates are extremely low.[75] Blind segmental resection is contraindicated because this procedure is associated with excessive rates of rebleeding, morbidity, and mortality.[75]

Obscure Bleeding and Small Bowel Evaluation

Occasionally, a patient presenting with acute gastrointestinal bleeding undergoes a nondiagnostic evaluation with endoscopy, radionuclide imaging, and angiography but clinically stabilizes owing to intermittent or permanent cessation of bleeding. In such a situation, emergent surgical exploration and intraoperative endoscopy may not be indicated. Instead, further diagnostic evaluation should be directed specifically at the small bowel, which is the likely source of obscure bleeding in many cases, with angiodysplasia being the most common lesion. Recent advances in endoscopic technology have enabled the gastroenterologist to visualize more distal portions of the small bowel compared with traditional upper endoscopy. These novel endoscopic modalities will be reviewed and will be followed by a discussion of specific lesions associated with obscure bleeding.

NOVEL ENDOSCOPIC MODALITIES

PUSH ENTEROSCOPY

An orally inserted adult/pediatric colonoscope or special enteroscope is passed with or without an overtube as far as possible beyond the ligament of Treitz and allows visualization of the proximal 60 cm of jejunum. The diagnostic yield of this procedure is as high as 50%, with angiodysplasia being the most common lesion.[76] In addition, this technique allows biopsy or therapy of visualized lesions.

SONDE ENTEROSCOPY

This technique should be considered in the setting of a negative push enteroscopy and allows visualization of small bowel distal to the limits of push enteroscopy. During this procedure, a long flexible fiberoptic enteroscope without controls is propelled passively by intestinal peristalsis, allowing a view of the distal small bowel beyond the visualization by push enteroscopy. The endoscopic examination is performed during withdrawal of the instrument. In contrast to push enteroscopy, this technique does not allow biopsy or therapy of visualized lesions, and additional limitations include high equipment costs and a long procedure time.

WIRELESS CAPSULE ENDOSCOPY

This technique has been introduced into clinical practice recently and provides a noninvasive method of examining the entire small bowel via peristaltic propulsion of the endoscopic capsule. The patient swallows a capsule that produces approximately 50,000 images while it traverses the small bowel over 12 to 15 hours. Recent versions of this technique are able to approximate the location of the bleeding lesion within the small bowel. A limitation similar to that for the sonde enteroscopy is the fact that tissue sampling or therapeutic intervention cannot be performed. Experience with this technique is growing rapidly, but extensive studies are yet to be performed.

In addition to the preceding endoscopic modalities, *enteroclysis* radiography can be considered for the evaluation of potential small bowel bleeding sources, although the yield of this test is only about 10%.[77] This study is a double-contrast study performed by passing a tube into the proximal small bowel and injecting barium, methylcellulose, and air. Despite the low sensitivity of this study, it is considered superior to standard imaging using small bowel follow-through.

LESIONS ASSOCIATED WITH OBSCURE BLEEDING

Small intestinal angiodysplasia accounts for the majority of small bowel lesions associated with obscure bleeding. An increased incidence of small bowel angiodyplasia has been reported in patients with end-stage renal disease (ESRD), Von Willebrand disease, and Osler-Weber-Rendu (OWR) syndrome. In the setting of proximal lesions located approximately in the first 60 cm of jejunum, therapeutic push enteroscopy may achieve permanent endoscopic hemostasis. However, more distal lesions are not amenable to endoscopic therapy. In select patient populations, including those with ESRD, Von Willebrand disease, and OWR syndrome, hormonal therapy with estrogen, with or without progesterone, may be useful in controlling bleeding from angiodysplasia.[78] In patients refractory to endoscopic and medical therapy, chronic iron supplementation and periodic transfusions are indicated.

Hemobilia is bleeding from the liver, bile ducts, or pancreas and is characterized by blood emanating from the ampulla of Vater. Hepatic hemobilia usually results from blunt or sharp trauma to the liver. A hepatic artery aneurysm that erodes into the right hepatic or common bile duct produces melena and occasionally presents with right upper quadrant abdominal pain and jaundice. Pancreatic hemobilia is even less common and usually results from pancreatitis-induced pseudoaneurysm formation in the splenic artery. Acquired splenic artery aneurysms may erode into the pancreas, resulting in hemobilia without pancreatitis.

Hemobilia should be suspected when melena occurs in conjunction with jaundice or after blunt trauma or acute pancreatitis. Following a negative forward-viewing upper endoscopy, the endoscopist should examine the duodenal papilla using a side-viewing duodenoscope. Active bleeding

or a clot emanating from the papilla may be seen. Alternatively, angiography may reveal active bleeding or associated aneurysms in the hepatic or splenic artery. Angiographic therapy may provide temporary control of hematobilia,[79] but generally definitive surgery is required.

Aortoenteric fistula is a rare development following abdominal vascular surgery involving placement of a synthetic graft. The fistula arises commonly from the proximal anastomosis of the graft and communicates with the fourth portion of the duodenum. Graft infection generally is present and likely plays a role in the pathogenesis of the fistula. Bleeding from aortoenteric fistulas is typically intermittent and profuse. The evaluation of a suspected aortoduodenal fistula should begin with endoscopy. The endoscopist must examine the fourth portion of the duodenum, where bleeding or the graft itself may be seen. If endoscopy fails to identify a fistula, angiography should be performed if clinical suspicion is high. Surgical correction of the fistula, including removal of the graft, is necessary to prevent potential exsanguination.

Meckel's diverticulum should be considered in younger patients presenting with massive bleeding. The diagnosis often is made by a ^{99m}Tc-pertechnetate scan, which has a sensitivity of 75%.[80] Surgical resection of an identified Meckel's diverticulum provides definitive therapy.

Chapter 83

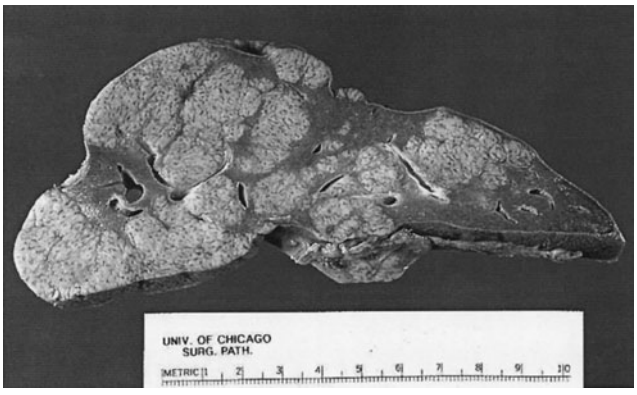
FULMINANT HEPATIC FAILURE

SANJAY KULKARNI
DAVID C. CRONIN II

KEY POINTS

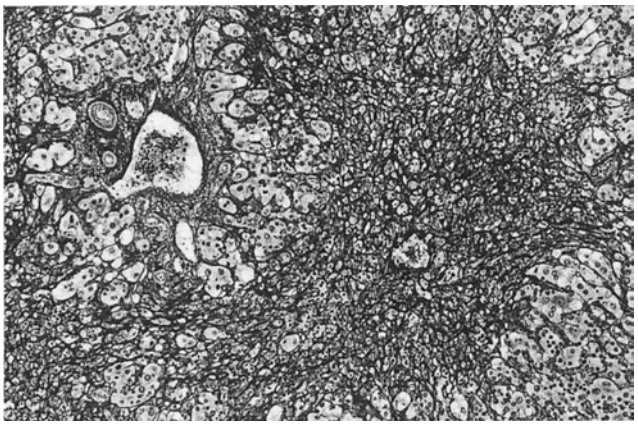
- *Fulminant hepatic failure (FHF) is defined as the onset of hepatic encephalopathy (HE) within 8 weeks of the onset of liver-related symptoms.*
- *Common complications in patients with FHF include encephalopathy, cerebral edema, cardiovascular instability, renal failure, and infection.*
- *Supportive management of FHF consists of (1) airway protection, (2) intracranial pressure monitoring in the sickest patients, and (3) treatment of complications and vigilance for infection.*
- *Orthotopic liver transplantation (OLT) is the definitive therapy for FHF. Extracorporeal liver support remains investigational.*

Fulminant hepatic failure (FHF) describes a clinical syndrome of progressive hepatocyte necrosis resulting in the dysfunction of virtually every major organ system. Consequently, management of patients with FHF is complicated and unpredictable, where many of the therapies initiated have not been proven effective in controlled clinical trials. Management of this syndrome requires early recognition and treatment of organ system deterioration because overall patient survival is inversely related to the number and extent of extrahepatic organ dysfunction. Therefore, treatment of these organ failures should be highly individualized and tailored toward anticipation and prevention of multisystem organ failure while waiting for recovery of hepatic function or liver transplantation.



Perhaps the most difficult dilemma in treating patients with FHF is the inability to predict which patients will recover adequate liver function and survive an episode of FHF without liver transplantation. Among patients with FHF who have progressed to grade 3 or 4 encephalopathy, expected recovery with medical management alone is approximately 10% to 40%.[1] The advent of liver transplantation has improved survival markedly to 60% to 80% and is currently considered the treatment of choice for progressive FHF.[1] Thus the overall treatment strategy has evolved into early stabilization of the FHF patient, optimization of the patient's general condition, and early and continued evaluation for liver transplantation.

Definitions and Etiology



Trey and Davidson[2] originally proposed the term *fulminant hepatic failure*, which describes a condition of massive hepatic cell necrosis (Fig. 83-1) that is clinically evident by the progression to encephalopathy within 8 weeks of the onset of jaundice. Since this initial definition, numerous alterations and terms have been proposed that often complicate rather than clarify understanding of this disease process. A more concise definition proposed by O'Grady and colleagues[3] attempts to precisely categorize liver failure into three types based on the time interval between the onset of jaundice and the emergence of encephalopathy: hyperacute (0 to 7 days), acute (8 to 28 days), and subacute (29 days to 12 weeks). The utility of this terminology is supported by the different clinical features and associated mortalities within each category (Table 83-1). Patients with hyperacute FHF tend to have rapidly progressive cerebral edema, to improve with medical management, and to have an overall favorable prognosis. Patients with acute FHF also have rapidly progressive FHF, but they tend to have a worse prognosis without liver transplant. Subacute FHF patients have a lower incidence of cerebral edema but an overall poor prognosis. It is important to distinguish hyperacute and acute FHF from subacute FHF. A recent modification of the nomenclature for liver failure was presented by the International Association for the Study of Liver (IASL) stressing the differences between hyperacute and acute versus subacute liver failure.[4] The modified terminology includes only two groups, acute and subacute liver failure. However, there are temporal subcategories within acute liver failure that include hyperacute (onset less the 10 days), fulminant (onset 10 to 30 days), and acute hepatic failure not otherwise specified (AHF-NOS) that use the time from onset of jaundice to the onset of encephalopathy as the main differentiating feature. Subacute FHF is characterized by persistent, irreversible hepatitis leading to the development of ascites and/or encephalopathy over a protracted period of time (5 to 24 weeks). Wider acceptance of this new classification system will continue when analysis of FHF using this schema becomes more prevalent. Regardless of the classification system used, categorization of FHF is useful for retrospective analyses of patients but does not provide prospective guidelines for initial management. Therefore, all patients should be assumed to have an unpredictable clinical course that may require liver transplantation.

The causes of FHF are numerous and not always known at the time of presentation. Careful history taking from the patient, family, and significant others is mandatory and may provide valuable information for identifying the etiology of FHF. Additionally, certain causes require specific therapies or influence the appropriateness of liver transplantation. In the United States, acetaminophen toxicity has replaced acute viral hepatitis as the most common cause of FHF.[5] Usually, metabolites of acetaminophen are direct hepatotoxins as compared with the hypersensitivity reactions associated with other drugs that cause FHF (e.g., halothane, antidepressants, and nonsteroidal anti-inflammatory drugs). Cellular damage secondary to acetaminophen intoxication is not isolated to the liver and often is associated with other signs of systemic toxicity, most commonly renal dysfunction. In addition to intentional ingestion of large doses of acetaminophen, therapeutic doses of acetaminophen can result in FHF. This therapeutic misadventure occurs when therapeutic doses of acetaminophen undergo rapid conversion to the toxic metabolite at a rate that exceeds the detoxification reaction. The potential for this situation exists in patients

with hepatic enzymes that have been induced by exposure to drugs (alcohol, barbiturates, phenytoin, etc.) or in patients with malnutrition resulting in limited detoxification capacity.[6] Of the viral causes of FHF, hepatitis A and hepatitis B are the most common. Hepatitis C infection rarely causes FHF unless coinfection with another hepatitis virus exists.[7] In rare instances, categorized as non-A, non-E hepatitis, no etiologic cause of FHF is clearly evident, but the course is consistent with a viral etiology. Additional causes of FHF are listed in Table 83-2, including rare causes, which always need to be considered, especially when no clear basis for FHF is evident.

TABLE 83-1 Subcategories of FHF

	Hyperacute	Acute	Subacute
Encephalopathy	Yes	Yes	Yes
Onset of jaundice	0–7 days	8–28 days	29–72 days
Cerebral edema	Common	Common	Uncommon
Serum bilirubin	Least elevated	Elevated	Elevated
Prognosis	Intermediate	Poor	Poor

TABLE 83-2 Causes of FHF

Viral	HAV, HBV, HCV (usually coinfection), HDV, HEV, HGV
	Herpes simplex virus
	Epstein-Barr virus
Drug toxcity	Acetaminophen
	Halothane, ampicillin-clavulanate, ciprofloxacin, erythromycin, isoniazid, nitrofurantoin, tetracycline, sodium valproate, phenytoin, lovastatin, tricyclic anti-depressants, gold, flutamide, dipyridium, antabuse, cyclophosphamide, methyldioxy-methamphetamine (ecstasy), loratadine, propylthiouracil, troglitazone
Other toxins	*Amanita phalloides*, organic solvents, herbal medicines, bacterial toxins (*Bacillus cereus* and cyanobacteria)
Miscellaneous	Acute Budd-Chiari
	Hepatic ischemia from shock
	Wilson's disease
	Reye's syndrome
	Acute fatty liver of pregnancy
	Heatstroke
	Extensive hepatectomy
	Autoimmune hepatitis
	Lymphoma

Initial Evaluation and Management

INITIAL ASSESSMENT

Patients suspected of having FHF should be managed in a critical care unit associated with an active liver transplant program. A multidisciplinary team composed of critical care specialists, hepatologists, transplant surgeons, and neurointensivists is essential for evaluating the patient and defining a plan of treatment. Ideally, this multidisciplinary care will be provided throughout the ICU admission, and members will participate in the decision making for liver replacement. The diagnosis of FHF is made by careful history, clinical assessment, and biochemical confirmation. A history of preexisting liver disease, toxin exposure (e.g., alcohol, acetaminophen, NSAIDs, etc.), acute viral illness, or a predisposing medical condition should increase suspicion of FHF in a patient presenting with altered mental status, transaminase elevation, and synthetic dysfunction. The latter is best reflected by an elevation in the International Normalization Ratio (INR) of prothrombin time. A rising INR coincident with falling liver transaminases is an ominous sign suggestive of nonrecoverable ongoing hepatic necrosis.

During the initial evaluation, the importance of a detailed history and physical examination cannot be overstated. Interviews with the patient, friends, and family and direct contact with referring physicians may provide insight into the acuity of the illness, social background, and possible coexisting medical conditions that may alter the patient's expected recovery and candidacy for transplantation. Medical records of patients transferred from outside institutions should be reviewed for evidence of administration of sedatives that may have an impact on the initial neurologic examination. Patients with FHF may present with confusion or combative behavior, which is often treated with benzodiazpines or narcotics. Administration of flumazenil or naloxone may be necessary, depending on the amount and type of benzodiazapine or narcotic exposure, to allow for an accurate baseline neurologic evaluation.

MONITORING

The degree of neurologic dysfunction, as measured by encephalopathy grade, should guide the initial level of invasive monitoring. This monitoring strategy is supported by the observation that hemodynamic instability in FHF is usually a late finding and most often occurs among patients in grade 3 or 4 encephalopathy. Large-bore peripheral intravenous lines, a nasogastric tube (or an orogastric tube if there is an uncorrected coagulopathy), a urinary catheter, an electrocardiogram, noninvasive blood pressure monitoring, and pulse oximetery are adequate for patients presenting with grade 1 or 2 encephalopathy. Excessive initial monitoring with invasive catheters is unnecessary and is associated with an increased risk of complications and infection. Among patients with grade 3 or 4 encephalopathy, endotracheal intubation is necessary for maintaining airway patency, oxygenation, and control of respiratory acidosis. Because patients with grade 3 or 4 encephalopathy may become combative and require sedation or have lapsed into coma, intracranial pressure (ICP) monitoring is strongly recommended. Extradural catheter monitoring is preferred in this setting for its safety and ease in placement.[8] This subset of patients also may benefit from central venous or pulmonary artery monitoring, especially those receiving vasoactive drugs or mannitol to treat intracranial hypertension. Central venous, arterial, and extradural catheters can be inserted safely by experienced staff in the setting of an INR between 2 and 3. The risk of hemorrhage can be reduced further by choosing compressible sites, and using ultrasound guidance for venous and arterial access. For patients with greater degrees of coagulopathy, fresh frozen plasma (FFP) should be given in a limited window during which all necessary invasive procedures are planned. Repeated and intermittent FFP infusion obscures the clinician's ability to assess hepatic synthetic recovery and poses the additional risks of fluid overload and transfusion reaction.

WORKUP

The goal of initial laboratory evaluation is to find the potential causes of FHF, as well as to evaluate other organ system function. On arrival, the patient should have a complete blood count, platelet count, chemistries, liver function tests (albumin, bilirubin, alkaline phosphatase, AST, and ALT), prothrombin time (INR), arterial blood gas, factor V level, blood glucose level, and ammonia level. The preceding tests should be performed on a scheduled basis because clinical deterioration may be swift and unpredictable. Possible causes of FHF are sought through serologic assays for hepatitis A (anti-HAV IgM) and hepatitis B (anti-HBV IgM, HBsAg, HBcAb) and serum assays for ceruloplasmin, iron-binding capacity, toxic substances, and acetaminophen. A right upper quadrant ultrasound is useful in providing information regarding the patency of the hepatic vessels, liver size, presence of acites, and degree of compression of the porta hepatitis by intraabdominal masses. The role for liver biopsy is controversial. Although transjugular liver biopsies can be performed safely, there is little correlation between the extent of hepatic necrosis and the recoverability of the liver likely owing to sampling error. Despite this, liver biopsies are useful in patients for whom the cause of FHF is uncertain, or when lymphoma is a possible cause.

ACETAMINOPHEN INTOXICATION

Patients suspected of acetaminophen intoxication should be treated immediately with oral *N*-acetylcysteine, a proven free-radical scavenger that improves overall survival among patients with acetaminophen-induced FHF.[9] The biochemical basis for this therapy is that the hepatoxicity induced by acetaminophen is mediated by its metabolite *N*-acetyl-benzoquinoneimine, which binds sulfhydryl groups in heptocytes.[10] High levels of *N*-acetyl-benzoquinoneimine deplete glutathione stores, which normally reduce the toxic metabolites of acetaminophen. *N*-acetylcysteine functions by replenishing stores of intracellular reduced glutathione, thereby detoxifying *N*-acetyl-benzoquinoneimine. Recently, treatment with *N*-acetylcysteine also has shown beneficial affects in the overall hemodynamic status of patients with FHF by an undefined mechanism.[11] Regardless of the time elapsed from ingestion, there are significant benefits to giving *N*-acetylcysteine even 10 to 36 hours after ingestion.[11] Mortality was reduced from 58% to 37%, and significantly fewer patients progressed to grade 3 or 4 encephalopathy. *N*-Acetylcysteine is given orally in a 5% dextrose solution

with a loading dose of 140 mg/kg, followed by 17 doses of 70 mg/kg every 4 hours. The Food and Drug Administration (FDA) has not approved the use of intravenous *N*-acetylcysteine in the United States because of reported anaphylactic reactions and electrocardiographic (ECG) abnormalities. However, in patients who have intractable vomiting, intravenous administration of *N*-acetylcysteine may be the only recourse. One approach is to compound a 3% *N*-acetylcysteine solution dosed intravenously identically to the oral regimen.[12] For patients treated with *N*-acetylcysteine, the INR must be evaluated cautiously because false "improvements" in coagulation have been described.[13]

VIRUS-INDUCED FHF

Virus-induced FHF may present as a rapidly progressive new illness or an acute decompensation superimposed on preexisting liver disease. Regardless, many of these patients will require urgent liver transplantation if criteria for FHF are met. For patients with hepatitis B (with or without hepatitis D coinfection), antiviral therapy may be beneficial. Lamivudine, a nucleoside analog, improves Childs-Pugh status among patients with chronic hepatitis B cirrhosis.[14,15] Experience with its use in the setting of FHF is limited. However, preliminary evidence has demonstrated hepatitis B e-antigen seroconversion in patients with FHF.[16] Although this seroconversion is largely temporary, it suggests significant antiviral activity that may help an acutely decompenstated patient with hepatitis B from progressing to FHF. Despite the lack of definitive studies in acute decompensation, we recommend early lamivudine treatment in selected patients given the severity of illness and limited therapeutic options.

Encephalopathy and Cerebral Edema

Central to the care of patients with FHF is the management of encephalopathy and cerebral edema. Starling forces of hydrostatic and osmotic pressure gradients appear to favor cerebral edema in FHF patients.[17] Dysfunction of cerebral blood flow autoregulation, cerebral vasodilation, and a disrupted blood-brain barrier all contribute to the accumulation of interstitial cerebral fluid, resulting in increased ICP. A direct causative relationship between encephalopathy and cerebral edema has not been proven, and in patients with chronic liver failure, worsening encephalopathy is not associated with cerebral edema. In the acute setting, however, cerebral edema clearly is evident in patients with grade 3 or 4 encephalopathy. Progressive cerebral edema leading to uncal herniation and death unfortunately is the end point of many severely ill FHF patients who do not receive a liver transplant.

The extent of cerebral dysfunction should be determined repeatedly through careful neurologic examination. Owing to the limited sensitivity of computed tomography in detecting cerebral edema, repeated clinical evaluations and gradings of encephalopathy are required[18] (Table 83-3). Repeated examinations by the same critical care or neurointensivist staff are optimal because assessment is subjective. Recognizing external factors that can exacerbate encephalopathy is important and probably underemphasized. The most common clinical scenario is that of a combative and confused patient with grade 2 encephalopathy who is treated with sedatives and then appears to progress to grade 3. When sedatives must be given to facilitate care or ensure patient safety, we recommend low-dose, short-acting benzodiazapines (e.g., 0.5 mg IV lorazepam). The mental status then should be assessed carefully and serially during the period of sedation. If sedatives are dosed repeatedly, the safest approach may be to intubate the patient electively and place an extradural monitor. Other external variables that may contribute to worsening encephalopathy include hypoglycemia, hypoxia, electrolyte abnormalities, gastrointestinal bleeding, and sepsis.[19]

TABLE 83-3 Grades of Encephalopathy

Grade	Clinical Examination
1	Confused or altered mood
2	Somnolent or inappropriate behavior, impending stupor
3	Stuporous but arousable or markedly confused behavior
4	Unresponsive or comatose

Treatments effective in ameliorating the encephalopathy of decompensated cirrhosis, such as selective gut decontamination, lactulose, and dietary nitrogen restriction, have proven ineffective in FHF, and we do not recommend them.

Management of cerebral edema is based on principles of maintaining adequate cerebral perfusion while controlling factors that exacerbate interstitial cerebral fluid accumulation and increases in ICP. Initial measures should include avoidance of unnecessary stimulation, including respiratory suctioning in intubated patients, which may cause acute elevations in ICP. The head of the patient's bed should be elevated to 30 degrees, and the patient's head should be maintained in a neutral position. Simply avoiding, when possible, moving and provoking the patient will stabilize fluctuations in ICP and provide for more consistent assessment. Jugular venous lines risk potential obstruction of cerebral venous outflow, so some have advocated avoiding them, but the risks should be balanced against those of alternate sites (subclavian and bleeding, femoral and infection; see Chap. 12).

Brain blood flow is determined largely by the cerebral perfusion pressure (CPP), a function of mean arterial pressure (MAP) and ICP: CPP = MAP − ICP. At high levels of MAP, hydrostatic forces directly favor interstitial cerebral fluid accumulation. On the other hand, excessive lowering of MAP risks cerebral hypoperfusion if the limits of cerebral autoregulation are breached. Flow sufficiently low to cause brain hypoxia may amplify blood-brain barrier dysfunction.[17] Therefore, optimal CPP is between 60 and 80 mm Hg.

Cerebral capillary osmotic pressure gradients also play an important role in the development of cerebral edema. Blood-brain barrier disruption and elevated serum ammonia levels lead to accumulating cerebral interstitial osmotic forces favoring water efflux into the cerebral interstitium. Approaches to limit this efflux include repair of the blood-brain barrier or increasing the cerebral capillary oncotic pressure. Evidence that the blood-brain barrier can be reconstituted in the setting of FHF is preliminary and involves strategies to reduce serum ammonia levels by continuous venous hemofiltration or by plasma exchange.[20]

The mainstay of current therapy is mannitol, which was the first treatment demonstrated to improve survival in patients with FHF[21] (Fig. 83-2). By increasing cerebral capillary oncotic pressure, mannitol reduces the amount of water efflux into the interstitial space, resulting in lower ICPs. Mannitol (1 g/kg) usually is used in patients who have grade 4 encephalopathy, are intubated, and have appropriate monitoring of central venous pressure (CVP). Hypovolemic hypotension can be avoided by monitoring CVP and serum osmolarity and by ceasing mannitol infusion when osmolality exceeds 320 mOsm/L. In patients with renal failure, mannitol should be used only during continuous renal replacement therapy. In all patients, unnecessary free water should be avoided. Hypovolemia should be corrected using isotonic or hypertonic solutions.

Hyperventilation is no longer advocated to treat intracranial hypertension, except in a crisis (see Chaps. 65 and 93). Although hyperventilation is effective in the short term, tachyphylaxis follows. Moreover, the overall reduction in cerebral blood flow that results from hyperventilation-induced cerebral vasoconstriction may cause further disruption of the blood-brain barrier. The use of barbiturate coma is controversial, but it may be used in patients who have uncontrollable intracranial hypertension, often exacerbated by status epilepticus. Intentional hypothermia, sometimes used in conjunction with barbiturate coma to lower the metabolic demands of the brain, requires continuous electroencephalographic monitoring for titration of barbiturate doses to appropriate levels of sedation. There are many complications associated with barbiturate coma, including persistent post-transplant sedation, myocardial depression, and increased susceptibility to infection.[22] These patients should be placed on empirical prophylactic antimicrobial agents directed toward nosocomial organisms. Despite the risks, coma should be induced with barbiturates on an individualized basis in patients with refractory intracranial hypertension.

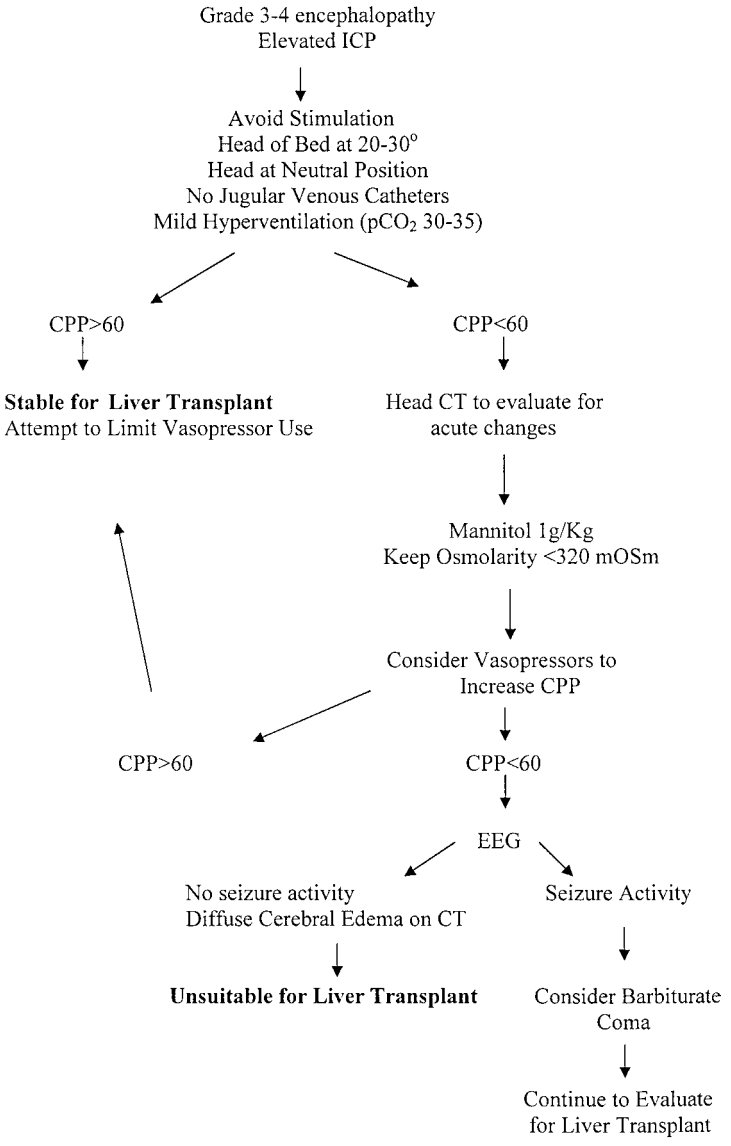

FIGURE 83-2 Management of intracranial hypertension.

Hemodynamic Management

Progression of FHF may lead to significant hemodynamic instability. Often, the hemodynamic changes resemble those associated with septic shock and include a hyperdynamic heart and a decreased systemic vascular resistance. Episodes of hypotension require aggressive evaluation and correction to prevent cerebral hypoperfusion, worsening injury to the blood-brain barrier, and multisystem organ failure. Although FHF is itself a common cause of hypotension (perhaps mediated by endotoxin[23]), each episode must be evaluated critically in order to recognize new sepsis, hemorrhage, myocardial dysfunction, or arrhythmia.[24]

Contrary to the management of septic shock, aggressive volume resuscitation has undesirable effects in FHF patients. Hypervolemia may contribute to pulmonary and cerebral edema from hydrostatic forces. Therefore, central venous or pulmonary artery monitoring are necessary to guide fluid and vasoactive drug use. When the ICP is being measured, CPP serves as the major parameter for titration of fluid and vasoactive therapy (goal >60 mm Hg) rather than the MAP. *N*-Acetylcysteine has shown some benefit in hemodynamic stabilization and improved oxygen consumption in FHF patients,[25] but its use has not expanded beyond acetaminophen-induced FHF.

Renal Failure

Acute renal failure is a frequent occurrence in the patients with FHF and is associated with a poor prognosis.[26] The incidence of renal insufficiently approaches 75% among patients with acetaminophen-induced FHF and 30% to 50% among patients with FHF from other causes.[27] Prerenal azotemia, acute tubular necrosis, hepatorenal syndrome, and nephrotoxic drugs may contribute to renal dysfunction and should be treated. One should maintain adequate intravascular volume, avoid and eliminate nephrotoxic agents, and ensure renal perfusion. Difficulties in the management of acute renal failure in the setting of FHF arise when indications for acute hemodialysis are met. Significant fluctuations in hemodynamic pressure and ICP have been demonstrated with intermittent hemodialysis in patients with FHF.[28] For this reason, continuous renal replacement therapies (e.g. CVVHD) are preferred in this setting. Regardless of the method, baseline serum osmolarity should be monitored and maintained under tight control because rapid changes in osmolarity may exacerbate interstitial cerebral edema.

Respiratory Failure

The onset of hypoxic respiratory failure usually is associated with the development of multisystem organ failure and predicts an overall poor prognosis. As an isolated event, hypoxia may be attributed to atelectasis, aspiration, pulmonary hemorrhage, acute respiratory distress syndrome (ARDS), or pneumonia. Diagnostic and therapeutic bronchoscopy generally should be avoided in these patients because of the potential to raise the ICP dramatically.

In patients with significant pulmonary dysfunction, the decision on suitability for liver transplantation is based largely on oxygen requirement and control of sepsis rather than on radiographic appearance. However, the presence of hypoxemia requiring greater than 60% FI_{O2} is likely to present difficulties with posttransplant management and survivability. During a liver transplant, reperfusion of a donor liver graft may exacerbate underlying pulmonary dysfunction, resulting in immediate right-sided heart failure. In addition, higher levels of positive end-expiratory pressure (PEEP) may reduce portal venous flow to the new graft,[29] provoking hepatoctye dysfunction. Thus preoperative assessment and optimization of respiratory function will have a significant impact on survival of a patient during and following liver transplantation.

Infectious Complications

Patients with FHF have a high incidence of bacterial and fungal infections. Most infections are diagnosed within 72 hours of hospital admission and commonly are localized to the respiratory and urinary tracts. Catheter-related sepsis is also common but usually occurs 72 hours after admission. Cultures often reveal *Staphylococcus aureus*, *Staphylococcus epidermidis,* and *Candida* spp. An analysis of infectious complications among patients with FHF revealed that up to 80% develop bacterial infections, whereas 30% develop fungal infections.[30] In addition, 18% of all patients with FHF ultimately died of infectious-related complications. Prevention, prophylaxis, and early detection are clearly the optimal approaches. Central venous catheters should be inserted using full barrier precautions and maintained with sterile technique (see Chaps. 4 and 12). When line sepsis is suspected, all lines must be removed and (if still necessary) replaced at alternative sites. Urinary catheters can be removed from anuric patients to limit the risk of an ascending urinary tract infection. We recommend prophylactic broad-spectrum antibiotic coverage at the time of hospital admission and adding antifungal coverage if sepsis develops while the patient is on the initial antibiotic regimen. This strategy is unproven and controversial, but it is supported by success in limiting postoperative infectious complications among patients with FHF.[31] Early initiation of prophylactic antibiotic therapy also can be justified on the basis that the development of infection may terminate a patient's candidacy for transplantation, the consequences of which may be lethal.

Systemic infection usually contraindicates transplantation because of the high level of immunosuppression subsequently required. However, this contraindication is not absolute when considering the patient with FHF because recovery depends so heavily on getting a transplant. Thus positive blood, urine, or respiratory cultures are acceptable in a patient urgently needing transplantation so long as there is no associated uncontrollable sepsis with hemodynamic instability. A further difficulty in the patient with FHF is assessing the severity of infection because some consequences of hepatic failure reduce the manifestations of infection (such as a reduced incidence of fever and leukocytosis), whereas others amplify them (such as vasodilatation and hyperdynamic circulation). Proceeding with transplantation in an infected patient with FHF must be a highly individualized decision, with clear delineation of the risk-benefit situation for all involved.

Liver Transplantation

The emergence of liver transplantation for the treatment of FHF has improved survival dramatically and should be considered the primary mode of therapy. Patients with evidence of encephalopathy should be referred to a tertiary care medical center with liver transplant capabilities and should be listed for emergency liver transplantation. The principal clinical dilemma is determining which patients with FHF should undergo liver transplantation and which patients will recover enough of their native livers to allow a reasonable chance of survival without transplantation. Adding to the complexity of decision making, the window of opportunity to benefit from a liver transplant is narrow. Therefore, the longer one waits to assess progress, the greater is the chance of missing the best treatment. One recent study demonstrated that the pretransplant median hospital stay was 3 days, whereas patients who did not receive a transplant died on median hospital day 5.[5] This underscores the need for prognostic indicators capable of predicting survivability of FHF without liver transplantation.

The U.S. Acute Liver Failure Study Group has presented data from 17 tertiary care centers on 308 consecutive patients with FHF.[5] The short-term patient survival was 67%. Twenty-nine percent of patients required liver transplantation, whereas 43% survived without transplantation. The only factor consistently associated with poor outcome was level of encephalopathy at the time of admission. Short-term transplant-free survival varied with the etiology of FHF. Patients with acetaminophen-induced FHF had a 68% survival compared with 25% and 17% for drug reaction and indeterminate-cause FHF, respectively. No consistent patient characteristic could be correlated with survivability without liver transplantation.

Attempts at developing criteria for determining the need for liver transplantation have met with only limited success. The Kings College criteria, developed after retrospective analysis of 580 patients with FHF, uses the following to predict outcome in non-acetaminophen-induced FHF: prothrombin time, age, etiology, time between onset of jaundice and onset of encephalopathy, and bilirubin levels. Criteria for patients with acetaminophen-induced FHF include factor V levels, blood pH, prothrombin time, serum creatinine concentration, and grade of encephalopathy. The Clichy criteria use factor V levels to assess severity of illness. Additional investigators have proposed alternative measurements, including serial prothrombin times,[32] factor VIII/V ratios,[33] serum Gc protein,[34] and Acute Physiology and Chronic Health Evaluation (APACHE) II score. Although both the Kings College and Clichy criteria identify factors that predict poor prognosis, neither provides a clear assessment of which individual patient will survive an episode of FHF without liver transplantation. Moreover, both criteria have failed to predict reproducibly which patients will or will not require liver transplantation.[35,36] Until better prognostic indicators can be developed to ascertain which patients with FHF will recover without liver transplantation, patients must be evaluated on a case-by-case basis.

Other Therapeutic Interventions

The high mortality associated with FHF has prompted the use of many innovative treatments in an effort to improve outcomes. Most of these treatments were embraced initially for their potential but failed in clinical trials. Some of these continue to be of interest for their potential benefit; none, however, are of proven benefit.

HIGH-VOLUME PLASMA EXCHANGE

High-volume plasma exchange is conducted similar to standard plasmapheresis protocols but with exchange volumes in excess of 8 L to improve the clearance of "harmful substances" that accumulate in FHF. The rationale for this approach is to reduce serum ammonia, control coagulopathy, and lower the metabolic demands on the injured liver. High-volume plasma exchange has been shown to reduce serum ammonia levels[37] and improve hemodynamics in the setting of FHF.[38] Although ammonia levels appear to be correlated with severity of encephalopathy, the exact mechanism involved is unknown.[39] In the pediatric population, high-volume plasma exchange has been shown to improve homeostasis and coagulation profiles.[40,41] All the studies have been uncontrolled, and none showed an improvement in overall survival. Randomized, controlled studies are needed before this potential treatment can be advocated.

STEROIDS

Steroid therapy has been tested under controlled conditions and does not confer benefit in clinical course or survival of patients with FHF.[42] Moreover, steroid therapy is ineffective for established cerebral edema.[43] Because steroids probably raise the risk of sepsis while being of no proven benefit, they have no role in the treatment of most FHF patients. One exception is the occasional patient with autoimmune hepatitis, in whom ongoing hepatic inflammation has culminated in FHF. For such patients, steroid therapy is beneficial and can significantly reverse liver failure.[44]

PROSTAGLANDIN E

Prostaglandins E_1 and E_2 (PGEs) have cytoprotective effects and raise hepatic arterial perfusion, both characteristics that could benefit FHF patient survival. However, two clinical trails from Europe and Canada have shown that use of PGEs is not associated with an improved outcome.[45,46] PGEs also may lower MAP, which could compromise CPP in patients with cerebral edema. Thus, until more compelling evidence is available, PGEs cannot be recommended.

AUXILIARY LIVER TRANSPLANTATION

Auxiliary liver transplantation has gained interest in Europe as a potential therapeutic option for FHF.[47] Essentially, a reduced-size liver graft, obtained from living or deceased donors, is transplanted without removal of the recipient's native liver. The potential advantage of this procedure is to provide temporary hepatic function while awaiting recovery of the native liver and then to halt immunosuppression, causing atrophy of the (now redundant) auxiliary liver graft. This approach has not been tested in controlled clinical trials, and it should only be carried out only in highly specialized liver transplant centers with experience in reduced-size and other innovative techniques in liver transplantation.

EXTRACORPOREAL LIVER SUPPORT

Extracorporeal liver-assist devices aim to provide temporary liver function as a bridge to liver transplant or to provide time for recovery of native liver function. There have been many different approaches to supporting liver function extracorporally, including ex vivo whole-organ perfusion,[48] nonbiologic systems using dialysis against charcoal and anion-exchange adsorption (Molecular Adsorbent Recirculating System [MARS][49]), combined nonbiologic-biologic systems that use both synthetic dialysis adsorption and hepatocyte cell mass (HepatAssist[50]), and purely biologic systems that use porcine hepatocytes (AMC Bioreactor[51]) or human hepatoma cell lines (ELAD).[52] Many of these systems continue to be investigational, but some are promising. The combined nonbiologic-biologic system HepatAssist was evaluated in the largest, randomized phase I and II trails reported for extracorporeal liver support systems. A total of 171 patients with FHF ($n = 147$) or primary nonfunction (PNF) ($n = 24$) following liver transplant were randomized to receive standard medical management or medical management with the addition of HepatAssist. Overall, there was no statistically significant survival difference between the groups. However, subgroup analysis demonstrated a significant improvement in outcome following liver transplant in the HepatAssist group and a considerable improvement in a secondary end point (time to death) in patients with acetaminophen toxicity who ultimately underwent liver transplantation. Although extracorporeal liver-assist systems retain promise, they are only available investigationally.

Chapter 84

MANAGEMENT OF THE PATIENT WITH CIRRHOSIS

ROHIT SATOSKAR
DAVID T. RUBIN

KEY POINTS

- *Patients with cirrhosis admitted to the ICU are at risk of death due not only to liver disease, but also due to the many complications to which such patients are at risk.*
- *Worsening encephalopathy and loss of the gag reflex are indications for elective intubation in order to forestall potentially catastrophic aspiration or respiratory arrest.*
- *Invasive procedures carry extra risk in cirrhotics. When a procedure must be performed, care should be taken to minimize the likelihood of hemorrhagic complications.*
- *Spontaneous bacterial peritonitis should be considered and excluded in all cirrhotics with fever, encephalopathy, abdominal pain, or sepsis.*
- *Neomycin and metronidazole are superior to lactulose for the treatment of hepatic encephalopathy.*
- *The MELD score is a reliable method for predicting 3-month mortality and is currently used to determine transplant status.*
- *Transplant candidates who are deteriorating from chronic liver disease or its complications should be transferred to a transplant center for management.*

Liver disease in the ICU may be secondary to the acute illness of patients or a complication of chronic disease. The focus of this chapter is to outline issues in the care of those with severe chronic liver disease, namely cirrhosis. Patients with cirrhosis who are admitted to the ICU have a very high risk of death. This stems not only from the underlying liver disease, but also from the complications to which these patients are prone. This chapter discusses the etiology of cirrhosis, the pathophysiology that leads to the complexity in management, common complications of cirrhosis, and a systematic approach to management of the critically ill liver patient. Hospitalized cirrhotic patients are more likely to die or to develop sepsis and respiratory failure than similar patients without cirrhosis. Due to the wide variety of complications and disease manifestations experienced by cirrhotic patients in the intensive care unit, a multidisciplinary approach involving gastroenterologists, hepatologists, intensivists, and transplant physicians must be employed. Particular attention should be given to preventing infection, assuring adequate nutrition and airway protection, and aggressively treating established infection, ascites, electrolyte disturbances, coagulopathy, encephalopathy, and bleeding.

Transfer to ICU

Patients with stable chronic liver disease may suffer from decompensation due to progression of the underlying liver disease or to a comorbid illness that overwhelms the reserve of the diseased liver. Decompensation may be characterized by acute deterioration of otherwise stable clinical parameters such as mental status, coagulation, or hemodynamics. These patients may deteriorate rapidly, and therefore should be monitored closely with a low threshold for transfer to the ICU. Indications for transfer to the ICU include hemodynamic instability, suspected sepsis, decline in mental status, and need for more intensive nursing care.

Etiology

The etiology of cirrhosis can vary greatly (Table 84-1) yet the clinical manifestations and complications due to scarring and fibrosis are similar. Therefore the approach to treatment and management of the cirrhotic is similar no matter what the underlying basis of the liver disease.

Pathophysiology of Portal Hypertension

The majority of complications in patients with cirrhosis arise from hemodynamic changes. The hemodynamic changes seen in cirrhosis can be divided into portal hypertension and a systemic hyperdynamic state. Most cirrhotic patients have increased resistance to portal blood flow as a result of intraparenchymal fibrosis and architectural distortion. In healthy livers, the portal vein comprises approximately two-thirds of the blood flow to the liver, carrying poorly oxygenated but nutrient rich blood from the gut, while the hepatic artery delivers the remaining one-third with primarily oxygen rich blood. The delivered blood enters at the portal triad and subsequently feeds the hepatic sinusoids. The progressive fibrosis associated with many chronic liver diseases eventually results in bridging between portal tracts and subsequent increased resistance to blood flow. As the portocaval gradient increases above the normal range of 2 to 6 mm Hg, collateral blood flow develops that may cause variceal bleeding and encephalopathy.

The hemodynamic state seen in cirrhosis results from decreased effective circulating volume due to massive splanchnic dilation. The forward increase in capillary pressure results in increased lymph oncotic pressure, contributing to production of ascites. The response of the kidneys to arterial underfilling results in activation of the renin-angiotensin system, further contributing to sodium and water retention, and may cause hepatorenal syndrome.

Cirrhosis is also accompanied by systemic circulatory dysfunction, owing largely to splanchnic arterial vasodilation. Nitric oxide (NO), a potent vasodilator elevated in the splanchnic circulation of cirrhotic patients, is thought to reduce the effective arterial blood volume and activate compensatory vasoconstrictors and antinatriuretic factors. Fluid and sodium retention as well as renal dysfunction follow as consequences of arterial underfilling. Hypoalbuminemia and increased splanchnic lymphatic hydrostatic pressure combine with sodium retention to produce ascites and edema.

Severe right-sided heart failure

General Supportive Measures

SURVEILLANCE FOR INFECTION

Infection is common in patients suffering from chronic liver disease. Analysis of 1.7 million patients with cirrhosis from the National Hospital Discharge Summary reveals that patients with cirrhosis are more likely to have hospitalizations associated with sepsis (adjusted relative risk [RR] 2.6) and to die from sepsis (adjusted RR 2.0) than patients without cirrhosis. Other studies have corroborated that patients with cirrhosis who develop bacterial sepsis in the ICU setting are more likely to die than those without cirrhosis.[1] Urinary tract infection is the most frequently encountered, followed by infections of ascites, blood, and the respiratory tract.[2]

The increased incidence of infection leads to both longer hospital stays and increased mortality. While the incidence of infection is elevated in all patients with cirrhosis, patients whose hepatic disease is secondary to alcohol use appear to have an elevated risk.[3] Specific to the ICU setting, the use of invasive monitoring techniques and instrumentation places the patient at even higher risk for introduction of infection.

PATHOPHYSIOLOGY

The propensity for infection in cirrhotic patients is believed due to decreased complement levels, impaired phagocytic activity of macrophages, and impaired neutrophil activity. A prospective study of 49 cirrhotic patients showed that the function of macrophage Fcγ receptors is impaired, resulting in decreased phagocytic ability.[4] The presence of extensive portosystemic collaterals that bypass the reticuloendothelial system, decreased complement levels due to poor hepatic synthesis, and ineffective opsonization may also contribute to the cirrhotic patient's heightened risk of infection.

MANAGEMENT RECOMMENDATIONS

All decompensating patients with cirrhosis should be closely investigated for infection by obtaining cultures of blood, urine, and ascites; analyzing urine and ascitic fluid; examining invasive hardware; and when appropriate, imaging potential sources of sepsis. Patients who exhibit fever or signs of impending sepsis should be treated with broad-spectrum antimicrobial therapy pending confirmation of infection.

AIRWAY PROTECTION

Decompensated cirrhotics often develop airway compromise and respiratory failure. Worsening of hepatic encephalopathy, aspiration, variceal bleeding, and the consequences of sepsis can precipitate respiratory decompensation. Progressively worsening mental status or loss of gag reflex are indications for intubation. Timely elective intubation in such a situation, or prior to high-risk procedures such as endoscopy, can prevent catastrophic respiratory deterioration. Analysis of large numbers of cirrhotic patients has revealed that underlying chronic liver disease places patients at higher risk for acute respiratory failure and resultant death.[5] In addition, cirrhosis is an independent predictor of death in patients who meet criteria for acute respiratory distress syndrome.[6]

COAGULOPATHY

Coagulopathy in patients with chronic liver disease generally arises from low levels of circulating clotting factors secondary to decreased hepatic synthesis. In addition, the risk for bleeding may be increased by underlying malnutrition and vitamin K deficiency as well as thrombocytopenia due to splenic sequestration. All patients with chronic liver disease and an elevated prothrombin time should receive parenteral vitamin K to correct any underlying vitamin K deficiency. In the setting of severe cholestasis, oral vitamin K may be absorbed poorly and unreliably. Great care must be taken when contemplating invasive procedures so that only truly necessary procedures are performed, experienced practitioners are available to perform or supervise them, and that reasonable measures to reduce hemorrhagic risk are taken when practical. Actively bleeding cirrhotics should be transfused with fresh frozen plasma and platelets, guided when possible by measurements of coagulation and platelet count. Since underlying coagulopathy and mechanical ventilation are independent risk factors for gastrointestinal bleeding,[7] our practice is to use H_2 blockers or proton pump inhibitors prophylactically to reduce this risk. Variceal hemorrhage, a catastrophic complication of portal hypertension, is discussed fully in Chap. 82.

NUTRITION

Decreased oral intake as well as underproduction may cause protein calorie malnutrition. The severity of underlying liver disease correlates directly with its degree. In addition, the increasing severity of malnutrition predicts mortality. The majority of cirrhotic patients in the ICU will already have some degree of preexisting malnutrition so that every effort should be made to prevent further deterioration. Unfortunately, even enteral supplementation late in the setting of advanced cirrhosis appears to have no benefit on survival.[8]

TABLE 84-2 Diagnostic Paracentesis

Always Send	Sometimes Send	Rarely Send	Unhelpful
Cell count	Lactate dehydrogenase	Cytology	pH
Culture	Amylase	Triglycerides	Lactate
Total protein	Gram stain	Tuberculosis smear/culture	Tumor markers
Albumin (on first paracentesis)	Glucose	Adenosine deaminase	Cholesterol

Complications of Cirrhosis

ASCITES

The majority of patients with cirrhosis will have ascites at presentation. Ascites can be detected on physical examination using various techniques. In patients with known cirrhosis and a largely distended or tense abdomen, the presence of ascites may be obvious, but in other patients percussion of the abdomen for flank dullness or shifting dullness and the presence of a fluid wave can confirm the diagnosis. However, physical exam is not a sensitive way to determine the presence or absence of a mild or moderate amount of ascites. Ultrasound provides a readily available, quick, and inexpensive way to determine the amount and location of ascites and to facilitate paracentesis. Computed tomography also shows the presence and extent of ascites, but is more cumbersome than ultrasound.

DIAGNOSTIC PARACENTESIS

Examination of ascitic fluid is crucially important in the cirrhotic with new-onset ascites, clinical deterioration, change in mental status, or fever. This procedure can be performed using a commercial kit or by using a 14- to 18-gauge IV catheter. The peritoneal cavity can be entered in the midline (infraumbilical) or in the lower quadrants, taking care to avoid the inferior epigastric vessels and any grossly dilated abdominal wall veins. Ascitic fluid obtained from a diagnostic paracentesis should be sent for cell count, culture, and total protein concentration. Inoculating blood culture bottles at the bedside prior to sending them to the laboratory increases clinical yield.[9] Other tests that may be helpful in selected situations are highlighted in Table 84-2. Large-volume ascites and the presence of a tense abdomen are indications for large-volume paracentesis, especially when the patient's respiratory status is compromised due to the restrictive effect on the diaphragm.

SPONTANEOUS BACTERIAL PERITONITIS

One of the primary reasons to perform diagnostic paracentesis in the ICU is to detect the presence of infection, most importantly spontaneous bacterial peritonitis (SBP). SBP should be suspected in a cirrhotic with fever, abdominal pain, encephalopathy, or acute hemodynamic decompensation. Previous studies have shown that regardless of the reason a patient with cirrhosis requires admission to the hospital, a diagnostic paracentesis will reveal evidence of SBP in 7% to 17%, so any patient with ascites who is transferred to the ICU should be monitored carefully for SBP.[10] Definitive diagnosis of SBP is made by finding >250 polymorphonuclear leukocytes (PMNs)/mm^3 on diagnostic paracentesis, as well as a culture positive for a single organism. If only one of the above criteria is met the condition is termed culture-negative neutrocytic ascites or bacterascites, respectively (Table 84-3), but this is generally treated the same as confirmed SBP. Culture of more than one bacterial species should prompt suspicion for secondary peritonitis or perforated viscus. The bacterial pathogens that cause SBP are typically *Escherichia coli* (43%), *Streptococcus* species (23%), or *Klebsiella pneumoniae* (11%). Anaerobic organisms, *Enterococcus* spp., and *Pseudomonas* spp. are rarely involved. Treatment of SBP requires parenteral antibiotics that cover these common pathogens. Those with evidence of SBP should be treated with an intravenous third-generation cephalosporin such as cefotaxime at a dose of 2 g IV every 8 hours.[11] Treatment for 5 days appears equivalent to a longer regimen of 10 days.[12] Evidence also suggests that patients at risk for SBP (i.e., ascitic protein <1 g/dL, gastrointestinal hemorrhage, and previous episode of SBP) should be given prophylaxis with an oral fluoroquinolone.[13] Unfortunately, increasing frequency of quinolone-resistant SBP and gram-positive infection, especially in the ICU setting, may be related to such long-term prophylaxis.[14] Once a particular organism is identified, antibiotic coverage can be narrowed. In patients who do not adequately respond or continue to worsen on empiric antibiotic

TABLE 84-3 Diagnosis of Peritonitis

	Spontaneous Bacterial Peritonitis	Culture-Negative Neutrocytic Ascites	Bacterascites	Secondary Peritonitis
PMN count (cells/mm^3)	>250	>250	<250	>250
Culture	Single organism	Negative	Single organism	Multiple organisms
Protein	Usually low	Usually low	Usually low	Usually >1g/dL
LDH	Normal	Normal	Normal	High
Glucose	Normal	Normal	Normal	Low
Treatment	Third-generation cephalosporin	Third-generation cephalosporin	Directed antibiotics	Empiric broad-spectrum antibiotics, surgical intervention

LDH, lactate dehydrogenase; PMN, polymorphonuclear leukocyte.

coverage, the antibiotic regimen should be revised and alternative bases for treatment failure considered.

MANAGEMENT OF ASCITES

Sodium restriction and diuretics are first-line treatments in the management of ascites. Patients should not receive more than 2 g sodium (88 mEq) per day. Optimal treatment usually involves the combination of spironolactone with a loop diuretic. It is our practice to maintain a ratio of 40 mg of oral furosemide to 100 mg of oral spironolactone. In patients with severe liver compromise, spironolactone should only be administered once daily, as the half-life is increased by hepatic insufficiency. These doses can be increased to 160 mg of furosemide and 400 mg of spironolactone daily if the patient has stable renal function. The dose of diuretics should be reduced if the patient develops increasing hyponatremia or worsening renal function.[15]

DIURETIC-RESISTANT AND RECURRENT ASCITES

Repeated large-volume paracentesis of up to 4 to 6 L/day can be performed safely in patients who are diuretic resistant or difficult to control. Postparacentesis circulatory dysfunction, characterized by decreased peripheral vascular resistance, increased plasma renin activity, hyponatremia, and azotemia has been described in patients receiving large-volume paracentesis without volume expansion.[16,17] Paracentesis of 6 L or more should be supplemented by intravenous albumin at 6 to 8 g per liter removed. In patients undergoing paracentesis of less than 6 L, no fluid replacement may be needed or normal saline can be given.[18] Transjugular intrahepatic portosystemic shunting (TIPSS) should be considered for patients who are unable to tolerate diuretics or are diuretic resistant.[19]

COMPLICATIONS OF PARACENTESIS

Paracentesis is considered a relatively safe procedure, with the most common complication being persistent drainage from the abdominal wall. Significant bleeding complications even in patients with thrombocytopenia and coagulopathy are rare, so it is not necessary to routinely administer blood products to all patients.[20] Abdominal wall hematoma and hemoperitoneum occur rarely and may require investigation in patients who develop severe hemodynamic instability after paracentesis.

ELECTROLYTE DISTURBANCES

HYPONATREMIA

Up to 30% of cirrhotic patients with ascites have hyponatremia. Elevated levels and increased half-life of vasopressin contribute to the inability to excrete free water. Even modest decreases in serum sodium may have an adverse effect on hepatic encephalopathy. In general, severe hyponatremia indicates a poor prognosis. The presence of this electrolyte abnormality becomes more important in the ICU when diuretics, fluids for nutrition, or vasopressin analogues are given for sepsis or variceal bleeding. Patients with moderate to severe hyponatremia should be placed on free water restriction with strict monitoring of input and output.[21] Diuretics should be given judiciously and use of vasopressin analogues should be limited. Recent studies of an orally active vasopressin V2 receptor antagonist suggest that this therapy has promise in correcting hyponatremia and fluid overload in this patient population.[22]

HYPERKALEMIA

Widespread use of potassium-sparing diuretics and predisposition to development of renal failure in severe liver disease can cause hyperkalemia. As in any other setting, severe hyperkalemia is a relative emergency and should be managed accordingly. Potassium-sparing diuretics should be discontinued with the knowledge that the half-life of drugs such as spironolactone is increased in the setting of liver disease. Sodium polystyrene compounds may be used cautiously with attention given to further sodium and water retention.[23]

HEPATIC ENCEPHALOPATHY

Cirrhosis is frequently complicated by the presence of hepatic encephalopathy (HE) or portosystemic encephalopathy (PSE). HE can be characterized as a range of neurologic and psychiatric disorders caused by underlying severe liver disease in the absence of other known neurologic disease. In cirrhosis, HE is generally reversible if a precipitant can be determined.

PATHOPHYSIOLOGY

Though HE is commonly recognized clinically, the lack of standardization to describe the syndrome has led to difficulty in determining the pathophysiology and performing valid clinical trials. HE in chronic liver disease likely results from the actions of circulating substances on the brain that are normally cleared by the working liver. Ammonia has long been implicated in the pathogenesis of encephalopathy, though serum levels tend to correlate poorly with grade of encephalopathy. Evidence currently suggests that the astrocyte is a key to the development of hepatic encephalopathy. Astrocytes treated in vitro with ammonia show morphologic changes similar to those seen in vivo in both humans and animals with chronic liver disease and HE. These changes also include alterations seen in Alzheimer's type II astrocytosis. Changes in astrocytes, which normally regulate the extracellular environment and excitability of neurons, result in changes in neurotransmission. Elevated serum ammonia levels decrease glutamate uptake by astrocytes and increase extracellular glutamate concentrations. These changes in glutamate metabolism may be responsible for the disordered neurotransmission seen in HE. Other studies have implicated increased tone at γ-aminobutyric acid (GABA) receptors due to endogenously-derived benzodiazepines in HE. The peripheral-type benzodiazepine (PBR) receptor, located on the outer mitochondrial membrane of astrocytes, has been shown to be upregulated both in postmortem human brains from encephalopathic patients, and in vitro by astrocytes exposed to ammonia. The PBR is intimately involved in regulating synthesis of neurosteroids, which are potent ligands of the GABA-A receptor. Finally, in vitro, astrocytes exposed to elevated manganese levels show similar changes in glutamate uptake to those exposed to ammonia. Interestingly, the increased signal seen on T1 magnetic resonance imaging of the basal ganglia in the majority of cirrhotic patients has been attributed to manganese, and suggests that it has a role in the pathogenesis of HE.[24–27]

CLINICAL MANIFESTATIONS

Due to the lack of standardization in defining and clinically diagnosing HE, a working party was assembled in 1998

and recently published a consensus statement. Type A encephalopathy is defined as that associated with acute liver failure. Type B encephalopathy is that associated with portosystemic bypass in the absence of underlying hepatocellular disease. Type C encephalopathy is that associated with cirrhosis and portal hypertension or portosystemic shunts. Type C hepatic encephalopathy, the focus of this chapter, is further subdivided into minimal, episodic, and persistent. Episodic encephalopathy can further be divided into spontaneous (without a known precipitant), precipitated, and recurrent. Precipitants include drugs that alter mental status, GI bleeding, overdiuresis, azotemia, electrolyte abnormalities, or infection. Recurrent encephalopathy is defined as two or more episodes occurring within 1 year. Minimal encephalopathy is brain dysfunction in the absence of clinical symptoms. Stages of hepatic encephalopathy can range from derangements only detectable by psychometric testing to overt coma. Early findings may include depression, reversal of the sleep-wake cycle, or difficulty concentrating. As encephalopathy worsens, physical signs such as asterixis and "milk-maid's grip" become apparent. Still later, the patient may progress to increasing confusion, obtundation, and overt coma.[28] In the intensive care unit, protection of the airway is most critical in patients entering the later stages of encephalopathy (stages 3 and 4). Patients who have lesser degrees of encephalopathy in the setting of cirrhosis should be treated and offending factors removed to prevent escalation of the problem (Table 84-4).

TREATMENT

The presence of worsening encephalopathy warrants a search for underlying precipitants (Table 84-5). If possible, psychoactive drugs such as narcotics and benzodiazepines should be discontinued immediately. Underlying occult and overt gastrointestinal bleeding and infection should also be ruled out and treated if present. Electrolyte abnormalities should be corrected. Once underlying precipitants have been sought and adequately managed, treatment of hepatic encephalopathy is aimed at reducing further absorption of toxins from the gut. Lactulose, a nonabsorbable disaccharide, can be administered orally every 1 to 2 hours until a bowel movement is produced. At this point, lactulose can be given at regular intervals to produce two to three soft bowel movements per day. Lactulose likely exerts its effects by reducing absorption of toxins from the gut, both by decreasing transit time through the gut, as well as by altering the luminal pH. The change in pH effectively converts intraluminal ammonia to a quaternary ion and hinders its absorption. Despite the widespread use of lactulose and other nonabsorbable disaccharides for HE, a recent review of 22 trials showed the benefit of these therapies to be mild or nil, and inferior to antibiotics.[29] Therefore if lactulose fails to improve encephalopathy, antibiotics such as neomycin and metronidazole, which presumably alter the gut flora, should be given.[30] More recently, a novel nonabsorbed antibiotic (rifaximin) has been studied in hepatic encephalopathy with encouraging results.[31] Although available in the U.S., this product is not yet FDA-approved for treatment of HE. Based on the "endogenous benzodiazepine" hypothesis of hepatic encephalopathy, the use of flumazenil, a benzodiazepine antagonist, has been studied and may have some beneficial effects in severe HE. A randomized, placebo-controlled study of 527 cirrhotic patients with stage 3 and 4 encephalopathy revealed improvement of both neurologic and electroencephalographic scores after administration of flumazenil with lactulose. Use of flumazenil in unselected patients with hepatic encephalopathy has not been validated.[32]

HEPATORENAL SYNDROME

Renal dysfunction occurs at a high rate in patients with advanced cirrhosis. In the setting of advanced liver disease, hepatorenal syndrome (HRS) is defined as the development of

TABLE 84-4 Stages of Encephalopathy

	Findings	Asterixis	EEG Changes
Stage 0	No detectable changes in personality or behavior	Absent	None
Stage I	Depression, changes in sleep-wake cycle, behavioral changes, inattention, poor concentration	Usually absent	Usually none
Stage II	Mild somnolence or lethargy, inappropriate behavior	Grossly present	Diffuse slowing
Stage III	Increased somnolence, gross disorientation	Present or Absent	Abnormal
Stage IV	Coma	Absent	Abnormal

EEG, electroencephalographic.

renal failure with normal renal histology in the absence of nephrotoxic drugs, sepsis, intrinsic renal disease, and hypovolemia. Hepatorenal syndrome usually occurs in the setting of advanced liver disease with ascites and is often a lethal complication. It occurs in up to 39% of patients with underlying cirrhosis and ascites within 5 years.[33] Hepatorenal syndrome is divided into two types, based on severity of kidney dysfunction. Type I hepatorenal syndrome is rapidly progressive, defined as doubling of the serum creatinine level to >2.5 mg/dL or a 50% reduction in 24-hour creatinine clearance to a level <20 mL/min in less than 2 weeks. Type II HRS progresses slowly and renal function may remain stable for extended periods of time. Precipitants of hepatorenal syndrome may include excessive diuresis, use of prostaglandin inhibitors such as nonsteroidal anti-inflammatory drugs, and large-volume paracentesis or underlying critical illness such as sepsis, hypovolemia, or gastrointestinal bleeding. Severe electrolyte abnormalities (e.g., hyponatremia) and fluid overload are common once renal dysfunction is established, and these must be frequently sought and treated. Medications affected by renal dysfunction may require dose reduction.

PATHOPHYSIOLOGY

The pathogenesis of hepatorenal syndrome appears to be due to severe renal vasoconstriction and decreased renal perfusion. In the peripheral vasodilation model of advanced liver disease, the kidneys perceive a persistent prerenal state and adapt accordingly through vasoconstriction. Activation of the renin-angiotensin system results in increased levels of angiotensin and aldosterone. Levels of antidiuretic hormone and norepinephrine also increase, causing severe renal vasoconstriction. As a consequence, sodium and water retention is exaggerated, exacerbating both ascites and peripheral edema. Early in cirrhosis, the kidneys adapt by overproducing renal prostaglandins, resulting in renal vasodilation and preservation of renal perfusion and function. The importance of prostaglandins in preserving renal function explains the cirrhotic patient's increased sensitivity to the effects of prostaglandin inhibitors such as nonsteroidal anti-inflammatory drugs. As liver disease progresses and splanchnic vasodilation predominates, the heightened effects of potent vasoconstrictors dominate the kidney and override the prostaglandin effect, leading to the hepatorenal syndrome.[34]

DIAGNOSIS

Hepatorenal syndrome is diagnosed in the setting of advanced liver disease by excluding other causes of renal failure. In the ICU, patients may have multiple reasons for renal failure. Other causes need to be systematically excluded prior to delivering a diagnosis of HRS. In diagnosing HRS, underlying intrinsic renal disease should be ruled out by examining urine sediment and imaging the kidneys with ultrasound. Nephrotoxicity due to drugs such as aminoglycosides, cyclosporine, and tacrolimus should also be considered. Hypovolemia can closely mimic HRS and deserves special mention here. Patients should be given a fluid challenge of 1.5 L normal saline with repeat measurement of serum creatinine. No change in the value supports the diagnosis of HRS. Acute tubular necrosis, commonly seen in the critical care setting, can be differentiated from HRS through measurement of the urine sodium. Urine sodium is usually <10 mEq/L in HRS and >20 mEq/L in acute tubular necrosis. In 1998, the International Ascites Club proposed consensus criteria for diagnosis of HRS. In addition to the presence of chronic or acute liver disease with advanced hepatic failure and portal hypertension, major criteria include: (1) serum creatinine >1.5 or creatinine clearance <40 mL/min, (2) absence of shock, bacterial infection, nephrotoxic drugs and fluid losses, (3) no improvement in serum creatinine following withdrawal of diuretics and 1.5 L fluid challenge with normal saline, and (4) proteinuria <500 mg/dL and normal renal ultrasound.[35]

PREVENTION

While prevention of HRS largely depends on the natural history of the underlying liver disease, the setting of spontaneous bacterial peritonitis warrants special consideration. One third of patients with SBP will develop some degree of renal impairment.[36] Recent evidence suggests that intravenous albumin administration during treatment of SBP can prevent development of renal impairment. In a study of 126 patients with cirrhosis and SBP, administration of intravenous albumin along with an antibiotic resulted in a decreased development of renal impairment and decreased mortality. Patients were randomized to receive cefotaxime or cefotaxime plus intravenous albumin (1.5 g/kg on day 1, followed by 1 g/kg on day 3). Rates for development of nonreversible renal impairment during hospitalization were 33% vs. 10% in the antibiotic and antibiotic plus albumin groups, respectively. At 3 months, the mortality rate for the combined treatment group was nearly half that of the antibiotic-alone group.[37]

TREATMENT

Of the complications of cirrhosis, HRS has the worst prognosis. Expected median survival time is 2 weeks and 6 months for type I and II HRS, respectively. Liver transplantation is the only definitive means for reversal and cure of HRS. Unfortunately, in the critically ill, concomitant factors such as sepsis may render the patient unsuitable for transplant. Generally, patients in the ICU with HRS should have aggressive monitoring of fluid balance and weight, as well as evaluation and treatment of electrolyte abnormalities. Fluid overload and refractory ascites are common in patients with HRS. Patients with type I HRS should be managed with fluid restriction to avoid a positive fluid balance. Fluid overload in type II HRS can be managed with diuretics as long as a significant natriuresis is obtained. Potassium-sparing diuretics should be discontinued or used very cautiously in both groups to avoid hyperkalemia. Renal replacement therapy may be needed for patients with severe electrolyte disturbance, fluid overload, or acidosis. Vasoconstrictor therapy has been relatively well studied in the treatment of HRS. The theory behind treatment with vasoconstrictors suggests that administration results in constriction of the dilated splanchnic circulation, alleviating the intense vasoconstriction caused by endogenous vasoconstrictors released by the renal axis. Both vasopressin analogues and α-adrenergic agonists in combination with intravenous albumin have been studied in this setting. Terlipressin, a vasopressin analogue that acts at V1 receptors, when administered with albumin, resulted in improved renal function in 60% of patients, suppression of the renin-angiotensin and sympathetic systems, and a survival advantage in those who responded. Complete responders to terlipressin treatment have a low recurrence rate of HRS. While median survival time is only increased moderately,

this may allow enough time for definitive treatment by liver transplantation.[38,39] The use of midodrine, an orally administered α-adrenergic agonist, along with octreotide also improved renal function for a large majority of patients, while octreotide alone seems to have no effect.[40,41] The use of TIPSS appears to improve renal function in patients with both type I and II HRS.[42,43] In type I HRS, TIPSS should be considered in patients who fail to respond to vasoconstrictors. In type II HRS, TIPSS results in decreased progression to type I HRS, improved hemodynamics, and benefit for refractory ascites, but overall survival is unchanged compared to patients managed with repeated paracentesis and intravenous albumin.[43,44]

HEPATOPULMONARY SYNDROME

The relationship between severe liver disease and pulmonary abnormalities has long been recognized. Pulmonary disease secondary to hepatic injury can be divided into hepatopulmonary syndrome (HPS) and portopulmonary hypertension. Hepatopulmonary syndrome, characterized by an increased alveolar-arterial oxygen gradient $(A\text{-}a)_{O_2}$, varying degrees of hypoxemia, and pulmonary vasodilation in the setting of liver disease is more common than previously thought. Recent studies suggest that up to 47% of patients with cirrhosis have some degree of pulmonary vasodilation detectable by diagnostic studies.[45] The pathogenesis of the HPS lies in vasodilation of the capillary and precapillary beds of the lung due to increased circulating vasodilators such as nitric oxide (NO) in severe liver disease. In some patients, hypoxemia is seen due to dilation of the pulmonary vasculature that results in right-to-left shunting. In others, ventilation-perfusion mismatch causes hypoxemia, and other theories have been proposed. Clinical manifestations of HPS include platypnea, orthodeoxia, and reduced diffusing capacity for carbon monoxide. Platypnea, defined as dyspnea in the upright position that is relieved by lying supine, and orthodeoxia, which is defined as arterial deoxygenation in the upright position that is relieved by recumbancy, are seen in a majority of patients with severe hypoxemia. In the ICU setting, the importance of HPS lies in the increased mortality of these patients. A recent prospective study of 111 patients with cirrhosis showed that the presence and severity of HPS were independent risk factors for death.[46] HPS is diagnosed by demonstrating an increased age-adjusted $(A\text{-}a)_{O_2}$ along with intrapulmonary vascular dilation. Perfusion scanning using technetium 99m-labeled macroaggregated albumin and subsequent demonstration of uptake in the kidneys or brain suggests intracardiac or intrapulmonary shunt. More commonly and easily, the shunt may be demonstrated by contrast echocardiography using microbubbles. The presence of the microbubbles in the left side of the heart after four to six cardiac cycles demonstrates the intrapulmonary shunt.[47] Despite significant ventilation-perfusion mismatch, some cirrhotic patients may not manifest hypoxemia due to increased cardiac output and hyperventilation. This may bear on the cirrhotic patient who becomes critically ill, because as oxygen consumption rises or cardiac output becomes limited, the gas-exchange defect may become manifest.

TREATMENT

Medical therapies in general have proved ineffective for the treatment of HPS. Supplemental oxygen may only temporarily correct the underlying hypoxemia. For many years, hypoxemia has been a contraindication to liver transplantation. Recently, studies showing reversal of the findings of HPS in transplanted patients have resulted in rethinking of this doctrine.[48] As a result, HPS is an indication for orthotopic liver transplantation. However, perioperative complications are frequent in these patients, and at times the resolution of hypoxemia is very protracted, even following successful transplantation. Since the institution of the model for end-stage liver disease (MELD) score in 2002, the United Network for Organ Sharing now reviews cases of hepatopulmonary syndrome for possible assigning of additional points.

PORTOPULMONARY HYPERTENSION

Portopulmonary hypertension is the presence of mean pulmonary pressure >25 mm Hg in the presence of portal hypertension and the absence of left heart failure. The condition is present in 5% to 10% of patients undergoing evaluation for liver transplant. Overall, mortality is greatly increased, with a median survival time of 6 months.[49] Many medical therapies have been tried in the setting of portopulmonary hypertension, yet long-term studies and adequate guidelines are lacking. Intravenous prostacyclin, β-blockers, nitrates, and inhaled NO all show promise in treatment of this condition. Multiple reports show improvement of pulmonary artery pressure (PAP) after liver transplantation, but intraoperative and perioperative mortality is high for patients with a mean PAP >40.[50–52]

LIVER TRANSPLANTATION

Judging expected survival and allocating available donor livers for liver transplantation has historically raised questions rooted in both medicine and ethics. The Child-Turcotte-Pugh (CTP) classification, based on degree of encephalopathy, amount of ascites, serum bilirubin, albumin, and prothrombin time, predicts both survival and surgical risk in cirrhotic patients. Until 2002, the CTP classification was intricately tied to allocation of donor livers. Unfortunately, the classification inherently had values that lacked objectivity in predicting survival. The MELD score was developed prospectively, using methodologically accurate methods and continuous variables, in contrast to the CTP score, and is currently used to stratify potential liver recipients.[53]

MODEL FOR END-STAGE LIVER DISEASE

The model for end-stage liver disease (MELD), a purely objective measurement adopted by the Organ Procurement and Transplantation Network (OPTN) in 2002, has been validated in many studies to predict survival.[54] (Table 84-6). The MELD score is now used as one measure in allocation of donor livers

TABLE 84-6 Calculating the Model for End-Stage Liver Disease (MELD) Score

$$\text{MELD score} = [0.957 \times \text{Log}_e(\text{creatinine mg/dL}) + 0.378 \times \text{Log}_e(\text{bilirubin mg/dL}) + 1.120 \times \text{Log}_e(\text{International Normalized Ratio}) + 0.643] \times 10$$

Round to the nearest whole number. Laboratory values less than 1 are set to 1 for the purposes of the MELD score calculation. The maximum serum creatinine considered within the MELD score equation is 4 mg/dL.

and has been validated in patients on the transplantation waiting list. The MELD score predicts severity of liver disease based on serum creatinine, serum bilirubin, and International Normalized Ratio. The variable for etiology of liver disease has been omitted in the currently used classification. Three-month mortality with a MELD score <9 is 1.9%. Three-month mortality with a MELD score of ≥40 is 71%.[55,56]

Chapter 85

ACUTE PANCREATITIS IN THE CRITICALLY ILL

BRYCE R. TAYLOR

KEY POINTS

- *Hypoperfusion injury is the most important of many possible causes of pancreatitis in the ICU setting.*
- *Serial computed tomography is most useful in confirming the diagnosis and in following the inflammatory process.*
- *The likelihood of multisystem failure is high, and preventive measures must be instituted early.*
- *Initial treatment is supportive, with aggressive fluid and electrolyte replacement and close monitoring of hemodynamic, pulmonary, and renal status.*
- *Surgical intervention is indicated for deteriorating patients with a surgically correctable lesion and in patients with complications of the disease, such as major hemorrhage, abscess, or symptomatic pseudocyst.*
- *Close supervision by an experienced abdominal surgeon in collaboration with an intensivist is important in recognizing the indications for surgical exploration.*

Acute pancreatitis can be a frustrating disease to diagnose and treat. Causes are myriad and poorly understood, pathologic variation is great, diagnosis is often difficult, and treatment in most cases is nonspecific and supportive only. Pancreatitis usually presents as a self-limiting disease from which the patient recovers without complication or intervention. In its most severe form (approximately 10% of cases), it is a potentially lethal disease that is complicated by multisystem failure and sepsis, often requires sophisticated intensive care and judiciously timed surgical débridement, and has a mortality rate of up to 30% to 40%.[1–4] Most intensivists therefore are quite familiar with the patient who presents with acute necrotizing pancreatitis and who may occupy a bed for many months, often ultimately dying of septic complications[5] that are generalized or are related to the secondary infection of pancreatic necrosis.[6]

The subject of this chapter is the increasingly recognized entity of acute pancreatitis in the patient who is already critically ill from other causes. Discussion will focus on the associated diseases reported to date, the pathogenesis of this unusual form, its recognition, and its management.

Etiology

Many causes of acute pancreatitis have been recognized, the most common being alcohol and gallstones. Table 85-1 lists the reported causes of acute pancreatitis.

Whatever the initiating cause, the pathogenetic mechanism common to all forms of acute pancreatitis seems to be an intense systemic inflammatory response syndrome (SIRS) caused by the release of activated pancreatic enzymes[7,8] and mediated by cytokines, immunocytes, and the complement system. Inflammatory cytokines (such as tumor necrosis factor) cause macrophages to migrate into tissues distant from the pancreas, including lungs and kidneys. Immunocytes attracted by cytokines released from macrophages release more cytokines, free radicals, and nitric oxide[9,10]; the result is tissue destruction, fluid and electrolyte loss, hypotension, renal and pulmonary complications, late septic complications, and in 20% to 40% of severe cases, multisystem organ failure (MSOF) and death.[11]

The list of illnesses in the critically ill patient that may precede the development of pancreatitis in the ICU is growing (Table 85-2). Why are these seemingly disparate groups of patients all at risk for this apparently unrelated and possibly lethal condition? The answer is not known and may be multifactorial.

In the case of pancreatitis developing after cardiopulmonary bypass, important factors may be microembolism

TABLE 85-1 Acute Pancreatitis—Etiologic Factors

Metabolic	Obstructive Mechanical	Infectious	Idiopathic	Hypoperfusion
Alcohol	Gallstones	Mumps	Familial	Vascular
Hypercalcemia	Afferent loop obstruction	Coxsackie virus infection		PAN[c] and other collagen disorders
Drugs	Duodenal obstruction	*Mycoplasma* infection		Embolic
Hyperlipidemia	Periampullary tumors	Ascariasis[b]		Low-flow states
	Duodenal ulcer	Clonorchiasis[b]		
	Pancreas divisum			
	Trauma			
	Blunt			
	Penetrating			
	Postoperative			
	After ERCP[a]

Shock from any cause
Major upper abdominal surgery

and venous thrombosis,[12,13] a low postoperative flow state, prolonged bypass,[14] intraoperative or postoperative bleeding, hypothermia,[15] and the use of both narcotics and vasopressors.[16] The frequent occurrence of pancreatitis after cardiac transplantation may be related to the effect of heparin on platelet aggregation[17] and to the administration of cyclosporine[18] and prednisone,[19] as well as to the factors suggested for cardiopulmonary bypass. Abdominal aortic aneurysm repair, especially after acute rupture, may produce hypotension, microemboli, and vasoconstriction, resulting in prolonged hypoperfusion of the pancreas.[20]

Pancreatitis developing after renal transplantation may be related to hypercalcemia,[21] specific operative factors, or immunosuppression as for cardiac transplantation. The reasons for severe pancreatitis after liver transplantation may include direct dissection in some cases, blood loss and hypovolemia, or obstruction to pancreatic venous outflow during prolonged venous bypass. One group has suggested that a hepatitis B infectious factor may be involved.[22]

Review of these possible mechanisms for the development of pancreatitis in the critically ill patient seems to confirm *hypoperfusion injury* as a major pathogenetic mechanism. In fact, one group has suggested that a patient in shock from any of a variety of causes (oligemic, cardiogenic, or septic) is at risk of developing pancreatitis.[23] The actual mechanism of this injury, resulting in the release of activated enzymes and an inflammatory response, is not known.

Hypoperfusion may play an important role in the conversion of a less severe, self-limiting pancreatitis into the more lethal necrotizing form, even when the more common etiologic factors, such as alcohol and gallstones, are major contributors in the non-critical-care setting.[24,25]

Many major upper abdominal procedures have been reported to be complicated by pancreatitis, usually as a result of direct dissection or injury of the gland at surgery (see Table 85-2). However, since any patient subjected to a period of hypotension intraoperatively is a candidate for hyperamylasemia, pancreatitis, or both, the cause of pancreatitis in these cases may have been multifactorial rather than purely mechanical, as originally thought.

Diagnosis

Whatever the cause of new pancreatitis in an ICU patient, the physician must diagnose the condition early, attempt to assess the severity of the process, institute appropriate aggressive supportive management, and use judgment in deciding on the timing and type of surgical intervention, if necessary. Most patients improve even if the disease is virtually ignored; those few whose pancreas becomes necrotic and infected need aggressive and timely surgery to avoid MSOF and death.

Clinical signs and symptoms are notoriously variable in patients with pancreatitis,[20] and they are even more difficult to evaluate in the critically ill. The patient may complain of abdominal pain, nausea, and vomiting; often there are nonspecific features such as elevated temperature, leukocytosis, or in more severe cases, unexplained hemodynamic instability and increased fluid requirements without major clinical findings. The serum amylase concentration,[26–28] random urinary amylase concentrations, and the amylase-creatinine clearance ratio may be useful indicators,[29,30] but they are not reliable in all patients. The serum lipase concentration[31] may be a more reliable and specific indicator than the serum amylase level, but its use has not gained wide acceptance. Serum lipase rises somewhat more slowly than amylase, peaks at 24 hours, and normalizes in 1 to 2 weeks.[32] The concentrations of isoamylase,[33] serum elastase, phospholipase A_2, and trypsin have been suggested as tests but have not been practically useful.[34,35]

In addition to clinical evaluation and frequently unreliable biochemical tests, morphologic assessment of the retroperitoneum is necessary. For patients presenting initially with suspected pancreatitis, standard abdominal and chest films usually were obtained routinely to rule out other significant catastrophes, such as perforation and mechanical intestinal obstruction. These films also may suggest pancreatitis by demonstrating pleural effusions, localized jejunal or colonic ileus, the outline of a widened duodenal C loop, pancreatic calcification, associated radiopaque gallstones, or obliteration of psoas shadows and free intraperitoneal fluid. In some cases,[36] laparoscopy may be useful in making a diagnosis of pancreatitis, although early intervention of any kind is to be avoided unless absolutely necessary. However, the increased availability and efficacy of ultrasound and computed tomographic (CT) scanning have made them the mainstays of routine investigation and monitoring of retroperitoneal inflammation.

ULTRASOUND

Ultrasonography is perhaps the most available test and can be carried out at the bedside of an acutely ill patient. It remains the most convenient modality for edematous pancreatitis that responds rapidly to conservative therapy, for suspected biliary pancreatitis with a mild clinical course, and for the monitoring of a retroperitoneal collection or phlegmon for resolution or the development of a pseudocyst.[37] It also has been suggested that Doppler ultrasound may be valuable in detecting pseudoaneurysms 0.1 cm in diameter. However, paralytic ileus and obesity together severely hamper the ultrasonographer's ability to evaluate the retroperitoneum in the acute stages.

The current generation of high-resolution real-time scanners makes it possible to examine in detail the pancreatic gland, its peripancreatic compartments, and the associated biliary tract, with the patient in the semierect, sitting, and supine positions. These maneuvers, unfortunately, may be difficult to perform in a critically ill patient.

The abnormalities detected by ultrasonography are variable. The gland itself may be diffusely enlarged and

hypoechoic or have a normal appearance, depending on a number of factors, such as the timing of the study, the presence of underlying chronic disease, and the amount of intrapancreatic fat or hemorrhage. Ductal diameter is similarly variable and may be increased, normal, or decreased. The ultrasonographer is just as interested in the peripancreatic retroperitoneal spaces, looking for evidence of acute fluid collections in the lesser sac, phlegmon, and hemorrhage. It is also possible to detect displacement of the gastrointestinal tract and the presence of intraperitoneal fluid. Fluid collections in the lesser sac usually regress as the clinical picture improves. Those which do not and are surrounded by a dense pseudocapsule legitimately may be termed *chronic pseudocysts* and often are treated by radiologic or surgical intervention.

Critical in the assessment of the retroperitoneum is the detection of scattered pancreatic necrosis and of the involvement of peripancreatic tissues with fat necrosis, hemorrhage, and ultimately, abscess formation; unfortunately, ultrasonography is limited in its ability to define these subtle changes in tissue density.[37]

COMPUTED TOMOGRAPHY

Computed tomography has become the "gold standard" for assessing retroperitoneal morphology, especially in complicated cases, and now is increasingly available in every clinical setting. The procedure in the acutely ill patient may be somewhat inconvenient and cumbersome because of endotracheal intubation, multiple lines, and hemodynamic instability, but these problems are not insurmountable. Images of the retroperitoneum are not compromised by obesity or bowel gas, as they may be with ultrasound.

A mildly inflamed pancreas may show slight diffuse enlargement with irregular borders and patchy densities. Peripancreatic fat may increase in density as it undergoes necrosis. The more severe forms of pancreatitis are accompanied by an increase in peripancreatic inflammatory exudate and intrapancreatic fluid collections. Often the pancreas is markedly enlarged, with irregular fluid collections in the retroperitoneum and poor enhancement in scattered areas within the gland. Unlike ultrasonography, computed tomography is an excellent method for identifying high-density fluid collections in the transverse mesocolon, small bowel mesentery, and pararenal and perirenal spaces[38]; by means of dynamic CT scanning, areas of necrosis in the gland itself may be demonstrated. In sick patients, however, one always must be aware of the potential negative effects of contrast infusion both on the patient and on the pancreatitis.[39]

The critical value of CT scanning is in the detection and follow-up of significant complications. A pancreatic abscess consists of pancreatic necrosis that becomes infected and liquefied; it appears on CT scans as ill-defined or poorly encapsulated fluid collections of different densities, with air bubbles being recognized in about 20% of cases. Pseudoaneurysms also may be detected by CT scanning and, with enhancement, may be highlighted.

Since infusion during CT scanning may present significant risks for the hypovolemic unstable patient, future applications of magnetic resonance imaging (MRI) must be considered in this situation. Currently, however, CT scanning remains the most useful tool for evaluation of retroperitoneal morphology.

SEVERITY OF DISEASE

The intensivist must identify not only the presence of the new condition but also its severity and the likelihood of progression to necrosis and complications. Staging of the acute disease is useful in selecting certain patients for early aggressive supportive therapy, those who may require immediate referral to a specialized center, and those who may be candidates for entry into clinical trials. Ranson's criteria[40] were used extensively in the past, but currently, a number of prognostic scoring systems with clinical, biochemical, and radiologic features are available. The Balthazar score is based primarily on CT findings, focusing on the presence or absence of pancreatic necrosis. It has been suggested that CT scores are more valuable than the Acute Physiologic and Chronic Health Evaluation (APACHE) II score in predicting regional complications associated with pancreatitis.[41] Many use the Atlanta classification, which defines severe acute pancreatitis using features such as clinical presentation, the Ranson criteria, the APACHE II criteria, and evidence of organ failure and anatomic changes. These indicators are directed toward assessing the systemic effects of the disease, and in a critically ill patient, a number of them already may be present before the onset of the pancreatitis.

Numerous blood tests have been suggested as indicators of severity (areas of necrosis within the gland), including the levels of cyclic adenosine monophosphate, albumin, methemalbumin,[42] ribonuclease,[43] C-reactive protein,[44,45] fibrinogen,[34] and urinary trypsinogen-activated polypeptide.[46] Another group has reported that the volume and color of peritoneal aspirate at diagnosis can be useful.[47] None of these tests has proved as accurate, however, as clinical assessment of the patient and serial CT scans of the abdomen, especially in the ICU setting.[48,49] The development of abdominal pain and tenderness, fever, leukocytosis, hemodynamic instability, and CT changes within 1 to 2 weeks of the presumed onset of the pancreatitis provides the best assessment of the severe complications of the disease.

In a patient who is deteriorating or is persistently septic and whose CT scan demonstrates features typical of pancreatic necrosis as listed earlier, percutaneous aspiration of the retroperitoneum with microscopic examination and cultures can be valuable[50–52]; this approach is used frequently in our unit to direct further management.

Treatment

After the patient has been stabilized systemically and the disease has been identified as severe, attention is turned initially to the possible etiologic factors listed in Table 85-1. An ICU patient may develop pancreatitis related to causes other than the described hypoperfusion injury; drugs, gallstones, or other obstructive mechanical factors may be critical. Very frequently, as is the case with gallstone pancreatitis, the disease is short and self-limiting, and in selected patients it can be treated with immediate or delayed endoscopic or surgical intervention as the case demands. The most common scenario is quick resolution of the acute inflammation and a

recommendation either for surgery in the same admission if the gallbladder is in situ[53] or for endoscopic sphincterotomy and gallstone removal if the gallbladder was removed previously. In the critically ill person, however, this intervention, unless indicated early by persistent jaundice and acute pancreatitis, should be delayed until after resolution of the primary illness. Some groups, however, advocate routine early endoscopic sphincterotomy and claim modest attendant morbidity.[54–57]

Assuming that the disease in the ICU patient was initiated by a hypoperfusion injury to the gland, however, and that no immediate "corrective" intervention is appropriate, the principles of treatment include careful monitoring, correction of the metabolic and hemodynamic effects of the inflammatory process, respiratory and renal support, nutrition, control of pancreatic enzyme secretion and its sequelae, and prevention and treatment of the local complications of necrotizing pancreatitis. The evaluation and management of such a patient from the outset must be a collaborative effort between the intensivist and an abdominal surgeon experienced in the medical and surgical measures that may become necessary. The decision making with regard to surgery is based to some extent on hard data that can be measured, such as biochemical indicators and radiographs, but it is also based on clinical experience and intuition.[58,59]

MONITORING

The critically ill patient who develops pancreatitis is likely already undergoing hemodynamic monitoring in the ICU setting, with close evaluation of heart rate, arterial blood pressure, hourly urine output, and central venous pressure. Since patients with severe pancreatitis may well have major fluid derangement, renal failure, sepsis, and especially pulmonary complications, a pulmonary artery catheter may be useful for monitoring, but the impact of this device remains controversial.

Frequent determinations of blood counts, blood urea nitrogen (BUN), blood sugar, electrolytes, creatinine, calcium, magnesium, and arterial blood gas levels are useful in detecting deteriorating pulmonary or renal status, the adequacy of treatment, and the evolution of septic complications. In a patient who is slow to respond, serial ultrasound examinations and CT scans especially are critical to the ongoing evaluation of the retroperitoneum.

METABOLIC AND HEMODYNAMIC EFFECTS

The need for volume replacement in patients with severe pancreatitis cannot be overemphasized. Such patients, in effect, have a massive retroperitoneal burn, with ongoing third-space losses in the retroperitoneum, peritoneal cavity, and bowel lumen. Requirements may vary from small amounts to 8 to 10 L of isotonic fluid in the first 24-hour period. In the ICU, especially if the patient has a preexisting brittle cardiovascular status, fluid replacement and its effects may have to be followed even more closely; however, a patient who develops pancreatitis after a cardiopulmonary bypass or cardiac transplantation still requires adequate salt and fluid replacement. Patients who develop hemodynamic instability after appropriate massive fluid administration may benefit from support with vasoactive drugs.

Because hemorrhage can occur as a complication of the retroperitoneal extravasation of proteolytic enzymes, administration of blood may be necessary; for those who develop hypoalbuminemia as a result of significant protein loss, plasma or albumin or both may be indicated.

It should be stressed that the reason why one patient progresses to pancreatic necrosis and/or the development of SIRS and another has a benign, self-limiting course remains a mystery; however, in the usual case of pancreatitis, and especially in a critically ill patient in the ICU, this deterioration may well be exacerbated by hypotension and hypoperfusion related to inadequate attention to volume replacement.

Metabolic abnormalities should be recognized and treated. For example, early fluid management and stabilization usually are sufficient to correct metabolic acidosis. Whether hypocalcemia—even ionized hypocalcemia—should be corrected is controversial, given the central role of elevated intracellular calcium in the pathogenesis of pancreatitis.[60]

RESPIRATORY AND RENAL SUPPORT

Many mechanisms are implicated in the development of typical adult respiratory distress syndrome (ARDS) in this setting. After major heart or transplantation surgery, the patient's pulmonary function already may be compromised by anesthetics, opiates, and pain related to the procedure. In addition, elevation of the diaphragm, pleural effusion, abdominal pain leading to further splinting and atelectasis, and overaggressive fluid replacement may contribute to the respiratory failure. The most important factors may occur in the lung itself, with increased capillary permeability related to serotonin release, breakdown of surfactant by the enzyme phospholipase A released by the necrosing pancreas, or activation of the complement cascade with elaboration of vasoactive prostaglandins and leukotrienes. Whatever the mechanisms, aggressive ventilatory support is required frequently, and this possible need should be anticipated. If the patient was ill previously and develops respiratory insufficiency along with acute pancreatitis or requires multiple operations for complications of the latter, ventilatory support may be prolonged for many weeks. Tracheostomy may become necessary for adequate tracheobronchial toilet or occasionally for protracted ventilation.

No specific renal insult has been recognized in the patient with acute pancreatitis, apart from the secondary effects of volume loss and hypotension. However, as reviewed previously, many patients with ICU-related pancreatitis may have a hypoperfusion injury as a cause; therefore, renal dysfunction may be anticipated in many. Aggressive support with fluids, judicious use of diuretics when fluid has been replaced adequately, and hemodialysis in selected cases of acute tubular necrosis are all part of the therapeutic armamentarium.

One group examining the incidence of pancreatitis in patients undergoing abdominal aortic aneurysm repair found that there was a high correlation of pancreatic injury with ischemic injury to the kidney[23] (acute tubular necrosis), suggesting that the two conditions have similar etiologies and indicating the need for close monitoring of renal function.

NUTRITION

Nutritional support for the seriously ill patient is critical, even though no specific benefit to the patient with an inflamed

pancreas has been proven. Most of the conditions listed in Table 85-2 occur in patients at risk for developing pancreatitis; nevertheless, these patients enter the ICU with an expectation of returning to normal feeding within days. The recognition of pancreatitis, however, should carry with it the realization that a prolonged stay is possible. All too often the intensivist withholds total parenteral or enteral nutrition (TPN or EN) until the course of the disease is declared, only to find that after 2 weeks the patient is not improving significantly and now has been starved unnecessarily.

The patient who develops pancreatitis in this setting should be regarded with suspicion, and nutrition should be offered early with an objective of "pancreatic rest." Long-term TPN in a sick, possibly septic patient carries its own frequent complications, among which are line sepsis and opportunistic infections; enteral feeding through a nasojejunal or percutaneous jejunal tube is a valuable adjunct and should, whenever possible, be the feeding method of choice if severe paralytic ileus does not preclude its use.[61–63] Infusion of nutrients into the proximal jejunum bypasses the stimulatory effect of feeding on pancreatic secretion, has fewer complications, is much less costly than TPN, helps maintain mucosal function, and limits absorption of endotoxins and cytokines from the gut.[64–67] The feeding tubes also can be placed via laparoscopy or combined endoscopic and radiologic means.[68]

CONTROL OF PANCREATIC ENZYME SECRETION

Many therapeutic steps have been taken to minimize pancreatic enzyme secretion or limit its effects. Studies to examine the possible benefits in acute pancreatitis of nasogastric suction,[69] anticholinergic agents,[70] H_2-receptor blockers,[71] somatostatin,[72,73] calcitonin,[74] and glucagon[75] have not supported the routine use of these agents.

Similarly, the effects of the proteolytic enzyme inhibitor aprotinin (TRASYLOL),[76,77] the antitrypsin agent ϵ-aminocaproic acid (EACA),[78] and a phospholipase A inhibitor[79] have not been convincingly beneficial. Nasogastric suction is still used routinely, especially in the obtunded patient, to decompress paralytic ileus, control vomiting, perhaps decrease stimulation of the pancreas, and prevent aspiration.

The numerous modalities used and tested in the treatment of the severe form of this disease attest to the failure of most of them to alter the course of the inflammatory process. The mainstay of initial treatment is resuscitation with fluid and electrolytes combined with respiratory and nutritional support, as well as attention to the primary disease state in the case of a critically ill patient. Patients who die from necrotizing pancreatitis, however, do not usually die in the early resuscitation phase, or even in the first 2 weeks, owing to excellent intensive care.

The next step is to evaluate and follow the pathologic process in the retroperitoneum while all supportive measures are continued.

Local Complications of Necrotizing Pancreatitis

At the outset, the clinician must be aware of the pathologic conditions that occur secondarily as a result of acute pancreatitis. A relatively uncommon but potentially lethal complication is that of intraabdominal hemorrhage requiring immediate intervention.[80] The local complications of necrotizing pancreatitis are pancreatic necrosis, pancreatic abscess, and pseudocyst formation[81]; the process also may have more remote effects, such as formation of multiple intraabdominal collections, colonic perforation,[82] and even gallbladder necrosis[83] and abdominal compartment syndrome.[84] Aggressive early hemodynamic stabilization is probably the only rational way to prevent further hypoperfusion injury to the pancreas and the development of these complications. Institution of peritoneal dialysis via the percutaneous or minilaparotomy route accelerates early improvement in some patients but does not appear to offer any benefit in decreasing the likelihood of complications and death.[85] Patients in whom retroperitoneal necrosis (fat or pancreatic) develops are at high risk for morbidity and death.[6] Those in whom this complication does not develop usually will survive with appropriate supportive measures only.

PANCREATIC AND PERIPANCREATIC NECROSIS

Pancreatic necrosis consists of patchy devitalization of the pancreatic gland; it develops in a few days to weeks after the onset of the inflammatory process. The patient usually has abdominal pain, persistent fever (possibly low grade), and leukocytosis. CT scan with vascular enhancement may demonstrate local or diffuse areas of nonenhancement. Needle aspirates obtained at this stage will show no growth on culture if necrosis is present without infection.

Treatment of this entity is controversial. It is difficult to predict how many cases of pancreatic necrosis (without infection) will resolve spontaneously with simple supportive management and how many will develop sepsis and clearly require débridement. Undoubtedly, the condition does resolve in some patients, who clearly would not benefit from laparotomy. Every pancreatic surgeon has had the experience of extensively débriding sterile retroperitoneal necrosis, subjecting the patient to perhaps many future débridements (which then, of course, involve infected tissue), and wondering whether the original noninfected condition might have resolved spontaneously. In addition, many "sequestrectomies" performed for pancreatic necrosis likely are excisions only of necrotic fat and not of necrotic gland. No comparison of these two pathologic entities in terms of morbidity and mortality has been reported. A retroperitoneum with a well-perfused pancreas surrounded by necrotic fat may carry a different outlook than if the gland itself is compromised. Therefore, removal of uninfected necrotic fat only may be a fruitless and conceivably dangerous exercise.

It has been suggested that infection develops in only 40% of patients with pancreatic and peripancreatic necrosis.[86] Because of this and the aforementioned fear that surgery in the sterile situation actually may cause more harm than good, we tend to avoid major débridement unless sepsis is confirmed. Therefore, if the patient remains stable hemodynamically, has only low-grade fever and leukocytosis, has CT findings that do not suggest extensive glandular necrosis and infection, and has a sterile percutaneous retroperitoneal sample, we continue with supportive management without intervention. However, the patient ultimately may require intervention even in the absence of gross septic parameters simply

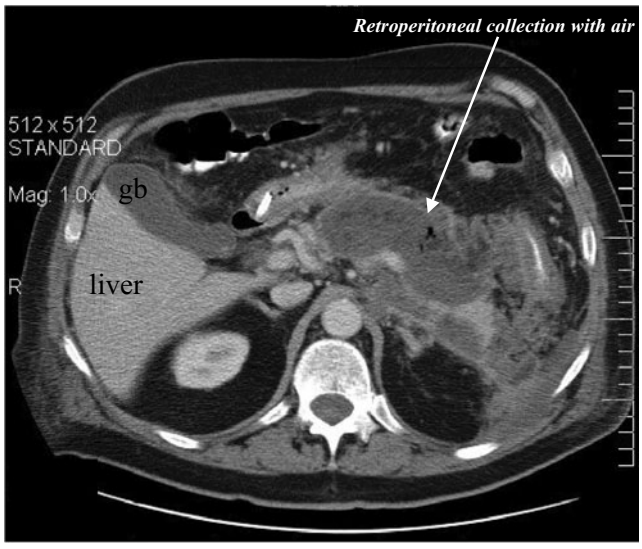

FIGURE 85-1 CT scan of patient with acute alcoholic pancreatitis and evidence of a retroperitoneal collection containing fluid and air bubbles. Aspiration and culture confirmed infection with gram-negative organisms, and the patient was managed eventually with surgical débridement, enteral nutrition, and antibiotic therapy.

because of a prolonged "smoldering" course showing no clinical improvement (Fig. 85-1).

ANTIBIOTIC THERAPY

The role of antibiotics in the patient with pancreatic necrosis or sepsis is similarly controversial.[87–91] Antibiotics are required in patients who have pancreatic necrosis (with or without sepsis), but their purpose is to provide systemic protection rather than local treatment or prophylaxis. Patients with sterile necrosis usually receive broad-spectrum antibiotics for systemic protection while the intensivist monitors the retroperitoneum, although this treatment undoubtedly brings with it a risk of opportunistic infection, such as disseminated candidiasis in the acutely ill host. In recent years, the case for routine antibiotic usage in such patients has strengthened. Certain antibiotics such as imipenem actually penetrate the pancreatic parenchyma, achieving good tissue levels during acute pancreatitis. In several studies, significant reduction in the incidence of septic complications followed the routine use of broad-spectrum antibiotics, but the effect on mortality has been less predictable. One study[92] showed that routine use of imipenem-cilastatin altered the bacteriology in severe acute pancreatitis from predominately gram-negative coliforms to predominately gram-positive organisms without altering the incidence of resistance or fungal superinfection.

Prophylactic antibiotics for the purpose of selective decontamination of the gastrointestinal tract may prevent translocation of bacteria to the inflamed pancreatic bed, presumably from the transverse colon.[93–96] Patients who develop infected necrosis must be treated actively to prevent or manage bacteremia and frequently require surgical débridement and drainage; however, even that approach is being challenged by some anecdotal evidence that antibiotics alone or in conjunction with percutaneous drainage without surgery may be sufficient to treat some patients with aspiration-proven retroperitoneal sepsis.[97–101] This strategy still may be difficult to accept for those intensivists who have treated patients who developed fatal opportunistic infections in the past after long-term antibiotic therapy.

INFECTED NECROSIS AND PANCREATIC ABSCESS

Some patients with pancreatic and peripancreatic necrosis develop spontaneous infection of the necrotic tissue presumably because of direct contamination by bacteria from the transverse colon. Although some authors do not distinguish between infected necrosis and pancreatic abscess, others differentiate them on the basis of suitability for percutaneous drainage: Infected pancreatic necrosis usually requires extensive surgical débridement and possibly pancreatic resection because of solid necrotic areas, whereas a pancreatic abscess may require just percutaneous drainage if liquefaction has taken place, leaving little solid necrotic tissue.

Notwithstanding the more conservative approach described earlier in selected patients, established sepsis in the retroperitoneum generally requires intervention to avoid the sequelae of systemic infection. This fact has significant implications in the patient who is critically ill from a primary illness. The diagnosis of retroperitoneal sepsis, whether infected pancreatic necrosis or pancreatic abscess, is made by recognition of clinical deterioration, which may be more precipitous than with pancreatic necrosis and may be accompanied by more pronounced fever and leukocytosis, typical CT findings, and a positive percutaneous aspirate.[59,102] When the patient is maintained on broad-spectrum antibiotics (with perhaps decreased immunosuppression in the transplant patient), preparations are made for surgical débridement. Although some cases may be amenable to percutaneous drainage only, as stated previously, in our experience, most require laparotomy.

PRINCIPLES OF SURGICAL DÉBRIDEMENT

The conventional indications for surgery in acute pancreatitis include failure of early medical management, unresolving gallstone pancreatitis, and pancreatic sepsis. In the critical care setting, aggressive supportive care has virtually eliminated the need for early operation. As stated earlier, a persistent gallstone pancreatitis may be treated effectively by early endoscopic sphincterotomy. Therefore, the main indication for surgery in the critically ill patient with pancreatitis is the late development of necrosis or sepsis.[58,59]

Recommended methods of surgical débridement vary considerably, and their description is beyond the scope of this chapter. The principles of the different approaches are similar, however; the critical steps are the recognition of the patient in whom débridement is appropriate and quick execution of the procedure, with excellent anesthesia and postoperative intensive care.

The timing of surgery for pancreatic sepsis is critical,[103] in that early débridement (done usually within 3 weeks of the onset of clinical pancreatitis) may encounter poor demarcation between necrotic and healthy tissue, leading to oozing from partially devitalized tissue after necrosectomy. If a wait can be tolerated by the patient, a late laparotomy (at 3 to 6 weeks) is likely to involve the removal of well-demarcated necrosis (often in a single procedure rather than multiple operations).

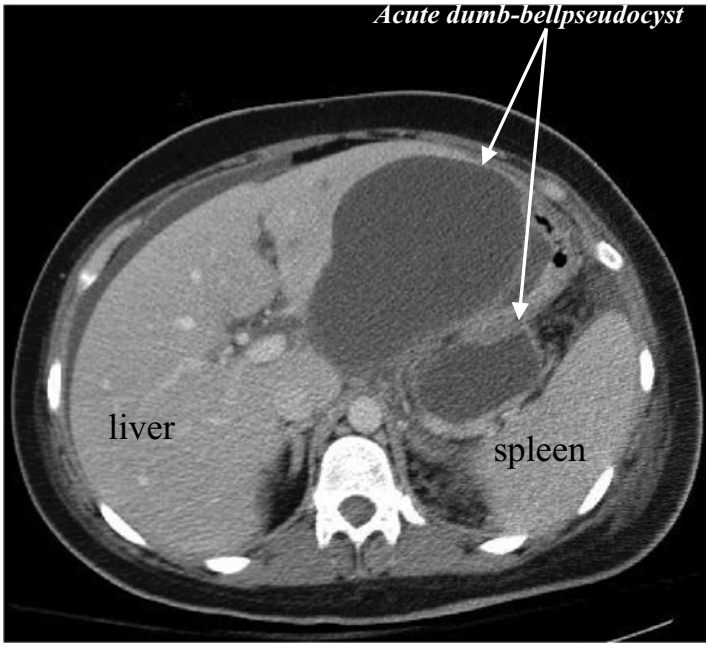

FIGURE 85-2 CT scan of patient with acute pancreatitis and acute pseudocyst formation. The dumbbell-shaped pseudocyst resolved gradually without internal or external drainage.

Surgery should consist of wide débridement of all devitalized peripancreatic fat and pancreatic tissue, followed by adequate dependent drainage, which should be generous enough to allow drainage of thick, purulent, often particulate material.[104,105] Since multiple operations for repeated abdominal toilet sometimes are required, some surgeons have advocated open packing of the abdomen in such cases.[102,106]

Our own preference is for radical excision of all necrotic and infected material followed by generous dependent sump drainage and closure of the abdomen, although some practitioners advocate closed lavage postoperatively.[107] Intubation of the gastrointestinal tract (cholecystostomy, gastrostomy, and jejunostomy were advocated enthusiastically in the past[108]) is to be avoided in this septic setting. Temporary packing of the retroperitoneum and scheduled reoperation occasionally are necessary to control venous oozing from the bed of the necrotic tissue.

The extent of pancreatic resection varies depending on the degree of necrosis of the gland itself. Although some surgeons have recommended routine performance of major pancreatic resection,[109,110] we débride the gland itself only if necessary; only necrotic portions are removed, and major anatomic dissections are avoided, if possible, in these often unstable patients.

The patient who suffers infected pancreatic necrosis and who requires intensive care, often multiple operations, and an extended hospital stay clearly will have a protracted convalescence. However, a recent quality-of-life study[111] found that the survivors of this morbid disease could look forward to good quality of life.

PANCREATIC PSEUDOCYST

With more frequent use of ultrasound and CT scanning in the early stages of pancreatitis, recognition of fluid collections in and around the lesser sac has become the rule rather than the exception. Most collections probably consist of inflammatory exudate, and in fact, most resolve as the pancreatitis settles (Fig. 85-2). The persistence of a lesser sac fluid collection (or of fluid in a variety of areas, such as the peritoneal cavity, the retroperitoneum, or even the mediastinum) implies a communication with a ruptured pancreatic duct system. A collection that develops thick, fibrous walls consisting of the surrounding stomach, colon, and mesentery properly can be termed a *chronic pseudocyst*. Diagnosis of such a condition does not mandate immediate treatment unless the pseudocyst becomes symptomatic, grows quickly, becomes infected, bleeds, or ruptures into the peritoneal cavity or adjacent bowel. In an already sick patient, a quickly enlarging or infected pseudocyst is best treated with percutaneous decompression or endoscopic pseudocyst drainage, whereas immediate surgery is required for bleeding or free rupture. Occasionally, transpapillary stent placement is useful if a direct communication exists between the main pancreatic duct and the pseudocyst.[112] The presence of a large collection does not of itself necessitate percutaneous decompression; in fact, one group found that collections that were drained early had a significantly increased chance of later developing septic complications requiring surgery and a longer hospital stay.[113] It also has been suggested that percutaneous treatment is effective for peripheral collections, whereas more centrally placed collections need operative decompression.[114] Spontaneous rupture into the intestinal tract, a rare occurrence, can be treated expectantly in this setting if the patient is otherwise stable. The uncomplicated pseudocyst that is stable in size and is at least 6 weeks old (to allow the walls to "mature" enough to accept sutures) is conventionally drained internally at laparotomy; in the intensive care situation, percutaneous drainage can be done safely to avoid the dreaded complications, but it must be used with full knowledge that recurrence is frequent.

Chapter 86

MESENTERIC ISCHEMIA

DENIS W. HARKIN
THOMAS F. LINDSAY

KEY POINTS

- *Acute mesenteric ischemia is a relatively rare clinical entity, but when diagnosis is delayed, it is almost always fatal; therefore, a high index of suspicion is required, especially in those at high risk: the elderly, those with cardiac dysfunction, patients with diffuse atherosclerosis, and those following aortic and cardiac surgery or arterial catheterization.*
- *The etiology of acute mesenteric ischemia may be embolic, thrombotic, primary vasoconstrictive, or secondary to venous thrombosis. Chronic ischemia is usually due to flow-limiting lesions (stenoses or occlusions) in the presence of inadequate collateralization.*
- *Classic symptoms of acute intestinal ischemia are central abdominal pain (often out of proportion to the benign abdominal examination), weight loss (an important clue even in the acute presentation), bowel emptying, and altered bowel function (vomiting, bloating, constipation, or diarrhea). Once signs of peritonitis or bloody diarrhea present, shock, sepsis, and death almost always follow.*
- *Mesenteric angiography is the investigation of choice, offering diagnostic and therapeutic options, whereas computed tomographic (CT) angiogram and duplex ultrasonography may not be definitive. Frequently, the diagnosis is confirmed only at laparotomy.*
- *Treatment is surgical, with restoration of flow by bypass or embolectomy, resection of nonviable intestine, and liberal use of "second look" laparotomy.*

Acute mesenteric ischemia is a relatively rare but often fatal clinical entity. Although little data exist on its true incidence, data from the Swedish Vascular Registry suggest that it may account for just 1 percent of reconstructions for acute thromboembolism.[1] Contemporary series, however, continue to report a mortality rate of between 32% and 48%.[2,3] Although autopsy studies suggest that atherosclerosis affecting the mesenteric arteries is common (6% to 10%),[4] symptomatic mesenteric occlusive disease is rare. However, of patients presenting with acute mesenteric ischemia, one large series found that 43% had prior symptoms of chronic mesenteric ischemia.[5] The spectrum of mesenteric ischemia includes occlusive disease secondary to atherosclerotic occlusion with thrombosis, embolism, mesenteric venous thrombosis, and nonocclusive mesenteric ischemia due to vasospasm (Table-86-1). At its most florid, it may present with mesenteric infarction, intestinal perforation, and septic circulatory collapse. This relatively rare but often fatal clinical entity must be considered early in the differential diagnosis of any patient with abdominal symptoms or signs but especially those with a history of intestinal angina, peripheral vascular disease, cardiac dysfunction, aortic surgery or recent aortic catherization, hypotension, or prothrombotic state. Noninvasive tests lack specificity and sensitivity, which indicates that the diagnosis often requires a high index of suspicion, supplemented by a liberal use of diagnostic arteriography (or computed tomographis angiogram) when uncertainty remains. Where doubt exists in the presence of emerging acute abdominal signs or clinical deterioration, diagnostic laparotomy is indicated. This discussion will focus on the etiology, pathophysiology, diagnosis, and management of acute mesenteric ischemia.

Anatomy and Dynamics of the Mesenteric Circulation

The mesenteric circulation is supplied in series by the three major midline branches of the abdominal aorta, namely, the celiac artery, supplying the foregut, hepatic, and splenic beds; the superior mesenteric artery (SMA), supplying the midgut; and the inferior mesenteric artery (IMA) and the internal iliac arteries, supplying the hindgut. An extensive network of actual or potential sites of collateralization exists between individual branch territories and their neighbors, as well as the systemic circulation. The celiac territory may gain supply proximally across the diaphragm from the phrenic and esophageal vessels (that arise from the aorta) and distally from the SMA via the gastroduodenal artery, including the

TABLE 86-1 Potential Causes of Acute Mesenteric Ischaemia

Occlusive disease	
Embolism	Cardiac diseases (atrial fibrillation, post-MI, valvular disease, SBE, dilated left ventricle, myxoma)
	Extracardiac arterial diseases
Arterial thrombosis	Acute on chronic atherosclerosis
	Low cardiac output states
Intrinsic arterial diseases	Occlusive atherosclerosis
	Aortic dissection
	Atherosclerotic aneurysm
	Arteritis and autoimmune diseases
	Fibromuscular dysplasia
Venous thrombosis	Thrombophilia
	Extrinsic compression
Iatrogenic	After aortoiliac surgery
	Catheter related (dissection, embolism)
	Irradiation arteritis
	Vasoconstrictive agents (epinephrine, norepinephrine, dopamine)
Trauma	Penetrating
	Blunt (including deceleration injuries)
Nonocclusive disease	
Shock	Cardiogenic shock
	Hypovolemic shock
	Septic shock
	Neurogenic shock
	Anaphylactic shock
Low cardiac output states	Heart failure
	Arrhythmia
	Acute coronary syndromes
	Pseudocoarctation (aortic dissection)
Pharmacologically induced	Digitalis, vasoactive substances (catecholamines, somatostatin analogues, etc.), ergotism.

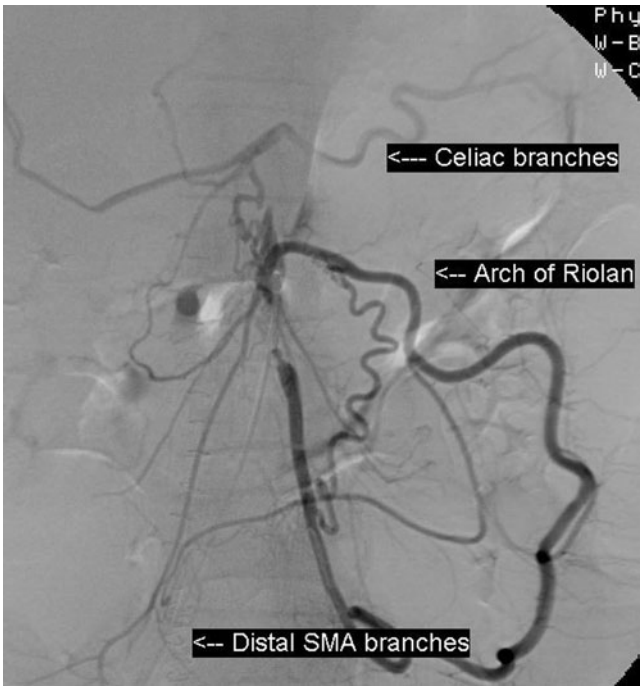

FIGURE 86-1 Late IMA injection demonstrating the IMA to the arch of Riolan, filling the stump of the SMA with its distal branches. Also note filling of hepatic and splenic branches.

superior and inferior gastroduodenal arteries. The SMA territory may be perfused from the celiac artery, as mentioned, or from the IMA territory via the *arch of Riolan*, a collateral that runs in the midmesentery and is fed via the ascending branch of the left colic artery (Fig. 86-1). The IMA territory may collateralize proximally, as described, or distally via the inferior hemorrhoidal arteries from the internal iliac artery. Blood from the pelvis may collateralize to the SMA or above from the communications between the sigmoidal-hemorrhoidal vessels to the marginal artery of Drummond (a collateral that runs within 1 to 2 cm of the mesenteric edge of the bowel) and via the arch of Riolan. Vessel caliber decreases progressively from the main aortic branch to the mesenteric vascular arcades distally, ending with an extensive communicating submucosal vascular plexus. This collateral network explains why many individuals may tolerate chronic occlusion of one or two mesenteric vessels without symptoms, but it also explains why acute-on-chronic occlusion of one branch may lead to a catastrophic loss of intestinal perfusion.

Control of the Mesenteric Circulation

The mesenteric circulation receives approximately 20% to 30% of the cardiac output at rest, which may increase by up to 50% after meals.[6] As such, the mesenteric circulation receives approximately three times more blood per unit weight than most other body tissues. This blood flow is partly to satisfy the absorptive function of the intestine and perfuse the liver via the portal vein, but it also represents a reservoir function from which blood can be mobilized to other sites (vital organs) at times of stress or increased demand. This preferential shunting of blood to vital organs, if acute or severe, can "sacrifice" the mesenteric circulation, leading to low-flow and ischemic injury. The more metabolically active mucosal layer receives 70% of blood flow, only 30% supplying the muscularis and serosal layers, placing the intestinal mucosa at greatest risk from ischemic injury.[6] Within the intestinal villus, passive exchange of oxygen typically occurs between the afferent arteriole and efferent venule, effectively bypassing the capillary network at the villus tip, a phenomenon called *oxygen countercurrent exchange.* In health, high partial pressures of oxygen ensure that the metabolic needs of the villus mucosa are met despite this shunting, but in deoxygenated states this shunting adversely affects oxygen delivery to the mucosal tip, making it most vulnerable to ischemic injury. A number of extrinsic and intrinsic factors regulate the mesenteric blood flow, leading to a complex interaction between neural, hormonal, and paracrine effectors that regulate the vascular smooth muscle tone in the mesenteric bed and control local blood flow. Vasoactive mediators alter the vascular smooth muscle (VSM) tone of multiple small afferent arterioles, collectively known as *resistance vessels,* changing their cross-sectional area and blood flow (Table 86-2). The interaction between extracellular agonist (first messenger) and VSM receptor leads to accumulation of intracellular second messengers, such as cyclic adenosine monophosphate (cAMP), Ca^{2+}, and cyclic guanosine monophosphate (cGMP). These second messengers directly or indirectly alter the cytosolic concentration of Ca^{2+} and dictate whether VSM contracts.[7] A functioning cardiovascular system is essential because the mesenteric circulation is often sacrificed to maintain blood flow to vital organs at times of detrimental alterations in cardiac output, blood volume, or arterial blood pressure. Increased sympathetic nervous activity associated with cardiogenic, septic, or hypovolemic shock can further compound flow-related ischemia by inducing intense vasoconstriction within the mesenteric bed. High-volume hemorrhage (> 35% of blood volume) leads to disproportionate visceral vasoconstriction compared with the reduction in cardiac output.[8] When activated postganglionic sympathetic nerves fibers release norepinephrine, stimulating α_2-adrenergic receptors on VSM of precapillary arterioles (which are the *resistance vessels*), this results in vasoconstriction and reduced intestinal blood flow. Some compensation is provided by the simultaneous stimulation of vasodilatory β_2-adrenergic receptors on VSM by norepinephrine.[9] However the net effect is a rapid reduction in flow followed by a gradual return to prestimulation blood flow levels, a phenomenon known as *autoregulatory escape*. Exogenously administered norepinephrine similarly can cause nonocclusive mesenteric ischemia (NOMI). Parasympathetic nerves induce vasodilation due to the effect of specific neurotransmitters acetylcholine (ACh, increases cGMP and NO), vasoactive intestinal protein (VIP, increases cAMP), and adenosine triphosphate (ATP). Primary sensory nerves also play a role because their activity through C fibers can inhibit sympathetic impulse flow through the spinal cord or sympathetic ganglia. Indeed, direct antidromic vasodilation can occur as C fibers release neuropeptides, including substance P, calcitonin gene–related peptide, and VIP, in response to luminal signals. Humoral (endocrine) messengers also can affect the mesenteric blood flow, most notably adrenal catecholamines in states of systemic stress, shock, or secreting tumor (pheochromocytoma). Similarly vasocontrictive effects are seen with renal-derived angiotensin II in congestive heart failure and pituitary-derived

TABLE 86-2 Potential Vasoactive Mediators of the Enteric Circulation

Mediator	Vasoconstrictors	Vasodilators
Neural	↑ Sympathetic tone (adrenergic) ↓ Parasympathetic tone Neuropeptide Y	↓ Sympathetic tone (cholinergic) ↑ Parasympathetic tone Substance P Vasoactive intestinal peptide (VIP) Calcitonin gene-related peptide (CGRPα)
Humoral	Catecholamines (except liver & muscle) Angiotenisin II Vasopressin Serotonin Activated complement (C5a)	Catecholamines (only liver & muscle) Histamine Bradykinin Activated complement (C3a, C5a) Adrenomedullin
Paracrine/ autocrine	Endothelin-1 (VSM cells) Platelet-activating factor Constrictor prostaglandins ($F_{2\alpha}$)	Endothelium-derived relaxing factor (EDRF) Endothelium-derived hyperpolarizing factor Dilator prostaglandins (I_2 or prostacyclin) Endothelin-1 (endothelial cells)

vasopressin in shock, respectively. Ingested meals and gastrointestinal luminal peptides stimulate a postprandial increase in mesenteric blood flow. This vasodilatory response is regulated, in part, by the increased metabolic activity in the tissues, leading to local accumulation of vasoactive metabolites such as amines, peptides, prostanoids, and adenosine in the presence of a reduced oxygen concentration. Adenosine itself, increasing as a result of energy-dependent processes, may vasodilate in a paracrine fashion. A number of hormones are also released in response to luminal contents, including gastrin, cholecystokinin, and secretin, with net vasodilatory effects.[10] Somatostatin, released by the mucosal D cells, induces mucosal vasoconstriction, and synthetic analogs (e.g., octreotide) can induce ischemia.

Pathophysiology of Intestinal Ischemia

The unique arrangement whereby the mesenteric blood flow continues in series via the portal vein, supplying much of the metabolic need of the liver, means that oxygen extraction by intestinal tissue remains low at rest. Therefore, intestinal tissues may respond to reduced flow by increasing oxygen extraction from the blood without a requirement for increased blood flow, but this deprives the liver of some of its portal-derived oxygenation, resulting in hepatic ischemia. On a biochemical and microscopic level, acute ischemia of the intestine is characterized by depletion of cellular adenosine triphosphate (ATP), failure of energy-dependent processes (in particular membrane ATPase pumps), cellular swelling, membrane disruption, metabolic arrest, and cell death.[11] Hypoxic conditions themselves favor the conversion of the abundant amounts of xanthine dehydrogenase to xanthine oxidase. Accumulating adenosine is metabolized further to inosine and then hypoxanthine but no further without oxygen. With the reintroduction of oxygen on reperfusion, xanthine oxidase converts hypoxanthine to xanthine, producing superoxide (reperfusion tissue injury[12]). Oxygen free-radicals (OFRs), including superoxide anions (O_2^-), hydrogen peroxide (H_2O_2), and hydroxyl radicals (OH^-), arise as by-products of the xanthine–xanthine oxidase system, the mitochondrial electron transport system, and the NADPH oxidase system of infiltrating neutrophils. Endogenous defenses against oxidative injury, including intracellular enzymes (superoxide dismutase, catalase, and glutathione peroxidase) and vitamins (C and E), are overwhelmed by the production of OFRs. The OFRs directly attack cell membranes, inducing lipid peroxidation and synthesis of lipid mediators (thromboxane A_2, leukotiene B_4) and chemotactic peptides (complement component C5a), which promote neutrophil activation and chemotaxis. Sequestration of circulating neutrophils in the microvessels of the intestine begins with constitutively expressed neutrophil L-selectin receptors binding to the postcapillary venule endothelial P-selectin and E-selectin receptors.[13] This is the first phase of neutrophil adhesion, manifested by neutrophil rolling along the venular luminal surface. The second phase of neutrophil adhesion occurs after upregulation of the CD11/CD18 integrins and shedding of L-selectin from the neutrophil surface, caused by release of proinflammatory cytokines, platelet-activating factor (PAF), and eicosanoids from the damaged endothelial cell. This halts neutrophil rolling by providing strong neutrophil–endothelial cell adhesion through the interaction of the CD11b/CD18 integrin with the endothelial receptor, intercellular adhesion molecule 1 (ICAM-1).[14] Finally, neutrophils transmigrate in response to chemotactic stimuli (such as interleukin-8) and binding by platelet–endothelial cell adhesion molecule 1 (PECAM-1). Neutrophils further damage tissue by releasing superoxide anions via the NADPH oxidase system, secreting myeloperoxidase that catalyzes the production of hypochlorous acid (HOCL), and releasing granular enzymes, including elastase, collagenase, and cathepsin G. Many capillaries fail to perfuse on reinstitution of blood flow, the *no-reflow phenomenon*, due to loss of local

autoregulation combined with mechanical obstruction of narrowed capillaries by enlarged adherent neutrophils.[15] This results in incomplete and patchy tissue reperfusion, prolonging hypoxia and exposure of the tissues to toxic metabolites. On a microscopic level, complete ischemia causes detectable injury to the superficial part of the mucosa (the villi) within 20 minutes. As the duration of ischemia increases, the villus loss can be complete before the muscular layers are damaged. Patchy cellular necrosis can extend to mucosal sloughing seen clinically as bloody diarrhea. Ultimately, there is transmural infarction, perforation, and septic peritonitis. Prior to reperfusion, metabolic products such as lactate and other acids are not absorbed via the neglible portal circulation but only through the peritoneal surfaces, accounting for the lack of acidosis commonly observed in patients with acute mesenteric ischemia.

Systemic Response to Mesenteric Revascularisation

On reperfusion of the acutely ischemic intestine, local injury can induce a systemic phenomenon as metabolic byproducts of the ischemic process (lactate, H^+, K^+, oxygen reactive species, arachidonic acid derivatives, cytokines, possibly endotoxin, and activated leukocytes) are flushed into the systemic circulation. A systemic inflammatory response syndrome (SIRS) is initiated, triggering the complement and coagulation cascades, elaborating cytokines, and provoking widespread endothelial dysfunction and vital organ injury. Even in those surviving this initial phase of acute gut-derived inflammation, the reperfused but injured intestine can continue to be detrimental to the host. The gastrointestinal tract normally is inhabited by a large collection of gram-negative bacteria. Gut-mucosal barrier disruption after ischemia-reperfusion injury allows translocation of these bacteria.[16,17] The vast hepatic sinusoid network, lined with fixed-tissue macrophages (Kupffer cells), is strategically located to interact with gut-derived endotoxin and contribute to multiple-organ-system failure (MOSF). Noncardiogenic pulmonary edema is well recognized after intestinal ischemia-reperfusion injury.[14,18] Postoperatively, renal and hepatic dysfunction also are common.

Intestinal Ischemia Risk Factors

A number of factors influence the development of and survival from acute mesenteric ischemia. Factors predisposing to occlusive mesenteric ischemia include hypertension, tobacco use, family history of cardiovascular disease, peripheral vascular disease, coronary artery disease, diabetes, congestive heart failure, prior myocardial infarction, cerebrovascular disease, hypercholesterolemia, and atrial fibrillation.[19,20] Nonocclusive mesenteric ischemia results from splanchnic vasoconstriction in response to systemic factors and is associated with acute cardiac dysfunction (myocardial infarction, arrhythmia, left ventricular dysfunction), hypovolemia, and pharmacotherapy.[21] Factors predictive of mortality secondary to intestinal ischemia include advanced age, generally poor health, diagnostic delay, and nonocclusive mesenteric ischemia.[5] Most patients with asymptomatic high-grade stenosis or occlusions of all three mesenteric trunks will develop symptoms or die during follow-up.[22] Therefore, elective revascularization should be considered if they are fit for surgery.

Clinical Presentation of Mesenteric Ischemia

The classic diagnostic triad for chronic intestinal ischemia includes weight loss, abdominal angina, and altered bowel habit.[4] The acute presentation may be on a background of chronic intestinal angina or de novo in a previously unsuspected individual with symptoms ranging from subtle signs of intraabdominal sepsis to the dramatic acute abdomen.

ACUTE EMBOLIC OBSTRUCTION

Acute embolic obstruction of the SMA is characterized by acute onset of severe central abdominal pain, often associated with nausea, vomiting, and even diarrhea or a bowel movement. Pain often is described as out of proportion to objective findings and is poorly localized until advanced signs of peritonitis ensue. The patient often adopts a chin-to-knees body habitus, initially restless but later lying quiety once peritonitis develops. In the early stages, abdominal examination may be truly unremarkable, perhaps with some diffuse tenderness without localized peritonitis. Development of an ileus or peritoneal findings is a grave sign suggestive of mesenteric infarction. Bloody diarrhea is a late sign associated with mucosal disruption.[20] Initial collapse is not uncommon, but sustained hypotension in the early stages is more likely due to a cardiac than an intestinal cause. Embolic sources, such as arrhythmia (atrial fibrillation), acute myocardial infarction, dilated cardiomyopathy, or a recently instrumented aorta, should be sought.

ACUTE THROMBOTIC OCCLUSION

Thrombotic occlusion occurs often in the setting of chronic symptoms of mesenteric ischemia. When possible, a history of weight loss, intestinal angina, or altered bowel habit should be sought. The presence of chronically developed collaterals may protect against distal ischemia, making the presentation subtle and gradual, with only vague abdominal pain and altered bowel habit initially. However, preexisting atherosclerotic disease in the other major mesenteric trunks will predispose to acute-on-chronic thrombosis of the remaining trunk, critically restricting flow to the entire mesenteric bed and leading to massive mesenteric infarction.

NONOCCLUSIVE MESENTERIC ISCHEMIA

There is increasing awareness of nonocclusive mesenteric ischemia (NOMI). Any systemic hypoperfusion state can threaten the mesenteric territory, with local vasoconstriction leading to a severely reduced mesenteric perfusion. Mesenteric vasoconstriction may be precipitated by a variety of shock states, namely, cardiogenic, septic, hypovolemic, and even anaphylaxis.[23] Furthermore, drugs commonly used to treat acute cardiac dysfunction (digoxin, β blockers) and those employed to support the failing circulation (catecholamines,

vasopressin) may exacerbate mesenteric vasoconstriction. Therefore, NOMI should be considered early in any hypotensive patient with suggestive findings.[21] Clinical signs are often vague, with new or persistent ileus, abdominal distention, or sepsis of unknown source. Rectal mucus, melena, or frank blood are nonspecific but may point to bowel ischemia. There may be a role for gastrointestinal balloon tonometry in indentifying patients with or at risk of developing NOMI. Recreational drugs (e.g., cocaine) have been reported recently to cause acute NOMI, and a history should be sought if suspicion arises.[24]

MESENTERIC VEIN THROMBOSIS

Mesenteric vein thrombosis most often results in a delayed presentation, often preceded by several weeks of intermittent abdominal pain and altered bowel habit,[2] but it also can cause acute abdominal signs and fever. It should be suspected in patients with previous abdominal surgery, thrombophilia, prior mesenteric or deep venous thrombosis, cirrhosis, or malignancy.

MISCELLANEOUS CAUSES OF ACUTE MESENTERIC ISCHEMIA

Other pathologic processes occasionally causing acute mesenteric ischemia include aortic surgery (when the IMA is ligated and collateral flow is insufficient[25]), aortic dissection[26] (even when mesenteric vessels are not directly involved, hypotension may combine with pseudocoarctation to provoke ischemia), aortic trauma, mesenteric aneurysm rupture, arteritis, fibromuscular dysplasia (FMD), and extrinsic mechanical vascular obstruction. Acute intestinal ischemia also may arise as a result of extrinsic mechanical compression of the arterial inflow or venous outflow. As low-pressure conduits, veins are most susceptible to extrinsic compression; intramural venous plexi may be obstructed due to wall distention, whereas mesenteric veins may be compressed by tumor, adhesion, volvulus, hernia, or intussusception.

Diagnosis of Acute Mesenteric Ischemia

The single most important factor is clinical suspicion followed by investigation. A delay in diagnosis may be lethal.[20] No single blood marker has proved to be an adequate screening test. Lactic acidosis has poor sensitivity in detecting bowel ischemia. Despite advances with noninvasive radiologic testing, mesenteric angiography remains the definitive test. ACT angiogram may yield similar information while also demonstrating abnormalities of the bowel wall. Even with high-quality imaging studies, laparotomy may be required for definitive diagnosis. A suggested algorithm for the initial approach to a patient with suspected acute mesenteric ischemia is given in Fig. 86-2.

LABORATORY SERUM PARAMETERS

No serum marker has been proven to be sensitive and/or specific enough to confirm reliably the presence or absence of acute mesenteric ischemia. Nevertheless, some are clinically useful. In acute mesenteric ischemia, a leukocytosis is almost invariably present, except in those who are immunocompromised owing to comorbid disease, advanced age,

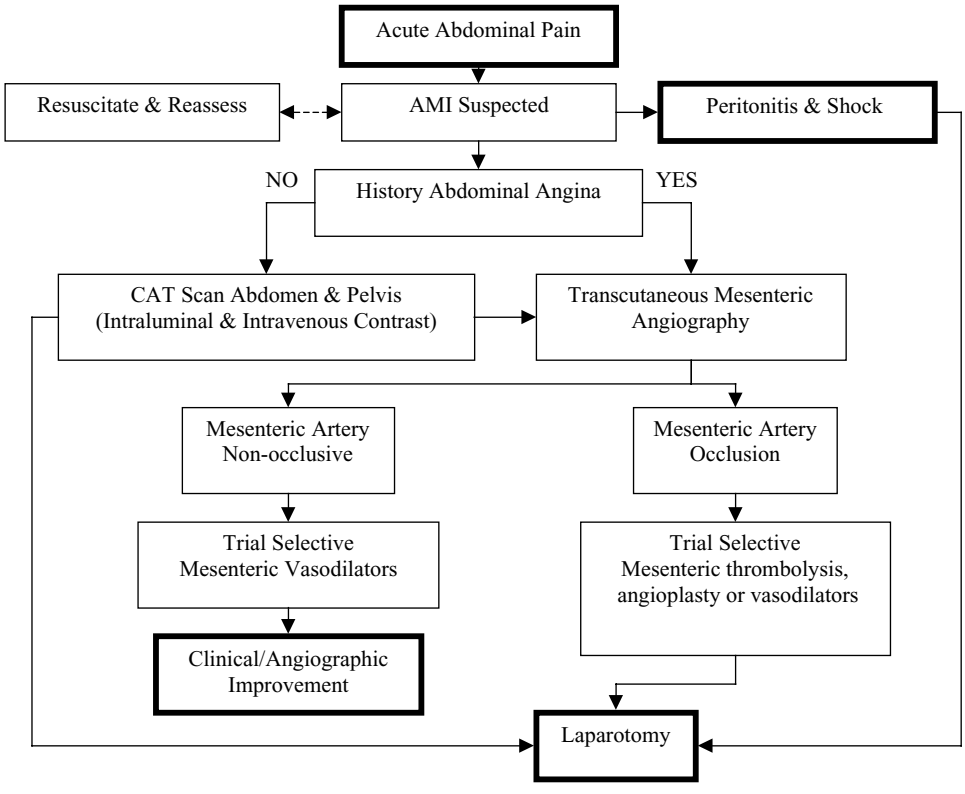

FIGURE 86-2 Algorithm for the diagnosis and investigation of mesenteric ischemia.

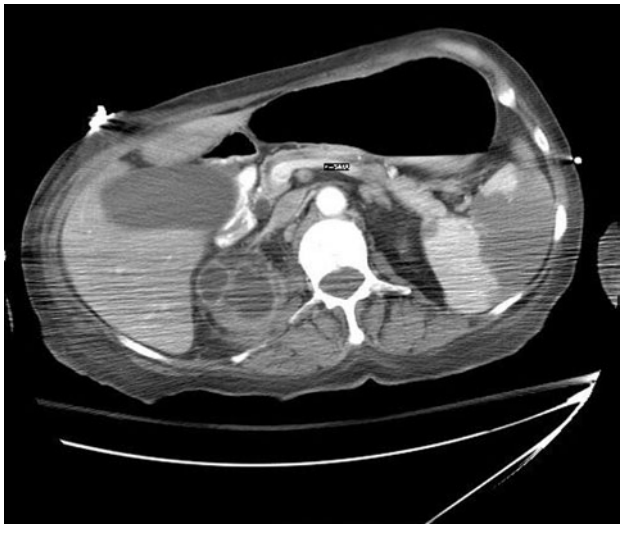
corticosteroid treatment, or profound critical illness. A neutrophilia is typical (total white blood cell typically = 16,000 to 30,000/μL), and early white cell forms are common. Platelets typically are reduced. Coagulopathy may be present in advanced mesenteric ischemia with sepsis or perforation. Arterial blood gases frequently are normal initially, but in the later stages, metabolic acidosis and acute hypoxia may supervene. Lactic acidosis is often a late finding. Prerenal azotemia is a grave indicator, signaling hypovolemia, sepsis, nephrotoxic effect, or disseminated intravascular coagulation (DIC). The erythrocyte sedimentation rate (ESR) and later C-reactive protein (CRP) level may rise. Potential alternative serum markers, such as creatinine kinase (CK) BB isoenzyme, lactate dehydrogenase, intestinal isoenzyme of alkaline phosphatase, diamine oxidase, hexosaminidase, and aspartate transferase, have not proved sufficiently sensitive or specific. The most encouraging markers are serum inorganic phosphate,[27] α-glutathione-*S*-transferase,[28] and D-lactate.[29] Another possible marker is intestinal fatty acid–binding protein (I-FABP), which is currently the focus of a prospective trial.

PLAIN ABDOMINAL RADIOGRAM

Plain abdominal radiographs may reveal supporting information such as heavy calcification of the abdominal vasculature, although this is neither sensitive nor specific. In a retrospective series of 23 patients with acute mesenteric ischemia, 26% had normal plain films. Nonspecific signs of ischemia, such as intestinal dilation or gasless abdomen, may be present, but the greatest value of the abdominal radiograph is in establishing an alternative diagnosis. In the advanced stages of mesenteric ischemia, mural changes such as wall thickening or valvulae conniventes, "thumb printing," or intramural gas (pneumatosis intestinalis) may be present.[30] Intrahepatic portal vein pneumatosis or free intraperitoneal gas also may be seen.

ULTRASOUND

B-mode ultrasonography is quick, readily available, noninvasive, and well tolerated by most patients with abdominal pain. When acute mesenteric ischemia is present, ultrasonography may reveal a thickened (>5 mm) bowel wall and signs of ileus (distended bowel loops and hypoperistalsis). In advanced cases (mesenteric infarction), ultrasound may show intraperitoneal fluid, pneumatosis, or intrahepatic portal venous gas. However, ultrasonography is operator-dependent and may be confounded by the degree of intraluminal intestinal gas or by obesity. For patients with suspected chronic mesenteric ischemia, duplex ultrasonography has become the investigation of choice by many. A peak systolic velocity of greater than 275 cm/s in the SMA or greater than 200 cm/s in the celiac artery or no flow signal (in the SMA or celiac artery) predicts a stenosis of greater than 70% with a sensitivity of 89% and aspecificity of 92%.[31]



CT SCAN AND CT-ANGIOGRAM

CT scanning is the radiologic investigation of choice for acute abdominal pain at many centers. Oral contrast enhancement may give better luminal definition but is not used by many centers, especially in the emergency situation. Intravenous contrast enhancement (CT-angiography, CTA) further elaborates the major vessel flow and tissue perfusion (Fig. 86-3). All three mesenteric vessels can be identified and patency assessed by their contrast content. Alternatives to iodinated contrast agents, such as gadolinium, may be used for patients with a contraindication to standard contrast material. Ischemic bowel wall typically is seen as thin and poorly enhanced, more prominent on the antimesenteric border in NOMI. Air may be seen in the bowel wall or the portal vein. Reperfused bowel segments appear enlarged and edematous, often with increased mucosal and submucosal enhancement due to interstitial extravasation of contrast material.[32] With the increased availability of modern multislice helical CT scanners, rapidly acquired high-quality CTA images of the main mesenteric trunks and small collaterals are possible.[64] Compared with mesenteric angiography, CTA may prove safer, cheaper, and better tolerated and result in decreased radiation exposure for both patient and staff.

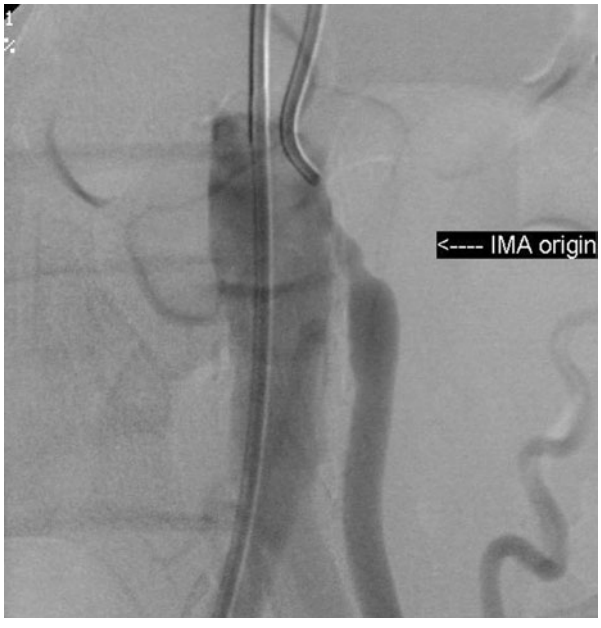
MRI AND MR-ANGIOGRAPHY (MRA)



The superior soft-tissue definition and non-contrast-enhanced angiographic ability of MRI give it potential advantages in patients with an acute abdomen.[33] Recent advances in MRA technology and the use of contrast-enhanced (CE) techniques have shortened acquisition times and reduced the impact of motion artifacts, which previously had restricted its use.[34] MRA may prove to be the investigation of choice in chronic mesenteric ischemia, where it has been suggested that CE-MRA is superior to digital subtraction angiography for simultaneous exploration of the abdominal aorta and its major branches, and it can be coupled with measurements of flow and assessment of surrounding soft tissues.[35] However, at present, its use in emergency practice remains experimental.

ANGIOGRAPHY

Mesenteric angiography remains the most specific test for the diagnosis of mesenteric ischemia, giving objective, reproducible evidence and in some instances providing therapeutic catheter-based options.[36] Not only does it identify the location of the flow-limiting lesion, but it also may give information about distal runoff and the extent of collateralization, allowing the most appropriate therapy to be planned. However, it cannot discern whether or not intestinal infarction has occurred, and therefore, treatment always must be planned with full assessment of clinical and laboratory parameters, especially if a catheter-based therapy is planned.[37]

Thrombotic occlusion usually occurs on a background of chronic atherosclerotic disease, where lesions tend to be at or near the ostium, producing an abrupt cutoff of contrast (Fig.-86-4). The chronicity of the atherosclerotic process may be indicated by the presence of multivessel disease or the presence of large collaterals refilling the branch territories distally. One must consider the clinical findings carefully because chronic mesenteric occlusions are seen in up to 60% of the octogenarian population but cause symptoms in only 5%.

FIGURE 86-4 Angiographic image of elective injection of the IMA with severe origin stenosis.

Mesenteric artery emboli present as sharp, rounded filling defects with a typical meniscus sign. Distal vessels may refill through collateral vessels. Emboli typically lodge at the sites of vessel narrowing, such as the origin or a bifurcation. The SMA is affected most often because it is a relatively large vessel with high flow, and its orientation encourages antegrade entry of the embolus. SMA emboli typically occlude the vessel just distal to the middle colic artery origin.

Nonocclusive mesenteric ischemia is typified by diffuse narrowing of the mesenteric artery and its branches, alternating areas of narrowing and dilation of the main trunk and branches ("string of sausages sign"), spasm of the peripheral vascular arcades, impaired filling of intramural vessels, and slow flow with increased reflux of contrast material into the aorta during selective injection. An increase in vessel caliber after transcatheter papaverine injection may clinch the diagnosis. Mesenteric venous thrombosis is seen on the later phase of angiography with contrast stasis and lack of portal venous phase filling.

Management

Initial management includes identifying and correcting immediately any life-threatening hypoperfusion or electrolyte abnormalities while planning further definitive steps toward diagnosis and treatment. Simple airway management with supplemental oxygen by mask, titrated to achieve oxygen saturation above 95%, will suffice in patients who are breathing spontaneously. Obtunded patients typically should be intubated electively, bearing in mind the risk of aspiration owing to gastroparesis and intestinal ileus. A wide-bore nasogastric tube should be placed for intestinal decompression. Acute electrolyte disturbances such as hypokalemia, hypomagnesemia, and hypophosphatemia should be corrected. Broad-spectrum antibiotics (e.g., second-generation penicillin or third-generation cephalosporin, along with anaerobic coverage) should be administered intravenously. Analgesia should not be withheld in the conscious patient. Systemic heparinization is advocated once the diagnosis is strongly suspected, unless there are absolute contraindications. The goal is a partial thromboplastin time (PTT) of greater than 2 times control.

DIAGNOSTIC AND THERAPEUTIC SELECTIVE MESENTERIC ANGIOGRAPHY

Where there is diagnostic doubt in a patient with suspected mesenteric ischemia but stable clinical assessment, diagnostic mesenteric angiography is advocated.[38] Modern catheters and techniques reduce the risks of bleeding, dissection, and embolization. In a well-resuscitated patient, small-volume nonionic contrast and digital subtraction angiography (DSA) limit the risk of nephrotoxicity and contrast reaction. An initial flush aortogram may define the origins of the major vessels and outline possible collateral pathways. Selective mesenteric artery catheterization allows for thorough assessment of individual arterial territories and opens up therapeutic options.[39]

For NOMI, catheter-based therapy is the treatment of choice in the absence of definitive signs of intestinal infarction.[40]

Papaverine (30 to 60 mg/h) is infused selectively into the SMA for a period of 24 hours. Repeat flush angiography should confirm partial or complete resolution of spasm 30 minutes after beginning the infusion and prior to the patient's return to the ICU. Papaverine is a potent phosphodiesterase inhibitor, leading to increased intracellular cAMP and vasodilation.[41] Because of extensive hepatic first-pass metabolism, systemic effects such as hypotension generally are modest. Failure of therapy may be signaled by cardiovascular instability, progression of clinical symptoms or signs, and catheter displacement or blockage.

Occlusive mesenteric ischemia traditionally requires surgery. However, increasing numbers of interventional radiologists are exploring the use of catheter-based therapies as long as there is no frank intestinal infarction. A number of techniques are available for recanalization, including suction clot retrieval, thrombolysis, angioplasty,[42] and stenting.[43] All these techniques remain investigational and should be conducted only in collaboration with an appropriately trained surgeon and an interventional radiologist and with appropriate monitoring and reassessment of the patient.[44] Even when a decision is made to proceed to surgery, continued infusion of papaverine or heparin into the occluded vessel may improve distal circulation and prevent clot propagation pending definitive surgery.

MINIMALLY INVASIVE SURGERY

In the setting of high suspicion of acute mesenteric ischemia, some have advocated laparoscopic assessment of the abdominal contents[45] and have suggested that this can be done safely with high diagnostic accuracy.[46] The minilaparoscopy is being advocated increasingly in the critical care setting where there remains diagnostic doubt in a deteriorating patient, and some have done this safely at the bedside.[47] The generally poor results of open surgery, even in good hands, have encouraged some surgeons to explore less invasive alternatives using laparoscopic techniques. Some practitioners have claimed improved survival and reduced morbidity using this approach, but whether these results in specialized centers can be extended to other settings is unknown.[48]

OPEN SURGERY

Often the definitive assessment and management of acute mesenteric ischemia require open surgery.[49] The surgeon should repeat the abdominal examination once the patient is anesthetized. In the absence of muscle tone and tenderness, new pathology, such as an abdominal mass or aortic aneurysm, may be detected. Adequate exposure generally requires a full midline laparotomy with transperitoneal approach. Although retroperitoneal approaches to the aorta and branches are useful in chronic mesenteric revascularization, they do not allow adequate assessment of intestinal perfusion and viability in the acute setting. The initial aim is to confirm the diagnosis and rule out any major confounding disease. The acutely ischemic intestine may appear remarkably normal prior to infarction and before reperfusion. Changes may be focal, segmental, or global depending on the etiology of the ischemia. The intestine is inspected for loss of sheen, discoloration (gray through black), and lack of peristalsis. SMA thrombosis typically occurs at the origin, so the distribution of ischemia classically involves the entire small bowel and proximal half of the colon. SMA embolism, on the other hand, may spare the right colic branch and proximal jejunum branches if it lodges distal to the origin. However, the clot may lodge at the origin, giving a similar pattern to thrombosis. Microemboli typically disperse and lodge distally, creating patchy areas of ischemia with normal intervening segments. Delicate palpation for arterial pulsation must be carried from the root of the SMA to its mesenteric branches. Visible pulsation may be seen in the mesenteric arterial arcades. More objective assessment by means of sterile Doppler ultrasound probe may reveal an absence of flow in the main branches, arcades, or the intestine itself. Previously used assessment with intravenous fluorescein dye and an ultraviolet lamp is now rarely practiced clinically.[50]

Except in very advanced cases where perforation has occurred or is imminent, revascularization should precede the resection of nonviable bowel. In the presence of frank necrosis, quick segmental resection may be carried out using a gastrointestinal linear stapling device without undue delay of revascularization. On reperfusion, remarkable recovery is often witnessed in seemingly unsalvageable segments, especially important when near-total small bowel resection seems inevitable at first inspection, with the consequent implications of lifelong parenteral nutrition therapy. Caution must be exercised in the setting of an elderly, infirm, or hypotensive patient because the systemic effects of reperfusion of a profoundly ischemic intestine may lead to catastrophic acidosis, hyperkalemia, myocardial depression, and refractory shock. The initial approach to revascularization in most cases is an attempt at embolectomy; if satisfactory antegrade flow cannot be achieved, then one proceeds to mesenteric artery bypass.

SUPERIOR MESENTERIC ARTERY EMBOLECTOMY

The superior mesenteric artery may be exposed and controlled transperitoneally at the base of the transverse mesocolon, where it courses from its midline aortic origin, obscured by the body of the pancreas in its proximal few centimetres, and then rises over the fourth part of duodenum to give off its first branch, the right colic artery, and enter the mesentery. Its localization by palpation may be assisted by sterile Doppler probe in the bulky mesentery. After splitting the mesentery and retroperitoneum in the line of the vessel, it is controlled with vascular loops at the level of its bifurcation. Only minimal dissection of the numerous small perivascular nerves and lymphatics is required. Standard approach is via a tranverse arteriotomy, but longitudinal opening may help if vessel caliber is small or if bypass is to be expected. Proximal embolectomy is carried out first with a balloon catheter (size 3F or 4F). If pulsatile aortic flow is restored, the vessel is reoccluded, and the surgeon proceeds to distal embolectomy.[51] Mesenteric bypass is indicated if there is failure to pass the catheter, inadequate inflow, or a heavily diseased vessel. Distal embolectomy is performed gently manually, guiding the balloon catheter (size 3F) into the major branches, until all thrombus is retrieved and backbleeding is seen. The arterial closure should maintain an adequate lumen and is best achieved with interrupted monofilament sutures, sometimes requiring a patch angioplasty with autologous

vein. Restoration of pulsatile flow should be assessed clinically by palpation and visualization of the intestinal perfusion and checked intraoperatively with sterile Doppler probe (at the bowel-intestinal margin) or duplex ultrasound. Spasm is common in the distal vessels and may be relieved by perivascular infusion of papaverine (30 mg).

SUPERIOR MESENTERIC ARTERY BYPASS

Mesenteric artery revascularization is indicated to restore intestinal blood flow if the diagnosis is mesenteric thrombotic occlusion or adequate inflow is not achieved at embolectomy.[1] A number of surgical approaches are available, but in these fragile patients a quick, durable approach is to bring retrograde inflow from the common iliac artery. The choice of inflow vessel is influenced by the quality and patency of the common iliac arteries. Either right or left can provide a suitable graft configuration. Should a vein be chosen secondary to a contaminated field, the left iliac is preferred to avoid potential kinking. If the infrarenal aorta is chosen, a nonocclusive clamp may be used. In the absence of a suitable infrarenal inflow vessel, the supraceliac aorta may be approached through the lesser sac for inflow. The choice of arterial bypass conduit is a matter of debate. Prosthetic material is easy to handle, obviates the need for autologous vein harvest, and reduces operative time. Indeed, even in the presence of moderate contamination, the risks of graft infection remain low when polytetrafluoroethylene (PTFE) or antibiotic-impregnated (rifampin 1 to 60 mg/mL) Dacron is used. In the presence of gross fecal contamination, an autologous vein graft is preferred, the reversed long saphenous vein being most suitable. The inflow anastomosis is classically end to side, and the outflow anastomosis is easiest to construct end to end after division of the superior mesenteric artery or end to side using the anterior arteriotomy employed for thrombectomy.

INTESTINAL VIABILITY

Clinical assessment by an experienced surgeon remains the most widely practiced method to determine intestinal viability. A sensitivity of 82% and a specificity of 91% were achieved using the following factors: presence of visible pulsation in the mesenteric arcades, bleeding, color, and peristalsis.[50] Increasingly, most vascular surgeons now confirm their clinical findings with a sterile Doppler ultrasound flow detector (5 MHz), detecting pulsatile Doppler signals at the mesenteric arcades and intestinal surface. The goal of intestinal resection is to remove areas of nonviable bowel and leave sufficient viable bowel to sustain independent life. In general, if a large segment (>6 ft of small intestine) of obviously viable bowel can be identified, then nonviable segments should be resected liberally. Restoration of continuity is preferred; anastomoses may be hand sewn to preserve more functioning intestine, but a stapler may be quicker. In the presence of gross contamination or doubtful viability, creating a stoma may be considered, but in this setting a "second look" laparotomy (after 18 to 36 hours) would allow adequate resuscitation of the patient and clearer differentiation of bowel viability.[52] In the case where a second look is required, obviously necrotic segments may be resected using a linear gastrointestinal stapling device, and continuity need not be restored, cutting operative time. A tunneled central venous catheter should be placed at the time of surgery in most of these patients to facilitate long-term parenteral nutrition.

POSTOPERATIVE CARE AND FOLLOW-UP SURVEILLANCE

Postoperative care must be in an intensive care setting if acceptable results are to be achieved in these high-risk patients. Second-look laparotomy should be the rule rather than the exception and, when planned at the initial surgery, must be adhered to despite the patient's clinical course.[19] Reperfusion of the ischemic intestine leads to inflammatory edema of the affected segments, and this, combined with large volumes of intraluminal fluid sequestration, places these patients at risk for developing abdominal compartment syndrome in the postoperative period[53] (see Chap. 42). Beyond basic fluid management and cardiorespiratory support, attention must be given to nutritional support. In the catabolic postoperative recovery phase, demands are increased, often on a background of chronic malnourishment and often compounded by dysfunctional reperfused bowel and short bowel syndromes. After major resections, postoperative parenteral nutrition invariably is required, often for extended periods, because even viable segments often have prolonged absorptive and motility dysfunction for extended periods.[54] Postoperative heparin therapy should be continued in the absence of bleeding diathesis, and oral warfarin should be commenced, with a target International Normailzation Ratio (INR) of 2.0 to 3.0, as soon as oral diet is resumed. In the case of embolic disease, a primary source should be sought by transthoracic or transesophageal echocardiography and full aortic (chest and abdomen) CT scanning.[65] Thoracic aortic mural thrombus is an infrequent cause of emboli that is being recognized with increasing frequency by transesophegeal echocardiography and confirmed by CT scanning.[65] Thrombotic occlusions especially of the mesenteric vein should prompt a thrombophilia evaluation. Secondary prevention strategies such as smoking cessation and dietary and therapeutic lipid

control may prevent further cerebrovascular and mesenteric vascular events.

Prognosis

Despite numerous advances in the assessment, diagnosis, and treatment of mesenteric ischemia, the mortality rate remains very high even in specialist centres (Table 86-3). Diagnostic delay is perhaps the greatest hurdle to improvement. Most patients who survive the initial perioperative period regain independent living, with results comparable with elective revascularization of chronic mesenteric ischaemia.[55] The sequelae of short-bowel syndrome may necessitate home parenteral feeding for a period in many and for the long term in a third of survivors.[54] Our group has highlighted the need for continued surveillance of mesenteric bypass grafts to improve the secondary patency and avoid recurrent ischemia.[56]

PART X
THE SURGICAL PATIENT

Chapter 87

SPECIAL CONSIDERATIONS IN THE SURGICAL PATIENT

JAMEEL ALI

KEY POINTS

- *The biologic response to surgery results in fluid, electrolyte, and systemic hormonal changes that must be considered in the ICU management of the surgical patient.*
- *Nutritional support of the critically ill surgical patient must involve consideration of the effect of surgical stress on nitrogen balance and on insulin and blood glucose levels.*
- *The hypercoagulable state that follows surgery warrants consideration of prophylaxis against thromboembolic complications, particularly in the ICU patient.*
- *Timely surgical intervention, and treating and preventing hemorrhage and sepsis are crucial in determining outcome in the critically ill.*
- *Surgery increases the demand on the cardiorespiratory system and the likelihood that temporary mechanical ventilatory assistance will be needed.*
- *Pulmonary edema and atelectasis characterize perioperative respiratory failure; hypoventilation and aspiration also contribute.*
- *Where possible a reduction of pulmonary capillary hydrostatic pressure in the perioperative period improves gas exchange by decreasing lung water.*
- *The concept of closing volume and its relationship to functional residual capacity is important in understanding perioperative atelectasis.*
- *Risk factors for perioperative atelectasis include obesity, smoking, advanced age, anesthesia, recumbency, and incisional pain.*
- *Diaphragmatic dysfunction is a major component of perioperative respiratory failure.*
- *Preoperative assessment of respiratory function makes it possible to predict operative risk and to correct abnormalities before operation, particularly in the patient undergoing lung resection.*
- *Early ambulation, physiotherapy, treatment of sepsis and shock, adequate analgesia, and early operative stabilization of fractures are key elements in the treatment and prevention of perioperative respiratory failure.*

The critically ill surgical patient is at risk for developing all of the potential problems that afflict nonsurgical patients in the intensive care unit (ICU). In addition, there are factors unique to the surgical patient that warrant special consideration if management is to be appropriately directed in the ICU environment.

Surgical stress or injury stimulates an orchestrated biologic response[1–4] aimed at preserving the milieu intérieur. This response includes the elaboration of adrenocortical hormones, catecholamines, and glucagon; a decrease in insulin release resulting in hyperglycemia; and the secretion of antidiuretic hormone (ADH) and aldosterone, as well as the release of cytokines and the stimulation of a hypercoagulable state.[5–10] These responses affect the critically ill surgical patient in many ways. Acute fluid and electrolyte shifts may occur, the renal response to volume infusion may be altered, and the catabolic response results in a phase of negative nitrogen balance.[11,12] All these responses vary in intensity, depending on the magnitude and duration of the injury, the adequacy of resuscitation, and the presence of complications such as hemorrhage and sepsis. The increase in metabolic rate increases oxygen requirement and consumption. The management implications of these responses to surgical stress are outlined in the following sections.

Considerations in Critically Ill Surgical Patients

THE ENDOCRINE RESPONSE

The glucagon and insulin response to injury can lead to major changes in glucose metabolism. Hyperglycemia may occur in a patient who has previously demonstrated no evidence of abnormality in glucose levels. This situation may also unmask a latent diabetic state in some patients, as well as complicating the management of already established diabetes mellitus in the critically ill surgical patient. Close monitoring of blood glucose, ketones, electrolytes, and acid-base status is essential for proper management of the surgical patient. Strict control of blood sugar (80 to 110 mg/dL) has been shown to improve outcome in surgical ICU patients,[13] but how to achieve this safely and how low the glucose must be to offer benefit are unknown. Alteration in the glucose content of infused fluids and administration of insulin may be necessary to overcome these responses to surgical stress.

ANTIDIURETIC HORMONE AND ALDOSTERONE

Blood loss, pain related to surgical incisions, fasting prior to surgery, nausea or vomiting, and various drug administrations are only a few of the factors that predispose the surgical patient to release of ADH and aldosterone. The resulting sodium and water retention make it very difficult to monitor the state of hydration of the patient by relying entirely on urine volumes, since these hormones tend to decrease urine output in spite of normovolemia. Other indices of adequacy of perfusion, such as level of consciousness, capillary return, skin warmth, pulse, and blood pressure need to be assessed. In situations in which these indices prove imprecise, central hemodynamic monitoring is required. In addition, the syndrome of inappropriate ADH release (SIADH) is relatively common in the postoperative period, placing patients at risk of water intoxication and severe hyponatremia when even modest water loads are administered. These problems can be largely avoided if treatment is guided by frequent routine monitoring of electrolytes and fluid volume status.

THIRD-SPACE FLUID SEQUESTRATION

Following surgical trauma, occult fluid loss may occur at several sites, including the area of injury, where extravascular

fluid may accumulate in the interstitial and intracellular spaces,[14,15] as well as in the retroperitoneal space during intra-abdominal manipulation. In addition, operations involving the gastrointestinal (GI) tract or abnormalities resulting from surgical diseases such as peritonitis may result in decreased motility of the gut and sequestration of large volumes of fluid within the gut lumen, the gut wall, and the entire large surface area of the peritoneal cavity. This type of fluid depletes circulating blood volume and is not easily measured by most available clinical methods. In the patient with compromised cardiorespiratory reserve, close titration of fluid balance is crucial. In such patients, central hemodynamic monitoring may be required in addition to other clinical indices of normal perfusion and volume status.

HYPERCOAGULABLE STATE

The hypercoagulable state resulting from surgical trauma necessitates monitoring of clotting parameters in the surgical patient and the institution of prophylactic measures against thromboembolic sequelae, as outlined in other parts of this text.[8,9] It is important to recognize that virtually every surgical patient is at risk for thromboembolic disease, and some are at extraordinarily high risk. Prophylactic regimens that include the appropriate administration of anticoagulants pose a minor risk of bleeding, but can be employed in most surgical patients.

NUTRITION

Although there is an early phase of negative nitrogen balance following surgical stress, it may be shortened or even aborted by appropriate nutritional support before and immediately after surgery.[16] Early institution of enteric feeding has been shown to be of benefit, including a reduction in septic sequelae, in surgical patients undergoing intra-abdominal procedures.[17] When a prolonged period of gut rest is anticipated, early institution of parenteral nutritional support should be considered to prevent further loss of muscle mass. This measure affects not only the maintenance of muscle mass, but also the maintenance of respiratory function, and thus both dependence on ventilatory support and weaning from mechanical ventilatory assistance.

MAGNITUDE AND DURATION OF SURGICAL INSULT

Since the duration and magnitude of surgical procedures affect the intensity of the metabolic and endocrine response, the aim should be to decrease the magnitude, duration, and frequency of surgical insults to the critically ill patient, particularly patients with poor nutritional and cardiorespiratory reserve. This goal, however, must be considered in the context of the underlying problem. The magnitude and duration of the surgical procedure should not be minimized at the expense of incomplete eradication of a surgical lesion, such as a source of sepsis, since failure to eradicate the septic focus would lead to further complications, such as respiratory failure and dependence on mechanical ventilation in the ICU. In the setting of the multiply-injured patient requiring massive blood transfusions that can lead to hypothermia, coagulopathy, and severe cardiorespiratory and renal compromise, "damage-control laparotomy" or abbreviated laparotomy should be considered. This consists of rapid control of hemorrhage (by ligation of vessels and packing) and removal of gross contamination followed by temporary closure, which should be followed as soon as possible by more definitive procedures as improvement in the patient's condition in the ICU allows.[18]

AVOIDANCE OF COMPLICATIONS

Hemorrhage is a frequent sequela to many surgical procedures. The resulting hypoperfusion of the myocardium, brain, and kidney produces further dysfunction in the critically ill ICU patient. All of these events result in deterioration of the patient's condition, with a requirement for further supportive measures, prolongation of the ICU stay, and the development of multiple organ failure. Aggressive replacement of lost blood with appropriate fluid resuscitation and correction of the source of any continuing hemorrhage helps minimize these problems.

Sepsis worsens the response to surgery. In addition, cytokine release and the effects of activated macrophages and neutrophils produce a cascade of systemic responses with attendant worsening of respiratory function and predisposition to multiple organ failure.[19] Early identification and drainage of sources of infection, specific antibiotic coverage, careful monitoring of invasive catheters and their removal when intravascular infection may be present, and débridement of areas of serious infection such as gas gangrene and fasciitis, are all necessary to halt this process and prevent further deterioration of the critically ill surgical patient.

INCREASED OXYGEN REQUIREMENTS

The increase in metabolic rate following surgical stress is associated with an increase in oxygen requirement and utilization.[20] In patients with a normal cardiorespiratory reserve, this increased oxygen demand is met without untoward sequelae. However, patients who are nutritionally depleted or whose cardiorespiratory function is already compromised may be unable to meet the increased oxygen demand. The result can be decompensation with anaerobic metabolism, muscle fatigue, and respiratory failure. In the high-risk patient, consideration should be given to providing temporary cardiorespiratory support during the phase of increased oxygen requirement. Such patients may require intubation and mechanical ventilation for short periods until the acute insult has abated.

The increased oxygen requirement of surgery and the postoperative state has caused some authors to recommend measuring and then maximizing oxygen delivery[20] in critically ill patients. Use of invasive hemodynamic monitoring or gastric tonometry allows titration of catecholamine infusions, blood products, or other therapies to increase oxygen delivery to targeted supranormal levels. Many studies supporting this approach were likely flawed by inappropriate methodology, although there is some indication in high-risk surgical patients that outcome can be improved.[21–23]

OTHER CONSIDERATIONS IN THE SURGICAL PATIENT

Pain from surgical incisions may exacerbate the metabolic response to injury and mechanically restrict respiratory function, the latter potentially necessitating mechanical ventilatory assistance. Judicious parenteral analgesia as well as

regional, intercostal, and epidural anesthesia may also be useful in these situations.

Neurosurgical patients and those who have suffered head trauma should be monitored closely for signs of increased intracranial pressure. If clinical signs cannot be easily elicited, an intracranial pressure monitoring device should be placed. Apart from the identification of mass lesions that may require evacuation, the mainstay of treatment for these patients is reduction of cerebral edema through the maintenance of cerebral blood flow and oxygenation and the avoidance of hypercapnia (see Chap. 93). The vascular surgery patient requires close monitoring of perfusion, particularly in the arterial territorial distribution of the repaired vessel. Skin temperature, Doppler ultrasound, and digital pressure measurements are required in the ICU setting to identify problems with vascular anastomoses as early as possible and permit early corrective measures. Immediately after surgery carotid artery surgery patients are at higher risk for developing neurologic complications from reocclusion at surgical sites of vascular repair, and careful monitoring of the neurologic status as well as maintenance of adequate oxygenation and perfusion are essential to avoid such complications.

Following GI surgical procedures, the gut should be used early for enteral nutrition whenever appropriate.[17] When that is not possible and a prolonged period of decreased motility is anticipated, intubation and decompression of the GI tract is necessary to prevent distention and to monitor the volume and character of losses. This intervention, together with replacement of measured losses as well as determination of serum electrolytes, allows early identification and correction of abnormalities and the prevention of complications. Patients who develop sepsis following GI surgical procedures should be considered to have a source of that sepsis within the abdomen until proven otherwise. Early aggressive investigation for identifying such a source of sepsis is essential in order to avoid further deterioration in the ICU.

The gut has also been considered to play a major role in the pathogenesis of multiple organ dysfunction syndrome and decontamination of the GI tract has been suggested as a prophylactic measure in this syndrome.[24]

Stress ulcers resulting in GI hemorrhage are a sequela not only of GI surgery, but of other forms of critical illness. As described elsewhere in this text (see Chap. 10), prophylactic measures against stress ulceration directed at decreasing acid injury to the gastroduodenal mucosa are an essential part of the management of critically ill patients.[25]

Perioperative Respiratory Failure

In the period before, during, and after surgical treatment, patients are unusually vulnerable to respiratory failure owing to special manifestations of pulmonary edema, atelectasis, hypoventilation, aspiration, sepsis, and hypotension. Awareness of the factors promoting each of these interrelated processes makes possible an effective prevention program or early diagnosis and treatment of perioperative respiratory failure.

PULMONARY EDEMA

Of the forces in the Starling equation governing transcapillary fluid flux, the ones of particular relevance to surgical patients are microvascular hydrostatic pressure and pulmonary capillary permeability.

MICROVASCULAR PRESSURE

As indicated, secretion of ADH and aldosterone is a major component of the metabolic response to surgery and trauma.[26] Both hormones tend to conserve water and decrease urine output in the postsurgical patient. However, a focus on increasing urine output in the surgical patient by administering large volumes of fluid without regard to this metabolic response could easily result in fluid overload and pulmonary edema, leading to hypoxemia. Guidelines for fluid resuscitation in the perioperative period that focus primarily on urine output and fluid replacements based on empirical values[27] can increase extravascular lung water and predispose the surgical patient to perioperative respiratory failure. Although a young, healthy patient with significant cardiopulmonary reserve will undoubtedly tolerate these insults, an elderly surgical patient with a brittle cardiorespiratory status is more likely to develop respiratory failure unless extreme caution is taken with fluid resuscitation, involving close, constant monitoring of central hemodynamics.

Pulmonary edema occurring in the head-injured patient, or *neurogenic edema,* may be associated with a transient increase in hydrostatic pressure because of intense sympathetic discharge, although it has been suggested that there may be a component of increased capillary permeability as well in this lesion.[28] Therefore, monitoring of pulmonary capillary hydrostatic pressure is important in determining therapeutic approaches to the head-injured patient with pulmonary edema.

High-pressure pulmonary edema does not resolve immediately after vascular pressures are normalized.[29] The implication of this finding is that the timing of the measurement of pulmonary artery wedge pressure (PAWP), which is used as a reflection of capillary hydrostatic pressure, is crucial in determining whether pulmonary edema is considered to be due to high vascular pressures or to an increase in capillary permeability. Ordinarily, the presence of normal or low PAWP in the presence of pulmonary edema would be regarded as evidence of capillary-leak pulmonary edema. However, if the PAWP is measured during the lag phase of resolution of high-pressure pulmonary edema after PAWP has been decreased, then inappropriate therapy directed at capillary leakage may be given, while the role of the cardiogenic edema that is already resolving slowly is overlooked.

Diuretics such as furosemide clear edema by decreasing the central blood volume and pulmonary capillary hydrostatic pressure.[30] However, these agents may produce effects on gas exchange before pulmonary edema has cleared.[31] Accordingly, diuretic therapy and fluid management of the oliguric, hypoxemic perioperative patient may confuse the student of critical care at several levels. First, oliguria in the immediate postoperative period is not necessarily due to reduced blood flow to the renal cortex (prerenal oliguria), so fluid challenges aimed at increasing renal blood flow may not be appropriate in this setting. The consequent increase in pulmonary blood volume and pressure predictably increases pulmonary edema. On the other hand, diuretic therapy in such a patient will increase urine output, even when the oliguria is due to reduced renal blood flow, thereby aggravating the prerenal failure. The best approach to this common perioperative

conundrum is to recognize that urine output may be an unreliable index of adequate perfusion in the immediate postoperative period, and to seek other indices of perfusion through careful history-taking, physical examination, and first-hand knowledge of the patient's perioperative course. For example, a prior history of congestive heart failure predicts susceptibility to fluid overload, and thus should slow the physician's hand in administering fluid. Similarly, familiarity with the patient's preoperative blood pressure, heart rate, heart sounds, pulse volume, and digital perfusion allow the discerning physician to detect early signs of hypoperfusion requiring volume replacement. Often, the critical distinction between fluid overload and hypovolemia is not clear even to the astute clinician, and in such cases a low threshold for instituting central hemodynamic measurements is indicated.[32] Once these steps have been taken, fluid can be administered in the setting of low PAWP, low cardiac output, and oliguria in an attempt to return blood flow toward normal without risking edema. An untoward increase in PAWP without much increase in blood flow warrants immediate re-evaluation of the patient's cardiac function, including an electrocardiogram (ECG) and measurement of cardiac enzymes, and administration of vasoactive drug therapy (e.g., dobutamine, 2 to 10 μg/kg per minute), to increase ventricular contractility and output at reduced PAWP.

PULMONARY CAPILLARY PERMEABILITY

A frequent cause of increased capillary permeability and respiratory failure in the surgical patient is unrecognized sepsis, which is commonly seen in the abdomen; this source often requires a surgical or percutaneous radiologic approach. Therefore, a major component of the prevention and treatment of respiratory failure in the surgical patient is the early identification of occult sources of sepsis, aggressive investigation for abdominal causes of sepsis, and the provision of adequate drainage and treatment of septic foci, particularly within the abdomen.

Although both increased microvascular hydrostatic pressure and pulmonary capillary permeability are important factors in the elaboration of extravascular lung water, manipulation of the microvascular pressure (by the use of vasoactive agents and regulation of the state of hydration) is the most direct means of altering pulmonary edema in the surgical patient. A search for a septic focus in the surgical patient is crucial whenever there is evidence of increased capillary permeability. Control of capillary permeability can then be achieved, although only indirectly, by treating the source of sepsis, which may be surgically approachable. The link between sepsis and capillary permeability is thus broken, and the capillary permeability lesion is allowed to resolve with time; its resolution is accompanied by improvement in perioperative respiratory failure. Until the permeability corrects itself, reduction of PAWP to the lowest level associated with adequate peripheral perfusion seems to reduce the edema.[30]

ATELECTASIS

In the normal lung, ventilation and perfusion are not equally matched, because the shape of the thoracic cavity and the descent of the diaphragm result in greater expansion and ventilation of the lower lobes. Also, blood flow is greater in the dependent areas of the lung during spontaneous ventilation and changes with body position. Therefore the normal lung has an average ventilation:perfusion ratio ($\dot{V}/\dot{Q}$) of approximately 0.8. Many factors in the surgical patient reduce this ratio to very low values, causing hypoxemia, and similar factors lead to resorption of alveolar gas behind closed airways or to compression atelectasis.[33,34] This phenomenon of compression atelectasis in the dependent lung is thought to occur within 5 minutes after induction of general anesthesia.

Shunting results from continued perfusion of nonventilated lung units, and the major cause of this imbalance in the surgical patient is perioperative atelectasis, although alveolar edema from fluid overload or capillary leakage could also result in an increase in shunting.

AGE, POSITION, AND AIRWAY CLOSURE

Most surgical patients undergo procedures in the supine position, and we are operating increasingly on elderly patients. Also, one of the major effects of surgery is the pain resulting from surgical incisions. Body position, incisional pain, and age all affect the relationship between the functional residual capacity (FRC) and the closing volume. The FRC has been considered the most important index of mechanical abnormality in the lung because it represents the balance of opposing forces on the rib cage at resting lung volume. The closing volume is the measure of gas in the lung at the time when airway closure begins. When FRC exceeds closing volume, lower airway patency is maintained, while airway closure begins when the FRC falls below the closing volume.[35] FRC falls with age, and in all patients it is lower in the supine position than in the upright position (Fig. 87-1). The commonly used lithotomy position results in a further decrease in FRC relative to closing volume.

When the difference between FRC and closing volume is plotted against the alveolar-arterial oxygen tension gradient $(A\text{-}a)_{O_2}$,[36] it is evident that the $(A\text{-}a)_{O_2}$ oxygen tension gradient increases as FRC falls below closing volume.

Airway closure tends to occur in the most dependent areas of the lung, and in the supine position, more areas of the lung are dependent, thus predisposing the patient to a greater degree of airway closure and hypoxemia. As indicated above,[33,34] general anesthesia itself may predispose the patient to compression atelectasis in dependent areas of the lung. Also, in both normal individuals and smokers, increasing age is associated with an increase in closing volume, predisposing the patient to airway closure at higher lung volumes.[37] As a group, smokers tend to have higher closing volumes, so that the combination of age and smoking increases the likelihood of significant postoperative hypoxemia. It has generally been accepted that chronic cigarette smoking increases the incidence of postoperative respiratory complications, which may result not only from an alteration in the respiratory defense mechanisms, but also an increase in airway resistance and the work of breathing. It has been demonstrated that cessation of smoking for over 8 weeks is an effective means of decreasing postoperative respiratory complications.[38] Although it has been suggested that abstinence too soon prior to surgery may increase the risk of postoperative pulmonary complications, aggressive counseling for smoking cessation prior to any elective surgical procedure still appears to be the best approach.[39]

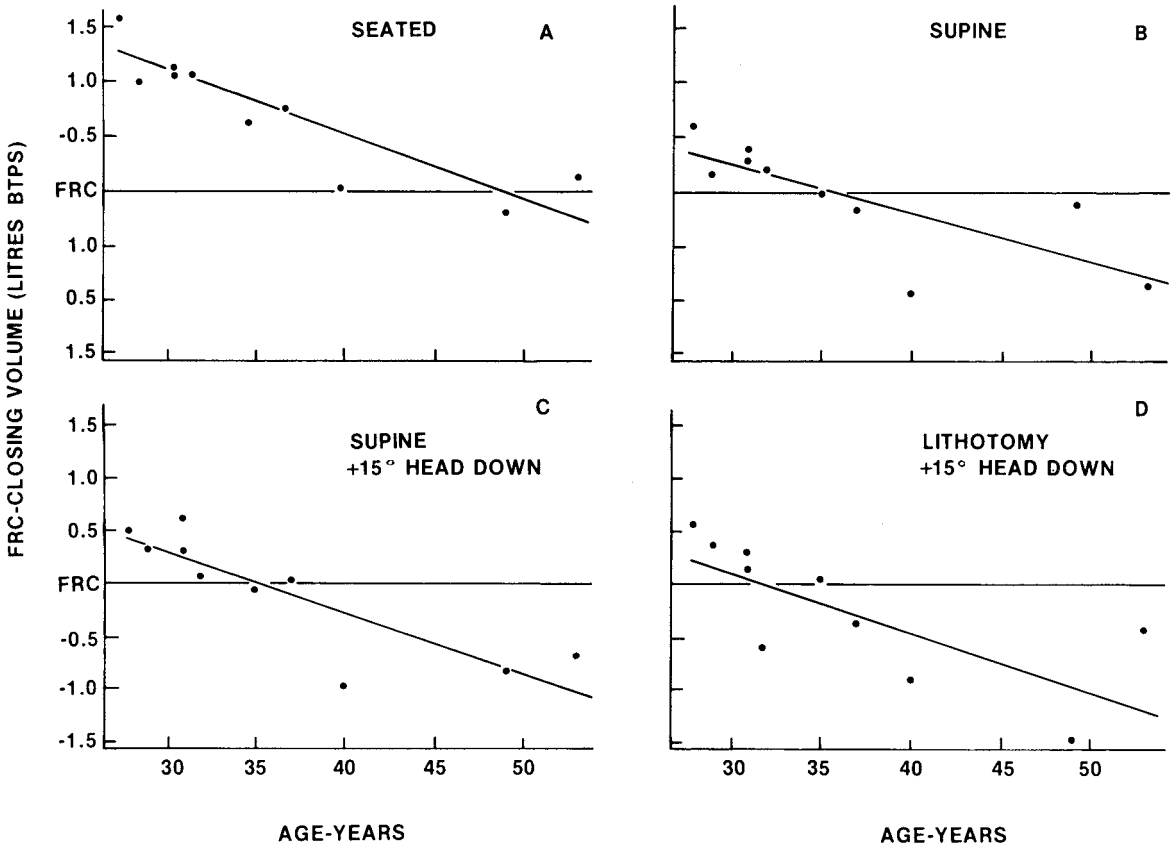

FIGURE 87-1 The difference between FRC and closing volume plotted against age in different surgical positions. Both age and position affect airway closure. ***(Reproduced with permission from Craig DB, Wahba WM, Don H: Airway closure and lung volumes in surgical positions. Can Anaesth Soc J 18:95, 1971.)***

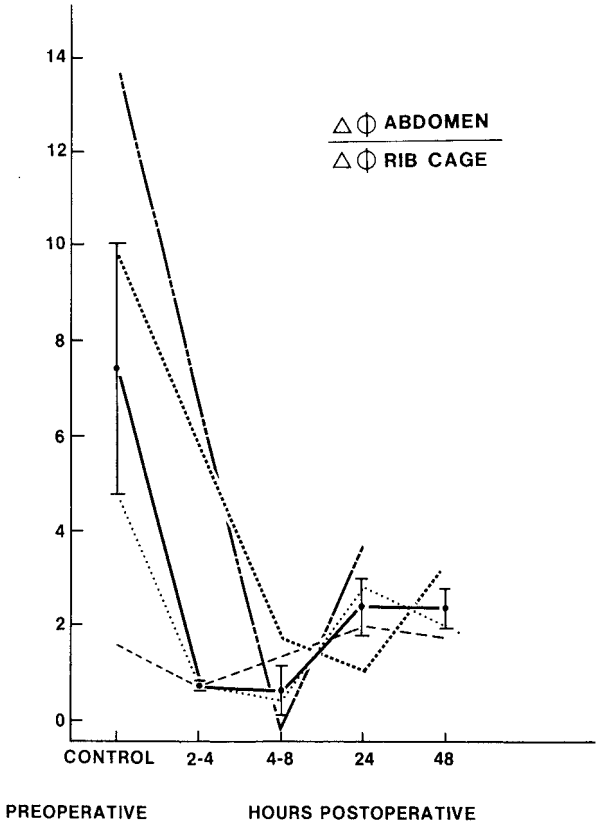
Because small airways in the periphery of the lung are not supported by cartilage, they tend to be influenced significantly by changes in pleural pressures. The maintenance of a positive transpulmonary pressure resulting from the negative intrapleural pressure maintains patency of the small airways. Breathing at a reduced FRC, such as occurs with abdominal pain, tends to lead to positive pleural pressures in the dependent areas of the lung, and therefore creates a predisposition to alveolar collapse. Complete collapse results in continued perfusion of nonventilated areas, or shunting; when the airways are merely narrowed, the ventilation:perfusion ratio may be low, which also impairs gas exchange and leads to hypoxemia.

The patient with multiple fractures is at increased risk for developing pulmonary complications, not only from thromboembolic complications, including fat embolism, but also from atelectasis and pneumonia. A major predisposing factor in these patients is the prolonged period of imposed bed rest, particularly in the supine position, with its resultant effect on lung mechanics and lung volumes. Early operative stabilization of fractures in these patients has been shown to decrease pulmonary morbidity[40] because it allows more effective respiratory physiotherapy and early ambulation, as well as frequent changes in body position to minimize dependant alveolar volume loss.

A major cause of morbidity in traumatic quadriplegic patients is respiratory failure secondary to loss of use of the intercostal muscles of respiration.[41] It has been suggested that the best position for respiratory therapy in these patients is from horizontal to 35° head-up,[42] whereas the maximum FRC is achieved in the 60° to 90° head-up position.



UPPER ABDOMINAL SURGERY AND DIAPHRAGM DYSFUNCTION

Although many of the factors discussed above are present in patients undergoing most surgical procedures, the most serious sequelae are found in patients undergoing upper abdominal procedures. In these patients there is a significant fall in vital capacity (VC) almost immediately postoperatively, within the first 4 hours.[43] There is a slower but definite fall in FRC, which peaks at about 24 hours and is associated with significant hypoxemia. In most patients with no pre-existing lung disease, this effect of upper abdominal intervention on VC and FRC does not result in clinically significant respiratory complications. However, in patients who already have abnormalities of gas exchange, these effects can lead to severe respiratory failure. The postoperative decrease in VC is primarily a restrictive rather than obstructive phenomenon, as evidenced by the maintenance of a normal ratio between the forced expiratory volume at 1 second and the forced vital capacity (FEV_1/FVC).[44] This restriction may be related to incisional pain, which decreases the patient's ability to cough and clear secretions, and eventually leads to an increase in closing volume and a decrease in FRC. If not corrected, a fall in VC results in atelectasis and hypoxemia and a decrease in FRC. To correct this abnormality, transcutaneous electrical nerve

stimulation has been used to provide postoperative analgesia after abdominal surgery.[45] Epidural analgesia and intercostal blockade have also been used for this purpose. Although all of these techniques have produced improvements in VC and FRC, none immediately returns VC or FRC to preoperative values. This suggests either that these techniques do not adequately control pain, or that pain is not the only cause of postoperative respiratory dysfunction after upper abdominal surgery.

Patients undergoing upper abdominal operations have a significant decrease in the maximal transdiaphragmatic pressure at FRC, which is not altered by use of epidural analgesia.[46] This finding suggests that the respiratory dysfunction after upper abdominal surgery may result from a primary effect of the procedure on diaphragmatic function. Ford and coworkers showed that there is a switch from predominantly abdominal breathing to rib cage breathing in the postoperative period in patients undergoing upper abdominal surgery (Fig. 87-2).[47] Diaphragmatic dysfunction was similarly identified in an animal model undergoing cholecystectomy.[48] These studies suggest that general anesthesia may not be responsible for the postoperative diaphragmatic dysfunction. Mere traction on the gallbladder in an animal model also produced similar effects on diaphragmatic function.[49]

FIGURE 87-2 Relationship between the ratio of abdominal to rib cage diameter and time after abdominal surgery. Interrupted lines represent individual patients and the solid line represents the mean values for these four patients. Note the switch from predominantly abdominal breathing preoperatively to rib cage breathing postoperatively. ***(Reproduced with permission from Ford et al.[47])***

Although open cholecystectomy has been associated with significant depression in postoperative pulmonary function, several reports[50–52] have demonstrated less impairment of postoperative pulmonary function following laparoscopic cholecystectomy. There still is a decrease in FRC immediately after the operation, but it is much smaller and of significantly shorter duration than with the open procedure, and the VC and FRC return to essentially preoperative levels within 24 hours.[52] Therefore from the respiratory standpoint, laparoscopic cholecystectomy is superior to open cholecystectomy and should be the preferred method for critically ill patients requiring this procedure. The increase in intra-abdominal pressure with pneumoperitoneum associated with the laparoscopic procedure has a minimal hemodynamic effect, and in patients with decreased cardiopulmonary reserve may prove significant, warranting close hemodynamic monitoring in the operating room in such patients.[53] As indicated in Chap. 89, less aggressive procedures such as percutaneous drainage of the biliary tract may be indicated in situations in which the patient is too unstable to be taken to the operating room or to be subjected to a general anesthetic.

Apart from the factors identified above, aging has been associated with reduced elastic lung recoil, decreased expiratory flow rate, and diminished airway protective reflexes.[37] Obesity is also a major risk factor for postoperative pulmonary complications, because these patients tend to breathe at reduced lung volumes, so closing volume frequently exceeds FRC, leading to hypoxemia and atelectasis.[53a] The increased work of breathing produced by the increased mass also contributes to respiratory dysfunction. Not only the type of operation, but the location of the incision tends to affect the degree of respiratory impairment seen in the postoperative period.[54] In open cholecystectomy, the subcostal incision tends to produce less impairment than a midline incision. The severity of postoperative lung impairment decreases in the following order: thoracic surgery, upper abdominal surgery, lower abdominal surgery, and superficial surgery (Fig. 87-3).

As pointed out in earlier chapters, shock and pulmonary edema in the form of cardiac failure also affect diaphragmatic function through changes in diaphragmatic force as well as glycogen depletion in diaphragmatic muscle.[55] Table 87-1 summarizes preventive measures as well as some of the factors that reduce the FRC and increase closing volume in the postoperative patient.

ALVEOLAR HYPOVENTILATION

In surgical patients, hypoventilation is characteristically caused by impairment of ventilation resulting from the restrictive effect of painful incisions or peritonitis. It may also result from central nervous system (CNS) depression due to anesthesia, analgesia, or CNS injury. The increased metabolic requirement after injury places a significant demand on the respiratory system. When calories, particularly in the form of carbohydrates, are provided to match this increased energy expenditure, the increase in CO_2 production necessitates a significant increase in ventilation to maintain normocapnia.[56] In surgical patients with significant pulmonary reserve, this added demand can be met without untoward effects. However, in depleted surgical patients with borderline respiratory reserve, this extra demand may precipitate respiratory failure

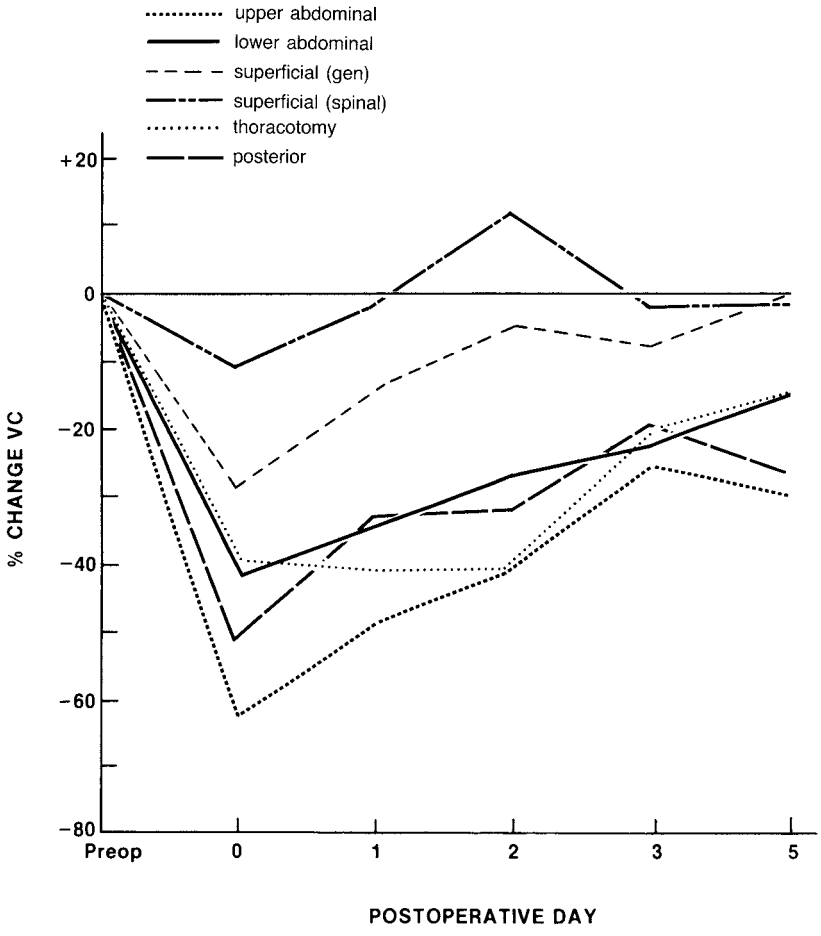


FIGURE 87-3 Postoperative changes in VC for different surgical incisions. Note that the upper abdominal surgery patients have the greatest postoperative depression in VC. (*Reproduced with permission from Ali et al.*[43])

or lead to other manifestations such as prolonged ventilator dependency.

The respiratory system is protected from sepsis and atelectasis by a respiratory control mechanism that responds to hypoxemia, hypercapnia, acidosis, and the presence of irritating or noxious stimuli in the airway. These mechanisms can be significantly depressed in the postoperative patient as a result of anesthesia or excessive narcotic analgesia. Inhalational anesthetics are known for their respiratory depressive effect, which results in alveolar hypoventilation and a reduced response to carbon dioxide, as well as a blunted response to hypoxemia and acidosis.[57] In the postoperative period, narcotic analgesics may have undesirable effects. Whereas in optimal doses they decrease abdominal pain and increase the ability to cough and clear secretions, in larger doses they may depress the respiratory center, producing alveolar hypoventilation as manifested by hypercapnia and secondary hypoxemia.

The cough reflex is the main mechanism by which particles are cleared from the upper airway. The cough response is altered not only by anesthesia, but also by narcotic agents. Clearance of particles from the lower airways depends

TABLE 87-1 Perioperative Atelectasis

Component of the Tendency Toward Atelectasis	Promoting Factors	Preventing Factors
Reduced functional residual capacity	Supine position	45° upright position
	Obesity	Alternating postures
	Ascites	Positive end-expiratory pressure
	Peritonitis	
	Upper abdominal incision	Sighs
		Analgesia
Increased closing volume	Age	Preoperative physiotherapy
	History of smoking	Smoking cessation
	Bronchospasm	Bronchodilation
	Airway secretions	Cough, suction, deep breathing
	Pulmonary edema	Avoidance of overhydration

primarily on the mucociliary system, which can be disturbed by several factors in the postoperative period. Anesthetics alter ciliary activity and mucus production which leads to the production of mucus plugs that block the lower airways. In addition, the cellular defense mechanisms of the respiratory system may be altered by anesthetic agents.[58]

ASPIRATION

The supine position and depression of normal protective reflexes during general anesthesia predispose the surgical patient to aspiration of gastric acid, which is one of the major causes of perioperative morbidity and mortality.[59] This event can first produce airway obstruction (from aspirated debris and chemically induced bronchoconstriction), then a chemical burn of the airway (with fluid loss into the injured area), an intense inflammatory response, and finally lung infection. The clinical presentation of patients with gastric acid aspiration varies widely. Very mild cases present only with transient coughing and minimal bronchospasm; the most severe cases exhibit a progressive downhill course characterized by hypovolemia, hypoxemia, and finally fulminant bacterial pneumonia.

The treatment of acid aspiration consists of the following: (1) rapid removal of debris by immediate suction (endotracheal intubation and fiberoptic bronchoscopy may be necessary at this stage); (2) placement of a nasogastric tube to evacuate the stomach and prevent further episodes; (3) oxygen administration and mechanical ventilation if indicated by the degree of respiratory failure; (4) bronchodilator therapy if bronchospasm is significant; (5) maintenance of normovolemia and normal perfusion by monitoring and replacement of lost fluid, as well as vasoactive and inotropic support where necessary; and (6) treatment of pneumonia by appropriate antimicrobial agents on the basis of Gram stain and culture findings. Steroids have not been of any benefit in treating these patients. Preventive measures that can be taken in high-risk patients to prevent the aspiration of low-pH gastric contents include gastric decompression and the use of agents that decrease gastric acid production, although there is evidence that this may predispose to nosocomial pneumonia.[60–62]

PREDICTING AND PREVENTING PERIOPERATIVE LUNG DYSFUNCTION

Many attempts have been made to correct the postoperative abnormalities in lung function, using techniques such as incentive spirometry, intermittent positive-pressure breathing (IPPB), and nasal continuous positive airway pressure (CPAP).[63–65] Although incentive spirometry has been reported to be ineffective in decreasing postoperative pulmonary complications following cardiac and upper abdominal surgery,[64] IPPB, incentive spirometry, CPAP,[65] and physiotherapy generally improve postoperative respiratory function; IPPB offers no advantage over physiotherapy when the latter is maximized in the postoperative period.[66] Although nonyielding abdominal binders have a further restrictive effect on lung volumes postoperatively, the elastic binders may produce some benefit.[67] It must be recognized, however, that none of these methods completely reverses the postoperative respiratory dysfunction.

Attempts have been made to predict postoperative pulmonary morbidity by assessing respiratory mechanics preoperatively, as well as by identifying risk factors such as age, obesity, smoking, and location of incisions. No individual respiratory parameter predicts respiratory morbidity or mortality in an individual patient. In general, however, the poorer the preoperative respiratory function, the more likely the patient is to have severe postoperative respiratory complications. Based on cumulative experience, the following spirometric criteria for predicting morbidity and mortality in postoperative adult patients have been proposed.[68,69] If the FEV_1 is <1 L, the FVC <1.5 L, the FEV_1/FVC is <30%, or the forced expiratory flow [$FEF_{25\%–75\%}$] is <0.6 L/s, and if the maximum minute ventilation is <50% of the predicted value, then the risk of postoperative pulmonary complications is very high. In patients whose respiratory function is below this threshold, the strategy is to provide treatment that will improve respiratory function to a level above this threshold. Such treatment may involve cessation of smoking, diaphragm muscle conditioning, weight loss, and the treatment of heart failure, fluid overload, and any identifiable reactive airway disease.

A patient who undergoes lung resection is at even greater risk of postoperative pulmonary complication, particularly if the excised lung tissue was functional.[68,69] In these patients, the effect of the lost lung volume must be considered along with the factors discussed above. A quantitative perfusion lung scan can help to predict the postoperative pulmonary spirometric performance of these patients by indicating how much of the lung will remain after the planned procedure. The postoperative FEV_1 is then calculated as the product of the preoperative FEV_1 and the fractional perfusion of the remaining lung. The usual rule for an adult patient is that the operative risk is prohibitive if the predicted postoperative FEV_1 is $\leq$0.8 L. The prediction can be made more accurate by also measuring the diffusing capacity, which is an independent predictor of morbidity and mortality after major lung resection. A useful guideline is to exclude from major lung resection all patients whose diffusing capacity is <60% of the predicted value, even if spirometric values are considered satisfactory.[69] Patients with only slightly impaired pulmonary function (FEV_1 and diffusing capacity $\geq$80% predicted) with no cardiovascular risk factors can undergo pulmonary resections including pneumonectomy without further investigation. For others, exercise testing as well as pulmonary split-function test studies are recommended. The symptom limited cardiopulmonary exercise testing measures the maximum volume of oxygen utilization (V_{O_2}max) as an index of pulmonary and cardiovascular reserve. A V_{O_2}max <10 mL/kg per minute is generally considered a contraindication to any resection, whereas a value >20 mL/kg per minute or >75% of predicted normal is considered safe for major resections. Resections that involve no more than one lobe usually lead to early functional deficit followed by recovery, and permanent loss in pulmonary function is usually <10%. Generally, pulmonary function tests tend to overestimate the functional loss after lung resection.[70] Arterial blood gas criteria may also be used to exclude patients from major lung resection because of the prohibitive risk of postoperative morbidity and mortality. Patients who have a room-air partial pressure of arterial oxygen (Pa_{O_2}) of <50 mm Hg or a partial pressure of carbon dioxide (P_{CO_2}) of >45 mm Hg at rest are considered to have a prohibitive operative risk and should not undergo major pulmonary resection. Other forms of surgical intervention are

justifiable in the presence of these blood gas criteria only if they are considered mandatory and lifesaving.

TREATMENT PRINCIPLES FOR PERIOPERATIVE RESPIRATORY FAILURE

At present, no specific therapy exists for underlying diaphragmatic dysfunction. Therefore the principles of respiratory care in the surgical patient are as follows:

1. Maximization of the preoperative respiratory status. Meeting this goal may entail cessation of smoking, diaphragmatic conditioning exercises, reduction in obesity, and treatment of any identified cardiorespiratory disease, including congestive heart failure, bronchopneumonia, or bronchospasm.
2. Aggressive physiotherapy and early ambulation to overcome the effects of the supine position on changes in lung volumes, particularly the relationship between closing volume and FRC. In patients with multiple fractures, early operative stabilization will decrease the period of recumbency.
3. Adequate treatment of sepsis and shock, with recognition of the important role of surgery or interventional radiology in the identification and drainage of areas of sepsis such as intra-abdominal abscesses.
4. Judicious use of intravenous fluids to maintain adequate perfusion while avoiding overhydration and pulmonary edema.
5. Optimal use of analgesics to control pain without producing respiratory depression.
6. Administration of supplemental oxygen to hypoxemic patients to improve arterial oxygenation.
7. Treatment (as specific as possible) of any identifiable cause of hypoxemia; for example, bronchodilator therapy for a patient with bronchospasm, or antibiotic therapy directed against a specific organism isolated in a patient with a pneumonic process.
8. Preoperative pulmonary assessment, especially in patients with poor pulmonary reserve and most especially in those undergoing lung resection. This will allow an assessment of the relative risk of postoperative morbidity.
9. Institution of mechanical ventilation when the above measures fail. Frequently, mechanical ventilation can be avoided if strict attention is paid to preventive measures. Also, vigorous application of these principles immediately after the patient is stabilized can shorten the duration of mechanical ventilation considerably.[71]

Chapter 88

PREOPERATIVE ASSESSMENT OF THE HIGH-RISK SURGICAL PATIENT

FERGUS WALSH
JAMEEL ALI

KEY POINTS

- *Perioperative risk assessment by careful history, physical examination, and selective investigation is essential for directing therapy in the high-risk surgical patient.*
- *To decrease mortality and morbidity, cardiac, pulmonary, and endocrine abnormalities must be identified and appropriately managed.*
- *Age >70 years, current or prior angina pectoris, prior myocardial infarction, Q wave on resting electrocardiogram, and cardiac failure are significant clinical risk factors for perioperative cardiac complications.*
- *Perioperative cardiac morbidity can be minimized with pre-emptive medical management which includes the perioperative administration of β-blockers.*
- *Postoperative pulmonary complications can be reduced by aggressive pre- and postoperative care.*
- *Diabetes mellitus, abnormalities in thyroid function, and steroid dependence can significantly influence perioperative morbidity and mortality.*

As indicated in Chap. 87, surgery and anesthesia trigger a host of physiologic responses. In the average otherwise healthy patient these responses result in no major untoward postoperative sequelae. However, in the medically compromised patient the additional burden of surgical stress can prove to be very challenging and sometimes insurmountable. Such patients frequently require detailed evaluation and monitoring in the preoperative as well as postoperative periods in the intensive care unit (ICU) setting. Careful planning of the preoperative assessment and management of identified abnormalities in these patients are crucial to optimize chances of a good postoperative outcome. A major component of this planning involves the assessment of risks for intraoperative and postoperative morbidity. Patients with cardiac, respiratory and endocrine abnormalities pose special risks for postoperative complications. In this chapter we present guidelines for identifying and managing patients at risk of developing postoperative cardiac-, respiratory-, and endocrine-related postoperative morbidity.

Assessment of Cardiac Morbidity for Noncardiac Surgery

CLINICAL ASSESSMENT OF CARDIAC RISK

Over 25% of patients presenting for noncardiac surgery have diagnosed or clinically suspected ischemic heart disease with increased risk for perioperative complications.[1] The American Society of Anesthesiologists' (ASA) classification of physical status (Table 88-1) is still commonly used as an index of surgical risk.[2] Using multivariate analysis of 1001 consecutive patients presenting for noncardiac surgery, Goldman and associates developed an index for perioperative risk (Cardiac Risk Index; CRI) based on clinical, electrocardiographic (ECG), and routine biochemical parameters (Table 88-2).[3] The strongest predictors of cardiac morbidity were the severity of coronary artery disease, a recent myocardial infarction (MI) and perioperative heart failure. Detsky and coworkers developed a more elaborate scoring system.[4] Such studies suggest an overall perioperative cardiac risk for consecutive patients presenting for noncardiac surgery of 1.4%, and the risk of cardiac death at approximately 1%. However, in patients with previously documented or clinically suspected ischemic heart disease, the rates of perioperative MI (4.1%) and death (1.7%) were markedly higher. The retrospective analysis of 1001 patients from whom the CRI was derived is shown in Table 88-3. Those patients in class IV had a 22% incidence of major cardiac complications and a 56% mortality rate.

Table 88-4 compares the predictive values of the CRI with the ASA scoring system and other noninvasive tests used to assess cardiac risk. Class IV patients were still a high-risk group, but the positive predictive value (PPV) was lower at 0.5.[5] The ASA has a low PPV because of the high number of false-positive results (i.e., although it is sensitive, it is not specific). Although a patient falling into CRI class IV is at high risk, the utility of the test is reduced by its low sensitivity. Only 55% of the patients at risk were in classes III and IV. The sensitivity may be even less when dealing with patients undergoing major vascular surgery.[6]

In summary, generally accepted independent risk factors for perioperative cardiac morbidity include: *age >70 years, current or prior angina pectoris, prior MI, Q wave on resting ECG, and cardiac failure.* It is widely accepted that patients presenting for elective surgery with zero, one to two, or three or more of these clinical markers are at low-, intermediate-, or high-risk respectively, for cardiac complications in the perioperative period. It is clear that patients in the low-risk category may proceed to surgery with an expectation of a low rate of cardiac complications. Similarly, patients deemed to be in the high-risk group may need to proceed to intensive management of their cardiac disease before initiation of the surgery. It is the group of patients in the intermediate-risk category who will benefit most from the investigations described below, in an effort to further elucidate the extent of their underlying

TABLE 88-1 American Society of Anesthesiologists Preoperative Patient Classification

Class	Definition
I	Healthy patient
II	Mild systemic disease
III	Severe systemic disease, limits activity but is not incapacitating
IV	Incapacitating systemic disease which is a constant threat to life
V	Moribund, not expected to survive 24 h with or without operation
E	Added to class if an emergency

cardiac disease and to attempt to quantify the perioperative risks before the commencement of the surgical procedure.

Noninvasive Investigations to Stratify Risk

EXERCISE ELECTROCARDIOGRAM

Exercise ECG (ExECG) is a sensitive marker for subsequent myocardial infarction.[7] Treadmill ExECG, utilized to calculate ventricular response to increasing oxygen demand, has been shown to be a sensitive noninvasive indicator of ventricular performance and predictor of perioperative ventricular failure.[8] The prospective comparative value of ExECG was investigated in over 200 patients deemed to be at intermediate risk of adverse cardiac outcome following noncardiac surgery. Results showed odds ratios (OR) for ST-segment depression of 0.1 mV or greater in the ExECG (OR = 5.2) to be less than a known definite diagnosis of coronary artery disease (OR = 8.8), but greater than echocardiographic evidence of reduced left ventricular function (OR = 2.0). The combination of clinical variables and ExECG data improved preoperative risk stratification.[9] However, ExECG is rarely practical in critically ill patients.

AMBULATORY ELECTROCARDIOGRAM

Ambulatory electrocardiographic monitoring (AEM) using Holter monitors to detect silent preoperative and perioperative ischemia has been shown to be predictive of postoperative unstable angina, pulmonary edema, and MI.[10] Twenty percent of ischemic events have been shown to occur in the preoperative period, 25% intraoperatively, and 41% postoperatively, with 97% of all events being clinically silent.[11] Silent

TABLE 88-3 Assessment of Cardiac Risk Index in 1001 Patients

Class	Point Total	No or Only Minor Complication ($N = 943$)	Life-Threatening Complication[a] ($N = 39$)	Cardiac Deaths ($N = 19$)
I ($N = 537$)	0–5	532 (99)[b]	4 (0.7)	1 (0.2)
II ($N = 316$)	6–12	295 (93)	16 (5)	5 (2)
III ($N = 130$)	13–25	112 (86)	15 (11)	3 (2)
IV ($N = 18$)	26	4 (22)	4 (22)	10 (56)

ischemic episodes in the preoperative and postoperative periods are associated with perioperative cardiac morbidity; both of these factors are more clearly associated with postoperative MI than intraoperative ischemia. The absence of preoperative ischemia may predict the absence of postoperative MI;[12] however, this has not been a uniform finding.[13]

RADIONUCLIDE SCANNING

Dipyridamole-thallium scanning (DTS) has been shown to be a sensitive predictor of perioperative cardiac complications for patients who cannot exercise.[14] Dipyridamole dilates normal coronary vascular beds and diverts flow away from areas supplied by a stenotic vessel (usually indicative of >70% stenosis), resulting in a perfusion defect. Although DTS has been shown to be highly sensitive and specific in patients presenting for vascular surgery, it has proved less useful when consecutive patients have been studied and all researchers blinded.[15] A similar result was shown when diabetic patients presenting for vascular surgery were evaluated with DTS in addition to clinical risk stratification.[16] A large prospective study of DTS in 2000 vascular patients showed an OR of only 1.95.[17] The authors added that the value of DTS depends on the patient's risk profile (i.e., low-risk patient with positive DTS is a more significant result than a high-risk patient with positive DTS).

Single photon emission tomography (SPECT) may improve accuracy of DTS.[18] However, in patients presenting for abdominal aortic aneurysm surgery, SPECT has not accurately predicted adverse cardiac outcomes.[19] While DTS reflects perfusion defects, a particular form of SPECT imaging (FDG SPECT) allows analysis of myocardial glucose utilization. In a study of 148 patients with ECG and echocardiographic evidence of Q-wave infarction, SPECT diagnosed viable myocardium in 61% of myocardial areas with a Q-wave pattern (i.e., previously deemed to be scar tissue), and 75% of dysfunctional non-Q-wave areas.[20] Therefore, SPECT may have a further role in the evaluation of patients with evidence of myocardial damage.

ECHOCARDIOGRAPHIC IMAGING TECHNIQUES

Transthoracic echocardiography (TTE) provides the clinician with a detailed analysis of ventricular wall motion, ejection fraction, and if present, evidence of left ventricular hypertrophy. Resting TTE is noninvasive and readily applicable to the critically ill patient. Initial investigation of TTE as an assessment tool before noncardiac surgery did not support the routine use of TTE as a preoperative screening tool.[21] However, a larger study showed that when TTE reveals systolic dysfunction in preoperative testing, TTE is associated with an increased OR of postoperative MI (OR = 2.8) and cardiogenic pulmonary edema (OR = 3.2). The authors concluded that in selected intermediate-risk patients, TTE before noncardiac surgery may provide independent information about perioperative cardiac risk.[22]

Dobutamine stress echocardiography (DSE) is echocardiography performed before, during, and after an intravenous infusion of dobutamine. A positive DSE is one that shows ventricular wall motion abnormalities or evidence of ischemia-induced diastolic dysfunction. Initial investigation of DSE to stratify patients at cardiac risk proved superior to DTS.[23] The prognostic value of DSE in comparison to dipyridamole stress echocardiography (DiSE) and DTS was studied in over 2000 patients undergoing major vascular surgery. DSE and DiSE had significantly improved odds ratios for predicting cardiac complications (OR = 9.6 and 37.1, respectively) in comparison to DTS (OR = 1.95). The authors concluded that stress echocardiography effectively stratified patients into low- and high-risk groups regardless of clinical profile. In another study, when preoperative vascular surgery patients were selected to receive DSE according to protocol (one or more clinical risk factors), the prognostic value of DSE was again highlighted.[24] DSE has little prognostic value in low-risk patients, but in the clinically intermediate and high-risk population, DSE may help identify patients in whom cardiac revascularization should be considered before noncardiac surgery.

Clinical Risk Scenarios

RECENT MYOCARDIAL INFARCTION

A history of recent MI remains one of the most significant predictors of perioperative myocardial infarction (PMI). Risk of reinfarction is increased substantially if the infarct occurred within 6 months of proposed surgery. Early studies reported reinfarction rates of 15% if the infarct occurred within 3 to 6 months prior to noncardiac surgery, increasing to 30% if it was within 3 months. Rao and coworkers subsequently studied patients who were aggressively managed in the ICU for up to 96 hours postoperatively. These retrospective data in 733 patients undergoing major noncardiac surgery identified reinfarction rates of 5.7% in patients within 3 months of MI and 2.3% in patients within 6 months of MI.[25]

Patients who have suffered an infarction are frequently assessed by exercise testing or angiography at approximately 6 weeks following infarction, in an effort to provide objective evidence of ongoing ischemia. On the basis of this testing, if patients have good exercise tolerance and are deemed to be at low risk for ongoing ischemia, noncardiac surgery does not necessarily result in increased cardiac morbidity and mortality.[26]

A history of angina was not included in Goldman's original CRI; however, symptoms or signs of ongoing ischemia, whether clinically silent or overt, have been repeatedly shown to be significant predictors of perioperative cardiac events. Based on current knowledge, patients within the first 6 months following MI should all be deemed to be at intermediate risk. These patients will benefit from noninvasive testing to quantify perioperative cardiac risk.

CONGESTIVE HEART FAILURE

Preoperative signs of congestive cardiac failure, a third heart sound, and signs of pulmonary edema are persistently strong predictors of perioperative cardiac morbidity. Left ventricular dysfunction serves as a marker of prior MI, ongoing ischemia, significant valvular disease, or cardiomyopathy. The highest risk for development of perioperative pulmonary edema is among patients >40 years of age who have evidence of cardiac failure preoperatively (approximately 15%, compared to 5% in patients with well-controlled cardiac failure). Patients with no pre-existing diagnosis of cardiac failure have approximately a 2% incidence of developing postoperative pulmonary edema.[27]

AGE

Although multivariate analyses repeatedly show age to be a risk factor, other studies suggest age itself may not be a major risk factor independent of the general health of the patient.[28] However, signs of ischemic heart disease may not be as clinically obvious in the elderly population. One study compared coronary angiography results from 260 elderly (>70 years) patients to 260 control patients (age <60 years). The results for patients with zero, one to two, and three or more clinical markers who exhibited severe stenoses were 17%, 55%, and 85% in the elderly group, in comparison to 14%, 36%, and 68%, respectively, in the control group. Thus the presence of clinical markers of ischemia in the elderly should prompt careful evaluation and a lower threshold for the initiation of noninvasive testing.

DIABETES

Diabetes, like age, may not be an independent risk factor per se. A retrospective multivariate analysis of 282 diabetics who underwent surgery found that the risk of a major cardiac event was related to pre-existing cardiac failure, valvular heart disease, and age >75 years.[29] The age relation may reflect the duration of the diabetes. A large nationally based review of almost 15,000 patients who underwent vascular surgery revealed little influence of diabetes on subsequent cardiac mortality. After controlling for comorbid conditions, procedure type, and diabetic complications, only type 1 diabetics were at increased risk for cardiovascular complications. Neither type 1 nor type 2 diabetes was an independent risk factor for death.[30]

Risk Modification

IMPLEMENTATION OF RECOMMENDATIONS ON PREOPERATIVE TESTING

Recommendations from the American College of Cardiology/American Heart Association (ACC/AHA) have helped refine the clinician's approach to patients with known or suspected ischemic heart disease presenting for major surgery. Previously, 50% to 75% of patients presenting for major vascular surgery were investigated by noninvasive cardiac testing. By comparing historical data from the pre-guideline era (102 patients) and post-guideline implementation (94 patients), one center documented a dramatic reduction in preoperative stress testing (88% to 47%), cardiac catheterization (24% to 11%), and coronary revascularization (25% to 2%).[32] Stress tests were equally distributed between low- and high-risk groups in the pre-guideline era, but were utilized significantly less frequently in the low-risk group in the post-guideline era (31% low-risk, 61% high-risk). As expected, associated costs fell dramatically to 10% of the pre-guideline average, but death (4% vs. 3%) and myocardial infarction rates (7% vs. 5%) were not statistically altered by the reduced number of investigations.[31]

PREOPERATIVE PERCUTANEOUS TRANSLUMINAL ANGIOPLASTY

To date there are no randomized trials demonstrating the effectiveness of preoperative percutaneous transluminal angioplasty (PTCA) in patients presenting for major surgery with known ischemic heart disease. Elective PTCA carries inherent risks of acute MI (1% to 3%), emergency requirement for coronary artery bypass grafting (CABG) (0.2% to 3%), and in-hospital death (0.5% to 1.4%). The inevitable disruption of the atheromatous plaque in the stable patient may potentially increase the incidence of coronary thrombosis in the setting of major surgery. A retrospective study showed no reduction in perioperative MIs in patients treated with PTCA within 90 days of major surgery, compared to a known coronary artery disease control population.[32] One uncontrolled retrospective study of patients receiving coronary stents before intermediate- or high-risk surgery showed a high rate of perioperative MI (28%), major bleeding (24%), or cardiac death (32%).[33]

PREOPERATIVE CORONARY ARTERY BYPASS GRAFTING

Recommendations for preoperative CABG[34] were based on retrospective data, and either utilized historical controls or did not include the mortality associated with CABG itself. Preoperative prophylactic CABG still remains of unproven benefit. Since the first discernable survival benefit in CABG patients exists at 2 years post-CABG,[35] the relative benefit of preoperative CABG over medical therapy remains unproven.

PERIOPERATIVE BETA-BLOCKADE

Identification of patients at risk for perioperative ischemia facilitates the introduction of perioperative β-blockade. In patients with known reversible ischemia, administration of perioperative β-blockers reduced the MI and death rate from 32% to 12%.[36] This highly significant reduction in cardiac complications probably results from reduction in tachycardia and hypertension. The generalized acceptance of the safety and efficacy of β-blockers has led to calls for their routine use in patients who are at risk for ischemic heart disease. Mangano and coworkers studied 200 patients with known or suspected ischemic heart disease who underwent noncardiac surgery.[37] Patients were randomized to receive atenolol or placebo pre-, intra-, and postoperatively until hospital discharge. In-hospital cardiac mortality was unchanged between groups, but overall mortality was significantly reduced in the three time spans studied: 0 to 6 months following discharge (0% vs. 8%), 0 to 12 months (3% vs. 14%), and 0 to 24 months (10% vs. 21%). In a large group of vascular surgery patients, in the subgroup of patients with fewer than three risk factors (83% of total), patients who received β-blockers had a lower risk of cardiac complications (0.8%) than those not receiving β-blockers (2.3%). The same group reported a 12% incidence of cardiac events in a high-risk vascular surgery population randomized to receive bisoprolol, compared to 32% in patients without β-blockade.[38] They summarized that bisoprolol significantly reduced long-term cardiac death and MI in high-risk patients after major vascular surgery. Despite such widespread recommendations in favor of perioperative β-blockade, the optimal timing for stopping the β-blocker therapy has not been well elucidated. One small series suggested that abrupt withdrawal of β-blockers in the postoperative period may lead to increased postoperative MI (OR = 17.7).[39]

MODIFICATION OF SURGERY

Patients with concomitant unstable angina and recent MI rarely present for noncardiac surgery. However, such patients represent a significant risk for MI and cardiac death. Noncardiac operations in such circumstances should be deferred except in emergency situations. The substitution of major surgery for a minimally invasive approach is frequently impossible and may not lead to an improvement in cardiac risk. In a retrospective review of patients presenting for elective abdominal aortic aneurysm (AAA) repair, similar morbidity and mortality rates were found for an endovascular versus an open approach.[40] While there was a significant increase in preoperative pulmonary compromise in the endovascular group, there were no differences in history and symptoms of ischemic heart disease, blood pressure, lipid profile, or diabetes between groups.

INTENSIVE PERIOPERATIVE MANAGEMENT

The rationale for using aggressive perioperative medical intervention to reduce cardiac risk is compelling. Many of the major cardiac risk factors such as congestive heart failure, myocardial ischemia, and dysrhythmias are detectable and amenable to therapy. The mainstay of intra- and postoperative monitoring for many years has been the pulmonary artery catheter (PAC; see below).

Preoperative ICU admission for investigation and "fine tuning" has been extolled by some centers. The use of such invasive monitoring with aggressive perioperative control of hemodynamics (i.e., admission to the ICU for 72 to 96 hours postoperatively) has been credited for a five- to sevenfold reduction in the reinfarction rate of patients undergoing surgery within 6 months of MI (24 Assessment Section). Precise factors responsible for this reduction are difficult to determine. Others have also reported low perioperative MI rates in high-risk patients when similar pre-, intra-, and postoperative strategies have been employed.[41] However, the better outcomes could be due to factors such as better general medical management of the postinfarct patient prior to surgery, or the administration of β-blockade to the intensively managed patients (not commented upon in earlier papers). Postoperative cardiac morbidity following noncardiac surgery may be predicted. It may be that postoperative cardiac ischemia of long duration rather than the presence of ischemia itself is the factor most significantly associated with adverse cardiac outcome.

Perioperative optimization of oxygen delivery using intravenous fluid and inotropes has been reported to reduce overall mortality in high-risk surgical patients. Landmark papers in the 1980s suggested definitive end points of therapy (so-called "supranormalization"), but these were not specifically described for particular high-risk populations such as septic patients, the elderly, and those with ischemic heart disease. Some authors report higher mortality using an aggressive approach in such patients.[42]

PULMONARY ARTERY CATHETER

The routine use of the pulmonary artery catheter to aid decision making for the high-risk surgical patient has been called into question. A large prospective cohort study of mixed medical and surgical patients in the ICU showed increased mortality, length of ICU stay, and costs associated with use of the PAC.[43] A multicenter randomized trial of the use of the PAC in almost 2000 high-risk patients undergoing elective abdominal, thoracic, vascular, and major orthopedic surgery, showed no benefit to therapy directed by the PAC over standard care.[44] In addition, eight patients in the PAC group showed evidence of pulmonary emboli in comparison to zero in the control patients. This interesting finding prompts even more speculation about the safety of the PAC in surgical patients.

NEWER CARDIAC OUTPUT MONITORS

Such evidence suggests that the PAC may not be an appropriate monitoring tool in the elective surgical population. Newer less-invasive tools have come into clinical use. A central venous catheter capable of continuous measurement of central venous oxygen saturation was used by Rivers and associates to achieve early goal-directed therapy in medical patients, with dramatic improvement in mortality.[45] Another tool that is less invasive than the PAC is the pulse contour cardiac output (PiCCO) monitor. This device requires brachial or femoral arterial cannulation with a specialized arterial catheter containing a thermistor. Using standard cold saline dilution technique, cardiac output analysis and measurement of intrathoracic blood volume (ITBV) and extravascular lung water are possible. Reports suggest that ITBV more reliably predicted cardiac preload than central venous pressure or pulmonary capillary wedge pressure.[46]

TRANSESOPHAGEAL ECHOCARDIOGRAPHY

Transesophageal echocardiography (TEE) is a sensitive marker of myocardial ischemia, often revealing segmental wall motion abnormalities before other signs of ischemia become obvious. TEE has been advocated to detect intraoperative ischemia, and has been shown to have superior sensitivity and specificity (sensitivity 75%, specificity 100%) in comparison to two-lead ECG (sensitivity 56%, specificity 98%) and pulmonary capillary wedge pressure (sensitivity 25%, specificity 93%).[47] A larger study (224 patients) confirms this opinion, finding that TEE is frequently influential in guiding clinical decision making.[48] In comparison to two-lead ECG and PAC, TEE was the most important intraoperative guiding factor in decision making for anti-ischemic therapy (56% of decisions based on TEE), fluid administration (28%), and vasopressor or inotrope administration (16%).

RESOURCE ALLOCATION

If aggressive hemodynamic monitoring in the ICU is responsible for the improved survival of patients with ischemic heart disease following noncardiac surgery, the financial implications are staggering. In Rao's study, more than 1300 ICU days of care were required to bring about a 2.4% reduction in the reinfarction rate. However, if admission criteria were restricted to congestive heart failure, angina plus congestive heart failure, or angina plus hypertension, this would account for almost 80% of the perioperative infarctions, but reduce ICU days to <300. A more recent study found that 77% of postoperative infarctions occurred within 26 hours of surgery, and 100% within 48 hours, suggesting a shorter period of monitoring may be sufficient.

TYPE OF SURGERY: TYPE OF ANESTHETIC

Noncardiac operations may be divided into those that are likely to provoke perioperative ischemia and those that do not increase the risk of ischemia above normal. Major vascular procedures involving aortic cross-clamping and infrainguinal arterial bypass carry a high risk of postoperative ischemia,[49] as do major abdominal and thoracic procedures. Orthopedic procedures such as total hip arthroplasty have a lower incidence of cardiac morbidity, and are deemed intermediate risk. Peripheral nonvascular procedures such as transurethral resection of the prostate, an operation frequently performed in patients with coexisting coronary artery disease, are associated with a low incidence of perioperative MI.[50]

Major surgery is associated with an intense sympathetic and procoagulant response, which may be implicated in the development of myocardial ischemia. These neurohumoral responses to surgery may be diminished with the use of epidural anesthesia and analgesia (EAA) extending into the postoperative period.[51] Stress-mediated release of hormones such as cortisol, antidiuretic hormone, and catecholamines is blunted by epidural anesthesia.[52] In addition, postoperative pain may contribute to tachycardia and resultant subendocardial ischemia. Early studies showed a dramatic reduction in cardiac complications in patients treated with EAA in comparison to general anesthesia (GA) alone.[53] This opinion was further upheld by a large systematic review of relevant trials of epidural or spinal anesthesia vs. GA over the past 30 years, which showed a statistically and clinically significant reduction in mortality and morbidity after surgery.[54] This retrospective work was prospectively tested by a large (915 patients) randomized controlled trial of high-risk surgical patients who either received EAA (intraoperatively and up to 72 hours postoperatively) with GA or GA alone with intraoperative and postoperative opioids as the mainstay of the analgesic regimen.[55] The group observed no reduction in mortality or cardiac morbidity between groups. The only clinical benefit documented was a reduction in postoperative respiratory failure. However, the authors commented that 15 epidurals were required to prevent one episode of respiratory failure. The authors also commented that in no cases were there any serious complications with catheter placement or postoperative problems directly attributable to the placement of the epidural.

RECOMMENDATIONS

Evaluation and treatment of patients presenting for noncardiac surgery requires careful attention to history, functional status, and assessment of clinical evidence of reversible cardiac failure or dysrhythmias, in addition to consideration of the timing and indications for the proposed surgery. There is no doubt that clinical risk factors such as known ischemic heart disease, cardiac failure, age >70 years, and Q waves on a resting ECG are all independently documented to be associated with an increase in perioperative cardiac morbidity. Despite published and validated clinical risk indexes, the clinician will daily assess the patient on the basis of the above criteria, and ascribe the category of low, intermediate, or high risk according to the number of risk factors elucidated.

Following published guidelines and analysis of the literature, it can be recommended that noninvasive cardiac testing will not add to the clinicians knowledge or improve risk stratification in patients with none of the above clinical criteria. Similarly, patients who present a significant clinical risk or who have recently suffered an MI may require interventional cardiology and possible revascularization prior to proposed noncardiac surgery. This high-risk group should be intensively monitored in the perioperative period, including a stay in the ICU for approximately 48 to 72 hours. It is the intermediate-risk group of patients, presenting with one to two clinical risk factors, who will benefit most from noninvasive testing. Current evidence suggests DSE may be superior to DTS, TTE, or ExECG in preoperative cardiac risk stratification. However, DSE is not widely available and requires specialized centers and expertise. Current treatment protocols suggest a significant clinical benefit from the widespread administration of β-blockers to all intermediate- and high-risk patients. Some caution may need to be exercised regarding the duration of dose and discontinuation of the drug. Finally, despite recent negative reports regarding the use of the pulmonary artery catheter, evidence continues to support noninvasive or minimally-invasive perioperative monitoring of high-risk patients following noncardiac surgery.

Assessment of Risk of Postoperative Pulmonary Complications

CLINICAL ASSESSMENT OF PULMONARY RISK

Postoperative alterations in pulmonary physiology predispose to the development of atelectasis (see Chap. 87). Marked decreases in forced expiratory volume in 1 second (FEV_1) and forced vital capacity (FVC) have been documented with serial postoperative pulmonary function tests.[56] A reduction in functional residual capacity (FRC) of approximately 70% of basal values may occur by about 18 hours after surgery, resulting in closure of small airways as FRC approximates closing volume.[57] Progressive loss of functional lung tissue results and intrapulmonary shunting leads to worsening hypoxemia.

Many risk factors for the development of postoperative atelectasis have been highlighted. Each of the following has been shown to predict postoperative atelectasis: preoperative severe bronchitis, FEV_1 more than two standard deviations less than predicted, obesity, malnutrition, abdominal surgery, and age. Analysis of risk factors in a group of 272 patients referred for preoperative assessment concluded that statistically significant predictors of postoperative pulmonary complications were: partial pressure of arterial carbon dioxide (Pa_{CO_2}) $\geq$45 mm Hg (OR = 61.0), FVC $\leq$1.5 L/min (OR = 11.1), maximum laryngeal height $\leq$4 cm (OR = 6.9), forced expiratory time $\geq$9 seconds (OR = 5.7), smoking $\geq$40 pack-years (OR = 5.7), and body mass index (BMI) $\geq$30 kg/m^2 (OR = 4.1).[58]

Bedside pulmonary function tests (PFTs) such as spirometry have been used to identify patients at risk of developing postoperative pulmonary complications, but lack of randomization, selection bias, and retrospective or unblended analysis of outcome invalidate conclusions.[59] Spirometry as a screening procedure for high-risk patients remains unproved and its routine use has been discouraged.[60] The American College of Physicians recommends preoperative pulmonary function testing in the following groups: patients with

unexplained dyspnea, patients undergoing high-risk surgery (cardiac, thoracic, and upper abdominal), cigarette smokers, symptoms of dyspnea on exertion, and patients undergoing head and neck or orthopedic surgery with uncharacterized lung disease. All patients undergoing lung resection should have PFTs.[61]

The inability to improve pulmonary function despite adequate therapy may be a more sensitive predictor of postoperative respiratory failure.[62] In a prospective study, those at risk of developing postoperative respiratory failure (defined as ventilator dependent >2 postoperative days) were best identified by the failure of 48 to 72 hours of intensive preoperative preparation to improve FVC, forced expiratory flow over 25% to 75% of the expiratory cycle ($FEF_{25–75}$), and maximal voluntary ventilation measured over 1 minute (MVV). Five percent of the study group developed postoperative respiratory failure, and all of these patients had an $FEF_{25–75}$ and MVV less than 50% of predicted values, which had not improved with preoperative therapy. The perioperative mortality in this subgroup was 60%.

EVALUATION OF RISK PRIOR TO PULMONARY RESECTION SURGERY

Approximately 80% of patients presenting for lung cancer surgery have concomitant chronic obstructive pulmonary disease (COPD) and 20% to 30% have severe pulmonary dysfunction.[63] Pulmonary resection for lung cancer has been associated with morbidity of 12% to 50% and mortality of 2% to 12%.[64] A more recent retrospective analysis confirms that these figures have not been markedly improved (morbidity 20%, mortality 3%).[65] In addition to the general preoperative preparation of the surgical patient, those patients who will require pulmonary resection must have a preoperative estimation of postoperative pulmonary reserve.

A multifactorial risk index was proposed for patients undergoing thoracic surgery consisting of the Cardiac Risk Index (CRI) and a pulmonary risk index (PRI), known as the cardiopulmonary risk-factor index (CPRI). These pulmonary risk factors had previously been validated as independent risk factors in univariate analysis. The CPRI assesses obesity, cigarette smoking within 8 weeks of surgery, productive cough within 5 days of surgery, FEV_1/FVC <70%, and Pa_{CO_2} >45 mm Hg. Each of these factors was assigned one point. By combining the CRI (0 to 4) and the PRI (0 to 6), patients classified as having a CPRI of 4 or greater were 17 times more likely to develop a postoperative pulmonary complication than patients with a CRPI less than 4.[66]

Guidelines for prediction of outcome following lung resection are generally based on preoperative whole lung function tests.[67] MVV (% of predicted), FEV_1 (liters), and FEV_1 (% of predicted) have been most commonly used. Guideline values for proceeding with pneumonectomy, lobectomy, or wedge/segmental resection are:

- For pneumonectomy MVV >55%, FEV_1 >2 L, FEV_1% >55%;
- For lobectomy MVV >40%, FEV_1 >1 L, FEV_1% 40% to 50%; and
- For wedge/segmental resection MVV >35%, FEV_1 >0.6 L, FEV_1% >40%.

Predicted postoperative FEV_1 has been suggested as a sensitive predictor of postoperative pulmonary complications. For this measurement, FEV_1 and CT calculation of the number of preoperative functioning lung segments are required. Predicted postoperative FEV_1 ($ppoFEV_1$) may then be calculated using the formula:

$$ppoFEV_1 = \text{preoperative } FEV_1/(\text{No. of preop functioning segments} \times \text{No. of postop functioning segments})$$

Studies have suggested that if $ppoFEV_1$ <40% of predicted, this may be a sensitive predictor of prohibitive operative risk and that resection should not be considered. More recent work suggests that a low $ppoFEV_1$ may indeed be a sensitive predictor of postoperative pulmonary complications in lung cancer resection patients, but only in the group without pre-existing COPD. $ppoFEV_1$ was not a significant predictor of postoperative pulmonary complications in patients with a preoperative diagnosis of COPD. This may be due to the fact that while these patients may have been losing lung tissue, a proportionally greater part of it was emphysematous and therefore less involved in gas exchange.[68]

In addition to these standard bedside tests, diffusing capacity (DLCO) may be helpful. If there is evidence of interstitial lung disease on chest x-ray or undue dyspnea on exertion, even if FEV_1 and FVC are normal, a DLCO should be obtained. If preoperative FEV_1 or DLCO is <40% of predicted, these are independent predictors of postoperative pulmonary complications. These patients may benefit from cardiopulmonary exercise testing. This is a sophisticated assessment of cardiopulmonary reserve and allows calculation of maximal oxygen consumption (V_{O_2}max). Risk of perioperative pulmonary complications can be stratified according the V_{O_2}max measured. Patients with a preoperative VO_{2max} >20 mL/kg are not at increased risk of complications; however, patients with V_{O_2}max of <15 mL/kg and <10 mL/kg are at intermediate- and high-risk, respectively, for perioperative pulmonary complications.

RISK MODIFICATION

PREOPERATIVE PREPARATION

Standard preoperative preparation, including the use of intensive chest physiotherapy, bronchodilators, and appropriate use of antibiotics are considered routine practice in an effort to reduce the risks of postoperative pulmonary complications. High-risk patients who were assigned to receive a protocol of intensive pre- and postoperative therapy (including delay of surgery if indicated) had a 22% incidence of postoperative complications, compared to 60% in a group in whom the preoperative preparation was at the discretion of the admitting physician. Aggressive pulmonary therapy resulted in shorter hospital stay despite frequent delays of surgery in the treatment group to improve pulmonary function.[69]

Despite the clinical application of deep breathing exercises, intermittent positive-pressure breathing (IPPB), and incentive spirometry, these treatments have not been shown to be independently successful in the prevention of postoperative pulmonary complications. Incentive spirometry has been shown to be of benefit, but only in high-risk patients. Pre- and

postoperative chest physiotherapy per se is of value only in the treatment of established pulmonary atelectasis.

However, high-risk morbidly obese (BMI >40 kg/m^2) patients may benefit significantly from the application of biphasic positive end-expiratory pressure noninvasively and prior to signs of respiratory distress.[70]

CESSATION OF CIGARETTE SMOKING

Continued smoking up to the time of surgery is associated with a significant increase in mortality. Cessation of smoking has been shown to result in a significant increase in FRC and reduced postoperative pulmonary complications. For maximum risk reduction, the patient should stop smoking at least 8 weeks prior to surgery.

SITE OF SURGICAL INCISION

Extremity surgical intervention leads to little alteration in lung volume. However, lower abdominal incision results in a 25% to 30% decrease in FVC and a mild decrease in oxygenation. Upper abdominal and thoracic surgery produces significant impairment of pulmonary ventilation and defense systems independent of the effect of anesthesia.

Maintenance of FVC is essential for effective secretion clearance and is reduced by 50% to 60% immediately following upper abdominal surgery. Gradual restoration of FVC over the next 5 to 7 days is usual. During the first 24 hours after upper abdominal or thoracic surgery, reductions occur in tidal volume (20%) and FRC (70% to 80%) as a result of incision pain and reflex diaphragmatic splinting, resulting in rapid shallow breathing, absence of spontaneous sigh, and chest wall splinting.[71]

Laparoscopic surgery has revolutionized the postoperative care of patients undergoing common surgical procedures such as cholecystectomy and fundoplication. Comparing the open subcostal cholecystectomy to the laparoscopic approach, significant improvements in FVC (52% vs. 73% baseline), FEV_1 (53% vs. 72% baseline), and FEF (53% vs. 81% baseline) were documented.[72] A similar comparison of the laparoscopic versus open approach resulted in quicker return of postoperative respiratory mechanics towards but not quite to normal compared to open cholecystectomy.[73] A review of over 300 patients following laparoscopic cholecystectomy showed no major postoperative pulmonary morbidity in the entire group, despite the fact that 45 were deemed to be obese, including 18 who were morbidly obese (BMI >45 kg/m^2).[74]

TYPE OF ANESTHESIA AND ANALGESIA

Repeated attempts to demonstrate a consistent decrease in postoperative pulmonary complications with the use of regional anesthesia alone or in combination with general anesthesia have failed. Anesthetic technique per se is not a significant determinant of postoperative respiratory complications.[75] All forms of regional anesthesia such as epidural local anesthetic, epidural narcotic, intercostal nerve blocks, and paravertebral nerve blocks have beneficial effects on postoperative FEV_1, FVC, and partial pressure of arterial oxygen (Pa_{O_2}).[76] However, these beneficial effects have not proved to alter outcome in terms of pneumonia, respiratory failure, or death. Perhaps this is because the delayed reduction in FRC, resulting in atelectasis and hypoxemia, remains largely unaffected by the intra- and immediate postoperative analgesic regimens.

Repeated studies of intraoperative positive end-expiratory pressure (PEEP) have failed to show benefit in normal patients; however, the intraoperative application of PEEP 10 cm H_2O to morbidly obese patients (BMI >40 kg/m^2) resulted in an improvement in perioperative oxygenation (110 to 130 mm Hg).[77] However, these patients were studied in the early postoperative period and this improvement may not have been maintained.

RECOMMENDATIONS

Although several questions concerning accurate preoperative assessment for prevention of clinically significant pulmonary complications remain unanswered, from available data a few guidelines may be generated. Likely to benefit the patient preoperatively are: cessation of smoking (at least 4 weeks, preferably >8 weeks abstinence), weight loss, and optimization of airway obstruction using bronchodilators. Intraoperative management options that may benefit the patient include: peripheral incision, limiting duration of surgery, endoscopic procedures, and the use of intraoperative PEEP. Postoperatively, good analgesia by the use of regional analgesia and patient-controlled analgesia delivery devices have been shown to be equally effective in reducing morbidity. Postoperative chest physiotherapy has proven value only for the treatment of atelectasis, but is useful as part of a program to encourage deep breathing exercises.

Thyroid Disorders, Diabetes, and Patients on Steroids

HYPERTHYROIDISM

Hyperthyroidism in the surgical patient may significantly alter surgical risk by imposing additional burden on the cardiovascular system.[78,79] Angina pectoris, atrial fibrillation, and cardiac failure may be precipitated, and other abnormalities include hypercalcemia, glucose intolerance, anorexia, myopathy, impaired drug absorption, and coagulation defects.

Preoperative preparation of a hyperthyroid patient includes deferral of elective surgery and optimization of thyroid function where possible. Most patients with hyperthyroidism have Graves disease and should be treated with a combination of antithyroid drugs (such as propylthiouracil and methimazole), iodide solutions, and possibly glucocorticoids to protect against adrenal insufficiency that may be associated with thyrotoxicosis.[80]

Surgical options for the treatment of a patient with Graves disease include subtotal or total thyroidectomy. A recent retrospective analysis of over 1200 patients over a 40-year period suggests that total thyroidectomy is the preferred surgical option for the treatment of Graves disease.[81]

If the surgery is emergent, the mainstay of treatment is perioperative β-blockade to reduce adrenergic thyroxine effects. Traditionally, propranolol has been recommended. However, esmolol may be preferred because of the rapid action and elimination, particularly when hemodynamic instability occurs.[82]

Thyroid storm is fortunately a rare event because of β-blockade prophylaxis, but when it occurs there is still a 40%

mortality rate. Tachydysrhythmias, frequently atrial fibrillation, are seen. Cardioversion is usually unsuccessful. Hyperthermia, hypertension, leukocytosis, and evidence of adrenal insufficiency may occur. Treatment with β-blockade should begin once the diagnosis is suspected. Invasive hemodynamic monitoring should be instituted to guide fluid and electrolyte therapy in the intensive care environment where possible.

HYPOTHYROIDISM

The incidence of hypothyroidism in the general population is 0.5% to 0.8%, increasing to 1% to 3% in patients over 65 years of age. Treatment with lithium or amiodarone, drugs not uncommonly associated with drug-induced hypothyroidism, may alert the clinician to this diagnosis.

Although there are many physical signs of hypothyroidism, the only sign statistically correlated with biochemical abnormalities is the presence of delayed ankle reflexes. Retrospective analysis suggests that postoperative complications are not increased in patients with mild to moderate hypothyroidism, but patients with severe hypothyroidism undergoing surgery are more prone to periods of hypotension, neuropsychiatric disturbance, and intestinal hypomotility.[83] Clinical assessment in addition to serum T_3, T_4, and thyrotropin levels should be used to assess thyroid status.[84]

Patients receiving regular thyroxine replacement, without signs and symptoms of hypothyroidism, can safely withhold oral thyroxine perioperatively for the majority of operations, as the half-life of levothyroxine is 1 week. If parenteral administration is required, thyroxine can safely be given intravenously at half the oral daily dose. Overtly hypothyroid patients undergoing emergency surgery should be treated with thyroxine replacement in addition to hydrocortisone 100 to 300 mg every 8 hours. Elderly patients with a clinical history or suspicion of coronary artery disease require cautious thyroxine replenishment and coadministration of nitrates.[85]

General anesthesia may be associated with profound cardiovascular depression in hypothyroid patients. Special consideration needs to be taken to titrate anaesthetic drugs to avoid this known effect. The use of newer anesthetic monitoring techniques such as bispectral index analysis may help titrate anaesthetic medications.[86]

DIABETES MELLITUS

Diabetes mellitus is the most common endocrine disorder encountered in the perioperative period, since it occurs in almost 5% of the general population.[87] Traditionally, diabetics presented for surgery for limb amputation and wound débridement, but owing to surgical advances in vitrectomy, cataract extraction, renal transplantation, and peripheral vascular repairs, diabetic patients are frequently presenting for preoperative assessment. Type I (insulin-dependent diabetes mellitus) comprises approximately 25% of the diabetic population, and affects a younger population (<35 years) which is prone to perioperative hyperglycemia and ketoacidosis because of inability to secrete insulin. Type II (non-insulin-dependent diabetes mellitus) patients are older and often obese and have a decrease in the number or responsiveness of insulin receptors, together with impaired insulin secretion, features which are accentuated in the perioperative period.[88,89]

The aim of therapy is to avoid excess morbidity and mortality which may be caused or exacerbated by extremes in blood glucose levels, undue protein catabolism, and fluid and electrolyte disturbances.

RISK ASSESSMENT

Although one study showed no difference in mortality and morbidity in vascular surgical patients, it is generally accepted that diabetics encounter increased perioperative morbidity and mortality.[90–92]

A perioperative myocardial infarction rate of 5.2% is reported in diabetics undergoing abdominal aortic reconstruction compared to 2.1% of nondiabetic patients. Inadequate control of blood glucose can lead to ketosis, acidemia, and dehydration. Decreased wound healing occurs at glucose levels greater than 200 mg/dL. Glucose concentrations greater than 250 mg/dL have been shown to impair leukocyte function and exacerbate ischemic brain damage. In addition to the effects of abnormal blood glucose levels, diabetics are at particular risk of atherosclerotic vascular disease, hypertension, and coronary artery disease.

Preoperative clinical markers for increased perioperative complications have been suggested. The presence of congestive cardiac failure, diabetic end-organ failure commonly associated with diabetes, valvular heart disease, and peripheral vascular disease associated with infection are statistically associated with increased mortality. Autonomic neuropathy is found in over 40% of patients presenting for surgery and may alter hemodynamic responses to intubation and surgery.[93,94]

Apart from anesthesia for cataract extraction, choice of anesthetic technique has not been associated with altered outcome.[95] Thoracic epidural and spinal anesthesia techniques are associated with reduced intraoperative catecholamine release. However, to date, no study of exclusively diabetic patients has compared outcome between regional and general anesthesia techniques.

RISK REDUCTION

Preoperative evaluation should include thorough clinical assessment for cardiac, neurologic, and peripheral vascular abnormalities. A careful history for the presence of ischemic heart disease or prior myocardial infarction should be supported by cardiac investigations where appropriate. Glycosylated hemoglobin (HbA_{1c}) levels less than 10% suggest satisfactory glycemic control. Renal failure may be present in up to 35% of diabetic patients upon presentation,[110] and plasma creatinine, urinary sediment examination, and urine analysis for infection should be assessed. Recent evidence that intensive insulin therapy to achieve strict control of blood sugar (80 to 110 mg/dL) improves outcome in nondiabetic surgical ICU patients suggests that general practice (to maintain a blood sugar <200 mg/dL) may be inadequate in the postoperative diabetic.[96]

Nondiabetic patients recovering from surgery commonly show transient hyperglycemia and diminished insulin secretion and end-organ responsiveness in response to increased circulating catecholamines.[97] However, these patients secrete sufficient insulin to suppress lipolysis and ketogenesis. Diabetics present with decreased or absent preoperative insulin secretion and a pre-existing insulin resistance, which serves to worsen the hyperglycemic response to surgery. Decreased

peripheral use of glucose results in lipolysis, ketogenesis, possible acidemia, glycosuria, and dehydration.[98]

A variety of insulin regimens have been suggested for the routine perioperative management of diabetics undergoing surgery. No single regimen has proved markedly superior. Currently, perioperative intravenous glucose infusions are recommended, and insulin may be administered via a variety of dosages and routes. Subcutaneous administration of half the regular daily dose before surgery, using a variable-rate glucose infusion to maintain normoglycemia, has proved successful.[99] Mixing insulin, potassium, and 5% or 10% glucose has also been suggested.[100,101] Most authors suggest a variable-rate insulin infusion using an automated syringe device with a simultaneous glucose infusion through an alternative intravenous access.[102,103]

Insulin requirements vary widely in the perioperative patient. The normal state (approximately 0.25 unit of insulin per gram of glucose) is influenced by many factors such as obesity, concomitant glucocorticoid administration, and the septic state, which may increase insulin requirements to as high as 0.4 to 0.8 unit of insulin per gram of glucose. The highest insulin requirements have been observed in patients undergoing CABG (0.8 to 1.2 U/g of glucose).[104]

Recommendations for glucose infusion to prevent catabolism suggest between 5 and 10 g of glucose per hour,[105] although the optimal dose of glucose necessary for prevention of fat and protein catabolism has not been clearly determined. However, clinical experience suggests that most surgical diabetics can be maintained within the normal blood glucose range with an insulin infusion set between 1 and 2 U/h.

Patients receiving total parenteral nutrition, which is generally up to 25% dextrose, usually require an additional 2 to 3 units of insulin per hour. Apart from careful monitoring of blood glucose levels, the patient's overall clinical status (particularly neurologic and hemodynamic) should be closely observed. Avoidance of hypoglycemic episodes while allowing mild hyperglycemia without ketosis is prudent in the diabetic whose blood sugar is extremely difficult to control.

What emerges from all the studies dealing with perioperative diabetes management is that the most important factor in optimal perioperative glycemic control is frequent measurement of blood sugar and appropriate therapeutic interventions by trained staff. Perioperative metabolic management should be planned and coordinated by surgeons, anesthetists, and diabetic care teams in conjunction with the patient when possible. With the exception of type II diabetic patients presenting for minor surgery, all diabetic patients should receive intravenous infusions of glucose with appropriate insulin to achieve normoglycemia until the preoperative regimen is resumed.

GLUCOCORTICOID SUPPLEMENTATION IN CHRONIC GLUCOCORTICOID USERS

Perioperative glucocorticoid supplementation for patients receiving steroid therapy is common. The rationale for its use is the avoidance of hypoadrenalism, resulting in a variety of clinical signs including fever, nausea, dehydration, abdominal pain, hypotension, and shock. Other evidence of hypoadrenalism includes low-voltage complexes on the ECG, hypoglycemia, and eosinophilia. Despite the common use of steroids in hospital patients, the incidence of perioperative adrenal insufficiency is low (0.01% to 0.1%).[106]

Retrospective and prospective data suggest that routine steroid supplementation for all glucocorticoid-treated patients may not be necessary.[107–109.] Well-known adverse effects of exogenous glucocorticoids include immunosuppression, exacerbation of osteoporosis, avascular necrosis of the femur, diabetes, peptic ulcer disease, diminished wound healing, and neuropsychiatric disorders.

Daily endogenous cortisol release in normal adults approximates 25 to 30 mg per day at rest. Stressors such as major surgery or critical illness increase endogenous production to 75 to 100 mg per day because of increased secretion of adrenocorticotropic hormone (ACTH) from the anterior pituitary gland. Increased cortisol secretion returns to normal within 24 hours of skin incision in uncomplicated minor surgery.[110]

The clinical rationale for steroid supplementation in the perioperative period is based on the known protracted recovery of the hypothalamus-pituitary-adrenal (HPA) axis following prolonged glucocorticoid administration.[111] However, the stress response observed in perioperative patients results in ACTH levels far in excess of that required for maximal adrenocortical stimulation.[112] A number of studies[113–115] have suggested that patients on chronic steroid therapy undergoing elective major surgery may not require perioperative steroid supplementation in addition to their regular steroid regimen. In a study of 40 renal transplant recipients on chronic prednisone therapy, none of the patients received more than baseline glucocorticoid therapy during admission for surgery or critical illness. Despite biochemical evidence of decreased adrenal response to exogenous ACTH in 67% of the patients, none of the patients exhibited clinically overt hypoadrenalism, and 97% of all patients excreted normal or increased urinary cortisol concentrations during their hospital stay. This suggested that cortisol concentrations were sufficient to meet requirements during the time of stress.[109]

Identification of patients at risk for perioperative hypoadrenalism by history alone is difficult.[113] Functional status of the adrenal gland may be assessed quickly and easily using the 30-minute ACTH test. This is the most effective and convenient tool for perioperative evaluation of HPA function.[116]

Baseline cortisol measurements are taken immediately prior to the intravenous administration of 250 μg of synthetic ACTH. Adequate adrenal function is diagnosed by baseline levels usually above 200 nmol/L, which rises above 500 nmol/L 30 minutes following ACTH administration (see Chap. 79).

Patients who exhibit a subnormal response to ACTH should receive supplemental steroids. Since endogenous cortisol secretion in normal individuals rarely exceeds 200 mg/d, exogenous steroid supplementation should range from 75 to 150 mg per day. To date, no data suggest that supplemental glucocorticoid therapy exceeding this amount is beneficial. Patients on chronic steroid therapy undergoing minor surgery should have their regular steroid dose on the morning of surgery and no additional doses if surgery is uncomplicated. Candidates for major surgery should receive 25 mg hydrocortisone intravenously on induction of anesthesia, and 100 to 150 mg per day over the following 24 to 72 hours. If a patient presenting for surgery is already receiving a maintenance steroid dose greater than the estimated requirement, additional steroid coverage is not necessary.[115]

Clinical and biochemical preoperative assessment of patients on chronic steroid therapy is invaluable in the identification of patients at risk for adrenal insufficiency in the perioperative period. Published recommendations for supplemental steroid coverage should be followed by dosing to physiologic levels. If doubt exists, a preoperative 30-minute ACTH test will clarify the need for perioperative supplemental glucocorticoid administration.

Chapter 89

THE ACUTE ABDOMEN AND INTRA-ABDOMINAL SEPSIS

J.M.A. BOHNEN
R.A. MUSTARD
B.D. SCHOUTEN

KEY POINTS

- *Patterns of presentation of the acute abdomen in the intensive care unit (ICU) may be unusual.*
- *Conjoint evaluation by intensivist, surgeon, and gastroenterologist is frequently needed.*
- *Prompt diagnosis is the key to successful management.*
- *Computed tomography (CT) or ultrasonography should be used liberally in the evaluation of intra-abdominal sepsis.*
- *Complications occur frequently in the postsurgical ICU patient; "stable vital signs" does not imply clinical stability.*
- *Postoperative residual or recurrent intra-abdominal sepsis may not be clinically obvious and may not be demonstrated by a CT scan; cardiorespiratory instability should prompt a high level of suspicion.*
- *The treatment of the febrile postsurgical patient is not simply the administration of further antibiotics.*
- *Acalculous cholecystitis is a treacherous disease which requires urgent treatment; definitive diagnosis is not always possible or necessary before treatment.*

Patients with an "acute abdomen" present challenging problems for surgeons and intensivists. The term *acute abdomen* refers to a patient whose chief presenting symptom is the acute onset of abdominal pain. The vast majority of these patients present in the emergency department and do not require treatment in an ICU. However, the small percentage of patients who do require such treatment constitute a significant fraction of the surgical ICU patients in most general hospitals. Furthermore, the intensivist must be aware that an ICU patient may develop an acute abdomen while being treated for some other condition.

In this chapter, we will first discuss the approach to the ICU patient who develops abdominal pain while undergoing treatment for some other disorder. The bulk of the chapter, however, will be directed to the patient with known intra-abdominal sepsis (IAS) who requires intensive care. Emphasis will be placed on the early diagnosis of intra-abdominal septic complications.

Evaluation of Acute Abdominal Pain in the Intensive Care Unit Patient

The diagnosis of abdominal pain depends heavily on an accurate history and a complete physical examination.[1] Both of these sources of data may be severely limited in the ICU patient. History may be unobtainable because of intubation or a decreased level of consciousness. Physical examination is made difficult by the many tubes emanating from the patient, and may be further compromised by medications such as corticosteroids. Indeed, abdominal pain itself may be masked by narcotics or other painful disease processes. Some physical signs, such as the absence of bowel sounds, which would be considered significant in an otherwise well patient, may not be significant in an ICU patient, in whom multiple extra-abdominal causes of ileus may be present. Hence, in the ICU setting, it is rare that an abdominal complaint comes to light because the patient complains of abdominal pain; rather, the physician usually must infer its presence on the basis of nonspecific findings such as unexplained sepsis, hypovolemia, and abdominal distention.

Table 89-1 provides an abbreviated summary of the many causes of acute abdominal pain. Rather than describing a complete algorithm for the diagnosis of these conditions in ICU patients, we will list some important principles.

1. The patient should be evaluated in the context of the underlying disorder(s). For example, sudden, severe abdominal pain in a patient with congestive heart failure secondary to myocardial infarction is much more likely to be due to mesenteric ischemia than to renal colic.
2. Liberal use should be made of surgical consultants. A patient with significant unexplained abdominal pain lasting more than 4 hours should be seen by a surgeon.
3. CT and ultrasound examination of the abdomen are excellent screening tests for acute abdominal problems in patients in whom the physical examination is unreliable.
4. Laparoscopy, carried out either in the ICU or in the operating room, may be of definite help, particularly in patients suspected of having ischemic bowel or acalculous cholecystitis.[2–4]

In summary, there is no straightforward approach to the ICU patient who develops an acute abdomen. Indeed, the major problem may be simply determining that the patient has an acute abdomen. Successful management of these patients depends on the close collaboration of the intensivist and the surgeon.

The Intensive Care Unit Management of the Patient with an Acute Abdomen

Most patients with an acute abdomen are diagnosed outside the ICU. These patients may require treatment in an ICU for one of four reasons:

1. The patient is very ill but may not require surgical intervention (e.g., severe pancreatitis).
2. The patient requires stabilization prior to operation (e.g., septic shock).
3. The patient has undergone definitive surgical treatment for the acute abdominal disease, but has unrelated medical problems requiring intensive care (e.g., chronic obstructive pulmonary disease [COPD]).

Medical disorders (e.g., lupus serositis, sickle cell crisis)

4. The patient has undergone definitive surgical treatment and requires intensive care because of the severity of the abdominal pathology or the occurrence of a postoperative complication such as sepsis.

In this chapter we will consider only patients in the fourth group, since the other groups are discussed in other areas of the text. We will primarily consider the ICU management of patients who have undergone treatment of a septic abdominal disease.

A classification of the sources of IAS is given in Table 89-2. Sepsis resulting from disease originating in the pancreas and infections arising in the urinary tract are discussed in other chapters.

The principles of treatment of IAS are well established and are as follows:

1. Prompt diagnosis and resuscitation
2. Prompt treatment of the underlying pathology and mechanical cleansing of the peritoneal cavity
3. Appropriate antibiotic administration
4. Supportive care of the patient
5. Constant vigilance to detect and treat aggressively any complications arising from the underlying disease or its treatment
6. Close collaboration among all physicians caring for the patient

The importance of prompt diagnosis and treatment cannot be overemphasized. This is one of the few prognostic variables that physicians can control, and prompt treatment has been shown repeatedly to result in decreased mortality.[5–7]

PRIMARY PERITONITIS

Primary peritonitis is a group of diseases characterized by infection in the peritoneal cavity without an obvious source such as a gastrointestinal (GI) tract perforation.[8,9] This most frequently occurs in patients who have ascites secondary to cirrhosis of the liver, congestive heart failure, and renal dialysis, among other disorders. Patients suffering from primary peritonitis rarely require intensive care. However, primary peritonitis may well be present in patients requiring intensive care for other reasons. For example, a cirrhotic patient with portal hypertension and ascites may develop primary peritonitis that precipitates hepatic decompensation, leading to variceal bleeding and hypovolemic shock necessitating ICU admission.

The clinical presentation is usually one of fever and physical signs of peritoneal irritation. However, approximately one third of patients with primary peritonitis have no signs or symptoms of sepsis referable to the abdomen. Diagnosis is based on clinical suspicion, the patient's presentation, and the Gram stain and culture results obtained from ascitic fluid aspiration. Culture of infected ascitic fluid usually yields aerobic enteric organisms; however, approximately 35% of patients with these diseases will have negative ascitic fluid cultures.[9] Blood cultures are also frequently positive in these patients. Primary bacterial peritonitis may be assumed to be present when the ascitic fluid neutrophil count is $>250/\mu L$. The diagnosis may be confirmed in culture-negative patients by the response to appropriate antibiotic treatment, which should be evident within 48 hours and is characterized by both clinical improvement and a decrease in the number of white blood cells present in the ascitic fluid.

It is most important to distinguish primary from secondary bacterial peritonitis. *Secondary bacterial peritonitis* is caused by contamination from the gut lumen, and multiple organisms thus are usually found in the ascitic fluid Gram stain or culture. Patients with secondary bacterial peritonitis are unlikely to respond to antibiotic administration alone, and usually require surgical treatment.

Antibiotic treatment should be initiated on clinical suspicion of primary peritonitis and before final culture and sensitivity results are available. Broad-spectrum treatment with either ampicillin and an aminoglycoside, a third-generation cephalosporin, or ciprofloxacin is usually sufficient. The prognosis of these patients depends almost entirely on the underlying liver disease responsible for the ascites.

Patients who develop peritonitis secondary to an infected peritoneal dialysis catheter may or may not respond to antibiotic treatment (usually instilled into the dialysis fluid). Nonresponse necessitates removal of the catheter and temporary hemodialysis.

BILIARY TRACT SEPSIS

Both sepsis and hyperbilirubinemia are common findings in critically ill patients. When these conditions coexist, the

question of biliary tract sepsis arises. However, most jaundiced ICU patients do not have pathology in their biliary tract.[10] Before we discuss biliary tract sepsis, we will briefly outline the approach to the jaundiced patient.

Infection in the biliary tree results in one or more of three rather different clinical entities. Most commonly, infection is only present in the gallbladder and is due to obstruction of the cystic duct by a gallstone. This entity, acute calculous cholecystitis, is usually treated surgically by removal of the gallbladder, and only results in ICU admission if the patient has other major medical problems. Of more relevance to the intensivist are the syndromes of acute cholangitis and acute acalculous cholecystitis.

THE JAUNDICED INTENSIVE CARE UNIT PATIENT

Abnormalities on liver function tests and even clinically evident jaundice are quite common in the ICU patient population. LaMont and Isselbacher, in a classic review article on postoperative jaundice,[10] provide a simple classification, distinguishing jaundice caused by increased pigment load, by impaired hepatocellular function, and by extrahepatic obstruction. The vast majority of ICU patients with abnormal liver function test results represent the first two categories. Exclusion of extrahepatic biliary obstruction is best accomplished[11] by history, physical examination, and routine laboratory tests (i.e., the clinical context) and ultrasonography to look specifically for evidence of bile duct dilation. In certain unusual circumstances,[11] obstructed bile ducts may not be dilated, and clinical suspicion will necessitate direct visualization of the biliary tree with either endoscopic retrograde cholangiopancreatography (ERCP) or percutaneous transhepatic cholangiography (PTC).

ACUTE CHOLANGITIS

Cholangitis is defined as a bacterial infection within bile ducts. It occurs when bacteria are introduced into a partially or totally obstructed duct system. In this situation the bacteria multiply rapidly in the bile and induce an inflammatory reaction around the small biliary radicles in the liver. When the hydrostatic pressure in the ducts exceeds a certain point, bacteria are literally forced out of the bile canaliculi and into the hepatic sinusoids, resulting in systemic bacteremia. The microbiology of this disease is similar to that of peritonitis caused by GI tract perforation. The portal of entry of bacteria into the biliary tree remains a topic of debate.

The clinical presentation is usually obvious, with right upper quadrant abdominal pain, jaundice, and fever (Charcot triad). Patients may be only mildly ill with bactobilia, or critically ill with frank pus under pressure in the biliary tree. Diagnosis may be confirmed with ultrasound, ERCP, or PTC. Treatment consists of biliary decompression and the administration of appropriate broad-spectrum antibiotics to cover aerobic gram-negative rods, anaerobic gram-negative bacilli, and enterococci. Bile and blood for culture are obtained before antibiotics are started (if possible) to be sure the antibiotic coverage is optimal.

These patients may require intensive care if they develop septic shock, either from the disease itself, or from bacteremia induced by an invasive procedure used to diagnose or treat the disease. From the intensivist's point of view, the management is straightforward—support the cardiorespiratory system until the ducts have been decompressed and the patient is hemodynamically stable and ensure that appropriate antibiotics are administered. It must be emphasized that the key to success is adequate biliary decompression. This may be accomplished either surgically (exploration of the common bile duct and insertion of a T tube), endoscopically (insertion of a nasobiliary drain, sphincterotomy and stone extraction, or placement of an internal stent), or percutaneously (placement of a transhepatic external drain). The adequacy of drainage is confirmed by rapid clinical and biochemical improvement (obvious within 24 to 48 hours). A patient with cholangitis who does not improve clinically and may require ongoing cardiopulmonary support must be assumed to have inadequate drainage. In this case, it is essential to image the biliary tree to determine the adequacy of the drainage and to plan for further decompression. It may also be necessary to obtain a CT scan to look for hepatic abscess(es) induced by the cholangitis.

ACALCULOUS CHOLECYSTITIS

This disease is a child of modern intensive care. It was well summarized in a 1978 article by Long and coworkers:

> Acute acalculous cholecystitis is a treacherous and potentially lethal disease. It may occur in patients without known biliary tract disease who are severely compromised by trauma or gastrointestinal dysfunction and require prolonged intensive care. Its onset is insidious, its presenting symptoms are inconstant, and its neglect can lead to necrosis of the gallbladder with sepsis and death.[12]

This disease occurs in approximately 0.5% to 1.5% of long-term (>1 week) ICU patients.[13,14] The etiology of this disease is unknown, and hence there are no known ways to prevent it.[15] It appears that in the occasional critically ill patient the gallbladder wall becomes inflamed and infected with enteric organisms. The cystic duct becomes edematous and occluded, but it is not known whether this event is the cause or a result of the disease. This condition may occur at any time during the patient's ICU stay. In about one-third of patients, the inflammation has induced partial or complete necrosis of the gallbladder by the time of diagnosis.

The real problem with this disease is the difficulty in achieving a definitive diagnosis without resorting to laparotomy or laparoscopy. Attention should be focused on the gallbladder when sepsis or organ failure occurs without a known cause. The patient may have right upper quadrant abdominal tenderness, but an ICU patient can have this sign without cholecystitis. Distention of the liver capsule due to increased venous pressure or sepsis can produce identical physical findings. Liver function tests are not helpful. A biliary radionuclide scan is helpful, in that filling of the gallbladder (perhaps with the aid of morphine-induced spasm of the sphincter of Oddi[16]) implies cystic duct patency, which effectively rules out cholecystitis. The most valuable tests are ultrasonography and CT. Findings of pericholecystic fluid (without ascites), intramural gas, or a sloughed mucosal membrane are virtually diagnostic (Fig. 89-1). Unfortunately, not all patients have these findings.[14] A thick-walled gallbladder is suggestive, unless the patient has generalized edema. Percutaneous bile aspiration for culture has high false-positive and false-negative rates and is therefore not helpful.

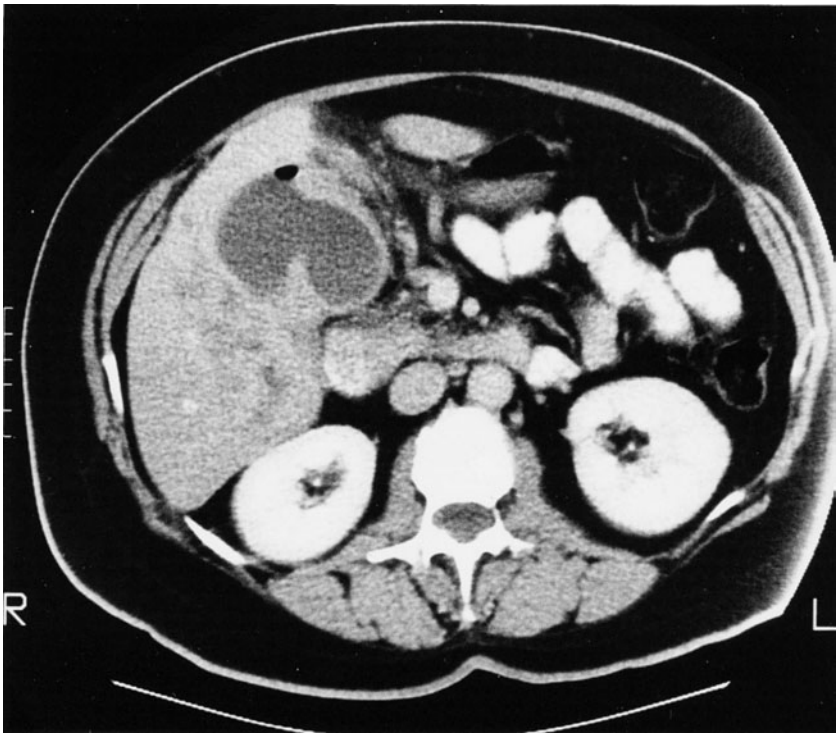

FIGURE 89-1 CT scan diagnostic of acalculous cholecystitis. The patient has an enlarged thick-walled gallbladder with intraluminal gas. The liver around the gallbladder fossa is markedly edematous.

It is our practice to operate on these patients if our clinical index of suspicion is sufficiently high and the patient is deteriorating without obvious cause. About half the patients we operate on for this reason have the disease. These patients are treated with cholecystectomy. In the remaining half, we place a cholecystostomy tube to prevent the disease in the future. To date, direct visualization of the gallbladder in the operating room is the only completely accurate method of diagnosis. This can be carried out under local anesthesia, but this approach seems somewhat pointless in the ventilated patient. In the rare patient who is felt to be "too sick to undergo laparotomy," percutaneous transhepatic drainage of the gallbladder may result in significant clinical improvement.[17] This procedure can be carried out at the bedside under ultrasound guidance. It is our experience, however, that these patients should later undergo cholecystectomy before the drainage tube is removed.

SECONDARY BACTERIAL PERITONITIS

In this section we will discuss the ICU management of patients with secondary bacterial peritonitis, defined as the presence of pus or gastrointestinal contents in the peritoneal cavity.[18] This condition may be either localized (an abscess) or diffuse (generalized peritonitis). Patients with physical signs of peritoneal irritation due to localized gastrointestinal tract infections are discussed elsewhere in this text.

Patients with secondary bacterial peritonitis requiring intensive care constitute a significant fraction both of all surgical ICU admissions and of all patients with peritonitis. For example, at our hospital, 300 patients with generalized peritonitis or abdominal abscess were treated in a recent 5-year period. Of these patients, 107 (mean Acute Physiology and Chronic Health Evaluation [APACHE] II score, 19.3) required posttreatment ventilatory support for an average of 9.6 days (78 treated surgically, 29 treated percutaneously), and 193 (mean APACHE II score, 10.4) did not require ventilation (137 treated surgically, 56 treated percutaneously). Patients requiring postoperative ventilatory support were severely ill and had a 64% mortality rate, compared to patients not requiring such treatment, who had only an 11% mortality rate. Therefore the need for mechanical ventilation may be a marker for general severity of illness, which results in a poor prognosis.

PATHOPHYSIOLOGY AND TREATMENT

Generalized peritonitis is usually caused by either bowel infarction, or more commonly, bowel perforation. Occasionally, generalized bacterial peritonitis results from perforation of an infected gallbladder, infected pancreatic pseudocyst, or other rare disease. We shall restrict our attention in this chapter to the vast majority of cases which are due to gastrointestinal tract perforation.

Patients with generalized peritonitis may become very ill because of the anatomy of the peritoneal cavity. Its large surface area permits massive loss of fluid into the abdomen and rapid absorption of bacteria, endotoxin, and inflammatory mediators into the systemic circulation. The hemodynamic effects of generalized peritonitis have been compared with those of a burn covering 50% of the body surface.

Treatment of this disease is well established.[19] Following rapid fluid resuscitation and the initiation of antibiotic therapy, patients undergo laparotomy to close the perforation (or resect, exteriorize, etc) and to remove as much of the contaminating material and inflammatory exudate as possible. Broad-spectrum antibiotics are used to eliminate residual bacterial contamination after laparotomy and because septicemia is common in these patients. The gold standard in antibiotic therapy is the combination of an aminoglycoside and an antianaerobe agent such as metronidazole

or clindamycin. To avoid nephrotoxicity, aminoglycosides should not be given to patients with a significantly decreased glomerular filtration rate (e.g., patients with elevated serum creatinine level, advanced age, or hypotension). In the last 15 years, a plethora of new and very effective antibiotics have appeared.[20,21] Aminoglycosides may be replaced with a third-generation cephalosporin or with ciprofloxacin. Single-agent therapy with a second-generation cephalosporin (cefotetan) is effective for mild to moderate infections. Imipenem should be reserved for severe infections. Since the administration of broad-spectrum antibiotics may lead to systemic candidiasis, pseudomembranous colitis, and the selection of multiply resistant organisms, the drugs should be discontinued as soon as the acute episode of abdominal infection has subsided. Unfortunately, there is no straightforward guide to antibiotic discontinuation. The conventional criteria of clinical improvement, no fever, and no leukocytosis are associated with an exceedingly small rate of relapse of peritoneal infection, but may never be achieved in many ICU patients.[22] In this group, we believe that it is reasonable to stop antibiotics when the patient no longer has physical signs of peritonitis or ileus. If the patient still has fever or leukocytosis, a CT scan should be obtained to rule out intra-abdominal abscess. If no abscess is found, antibiotics can be stopped and a search begun for an extraperitoneal source of infection.

The mortality rate of generalized peritonitis is about 30%. Known prognostic factors include age, pre-existing disease, severity of physiologic derangement at the time of diagnosis, steroid dependency, and peritonitis occurring in the postoperative period.[23] Interestingly, the site of perforation is not a determinant of mortality (with the exception of perforated appendicitis). Perforated peptic ulcers are just as deadly as perforated colons. The cause of death is usually uncontrolled sepsis. Of our 107 ICU patients with peritonitis, 68 died. IAS was considered the main cause in 37 patients (55%) and was a contributing cause in 24 patients (35%). Only 7 patients (10%) suffered a nonseptic death. Essentially all the septic deaths were due to multiple organ dysfunction syndrome (MODS).

It is widely assumed that the cause of MODS in these patients is bacterial infection. (It is also possible that the uncontrolled infections are just another result of MODS caused by an unknown disorder of immune regulation). When considering treatment of these patients, it is helpful to classify the possible anatomic sites of bacterial infection (Table 89-3). At present, we do not have specific treatments for all intra-abdominal sites of infection. The prevention and treatment of infection in fibrin deposits, tissues, or the gut lumen is a very active research field at this time. For example, many postoperative abscesses likely start as small collections of fibrin-encased bacteria. Translocation of bacteria from the gut lumen may be prevented with appropriate enteral nutrition. Interestingly, patients who developed nosocomial pneumonia complicating intra-abdominal sepsis were more likely to die than patients who developed recurrent intra-abdominal infection—perhaps because pneumonia is more difficult to treat than intra-abdominal abscess.[24]

Intravascular catheter infection
Disseminated candidiasis

The Intensivist's Role

It is the intensivist's role to support these patients postoperatively and be aware of the possible need for further surgical intervention as well as the potential for a large variety of possible complications. Close collaboration between the intensivist and the surgeon is essential for the optimal management of the patient. Supportive treatment is usually straightforward and includes hemodynamic support (recovering from shock), respiratory support, nutritional support, administration of antibiotics and activated protein C (beginning 12 hours postoperatively in selected patients), and if necessary, renal support with dialysis or hemofiltration. However, complications are many and varied and include complications of the supportive care (e.g., nosocomial infection), complications that may occur in any surgical patient (e.g., pulmonary embolus), and complications that are specific to patients treated surgically for peritonitis. We only consider the latter group of problems (Table 89-4).

These patients must be examined daily by the intensivist as well as the surgeon, with this list of complications in mind. First, all dressings covering the abdomen should be removed and the wound examined. The skin incision is usually packed open at operation to minimize the incidence of

Acalculous cholecystitis

wound infection.[25] Fascial dehiscence may be observed. This complication is not rare and should prompt an immediate surgical consultation. Dehiscence occurred in 17 of our 107 ventilated peritonitis patients. Dehiscence is most common on postoperative days 4 to 8 but may occur at any time. It is heralded by the drainage of serosanguineous fluid through the incision. The diagnosis is confirmed by palpation of the wound (if the skin incision was closed) or the observation of intra-abdominal contents in the wound (if the wound was packed open). The presence of loops of bowel in the wound poses the acute risk of evisceration. In some patients with particularly severe peritonitis, it is not technically possible to reapproximate the fascial edges at the end of the surgical procedure. The surgeon then sutures an artificial mesh or other pliable material to the fascia or skin to prevent postoperative evisceration, and the wound is packed with saline-soaked gauze.[26] These patients are particularly at risk for the formation of enterocutaneous fistulae at the surface of their open wounds, and this complication is easily diagnosed by inspection.[27] Finally, all tubes or drains should be inspected to make sure that they have not been dislodged and are functioning as intended. For example, sump drains should be checked to make sure that the air inlet ports are not occluded.

Second, the intensivist needs to determine whether the gastrointestinal tract is functioning well enough to allow enteral feedings. This is sometimes very difficult to determine in the sedated, ventilated patient, and it is frequently necessary to challenge the patient by starting tube feedings and simply checking the gastric residual volume every 4 hours. As discussed in Chap. 11, enteral feeding is preferred over parenteral feeding in this patient population, if technically feasible. Jejunal feeds are almost always tolerated, even in patients with severe peritonitis. Early enteral feeding may improve outcome.[28]

Third, the intensivist must determine if the patient is septic and if the septic focus is intra-abdominal. The most common IAS complication is abscess formation, which occurred in 21 of the 107 peritonitis patients who required postoperative ventilation in our series. It is often difficult to determine when the patient's original septic response is abating and when a new septic response is being mounted.[29] In general, if the patient is not improving steadily following surgery or if the patient begins to deteriorate in any way, a CT scan of the abdomen should be obtained to identify and localize a possible abscess (Fig. 89-2). However, it is usually not fruitful to scan the patient sooner than 5 to 7 days after laparotomy. Patients in this early postoperative period frequently have multiple intra-abdominal fluid collections, most of which are sterile. The patient who is deteriorating in the first week following surgery for peritonitis and who is thought to have persistent or recurrent peritoneal infection usually requires repeat laparotomy. Beyond this early phase, when abscesses are better formed and sterile collections have been resorbed, percutaneous drainage offers a safe and effective method for the diagnosis and control of abscesses.[30] The tendency to broaden the antibiotic coverage when a patient continues to have fever or develops recurrent fever should be resisted.[31]

Open Abdomen Treatment

In certain circumstances patients with peritonitis require "open abdomen" treatment. The skin and fascia are not closed and evisceration is prevented by suturing an artificial mesh to the fascia or skin. These patients fall into two categories—patients whose fascia could not be closed for technical reasons

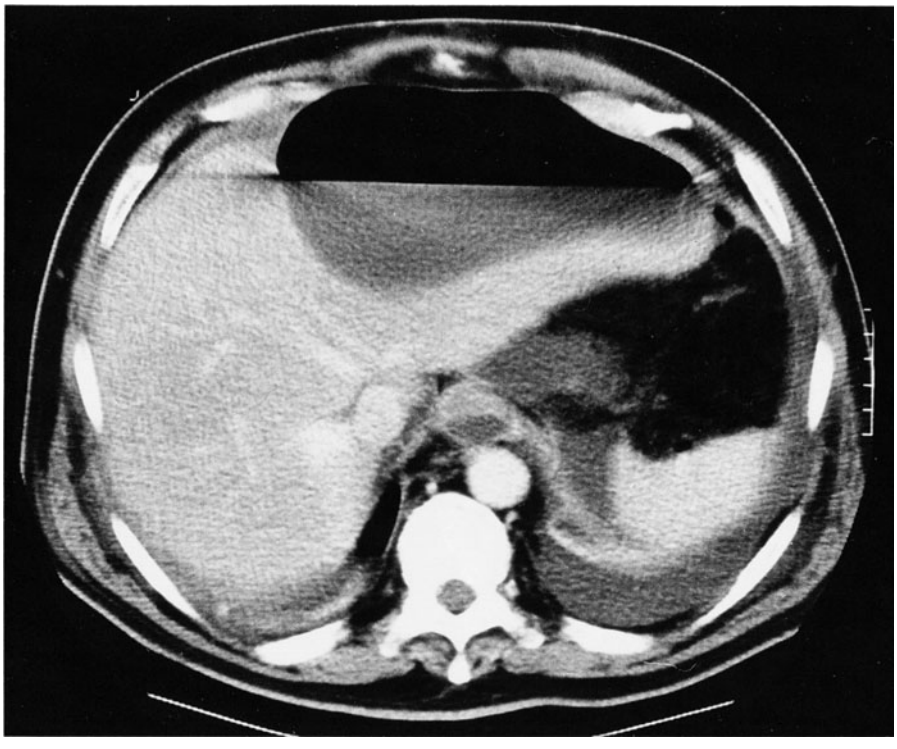

FIGURE 89-2 CT scan demonstrates massive left subphrenic abscess. The patient developed septic shock 11 days after total gastrectomy for adenocarcinoma of the stomach. Following resuscitation in the ICU, this scan was obtained and the abscess was drained percutaneously. The anastomotic leak was later repaired surgically.

but who are otherwise stable, and patients whose peritonitis is so severe that in the surgeon's opinion the abdomen should be left open to facilitate repeated laparotomies for peritoneal toilet. The latter group presents a major problem to the intensivist and the ICU nursing staff. These patients undergo laparotomy (through the mesh) every 1 to 3 days until the surgeon feels that the peritoneal cavity is sufficiently clean. Weaning from ventilatory support is almost always impossible until after the last scheduled relaparotomy.[32] Furthermore, during this period of repeated laparotomies, large quantities of proteinaceous fluids are lost through the open abdominal wound, and the patients may therefore require support with plasma as well as aggressive nutritional support. Fortunately, such drastic treatment for peritonitis is rarely required and has not been proved to be more efficacious than conventional management.[33]

VISCERAL ABSCESS

Pyogenic liver abscess is a rare condition that can occur in an ICU patient. Almost any bacterium may be cultured. A wide variety of conditions may give rise to a hepatic abscess (Table 89-5), but it should be noted that at least 20% of cases are cryptogenic.[34]

Patients with hepatic abscess usually present with sepsis associated with right upper quadrant pain and occasionally with peritoneal findings such as an enlarged liver. Liver function test results are frequently abnormal. The diagnosis is confirmed by CT or ultrasound examination (Fig. 89-3).

The preferred treatment of hepatic abscess is percutaneous drainage for large abscesses. It should be noted that the presence of more than one large abscess does not necessitate open surgical treatment. Antibiotics should be administered as described for patients with peritonitis until culture results are available. This may be the only treatment required for patients with multiple small abscesses, usually secondary to cholangitis, after bile duct drainage has been established.

Splenic abscess formation is rare. It may be due to trauma, direct extension of a septic process such as pancreatic abscess, infection of a splenic infarct, or bacteremia. These patients present with left upper quadrant abdominal pain, left pleural effusion, or sepsis of unknown etiology, and the diagnosis is established by CT or ultrasound examination of the abdomen. The optimal treatment is splenectomy, but percutaneous drainage may be used as a temporizing maneuver.[35]

The Abdomen as a Source of Occult Sepsis

A frequent clinical problem in the ICU is the patient with a septic picture or MODS (or both) with no obvious etiology. Line sepsis, soft tissue infection, foreign body infection, *Candida* septicemia, endocarditis, pneumonia, pseudomembranous colitis, and urosepsis can often be ruled out. Attention then focuses on the abdomen even if the patient had no known pre-existing gastrointestinal pathologic condition. A CT scan of the abdomen is an excellent screening test in this patient group. However, a negative CT scan or ultrasound does not absolutely rule out peritoneal infection.

There are several causes of occult IAS (Table 89-6). Acute acalculous cholecystitis was discussed previously.

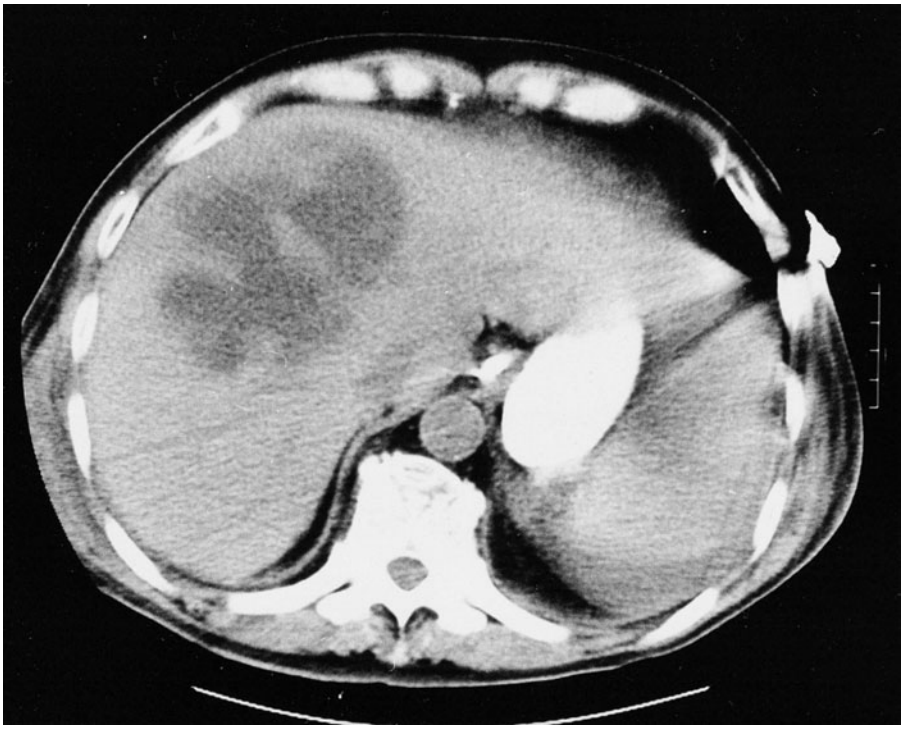

FIGURE 89-3 CT scan demonstrates large pyogenic liver abscess. The patient presented with septic shock and abnormal liver function test results. Following resuscitation in the ICU, an ultrasound examination failed to support the clinical diagnosis of acute cholangitis. This CT scan was therefore obtained, and the abscess was drained percutaneously. No cause for the abscess was found.

TABLE 89-6 Occult Sources of Intra-Abdominal Sepsis

Acalculous cholecystitis
Small intra-abdominal abscess(es)
Ischemic bowel—short segment
Tertiary peritonitis

Intra-abdominal abscesses that are too small to be seen by CT or ultrasound examination or that are hidden between loops of bowel (interloop abscesses) are a second well-recognized cause. These can only be diagnosed by laparotomy prompted by clinical suspicion and exclusion of other causes of sepsis. Rarely, a short segment of ischemic or necrotic bowel may be very difficult to detect. If the segment is in the small bowel, the patient will usually have a clinical picture of mechanical small bowel obstruction. However, if the segment is in the left colon, the patient may have no other obvious symptoms. Colonoscopy is the diagnostic method of choice if this condition is suspected.

Finally, experimental evidence suggests that the gastrointestinal tract itself is the source of systemic endotoxemia or bacteremia in some ICU patients.[36] It has been hypothesized that the patient's initial critical illness may result in increased permeability of the gut mucosa with resulting bacterial translocation, eventually leading to portal vein bacteremia. MODS that is triggered by the initial insult may then be perpetuated by this mechanism. Furthermore, as a result of the use of broad-spectrum antibiotics and potent inhibitors of gastric acid production, blood cultures may grow organisms not usually associated with the gastrointestinal tract, such as *Staphylococcus epidermidis* or *Candida* species. Clearly, diagnosis of this condition (usually called *tertiary peritonitis*) can be made only by exclusion of other causes of sepsis. Treatment (and prevention) consists of stopping all unnecessary antibiotics and initiating enteral feeds if at all possible. Food in the lumen of the gut is a major stimulant of mucosal growth, which preserves mucosal integrity.[37]

When all attempts at determining a definite etiology for the patient's septic state have failed, the intensivist is often tempted to recommend laparotomy as a diagnostic tool. Some have advocated the use of minilaparoscopy in the ICU for diagnosis, but this is rarely, if ever, useful.[37a] Laparotomy in the absence of clinical or laboratory findings pointing to a specific etiology or location of infection is rarely helpful in preventing death.[38] Finally, it must be noted that once MODS is far advanced, even definitive treatment of the underlying intra-abdominal source rarely succeeds in reversing this lethal syndrome.[39–41]

Chapter 90

THE TRANSPLANT PATIENT

DAMON C. SCALES
JOHN T. GRANTON

KEY POINTS

- *The critical care of the transplant recipient requires a multidisciplinary approach.*
- *Although some generalizations can be made regarding the management of all transplant patients, organ-specific considerations based on the particular allograft transplanted are often much more important.*
- *Risks and benefits of immunosuppressive therapy must be balanced in transplant recipients. Though immunosuppressive drugs are essential to prevent allograft rejection, they also increase the risk of infection and neoplasm.*
- *All immunosuppressive drugs have side effects and many have important drug-drug interactions that must be recognized by the intensivist.*
- *Rejection of the allograft can be divided into three broad categories: hyperacute, acute, and chronic rejection.*
- *Infections can reactivate in an immunocompromised recipient who has been previously exposed. Alternatively, a naïve recipient may acquire an infection following the transplant of an organ from a seropositive donor.*
- *Infections in transplant recipients can progress rapidly and hence must be promptly recognized and appropriately treated.*
- *Often immunosuppressive therapy must be adjusted or withdrawn in the presence of severe infection.*

This chapter provides a practical approach to the critical care of patients following the most common solid-organ transplant procedures. Important scientific advances have greatly improved our understanding of transplant immunology. Therapies have been developed that markedly decrease the incidence and severity of allograft rejection, and this has resulted in dramatic improvements in the outcomes of transplant recipients (Table 90-1). The major causes of morbidity and death in these patients depend on the time since transplantation. Technical and bacterial infectious complications predominate in the early postoperative period. Chronic rejection remains the major cause of death overall in these patients, occurring months to years after transplantation (Fig. 90-1).

An organ that has been transplanted from one individual to another (of the same species) is called an *allograft*. Although some generalizations can be made regarding the management of all transplant recipients, organ-specific considerations dependent upon the type of allograft that has been transplanted are often much more important. Following a brief introduction covering important aspects of immunosuppressive therapy, allograft rejection, and infectious complications, this chapter has been divided into sections that focus on considerations specific to the organ that has been transplanted.

In this chapter we will not deal with the management of patients following bone marrow transplantation, which is discussed in Chapter 73. Furthermore, as most recipients of kidney transplants now are cared for in step-down units or transplant wards rather than within ICUs, we have chosen to only discuss this procedure when it is performed at the same time as pancreas transplantation.

Immunosuppressive Therapy

The management of all transplant recipients involves a careful balance of the risks and benefits of immunosuppressive therapy. To avoid rejection of the allograft by the recipient's immune system, therapy with immunosuppressive agents is usually required. More than one agent is employed to allow for the targeting of different immunologic effector pathways (Fig. 90-2). As a consequence of the resultant modulation of the immune system's surveillance and response functions, the transplant recipient is placed at risk of developing infections and neoplasms.

Immunosuppressive therapy can be divided into three phases: induction, maintenance, and the treatment of acute rejection. The induction phase commences in the immediate postoperative period and involves intense immunosuppression which usually is continued for 2 to 4 weeks. Although practice at different centers varies, most regimens typically include the use of systemic corticosteroids in conjunction with a calcineurin inhibitor and a proliferation inhibitor (see below).[1] These agents may be started intravenously, but are switched to oral formulations to minimize toxicity once the patient is tolerating and absorbing enteral medications and feeds. To avoid some of the renal toxicity associated with the calcineurin inhibitors, antithymocyte immunoglobulin or anti–interleukin-2-receptor antibodies (IL-2R Abs) may be substituted in the early postoperative period.

The maintenance phase follows the induction period and is heralded by a reduction in the intensity of immunosuppression. Typically the maintenance phase is comprised of the planned regimen that will be used to suppress the immune response to the allograft and thus prevent rejection over a more prolonged period. Most patients will be maintained on either oral prednisone and cyclosporine or tacrolimus,

TABLE 90-1 One- and Five-Year Patient Survival by Organ

Organ Transplanted	1-Year Survival, %	5-Year Survival, %
Kidney		
Cadaveric donor	94.0	79.9
Living donor	97.7	89.7
Pancreas alone	97.8	76.7
Pancreas after kidney	95.4	77.3
Kidney-pancreas	95.1	82.6
Liver		
Deceased donor	86.3	72.4
Living donor	85.2	85.6
Intestine	80.7	48.6
Heart	85.1	69.8
Lung	77.3	42.4
Heart-lung	59.6	48.5

although it appears that in some patients receiving tacrolimus for maintenance the steroid component may be discontinued completely.[2] Azathioprine or mycophenolate mofetil (MMF) are often used during the maintenance phase to permit dose reduction of the other immunosuppressive drugs in order to minimize side effects.

The remaining phase of immunosuppressive therapy is not planned but it is anticipated and involves the treatment of acute rejection. Despite improvements that have been made in immunosuppressive strategies, episodes of acute rejection still commonly occur in the postoperative period, typically between 1 week and 1 year following the operation. Early recognition and prompt treatment of acute rejection is essential if long-term graft function is to be preserved. Treatment involves an intensification of the immunosuppressive regimen, which is usually accomplished through the use of high-dose steroids, short courses of antithymocyte globulin, and increased doses of the other immunosuppressive therapies. Issues pertaining to acute rejection will be discussed in greater detail in the sections dealing with organ-specific considerations.

CALCINEURIN INHIBITORS AND RELATED COMPOUNDS (CYCLOSPORINE, TACROLIMUS, AND SIROLIMUS)

The introduction of cyclosporine was one of the most revolutionary events in the field of transplant medicine,[3] and

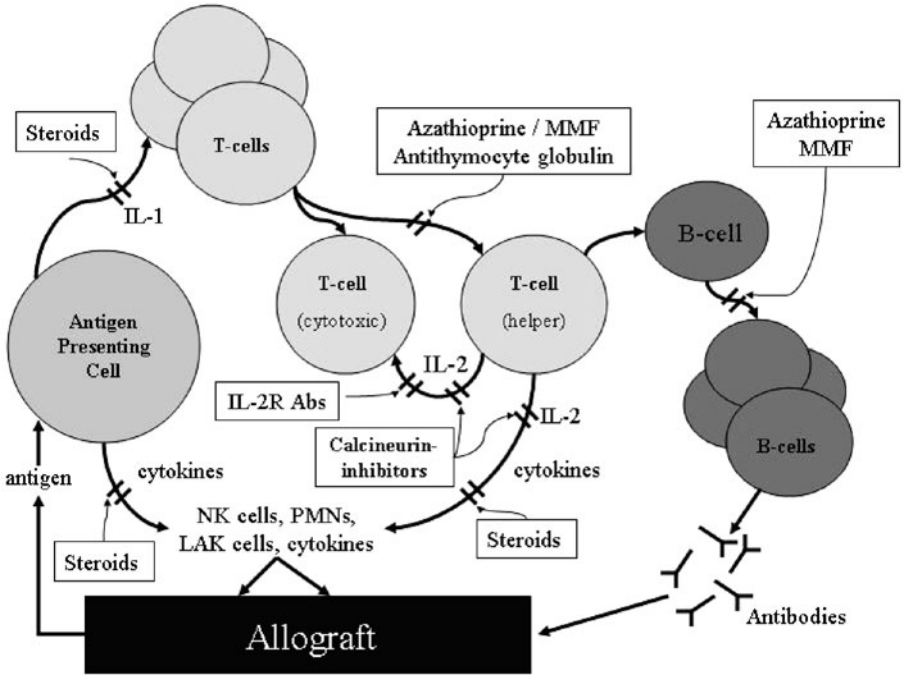

FIGURE 90-2 Sites of action of important immunosuppressive agents used to prevent allograft rejection in transplant recipients (see text for explanation). IL-1, interleukin-1; IL-2, interleukin-2; MMF, mycophenolate mofetil; IL-2R Abs, anti–interleukin-2-receptor antibodies; NK cells, natural killer cells; PMNs, polymorphonuclear neutrophils; LAK cells, lymphokine-activated killer cells.

the drug remains an important component of immunosuppressive regimens used by many institutions. Though in recent years some centers have switched to tacrolimus or sirolimus, two newer immunosuppressive agents, all agents in this class share several features. All provide effective inhibition of T-cell activation by interfering with a receptor on T cells that involves a calcium-dependent signal transduction pathway.

Cyclosporine binds to intracellular cyclophilin, and this complex interacts with calcineurin. Calcineurin is crucial for normal lymphokine gene activation, and its inhibition by cyclosporine consequently interferes with the production of interleukins-2, -3, and -4 (IL-2, IL-3, and IL-4), tumor necrosis factor-α (TNF-α), and other important mediators of inflammation. In turn, specific and potent inhibition of T-cell activation (especially CD4 cells) is achieved. It is important for the intensivist to understand the serious toxicities associated with the use of cyclosporine. The most frequently encountered problem is nephrotoxicity, and in many patients cyclosporine causes a rise in serum creatinine level and a reduction of glomerular filtration rate (GFR). The mechanism of this toxicity is felt to be related to vasoconstriction of the afferent glomerular arteriole.[3] Neurologic complications may be encountered in up to 20% of patients, including tremor, paresthesias, headache, confusion, seizures, and even coma. Other complications include hypertension (which often requires treatment), hyperkalemia, tremor, hirsutism, gingival hyperplasia, and glucose intolerance. Cyclosporine is metabolized by cytochrome P450-3A4 (CYP450-3A4) enzymes. Thus it is important to remember that inhibitors of cytochrome P450 (e.g., erythromycin, fluconazole, diltiazem, and verapamil) will increase serum cyclosporine levels, whereas inducers of these enzymes (e.g., phenobarbital, phenytoin, rifampin, and trimethoprim) will decrease the serum levels (Table 90-2). Previously trough drug concentrations were used to guide therapy. However, more recent recommendations have focused on the use of peak cyclosporine levels to monitor the adequacy of immunosuppression.[4] Ideally the dose of cyclosporine should be titrated using a biological assay or an assessment of the downstream effect of the drug on immune effector function. Such assays are under investigation.

Tacrolimus (formerly FK506) is a macrolide antibiotic with powerful immunosuppressive properties. Its mechanism of action is similar to cyclosporine, but the drug is more potent. Tacrolimus binds to a receptor known as FK-binding protein (FKBP), and suppresses calcineurin-dependent T-cell signaling.[5] Two controlled trials comparing tacrolimus to cyclosporine in liver transplant recipients demonstrated that tacrolimus reduces the incidence of acute rejection, refractory rejection, and chronic rejection[6–8] with similar patient and graft survival. However, the drug has important toxicities. As with cyclosporine, nephrotoxicity is the most troublesome side effect. Important neurotoxicity (seizures, tremor, psychoses, and coma) may also occur with its use. Both tacrolimus and cyclosporine decrease insulin secretion and can lead to hyperglycemia.[9,10] Interestingly, however, in renal transplant recipients who were converted from cyclosporine to tacrolimus, there was an improvement in other cardiovascular risk factors such as blood pressure and lipid profile.[11] The gingival hyperplasia and hirsutism commonly seen with cyclosporine do not occur with tacrolimus. Tacrolimus is also metabolized by CYP450-2A4 enzymes, and the clinician must be cognizant of the effects other drugs will have on its metabolism.

Sirolimus (rapamycin) is a drug related to tacrolimus that binds to FKBP. However, in contrast to tacrolimus it does not interfere with calcineurin activity and consequently does not interfere with the activation of cytokine genes. Its main effects are the inhibition of IL-2 production and the suppression of T-cell proliferation. Side effects include thrombocytopenia, hypercholesterolemia, and hypertriglyceridemia. Compared to cyclosporine and tacrolimus, the drug does not appear to have the same potential to cause renal failure. However, sirolimus may be associated with an increased risk of hepatic artery thrombosis and subsequent allograft loss[12] in liver transplant recipients. There have also been reports of interstitial pneumonitis associated with sirolimus.[13–16] Sirolimus is not recommended in the early postoperative period following lung transplantation, as it has been associated with bronchial anastomotic dehiscence.[17,18]

TABLE 90-2 Selected Compounds Which Interact with Cytochrome P450 Enzymes to Cause Drug-Drug Interactions with Calcineurin Inhibitors

Inducers of P450 Enzymes (Decrease Serum Levels of Cyclosporine, Tacrolimus, and Sirolimus)	Inhibitors of P450 Enzymes (Increase Serum Levels of Cyclosporine, Tacrolimus, and Sirolimus)
Phenobarbital	Diltiazem
Phenytoin	Verapamil
Rifampin	Erythromycin
Trimethoprim	Clarithromycin
Carbamazepine	Fluconazole
Nafcillin	Itraconazole
	Ketoconazole
	Metoclopramide
	Allopurinol
	Grapefruit juice

PROLIFERATION INHIBITORS (AZATHIOPRINE, MYCOPHENOLATE MOFETIL)

The proliferation inhibitors block DNA and RNA synthesis by interfering with normal purine metabolism. Since lymphocytes are unable to salvage purine as efficiently as most other cells, these drugs effectively inhibit lymphocyte proliferation and clonal expansion.

Azathioprine is a purine analogue that is converted in the liver to 6-mercaptopurine and which compromises synthesis of DNA and RNA. Its most important side effect is marrow suppression, and the drug can cause a profound leukopenia. Other important toxicities include hepatotoxicity and rarely fulminant hepatic failure, acute pancreatitis, skin malignancies, and increased susceptibility to infections.

Mycophenolate mofetil (MMF) interferes with purine metabolism as a reversible inhibitor of inosine monophosphate dehydrogenase. It also blocks clonal expansion of B- and T-lymphocytes. Important side effects of MMF include marrow depression (especially leukopenia and thrombocytopenia) and diarrhea. Less common problems include esophagitis, gastritis, and gastrointestinal bleeding. MMF may have an advantage over azathioprine in preventing acute rejection.[19]

Both azathioprine and MMF are now used predominantly as an adjunct to corticosteroid therapy in the maintenance phase of immunosuppression. The major advantage of these drugs is that their use will often enable the doses of corticosteroids and even of the calcineurin inhibitor to be reduced, thus avoiding some of the potential dose-related toxicity associated with these other agents.

ANTILYMPHOCYTE ANTIBODIES

Antibodies directed against lymphocytes were first introduced as an immunosuppressive therapy as antilymphocyte globulin (ALG). This therapeutic agent was created by immunizing animals with human lymphocytes and subsequently purifying the antibody-containing globulin fraction. ALG is very effective at depleting lymphocytes in the peripheral circulation, and quickly became an important component of regimens used for induction of immunosuppression and for the treatment of acute rejection. However, it was subsequently largely replaced by OKT3, a murine monoclonal preparation directed against T lymphocytes which could be used in much smaller doses because of its increased purity. OKT3 binds to the CD3-ε chain present on all human T cells, and causes a rapid clearance of peripheral T cells. Interestingly, it initially causes activation of T cells and the subsequent release of several lymphokines, including IL-2, IL-6, γ-interferon, and TNF. Rabbit antithymocyte globulin and to a lesser extent equine antithymocyte globulin are currently the antilymphocyte antibody preparations used most frequently by most centers.[1]

The antilymphocyte preparations are used primarily in the induction phase, and they have been shown to have higher success rates than steroids for the treatment of acute rejection.[20] When administered for this latter problem, prompt resolution of the rejection episode is usually observed. However, these preparations have significant toxicity. Fever is almost always observed at the time of infusion. Nonetheless, the importance of careful surveillance for infectious complications cannot be understated, as these therapies significantly attenuate the normal host immune response. The inflammatory response due to lymphokine production that is often seen with the initiation of therapy usually responds to corticosteroids, antihistamines, and acetaminophen.[21] Serum sickness has been observed with repeated use of these preparations. Furthermore, when these agents (especially OKT3) are administered more than once, the patient may develop antibodies directed against the globulin preparation that can substantially limit its efficacy. Long-term use is also associated with increased risk of viral infections (particularly cytomegalovirus) and posttransplant malignancy. Other less common complications of therapy include seizures (especially when concomitant hypocalcemia is present) and the acute respiratory distress syndrome (ARDS), possibly due to increased pulmonary capillary permeability arising from lymphokine stimulation.

SYSTEMIC CORTICOSTEROIDS

Systemic corticosteroids remain a key component of each phase of immunosuppression, and are received by over 95% of patients with pancreas, heart, lung, and heart-lung transplants.[1] They have multiple effects on the immune response. Importantly, steroids block T-cell proliferation and IL-2 synthesis. The phagocytic function of macrophages is inhibited, and in high doses corticosteroids prevent neutrophil degranulation.

Though they effectively attenuate the immune response and help prevent allograft rejection, corticosteroids also significantly increase the recipient's susceptibility to infection. In particular, viral and fungal infections appear to be highly associated with the use of corticosteroids. An important consideration is that steroids can also mask the typical signs of infection. For example, patients on high doses of these medications may not present with signs of peritonitis despite having intra-abdominal infections. As transplant patients typically remain on steroids chronically, the possibility of adrenal suppression and even overt adrenal insufficiency must be considered if these medications are discontinued. Despite their widespread use and important role in most immunosuppressive regimens, corticosteroids are associated with many of the significant side effects encountered by transplant patients. Insulin resistance is common, and the use of oral hypoglycemic agents and often insulin may be required. Both cyclosporine and tacrolimus affect insulin release and can induce insulin resistance, and may contribute to the hyperglycemia.[22–25] Increased sodium and water retention induced by steroids may aggravate posttransplant hypertension. Impaired wound healing has been well documented with the use of corticosteroids, and consequently these drugs may contribute to the development of postoperative surgical complications. Steroids are associated with increased risk of gastrointestinal hemorrhage, and thus most patients will be placed on routine stress ulcer prophylaxis, usually with either a histamine (H_2)-antagonist or a proton pump inhibitor. Long-term use of steroids often leads to osteopenia, overt osteoporosis, and fractures. Aseptic necrosis is a dreaded complication of steroid use that can occur at any time following the institution of therapy. Skin changes and fat redistribution are common. Steroids are also associated with mood changes and rarely even frank psychoses. Because of the significant side effects associated with steroid use, most maintenance immunosuppressive regimens now include antiproliferation inhibitors such as azathioprine or MMF to facilitate the early reduction of the corticosteroid dose.

NEW AGENTS

Recently, there has been increased use of anti–interleukin-2 receptor antibodies (basiliximab, daclizumab) during the induction phase.[1] Both agents bind to the α-chain of the IL-2 receptor, and competitively inhibit IL-2–induced proliferation of active T cells. The advantage of these compounds is that they are not associated with the toxicity produced by antilymphocyte preparations. Their use has been shown to decrease the rate of acute rejection following kidney[26,27] and heart transplantation.[28]

Rejection

Rejection of the allograft can be divided into three broad categories: hyperacute, acute, and chronic rejection. Hyperacute rejection is mediated by preformed antibodies directed against donor antigens, and occurs immediately following the transplant operation. Matching of donor and recipient major blood group type (A, B, O) essentially eliminates this class of rejection, which can have devastating consequences.

Immunosuppressive therapy is generally ineffective at treating this cause of graft failure, and retransplantation of the organ may be the only possible recourse to prevent death.

Acute rejection is much more commonly encountered, occurring in 20% of kidney-pancreas transplants, 30% of liver transplants, and 40% of lung and heart transplants during the first year.[1] Usually rejection does not manifest until the first several days following the transplant procedure. It occurs as the result of cell-mediated immunity, and it generally responds well to escalation of the immunosuppressive regimen.

Chronic rejection tends not to develop during the initial stay in the ICU, but patients may require ICU care as a result of the sequelae of the chronic inflammation and fibrosis that is the hallmark of this complication. Manifestations of chronic rejection are organ specific. In liver transplant recipients, it is characterized by the "vanishing-bile-duct syndrome," whereas bronchiolitis obliterans is the scourge that faces lung transplant recipients and is the leading cause of late death in these patients. Premature and accelerated atherosclerosis of the coronary arteries characterizes chronic rejection in heart transplant recipients.

Infectious Complications

Prior to the transplant procedure, it is important to know whether or not the transplant recipient has been exposed to common infections that can cause serious morbidity in the postoperative period when immunosuppressive therapies are instituted. Patients are routinely screened for antibodies to cytomegalovirus (CMV), Epstein-Barr virus (EBV), herpes viruses, hepatitis B and C viruses, human immunodeficiency virus (HIV), *Toxoplasma*, and tuberculosis exposure via skin testing. These infections can reactivate in an immunosuppressed recipient who has been previously exposed. Alternatively, a naïve recipient may acquire an infection following the transplant of an organ from a seropositive donor.

Because of the considerable morbidity associated with these infections, most transplant patients will receive prophylactic therapy if they are seronegative for any of these agents. If not already done preoperatively, transplant recipients can be vaccinated with killed vaccines in the postoperative period. Vaccination still confers some protection despite the attenuated humoral response in these patients.

In the early posttransplant period, however, bacterial and fungal infections predominate and are a frequent cause of morbidity and mortality (see Fig. 90-1). Since the regimens used for immunosuppression are similar for all solid-organ transplants, the recipients of such transplants will be susceptible to similar infectious agents. Specifically, using relatively high doses of calcineurin inhibitors such as cyclosporine or tacrolimus in combination with high doses of corticosteroids places the recipient at high risk of early infectious complications. This intensity of immunosuppression amplifies the risk of infection faced by all critically-ill patients.

Opportunistic infections can develop through three general mechanisms. A virulent pathogen may be acquired from the environment (e.g., pneumococcal pneumonia, *Aspergillus* infections, etc), an endogenous but latent organism may become reactivated (e.g., tuberculosis, herpes viruses, etc.), or there may be invasion of an endogenous organism (e.g., *Candida*, enteric bacteria, etc.) into a normally sterile site. Several authors have proposed an approach that classifies the most likely infectious complications according to the time that has elapsed since the original procedure (Fig. 90-3).[29,30]

INFECTIONS OCCURRING IN THE FIRST POSTTRANSPLANT MONTH

In the first month after transplantation most infections will be similar to those encountered following any major surgery, including bacterial or candidal infections involving the lungs, urinary tract, surgical wound, or indwelling catheters. Consequently, efforts should be made to remove all vascular-access catheters and drains as soon as possible. As with any critically-ill patient, strategies to facilitate liberation from mechanical ventilation should be employed. The high level of immunosuppression during the induction phase significantly contributes to the development of infections during this time period, but usually the state of immunosuppression has not been of sufficient duration to allow many of the opportunistic infections that become so problematic in subsequent months to develop.[31] Occasionally infections may be transmitted to the recipient by the allograft itself. The presence of bacteremia, fungemia, or active infection in a donor is generally considered a contraindication to organ donation given the associated high probability that infection will be transmitted to the host. Cultures obtained at the time of implantation (e.g., via bronchoscopic-guided lung lavage) may be used to guide treatment. Typically most centers employ prophylactic antibiotic strategies to empirically treat the microbes that are transplanted into the recipient. The choice of prophylactic antibiotics varies and usually reflects differences in the center's bacterial ecology. Parenteral, oral, topical, and inhaled medications are often used alone or in combination.

Similarly, any untreated infection that is present in the recipient at the time of the transplant may become a devastating problem following the initiation of immunosuppressive therapy. As a result, any active infection in a potential recipient is generally considered to be an absolute contraindication to transplant surgery.

INFECTIONS OCCURRING BETWEEN 1 AND 6 MONTHS POSTTRANSPLANT

Following the first month, the recipient is at risk for infections due to several viral infections that would normally be suppressed by an intact immune response. Particularly problematic are infections due to CMV, EBV, other herpes viruses, hepatitis B and C viruses, and HIV. Screening for these viruses is usually performed in both the donor and recipient prior to the transplant procedure, and pre-emptive therapy is often employed. Infection with HIV has traditionally been considered an absolute contraindication to transplantation. However, recently some experts have argued that asymptomatic HIV-positive patients should no longer be excluded from consideration for transplant of solid organs, citing the substantially improved survival of HIV carriers following the introduction of highly active antiretroviral therapy.[32–34]

The sustained immunosuppression used in the induction phase and early maintenance phase leads to an increased risk of opportunistic infections. Infections due to *Pneumocystis carinii*, *Aspergillus*, *Listeria monocytogenes*, and tuberculosis become important considerations. Most transplant

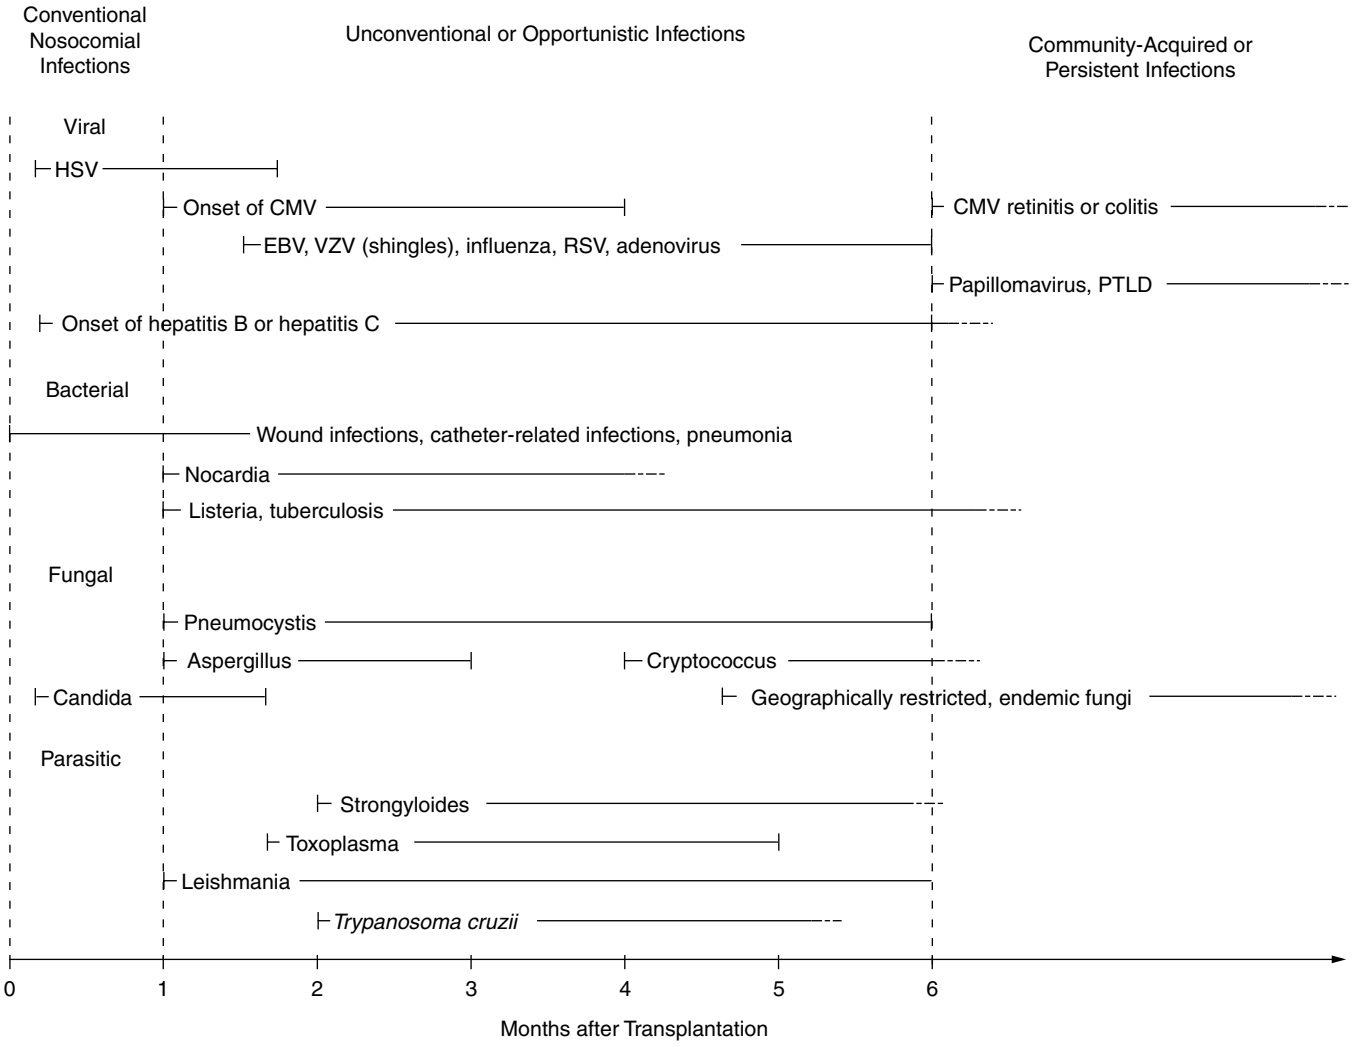

FIGURE 90-3 Usual sequence of infections after organ transplantation. Zero indicates the time of transplantation. Solid lines indicate the most common period for the onset of infection; dotted lines and arrows indicate periods of continued risk at reduced levels. HSV, herpes simplex virus; CMV, cytomegalovirus; EBV, Epstein-Barr virus; VZV, varicella-zoster virus; RSV, respiratory syncytial virus; PTLD, posttransplantation lymphoproliferative disease. (*Reproduced with permission from Fishman et al.*[29])

programs routinely provide recipients with trimethoprim-sulfamethoxazole (TMP-SMX) to reduce the risk of *Pneumocystis carinii* infection. Should a transplant patient develop *Pneumocystis carinii* pneumonia, the treatment of choice is intravenous TMP-SMX. Pentamidine can be used as an alternative, but it is associated with a greater incidence of toxicity and side effects, and is generally considered to be less effective therapy. In patients who have a positive purified protein derivative tuberculosis skin test (>5 mm induration[35]) or who are at high-risk for reactivation of latent tuberculosis infection, prophylactic therapy with isoniazid for 9 to 12 months should be considered.[35,36] *Aspergillus* infections are most problematic for lung transplant recipients, but they can develop in any patient who has undergone solid-organ transplantation and is receiving chronic immunosuppressive therapy. The treatment of choice is amphotericin; liposomal preparations of amphotericin are available that are associated with less nephrotoxicity, but these are much more expensive. More recently caspofungin the first in a new class of antifungal agents (echinocandins) has been shown to be active against *Aspergillus* species.[37–39] Although its role in treating immunosuppressed transplant patients has not been systematically evaluated, there is at least one suggestion that its antifungal effects (tested in vitro) may be enhanced in patients who are receiving concomitant calcineurin inhibitors.[40] Voriconazole, a newer azole anti-fungal agent, has demonstrated better outcomes and fewer side effects in comparison to amphotericin in patients with bone marrow transplantation.[40a] Experience in patients with solid organ transplantation is growing.

INFECTIONS OCCURRING MORE THAN 6 MONTHS POSTTRANSPLANT

Severe infections occurring more than 6 months following the transplant procedure may necessitate ICU admission. Most commonly these infections are similar to those experienced by the general community and involve the respiratory tract.[29] Other problems developing in this time frame include the

progression of underlying infection with hepatitis B or C, CMV, EBV, and human papillomavirus. There is also a continued risk for the opportunistic infections that develop after the first posttransplant month (discussed above) during this time period, and careful surveillance for their occurrence must be maintained.

INFECTION DUE TO CYTOMEGALOVIRUS

The most important and the most common viral infection for all solid-organ transplant recipients is CMV infection. Once an individual is infected by this herpes virus, they will be infected for life, though the virus generally remains in a latent or dormant phase. Recipients who are seronegative for CMV that receive an allograft from a seropositive donor are at greatest risk of developing symptomatic illness, including tissue-invasive disease from primary infection. Patients who are already seropositive for CMV prior to the procedure (indicating past exposure and latent infection) are at risk for reactivation following the initiation of immunosuppressive therapy. Superinfection by a new strain of CMV contracted from the allograft of a CMV-seropositive donor can also occur. Strategies to prevent CMV infection are usually based on the recipient's relative risk of developing infection, with those who are recipient-negative, donor-positive and recipient-positive, donor-negative (in the case of lung transplantation) receiving the more intense regimens.[41] The monitoring of CMV antigenemia or viral load using polymerase chain reaction may be a component of these regimens, and may be used to guide duration of prophylaxis and provide evidence of infection or emergence of a resistant strain.[42]

The spectrum of disease caused by CMV infection among transplant recipients is quite variable.[43] Infection can be completely asymptomatic or can be associated with an acute flu-like or mononucleosis-like illness characterized by fever and myalgias. The virus can cause bone marrow suppression and consequently leukopenia and thrombocytopenia. Infection of the allograft can cause organ-specific inflammation resulting in acute hepatitis, pneumonitis, myocarditis, nephritis, or pancreatitis, depending on the organ that was transplanted.[31] Active CMV infection is also associated with the development of other opportunistic infections, likely due to CMV-mediated immune defects, and consequently it should be considered whenever an unusual infection (such as *Pneumocystis carinii* pneumonia or invasive aspergillosis) develops.[29] Acute rejection has been associated with CMV infection. However, the role of CMV infection in contributing to chronic rejection is likely much more important. It has been associated with the development of bronchiolitis obliterans in lung transplant patients, the vanishing-bile-duct syndrome in recipients of liver allografts, and in premature and accelerated atherosclerosis of the coronary arteries following heart transplantation.[29] Though posttransplant lymphoproliferative disease is usually associated with EBV infection, active CMV infection has also been implicated as a risk factor for its development.[44–46]

Treatment of CMV infection generally consists of intravenous ganciclovir for 2 to 4 weeks. Confirmation that CMV viremia has resolved should be sought before therapy is discontinued. In the near future ganciclovir use may be replaced or consolidated with the use of newer oral analogues, especially for long-term regimens.[47,48] Occasionally a CMV isolate will be resistant to ganciclovir, and intravenous foscarnet must be used despite its increased toxicity.

ORGAN-SPECIFIC INFECTIOUS CONSIDERATIONS

LIVER TRANSPLANT RECIPIENTS

Bacterial infections are frequent among liver transplant patients, and the source is most often intra-abdominal.[49] Recognizing that overgrowth of pathogenic aerobic bacteria from the gastrointestinal tract may contribute to the development of many of these infections, some experts have recommended that oral selective bowel decontamination be started 3 days prior to the transplant operation.[31] Though this approach may decrease the relative incidence of gram-negative infections in the first month, selective bowel decontamination has not been adopted by all transplant programs.[50,51] Recent evidence suggests that this therapy only leads to a substitution for infections caused by gram-negative bacilli and *Candida* species with infections due to gram-positive organisms, and yet it is associated with a substantially increased cost.[52]

Transient biliary tree infection and subsequent bacteremia may occur following biliary tree manipulation (T-tube manipulation, cholangiography, etc). This has prompted many experts to advocate the use of pre-emptive systemic antibiotics around the time of such procedures.[31]

Liver disease resulting from hepatitis B or C infection remains one of the most common indications for liver transplant. The reactivation of these viruses in the recipient and resultant allograft infection remains a major challenge. Most patients who are seropositive for hepatitis B will receive hepatitis B immunoglobulin (HBIg) and lamivudine to suppress replication of the virus in the postoperative setting. These therapies are generally continued indefinitely, and have resulted in allograft and patient survival rates similar to those of patients not infected with hepatitis B.[53] Recipients who are positive for hepatitis C virus prior to transplant have also been shown to have poorer graft and patient survival rates.[54] However, no antiviral regimens have yet been shown to be effective at improving outcomes for these patients following orthotopic liver transplantation.[55]

Infections due to *Candida* are particularly common in liver transplant recipients, and the most common source is the gastrointestinal tract. Risk factors for these infections include concomitant CMV infection, retransplantation, the presence of choledochojejunostomy, and the use of OKT3 immunosuppression. The use of a regimen of oral selective bowel decontamination that includes an antifungal agent has already been discussed, and certainly this intervention decreases the incidence of candidal infections. There is evidence that the routine pre-emptive use of oral fluconazole (100 mg/d[56] to 400 mg/d[57]) or liposomal amphotericin B[58,59] after liver transplant is effective at reducing the incidence of these infections. However, some have cautioned that routine prophylaxis may encourage the emergence of resistant candidal strains, and have suggested that only high-risk patients be targeted for therapy.[60]

LUNG TRANSPLANT RECIPIENTS

Following lung transplantation, patients are at risk for all of the infections that plague individuals with a chronically immunosuppressed state. However, the incidence of infection in these patients is much higher than that reported for

recipients of other solid organs, presumably due to the exposure of the allograft to the external environment.[61,62] The development of CMV infection can cause significant morbidity and can increase transplant-related mortality, especially if new infection develops in a seronegative recipient who has received an allograft from a seropositive donor. Seropositive recipients can also be reinfected by a new strain of CMV, but these infections tend not to be as severe. Treatment consists of intravenous ganciclovir, and many centers will routinely use this agent as prophylaxis against CMV infection if either the donor or the recipient is seropositive.

Aspergillus is an organism that frequently colonizes the airways of lung transplant recipients, but may also lead to clinically important infections. Oral itraconazole or inhaled or intravenous amphotericin are usually effective therapies. In its most severe form, invasive aspergillosis and disseminated disease are associated with high mortality rates. The bronchial anastomosis is particularly vulnerable to infection with this organism, though the airways may become more diffusely affected, and mucosal edema, ulceration, and formation of pseudomembranes may occur.[61] Patients with septic lung disease (cystic fibrosis or bronchiectasis) are a unique group and have a very high risk of early infection. These patients' airways are typically highly colonized. Despite efforts to sterilize the trachea and major bronchi in the perioperative period, secretions originating from these recipients' upper airways and proximal lower airways likely contaminate the transplanted lungs. Consequently most centers employ an antibiotic strategy to deal with these colonizing organisms, which are typically *Staphylococcus aureus*, nontuberculosis mycobacteria, *Pseudomonas* species, or enteric gram-negative bacilli. Owing to longstanding antibiotic pressure these organisms are often highly resistant to first-line agents, and can be difficult to treat if an infection becomes established. In particular *Burkholderia cepacia* is a dreaded colonizer that represents a major threat for some centers caring for cystic fibrosis patients.[63] Indeed, patients with cystic fibrosis complicated by *B. cepacia* infection have a worse outcome than their counterparts without this infection.[64,65] *Aspergillus* lung infection may also be more common in patients transplanted for cystic fibrosis.[66]

Defining the etiology of new or progressive airspace opacities in the perioperative lung transplant period is a frequent dilemma. Airspace disease may represent reperfusion injury (see below), volume overload, acute lung injury, early rejection, or infection.[67] Computed tomographic (CT) scanning of the chest and bronchoscopic sampling of the distal airways is often required to rule out an infectious cause. A trial of diuresis or placement of a pulmonary arterial flotation catheter may be required to evaluate the contribution of volume overload to the opacities. The role of lung biopsy in establishing the cause of radiographic worsening is controversial. Transbronchial lung biopsy may lack sufficient sensitivity in the perioperative setting.[68] However, the utility of open lung biopsy (OLB) is variable,[69,70] and hence it should be carefully considered if the etiology of the lung infiltrates remains uncertain. In one retrospective series of 48 open biopsies from 42 patients, 32 (67%) of the biopsies confirmed the clinicians' initial suspicions and prompted the initiation of "new therapy" in 30 (71%) of the patients.[69] A new diagnosis was made following 14 of the biopsies (29%). Only two patients (4% of all OLBs) had a nondiagnostic OLB. Four biopsies (8% of all OLBs), including the two nondiagnostic OLBs, did not result in any change in therapy. Complications of the procedure were rare, though three (7%) patients developed an air leak which persisted more than 7 days. In contrast an earlier report of 38 biopsies (representing 32 patients) found that early open lung biopsies (performed <45 days after transplant) were not useful, and resulted in a change in therapy for only 1 of 11 cases.[70]

HEART TRANSPLANTATION

Most heart transplant recipients will receive intravenous ganciclovir for 3 to 4 weeks as prophylactic therapy if they are seropositive for CMV before transplantation. If a seronegative recipient receives an allograft from a seropositive donor, they are given prophylactic therapy for 12 weeks following the procedure.[71]

Infective endocarditis is an infrequent complication following heart transplantation, usually developing on the supravalvular suture line. Antibiotic prophylaxis is generally recommended for heart transplant recipients prior to dental, gastrointestinal, or genitourinary tract surgery.[72]

Organ-Specific Considerations

LIVER TRANSPLANTATION

THE PROCEDURE

During orthotopic liver transplantation, the native organ is removed and replaced by a cadaveric liver. Extracorporeal venovenous bypass is often used during the procedure to decompress the systemic and splanchnic venous systems. Although this may help preserve hemodynamic stability during the operation and decrease intraoperative bleeding problems, potential complications include intraoperative air embolism[73,74] and thromboembolism. The biliary tract will be reconstructed either by creating an end-to-end anastomosis of the donor and recipient common ducts (using a T-tube stent) or by connecting the donor's common duct to the recipient's jejunum. Anastomoses are created between the native and allograft cava (supra- and infrahepatic), portal veins, and hepatic arteries. Removal of the venous clamps leads to reperfusion of the organ, and this will often be associated with hemodynamic instability, coagulopathy, and electrolyte abnormalities (particularly hyperkalemia).

Recently, there have been a growing number of patients who undergo living-donor transplants. In Asia, almost all liver transplant procedures have involved living donors.[75] In this procedure, the right hepatic lobe from a donor with a compatible blood type is implanted into the recipient following hepatectomy of the diseased organ. Along with an often substantially reduced waiting time for the procedure, living related transplants may also allow for better selection of healthy donors (and consequently donor organs) and a considerably decreased cold ischemia time. The elective nature of the procedure also enables potential recipients to be medically stabilized preoperatively. The major disadvantage is the small but significant risk of complications for the donor. Biliary complications may occur in up to 6% of donors,[76] and other complications of abdominal surgery such as wound infection may develop; the reported mortality of donors following living-donor liver transplant is 0.28%.[75] One study suggests that in the United States approximately 99% of living donors are

genetically or emotionally related to the recipient,[76] creating important ethical and psychosocial challenges.

POSTOPERATIVE CONSIDERATIONS

Mechanical Ventilation

Most patients will require mechanical ventilation for the first 24 to 48 hours following the liver transplant procedure. Extubation should not be considered until there is evidence that the allograft is functioning properly and the patient's level of arousal is sufficient to allow for adequate airway protection. This latter consideration is especially important given that anesthetic agents and sedating medications may be cleared more slowly from the circulation by the newly transplanted liver. The need for reintubation in liver transplant patients has been associated with poorer outcomes and even increased mortality.[77] However, there is mounting evidence to support the notion that attempts at early extubation of liver transplant recipients may reduce ICU utilization. Selection of suitable candidates seems crucial.[78–82]

Monitoring of Liver Function

The function of the new allograft should be assessed in the same manner that liver function is assessed in any patient. Coagulopathy is often present in the immediate postoperative period, but should correct soon after the transplant. The prothrombin time (PT) or International Normalized Ratio (INR) should be followed closely. Administration of fresh frozen plasma will interfere with the ability to monitor these parameters. Consequently some programs avoid the transfusion of coagulation factors unless necessitated by bleeding complications.

Glucose should be monitored frequently during the ICU stay as liver failure will often result in refractory hypoglycemia. Conversely, the use of corticosteroids may lead to insulin resistance and hyperglycemia, which should be treated appropriately. Bilirubin often remains elevated for many days following the transplant, but should be followed closely as abrupt changes may herald complications involving the biliary tree or the vascular supply to the liver. Serum lactate levels are frequently elevated immediately following the operation, but if the graft is functioning properly they should return to normal within a few days.

Serum transaminase levels (AST/ALT) are usually measured postoperatively; these usually rise in the first 2 to 3 days following the procedure, but then can be expected to normalize. Similar to changes in bilirubin levels, abrupt changes or progressive elevations of these enzymes may also signify complications and mandate further evaluation.

Fluids and Hemodynamics

Physiologic derangements following liver transplantation are common. Intraoperative blood and fluid loss may be considerable. The use of aprotinin during the operation has been advocated by some as a means to reduce blood loss.[83–85] Interestingly, several studies also report decreased vasopressor requirements in patients who receive this therapy intraoperatively.[86,87] Its use has also been associated with an improvement in renal function.[88] However, this initial enthusiasm for aprotinin therapy needs to be tempered by concerns regarding a possible increased potential for thrombembolism.[89,90]

Following the operation, patients may lose significant amounts of fluid and protein via the abdominal drain, especially if massive ascites was present preoperatively owing to advanced cirrhosis and decompensated liver disease. These latter patients are at particularly high risk of developing intravascular volume depletion, and they must be monitored carefully and treated aggressively. Serial hematocrit determinations should be measured (usually every 4 to 6 hours) to ensure that significant bleeding is not present. It should be noted that the hyperdynamic circulatory state that characterizes liver dysfunction will often persist in the postoperative period, making interpretation of hemodynamic measurements difficult. An increased cardiac output with decreased systemic vascular resistance is often observed. Although aggressive fluid resuscitation is indicated to treat intravascular volume depletion, it should also be noted that patients are at particularly high risk of cardiopulmonary complications following liver transplantation.[91] Electrolyte abnormalities, particularly hyponatremia, are often observed. Overly aggressive treatment of derangements of sodium can precipitate the osmotic demyelination syndrome (formerly called central pontine myelinolysis).

Particular care is required for the patient who has significant preoperative portopulmonary hypertension. These patients will often encounter pulmonary hemodynamic instability and may have increased cardiopulmonary mortality, especially if the preoperative mean pulmonary artery pressure is greater than 35 mm Hg.[92] Invasive hemodynamic monitoring with a pulmonary artery catheter should be considered to guide therapy in these patients. Specific pulmonary vasodilators such as inhaled nitric oxide or nebulized prostaglandins may be required in the setting of right ventricular dysfunction in order to preserve cardiac output.

A system for classifying patients based on their anticipated need for fluid and electrolyte replacement has been proposed[93] and advocated by several experts.[94] Such an approach may be practically useful in that it creates a framework to understand the hemodynamic considerations for a given patient (Table 90-3). According to this classification, a patient with class I liver disease can be expected to have a normal postoperative response to intravenous fluid therapy. Patients with class II or III liver disease will have more ascites,

TABLE 90-3 Classification of End-Stage Liver Disease Severity for the Purposes of Intensive Care Unit Management

Class	Hyperdynamic Circulation	Hyponatremia	Malnutrition	Portopulmonary Hypertension	Cardiac Dysfunction
I	−	−	−	−	−
II	+	+/−	−	−	−
III	++	++	−	−	−
IV	++	++	+	+	+

SOURCE: Adapted with permission from Lowell et al[93] and McGilvray et al.[94]

leading to greater fluid and protein loss from the abdominal drain, and can be anticipated to need more fluids postoperatively and careful monitoring of electrolytes. Patients with class IV disease require the closest monitoring and may benefit from insertion of a pulmonary artery catheter to assist with the management of the portopulmonary hypertension and cardiac dysfunction that is often present.

Postoperative Renal Dysfunction

Following the liver transplant procedure renal dysfunction is frequently observed, and postoperative renal failure can be severe enough to require renal replacement therapy in up to one third of patients. However, kidney function generally improves, and only 5% of patients require chronic hemodialysis following liver transplant.[95]

The most common precipitant is intravascular volume depletion resulting in prerenal azotemia. However, nephrotoxicity due to the immunosuppressive drugs is also common. The development of hepatorenal syndrome occurs in 7% to 15%[94,96] of patients with cirrhosis, and is commonly observed following orthotopic liver transplant. It is likely that strategies aimed at preventing hepatorenal syndrome are the most effective. Thus care should be taken to promptly treat bleeding insults and to avoid intravascular volume depletion. When CT scanning or other imaging techniques are being considered, the use of intravenous contrast dye should be avoided if possible. If intravenous contrast is required for proper imaging (and the benefits outweigh the risks of the test), consideration should be given to the use of acetylcysteine if renal function has not completely returned to normal, in order to protect the kidney from further insult and contrast nephropathy.[97] Terlipressin (a long-acting vasopressin analogue) has been reported to be successful in improving urine output in cirrhotic patients with hepatorenal syndrome.[98,99] The relative contribution of albumin coadministration to the success of this pharmacologic strategy has been evaluated and supports the notion that maintenance of intravascular volume is integral in the treatment of these patients.[100] One study also advocates the addition of acetylcysteine to mitigate the potential ischemic nephropathy that may result from the vasoconstrictive effects of terlipressin on the kidney.[99] The role of terlipressin in patients with established hepatorenal failure following transplantation has not been systematically evaluated. Indeed, in theory, liver transplantation should correct hepatorenal failure.[101,102]

Primary Graft Nonfunction

Primary graft nonfunction refers to a failure of the transplanted liver early in the postoperative period. The characteristics of this devastating complication include minimal bile output, refractory coagulopathy, progressive elevation of transaminases, acidosis, hypoglycemia, and cerebral edema. The incidence of this dreaded complication is likely only between 3% and 5%,[103,104] but the associated mortality rate may be higher than 20%.[105–107]

Several considerations exist if the graft fails to work postoperatively. The possibility of vascular complications should be entertained and excluded with Doppler ultrasonography.[108] Investigations to detect severe infection or acute rejection should be initiated. If all these tests fail to elucidate the cause of graft failure, primary graft nonfunction is the likely cause.

Vascular Complications

The incidence of vascular complications following liver transplant ranges from 8% to 14%.[109,110] These develop most commonly on the first postoperative day, but may occur up to several weeks following the surgery.[108] Thombosis is the most common early complication, and stenosis and pseudoaneurysm formation generally develop later in the patient's course. The presentation of hepatic artery thrombosis has been associated with hepatic artery reconstruction with an interposition graft to the supraceliac aorta.[111] Despite reassurances, some concerns about an increased risk of hepatic artery thrombosis with the use of sirolimus remain.[112] The clinical picture of this complication can vary from the asymptomatic rise in liver enzymes to fulminant hepatic failure. Urgent laparotomy and revision of the hepatic artery anastomosis is required if this complication develops, and unfortunately retransplantation is often necessary if hepatic necrosis has occurred.

Portal vein thrombosis develops less frequently and may present more insidiously. Ascites may be seen to develop or worsen, and variceal bleeding (usually from pre-existing varices) may ensue. Thrombectomy and anastomotic revision can be successful if this complication is diagnosed early.

Biliary Leaks

Biliary complications occur in approximately 15% of patients following orthotopic liver transplantation.[113] Of these, bile leak is the most common early complication. Symptoms are nonspecific, and can include fever, abdominal discomfort, and signs of peritoneal irritation. Though ultrasound may demonstrate an intra-abdominal fluid collection, cholangiography will provide a definitive diagnosis. Endoscopic insertion of biliary stents can sometimes provide satisfactory results, but surgical repair of the leak may be required.

Biliary strictures and stones typically appear later in the postoperative period. Obstructions usually can be managed endoscopically[114] or through the use of interventional radiology techniques, but surgical correction is sometimes necessary. Strictures typically develop at the anastomotic site, and are likely the result of local ischemia. These may present as cholestasis or possibly as overt cholangitis. Balloon dilation of the stricture with or without stent placement usually is successful treatment, but surgical revision and even retransplantation may be required.

Intra-Abdominal Infections

Intra-abdominal infections ranging from local abscess formation to overt peritonitis can occur following liver transplantation. Development of these complications should always lead the clinician to suspect that a leak has occurred from the biliary anastomosis or from the jejunojejunostomy; correction of these problems will often require laparotomy and surgical repair. However, abscesses can usually be treated with CT-guided drainage and subsequent serial CT scans to ensure that the collection has been adequately drained.

Rejection

Rejection of the hepatic allograft is usually not seen until about 1 to 2 weeks following the procedure, and most often manifests as fever, right upper quadrant pain, and reduced bile pigment and volume. However, the most sensitive marker of early rejection is a rise in serum transaminase

(AST/ALT) levels and bilirubin. A rise in total white blood count may also develop. The most important consideration when elevation of these serum enzymes occurs early in the postoperative course is the exclusion of one of the various mechanical complications (such as vascular compromise, biliary obstruction, and primary graft nonfunction). After the biliary tree and vascular structures have been imaged using ultrasonography, a liver biopsy will help confirm the diagnosis of acute rejection. As is the case in any solid-organ transplant recipient, treatment of acute rejection should be aggressive and must be instituted promptly. For liver transplant recipients, therapy usually involves antithymocyte globulin and increased or pulsed doses of methylprednisolone.

The management of chronic rejection of the transplanted liver usually does not involve the intensivist, but occasionally these patients may require ICU admission. Chronic rejection of the liver presents clinically as progressive cholestasis and histologically with mononuclear infiltration of the allograft, vascular abnormalities, and fibrosis. These findings are most commonly seen as part of the vanishing-bile-duct syndrome; treatment is often unsuccessful and may require retransplantation.

LUNG TRANSPLANTATION

THE OPERATION

While combined heart-lung transplantation is still performed for patients with Eisenmenger syndrome and complex congenital cardiac defects that cannot be easily repaired at the time of the lung transplant, most patients will undergo either bilateral or single-lung transplantation. Bilateral lung transplantation is the preferred procedure for patients with septic pulmonary disorders such as cystic fibrosis and bronchiectasis. In contrast, single-lung transplantation can be performed in patients with chronic obstructive pulmonary disease (COPD) and idiopathic pulmonary fibrosis. The observation that right ventricular dysfunction generally improves in patients with pulmonary hypertension following single- or double-lung transplantation[115] has obviated the need for performing combined heart-lung transplantation in this group of patients.

During single-lung transplantation, sequential anastomoses are performed to attach the donor and recipient mainstem bronchus and pulmonary artery. The donor left atrial cuff and pulmonary veins are then attached to the recipient's left atrium. In a similar manner, bilateral lung transplantation is performed as two sequential single-lung transplant procedures. Most patients can be supported intraoperatively through the ventilation of a single lung while surgery is performed on the contralateral side. Consequently, cardiopulmonary bypass is generally only required if profound hypoxia is encountered.

COMPLICATIONS

Ischemia-Reperfusion Injury

Since hyperacute rejection (due to ABO mismatch) has become extremely rare, the earliest serious complication of the lung transplant operation is ischemia-reperfusion (IR) injury (also called primary graft failure or pulmonary reimplantation response). IR injury is a syndrome of severe allograft dysfunction characterized histologically by marked alveolar damage which manifests clinically as severe pulmonary edema. The incidence of this complication ranges from 10% to 20%, depending on the reporting center and the definition used,[116–118] and when severe, it is associated with a very poor prognosis; as many as 41% of affected patients may die.[117] A recent study also suggests that IR injury may be associated with the development of bronchiolitis obliterans later in the patient's course.[119] Most series of patients with IR injury demonstrate that recipients will develop pulmonary infiltrates on chest x-ray during the first 3 days following transplantation.[120] When entertaining this diagnosis, it is essential that the clinician perform a careful evaluation to exclude other possible complications. Confirmation should be sought that a donor-recipient cross-match (hyperacute rejection) has not occurred, that bacterial pneumonia has not developed (negative cultures from bronchoalveolar lavage), and that pulmonary venous return is not compromised owing to technical problems with the left atrial anastomosis (transesophageal echocardiography should be performed to ensure adequate blood flow through pulmonary veins). Invasive monitoring with a pulmonary catheter will help exclude volume overload or cardiogenic pulmonary edema. Transbronchial biopsy may be required to rule out the possibility of acute rejection. Treatment of IR injury is similar to the management of ARDS. Extending the results of trials of mechanical ventilation in patients with ARDS we recommend that lung-protective ventilation strategies with low tidal volumes be employed, with the use of sufficient positive end-expiratory pressure (PEEP) to reduce the fraction of inspired oxygen to acceptable levels.[121] Since IR is characterized by increased alveolar capillary permeability, care must be taken to provide judicious fluid management. Some success at attenuating the injury from IR has been observed with the administration of prostaglandin E_1, though this may lead to hypotension owing to the effects of the drug on the systemic vasculature. Inhaled nitric oxide (NO) has been advocated as a means to both treat and prevent IR injury. Initial preclinical and uncontrolled clinical studies of inhaled NO suggest that administration prior to IR injury may improve graft function.[122–126] However, a recent controlled study of NO administered 10 minutes after reperfusion failed to show any benefit in terms of graft function.[127] NO has also been used to improve oxygenation and reduce pulmonary arterial pressures in patients with oxygenation and vasomotor dysfunction after lung transplantation.[128–130] If inhaled NO is used for its pulmonary vasodilatory properties and to decrease ventilation/perfusion mismatch, it should be understood that these effects should be seen within minutes of the institution of this therapy. Daily measurements of methemoglobin levels are required. If one extrapolates from studies of NO use in acute lung injury, the effects of NO on lung function are likely short lived.[131] Consequently the rationale for long-term use of NO is unclear. Furthermore, the benefit of therapy is often difficult to assess owing to the development of rebound during attempts to withdraw NO therapy.[123] We often employ sildenafil to prevent such rebound associated with withdrawal of NO therapy in these patients.[132]

Following single-lung transplantation, IR injury will often compromise lung function in the allograft. To avoid exposing the native lung (which is often emphysematous and prone to hyperinflation) to potentially injurious high airway pressures and alveolar overdistention, independent lung

ventilation is often used. If conventional ventilation is causing overexpansion of the native lung leading to an increase in its pulmonary vascular resistance, blood may be preferentially shunted to the compromised graft. Independent lung ventilation involves the use of a double-lumen endotracheal tube (avoiding intubation of the transplanted bronchus), and enables each lung to be ventilated with different airway pressures and tidal volumes. This strategy can dramatically improve ventilation-perfusion ($\dot{V}/\dot{Q}$) mismatch. In the extreme case, the native lung may become sufficiently overdistended to cause mediastinal shift and lead to hypotension as a result of compromised venous return or cardiac tamponade.[133] Other measures that can ameliorate the $\dot{V}/\dot{Q}$ mismatch and other sequelae of native lung overexpansion include the positioning of the patient in a lateral decubitus position to direct the allograft superiorly (to preferentially perfuse the native lung) and the use of lower tidal volumes. The use of this latter strategy often comes at the expense of a mild respiratory acidosis. Rarely, lung reduction surgery performed on the native emphysematous lung may be required if the overdistension of this lung remains a problem.[134,135]

Airway and Mechanical Complications

Although the incidence of airway and other mechanical complications has decreased,[136] it is important for the intensive care physician to have an understanding of these problems. Bronchial dehiscence is an infrequent yet potentially devastating complication. It may manifest within a few days of the operation and is usually heralded by persistent or large air leaks from thoracostomy tubes, but may present as pneumomediastinum with or without mediastinitis, pneumopericardium, or empyema. Usually the complication results from ischemia and necrosis at the anastomosis suture line. Although most cases can be managed conservatively by decompressing the large extrapulmonary air collections, bronchoscopic débridement and even bronchial stenting may be required to ensure airway patency. Complete dehiscence of the anastomosis mandates surgical correction or retransplantation.

Bronchial strictures leading to airway stenosis and compromise are sequelae of bronchial dehiscence and/or ischemia, but usually do not develop until several weeks following the transplant procedure. Strictures typically arise in the mainstem bronchus at or just distal to the anastomosis. Ischemic injury to the bronchi may also lead to bronchomalacia, which is characterized by weakened cartilage that is prone to (expiratory) dynamic collapse. Permanent stenting is the preferred approach to this problem. More commonly patients develop inspissation of secretions in the bronchi that cannot be cleared. This may manifest as areas of airspace disease on chest x-ray, atelectasis, or a worsening in oxygenation. In this setting, bronchoscopy is valuable to both establish the cause and clear the retained secretions.

Extracorporeal Membrane Oxygenation

Extracorporeal membrane oxygenation (ECMO) has been used with success to support patients with severe graft dysfunction resulting from ischemia-reperfusion injury. This therapy has generally been used only once conventional strategies to improve oxygenation have failed. Mechanical support is employed in some centers to treat patients with moderate to severe IR injury. ECMO employs a membrane with a large surface area through which oxygen and carbon dioxide may passively diffuse to equalize their respective concentration gradients in the patient's blood. This exploits the notion that resting the lung will allow time for the graft to overcome the initial IR insult. At present a systematic evaluation of this treatment is lacking and experience is restricted to case series and registry databases.[137]

Acute Rejection

Acute rejection may occur while the transplant recipient is being cared for in the ICU, and generally occurs within the first 100 days. The signs are nonspecific, and thus it is important to differentiate the bilateral airspace infiltrates that characterize this complication from those caused by infections. Other features are also unreliable discriminators, and include low-grade fever, impaired oxygenation, and leukocytosis. Findings on chest radiography other than alveolar infiltrates include nodular or interstitial opacities and pleural effusions; after the first month acute rejection is often undetectable radiologically.[138] Routine bronchoscopy has become widely accepted as a means of differentiating infection from rejection. Bronchoalveolar lavage or protected-specimen brushing of the airways can exclude any important infection, whereas transbronchial lung biopsy (with at least five pieces of alveolated parenchyma, each containing bronchioles and more than 100 air sacs) can confirm rejection. Treatment of acute rejection entails the use of high-dose parenteral steroids (i.e., methylprednisolone 10 to 15 mg/kg daily), which usually provide a good response, though biopsy-proven rejection may persist in up to one third of patients.[61]

A detailed discussion of the problem of chronic rejection is beyond the scope of this chapter. However, intensivists may encounter these individuals who develop chronic airflow limitation (usually more than 6 months following the transplant) that is characterized histologically as bronchiolitis obliterans. Although aggressive immunosuppression is often employed, the prognosis for posttransplant bronchiolitis is still poor, with 2-year mortality rates approaching 40%.[139,140] The definitive treatment remains retransplantation.

HEART TRANSPLANTATION

THE OPERATION

Although other variations have been described, the standard approach for heart transplantation involves the creation of four separate anastomoses between the recipient atria and great vessels and the atria and great vessels of the donor heart (the biatrial technique). There has been renewed interest in bicaval and pulmonary vein to pulmonary vein anastomoses, and the bicaval technique has now been recommended by many experts.[141]

THE IMMEDIATE POSTOPERATIVE PERIOD

The care of the heart transplant recipient is similar in many respects to the care of patients who have undergone aortocoronary bypass and other cardiac operations involving cardiopulmonary bypass. The heart is denervated during the transplant procedure, and frequently a junctional rhythm develops, requiring atrial pacing and possibly isoproterenol infusion. Owing to this denervation, the transplanted heart will also have an altered physiologic response to stress. The heart becomes dependent on circulating catecholamines

rather than direct sympathetic stimulation, and consequently increases in heart rate and contractility in response to stress will occur more slowly. Changes in cardiac output become much more dependent on changes in stroke volume, which are in turn mediated by changes in venous return. Sinus bradycardia is the most common dysrhythmia present following heart transplantation, and usually lasts less than a week. Isoproterenol is frequently used for both its chronotropic and inotropic properties, and is typically titrated to achieve a heart rate between 90 and 100 beats per minute. As already mentioned, temporary atrial pacing may be required. If the recipient's native atrial appendage and sulcus terminalis including the sinoatrial (SA) node are preserved during the surgical procedure, two P waves may be seen on the postoperative electrocardiogram (one from the donor heart and one from the recipient's SA node). Other atrial dysrhythmias are frequently seen and include atrial fibrillation and flutter in 15% to 20% of patients.[142]

Nearly all patients will have a pulmonary artery catheter in place for hemodynamic monitoring following the operation to help guide fluid and vasoactive management. Generally, the goal is to keep both the central venous pressure (CVP) and the pulmonary capillary wedge pressure (PCWP) <10 mm Hg if possible, though these goals should be individualized, and the management should be guided by the clinical picture and not purely based on hemodynamic measurements. Consequently intravenous fluids are used sparingly and aggressive diuresis is continued postoperatively. However, the denervated heart will not be able to respond acutely to hypovolemia with reflex tachycardia, and adequate preload must be present to maintain stroke volume and to preserve blood pressure. A decreased cardiac output can be supported with inotropes (dobutamine or milrinone), but transient support with intra-aortic balloon counterpulsation may be required. If the cardiac output acutely deteriorates, urgent echocardiography should be obtained to exclude the possibility of tamponade and to evaluate left and right ventricular dysfunction. Left ventricular function of the allograft may also be reduced and a restrictive physiology may be observed if there has been prolonged ischemic time and poor myocardial preservation. Other causes of ventricular dysfunction should be sought such as acidemia, hypovolemia, hypoxemia, and medications. Systemic vascular resistance can be decreased following the procedure, and should be supported with vasopressors.

PULMONARY HYPERTENSION

If significant pulmonary hypertension was present before the transplant procedure, it may also persist in the postoperative period. This increase in right ventricular afterload can generate significant strain on the newly transplanted right ventricle (which is accustomed to pumping against a normal mean pulmonary artery pressure). Tricuspid regurgitation is often present following the transplant (especially if the biatrial technique was used), and this may be exacerbated by increased right ventricular strain. Through its effects as a pulmonary vasodilator, isoproterenol can often reduce the right ventricular afterload that is frequently present. However, when significant pulmonary hypertension persists postoperatively, intravenous nitroglycerine, nitroprusside, and prostaglandin E may be required. If vasodilators are used in this setting, systemic infusion of α-agonists such as norepinephrine or phenylephrine may be needed to support the systemic arterial pressure. Inhaled nitric oxide offers the advantage of reducing pulmonary vascular resistance while causing minimal systemic side effects and without increasing shunting.[143–147] Routine measurement of methemoglobin level is required when nitrate-containing pulmonary vasodilators are employed. Recently, sildenafil, a cyclic guanosine monophosphate (cGMP)-specific phosphodiesterase type 5 inhibitor has been used with success for persistent pulmonary hypertension, and to prevent rebound after withdrawal of inhaled NO.[132] Owing to the expense associated with the use of inhaled NO, other inhaled therapies have been evaluated (NO donors and prostaglandin analogues) and appear to be of equal benefit.[148–151] However, the half-lives of these medications mandate repeated dosing.

RIGHT AND LEFT VENTRICULAR ASSIST DEVICES

Patients with failing hearts are frequently bridged to transplantation using mechanical cardiac assist devices. Both left (LVAD) and right (RVAD) ventricular assist devices are used.[152,153] Preliminary reports suggest that although mechanical devices may be associated with more serious adverse effects, they may be superior to medical therapy alone in supporting the patient to transplantation.[154] The role of ventricular assist devices in right ventricular failure or primary graft failure following transplantation is evolving. A report from New York reviewed one institution's experience with assist devices in 462 transplants. Of the 20 patients diagnosed with primary cardiac graft dysfunction, 11 received RVAD, 4 required LVAD, 3 received biventricular support, and 2 were treated with intra-aortic balloon counterpulsation.[155] This group with primary graft dysfunction tended to have longer ischemic times and developed early noncardiac organ dysfunction, which was the primary mode of death in the nonsurvivors. Forty-five percent were weaned from mechanical support; the mean duration of support was 114.7 $\pm$ 207 hours (median = 54 hours). The 2-year survival in this group with primary graft dysfunction was 67% compared to 79% in the entire cohort. The authors reported that ventricular recovery within 96 hours was associated with better early survival.

REJECTION

Though immunosuppressive regimens have improved the impact of episodes of acute rejection on graft function and overall survival among heart transplant recipients, this complication still is responsible for 7% of deaths within the first 30 days of the procedure.[156] Most episodes of acute rejection are asymptomatic and are diagnosed on routine endomyocardial biopsy. When symptoms are present, they are often nonspecific and may include fever, malaise, hypotension, congestive heart failure, or reduced exercise tolerance and fatigue. Consequently, surveillance for rejection through the use of endomyocardial biopsy has become standard practice. When performed by an experienced operator, this procedure is associated with a morbidity of less than 1% and a procedure-related mortality of less than 0.2%.[157,158] The most concerning complication of this procedure is cardiac perforation with acute pericardial tamponade or injury to the tricuspid valve. Typically biopsies (with multiple sampling) are performed 5 to 7 days following the transplantation and then twice weekly for the first 2 months.

Once rejection is diagnosed histologically, imaging to assess cardiac function should be obtained (two-dimensional echocardiography or multiple-gated acquisition).[141] Mild rejection in the absence of cardiac dysfunction is usually treated conservatively with an increase in the dose of immunosuppressive agents. If moderate rejection or left ventricular dysfunction is present, the episode of rejection should be treated using high-dose pulsed steroids with or without cytolytic therapy (antithymocyte globulin or OKT3). Repeat endomyocardial biopsy should always be performed to assess the response to therapy.

Chronic rejection in the cardiac allograft typically manifests as aggressive and premature coronary artery disease. This complication usually develops months to years after the procedure, and usually will not involve the intensivist. In contrast to classic coronary artery disease, transplant-associated coronary artery disease is generally more diffuse, involving all the vessels of the heart including the arteries, veins, and great vessels. Because the allograft is denervated, classic angina only develops in a minority of patients, and coronary artery disease more typically presents with "angina-equivalent" symptoms such as dyspnea.

KIDNEY-PANCREAS TRANSPLANTATION

THE OPERATION

Kidney-pancreas transplantation is almost exclusively performed on patients with end-stage kidney disease secondary to diabetes mellitus.

POSTOPERATIVE CARE

Following kidney-pancreas transplantation many patients will not require ICU admission, and can be extubated before leaving the recovery room. However, ICU admission may be necessary for these patients because of pre-existing medical problems, due to difficulties encountered during the operation, or owing to complications that develop in the postoperative period.

The most common initial complication following the transplant of a kidney is oliguric or nonoliguric acute tubular necrosis (ATN) resulting from ischemic-preservation injury to the renal allograft. Care must be taken in this setting to avoid hypovolemia which can lead to prerenal azotemia and exacerbate the ATN. Urine output following the transplant procedure is usually high (800 to 1000 mL/h) and should be associated with a decline in creatinine; a lower urine output in the immediate postoperative period may herald graft dysfunction. Fluid management can often be facilitated through the use of a pulmonary artery catheter for hemodynamic monitoring. If oliguria develops, the urinary catheter should be flushed to ensure patency, especially if hematuria has been observed. Duplex sonography or radionuclide renal imaging should be considered to exclude the possibility of vascular thrombosis. If these interventions fail to elucidate the cause of the oliguria, the most likely remaining explanation is ATN and ischemic-preservation injury.

Following combined kidney-pancreas transplantation patients are at risk of developing metabolic derangements, and are particularly prone to developing hyper- or hypoglycemia. Usually a continuous intravenous infusion of insulin is started intraoperatively and continued through the postoperative period. A glucose-containing maintenance infusion should also be used to protect against the development of hypoglycemia. Care should be taken to avoid mixing medications in glucose-containing solutions, as these will provide boluses of glucose that can aggravate the control of blood sugar levels.

REJECTION

The diagnosis of rejection in recipients of pancreas transplants is often challenging. Overt hyperglycemia does not occur until approximately 80% to 90% of the allograft has been destroyed, and consequently by the time clinical evidence of rejection is present it is often too late for therapy to be effective. For this reason, diagnosis of pancreatic rejection is usually made by inference after diagnosing rejection in a kidney allograft. This likely explains the improved graft survival in recipients of combined kidney-pancreas transplants as compared to patients who only receive a pancreas transplant; in the former group rejection is likely diagnosed and treated at a much earlier stage. In contrast, rejection of a renal allograft is usually suspected when the serum creatinine rises by more than 10%. If another cause of renal dysfunction (such as prerenal azotemia, pyelonephritis, etc) is not readily apparent, kidney biopsy should be performed. This procedure is relatively safe and will enable treatment of rejection to be instituted early and promptly. Recent reports suggest that use of the renal arterial resistance index[159] or DNA microarray profiling[160] may become important methods for diagnosing rejection in the renal allograft in the future.[161]

Other Management Issues Involving Solid Organ Transplant Recipients

THE DEVELOPMENT OF LUNG INFILTRATES IN THE TRANSPLANT PATIENT

A frequently encountered problem following the transplant procedure is the development of lung infiltrates. Though pneumonia is common, there are a variety of other conditions that cause a similar appearance on chest radiography and must be considered. These include congestive heart failure, atelectasis, ARDS, aspiration, and transfusion-related acute lung injury. In the lung transplant recipient, IR injury or rejection of the allograft also have a nonspecific appearance on chest radiography. Thus it is important that the clinician have an approach to the patient who develops lung infiltrates.

Because pulmonary infections may progress rapidly in the immunocompromised host, empiric antimicrobial therapy should be started promptly if pneumonia is suspected. Usually the patient will have other signs of infection such as fever or leukocytosis, but these findings will not always be present, depending on the degree of immunosuppression. Usually there is increased quantity and purulence of sputum or secretions from the endotracheal tube. If possible, respiratory secretions should be cultured prior to the initiation of empiric antibiotics. Invasive tests such as bronchoalveolar lavage or protected brush specimen obtained through bronchoscopy may be useful to optimize culture yield and ensure that appropriate antibiotic therapy is chosen.[162] If culture results are negative, the empiric antibiotics should be discontinued, as the continued use of inappropriate therapy may increase antimicrobial resistance.

Pneumonia in transplant patients may be caused by a variety of organisms, including gram-negative aerobes, fungi, *Legionella*, *P. carinii*, and viruses (especially CMV). Consequently, broad-spectrum therapy should be initiated when infection is suspected, but treatment should be changed to an appropriate agent with the narrowest spectrum of activity possible once susceptibilities of the causative organism are known. Initial therapy should have activity against *Pseudomonas* and other gram-negative organisms as well as gram-positive bacteria. Appropriate choices would include ceftazidime, piperacillin-tazobactam, or meropenem or imipenem. Consideration should be given to also including trimethoprim-sulfamethoxazole (TMP-SMX) to treat possible *P. carinii*, ganciclovir to treat CMV infection, and a macrolide to treat *Legionella*, if infection with any of these organisms is suspected.

THE TRANSPLANT PATIENT WITH DECREASED LEVEL OF CONSCIOUSNESS

A frequently encountered postoperative problem in the transplant recipient is the development of a decreased level of consciousness. When this occurs, a systematic evaluation is required to ensure that the etiology is correctly identified and appropriately treated. Distinguishing between structural problems and metabolic or drug-induced disturbances is often useful. Though the former are less common, the development of any localizing neurologic findings suggests a structural lesion and mandates CT or MRI examination. Stroke can occur in the perioperative period, and may be ischemic or embolic in nature. Perioperative cardioembolic stroke is more commonly seen following heart transplantation, and can be the result of intracardiac or aortic thrombosis. Intracranial bleeding usually occurs following hemorrhagic transformation of an ischemic infarct or a central nervous system infection. Liver transplant patients commonly develop coagulopathy, and this likely explains the relatively higher incidence of intracranial hemorrhage seen in this group.[163] Air embolism has been described in liver transplant recipients,[164–168] especially following venovenous bypass, and in cardiac and lung transplant recipients.[73,74]

Metabolic derangements leading to alterations in mental status are commonly encountered by transplant recipients. Electrolyte and glucose abnormalities are often present and should be corrected. However, care is required to avoid overly aggressive and rapid correction of sodium problems, which can precipitate central demyelination syndromes following treatment of hyponatremia or cerebral edema following treatment of hypernatremia. When present, renal failure and associated uremic encephalopathy may contribute to abnormal mentation. Hepatic encephalopathy is common in liver transplant patients and should be treated in the same manner as for all patients with liver disease. Hypoxia and hypotension can both cause a decreased level of consciousness, but are usually easily recognized.

Drug-induced depression of the central nervous system (CNS) is common. Clearance of the anaesthetic agents used during the transplant procedure may take longer in the transplant recipient, especially following liver or kidney transplantation. Narcotic analgesics, benzodiazepines, and other CNS depressants are frequently required following transplantation, and these agents may accumulate and lead to decreased arousal. Importantly, both cyclosporine and tacrolimus are associated with neurologic toxicity and can even lead to coma.[169,170] Serum levels of these agents must be monitored carefully, and if no other explanation for the decreased level of consciousness can be found the drugs must occasionally be held or discontinued. The use of tacrolimus and cyclosporine has also been linked to the development of thrombotic thrombocytopenic purpura and the hemolytic uremic syndrome, which can have neurologic manifestations.[171–173] A very rare but potentially devastating complication of transplantation that leads to severe CNS depression is the hyperammonia syndrome.[174–177] This syndrome is characterized by tremulousness progressing to seizures, coma, brain edema, and death. Severe elevations in serum ammonia will be present despite normal or only minimally elevated liver enzymes and normal indices of hepatic function. The syndrome appears to develop in individuals with abnormalities or deficiencies of enzymes in the urea cycle. Therapy consists of minimizing amino acid intake (especially parenteral), and treatments that enhance or increase elimination of nitrogenous waste products.[176,177]

Systemic infections can be associated with severe encephalopathy. However, when caring for a transplant patient, the intensivist must have a heightened suspicion for infections that involve the CNS. When these infections develop in the early postoperative period, they are usually related to nosocomial or donor-related organisms.[178,179] Meningeal signs may be lacking in the transplant recipient, and so lumbar puncture with cerebrospinal fluid analysis should be considered if CNS infection is suspected and empiric therapy should be instituted promptly.

A rare but important cause of decreased level of consciousness or coma in the transplant recipient is nonconvulsive status epilepticus. Indeed, seizures may be the most common neurologic complication for all solid-organ transplant recipients.[179] These may be precipitated by electrolyte and metabolic disturbances (especially of sodium and glucose), drugs (cyclosporine, tacrolimus, OKT3, antibiotics, etc) or drug withdrawal, CNS infections, or intracranial lesions (stroke, hemorrhage, abscess, etc). Evaluation should include CT scan and electroencephalogram, and treatment should be focused on correcting the underlying problem if possible, and treatment with benzodiazepines. Since many transplant patients are hypoalbuminemic, when therapy with phenytoin is employed it is necessary to calculate the unbound fraction of the drug to avoid potential toxicity. Valproate is not commonly used because of its potential for myelosuppression and hepatotoxicity.[179]

Role of the Intensivist

The very nature of transplant medicine mandates the adoption of a multidisciplinary approach to patient care. As such, one of the most important roles the intensivist can assume is to coordinate the management of the patient and to act as an intermediary between the numerous specialists and professionals involved in the case. The transplant surgeon and the transplant team will need to be frequently consulted and kept informed of changes in the patient's status in order for appropriate modifications to the immunosuppressive regimen to be made or surgical intervention provided if necessary.

The needs of the transplant recipient are often quite complex, and the intensivist must frequently coordinate the involvement of other professionals, including dieticians, physiotherapists and occupational therapists, respiratory therapists, pharmacists, and nurses. It is usually the intensivist who will liaise with the patient's family and identify important psychosocial issues. Often the need to involve the social worker, psychiatrist, and chaplaincy is identified by the intensivist. Thus the critical care of the transplant patient requires the intensivist to be an expert in acute physiology and to have an understanding of the important medical issues facing the recipient, but also requires someone who can coordinate other professionals involved in the patient's care, and identify the medical and social needs of both the patient and family. It is only through such a multidisciplinary approach, coordinated by the intensivist, that transplant patients will achieve good outcomes.

Chapter 91

CARE OF THE MULTIORGAN DONOR

F. D'OVIDIO
D. MCRITCHIE
S. KESHAVJIE

KEY POINTS

- *Increasingly successful solid organ transplantation has increased the need for organ donors.*
- *Maximizing organ procurement and expanding donor acceptance criteria should decrease the organ shortage.*
- *Aggressive ongoing critical care of the multiorgan donor is essential to improve organ retrieval and posttransplant graft performance.*
- *Understanding the process of brain death is essential for directing donor treatment strategies to ensure preservation and function of donor organs.*
- *The goals of management of the multiorgan donor are to maximize organ function by maintaining organ perfusion and oxygenation, and to promptly recognize and treat potential complications such as hypotension, dysrhythmia, pulmonary edema, massive diuresis, coagulopathy, hypothermia, and sepsis.*

Organ transplantation has evolved rapidly from the first early successes to the current widespread use of donated organs for the treatment of end-stage kidney, liver, heart, and lung failure.[1] The success of solid organ transplantation has increased the need for an expanded supply of organ donors. In response to this need, the age limit for cadaveric donors has been increased, and donors over the age of 50 years are now routinely used. The use of organs from living related donors, living unrelated donors, and non–heart-beating donors (those declared dead on the basis of cardiopulmonary criteria) has also increased. Nevertheless, there has been a progressively widening gap between the number of patients waiting for transplants and the number of transplantations performed. The number of patients on the national waiting list was 25% higher than the number of transplantations in 1988.[2] According to the United Network for Organ Sharing (UNOS), as of April 24, 2003, the number of patient registrations was 81,208, with the majority of patients in the 18- to 64-year age range. In 2002 a total of 24,847 transplants were performed, thus the number of patients on the waiting list was about 325% higher than the number of transplanted patients.[3]

In the past 10 years, the waiting list has increased 229%, and waiting list deaths have increased 192%. In contrast, during this same time period, the number of cadaveric organ donors has increased only 32%, with donors younger than 50 years of age increasing only 10.3%. The largest increase in cadaveric donors has been in donors older than 50 years of age (135%). One consequence of the increased proportion of older and more diverse donors has been the increase in organs discarded after they had been procured.[3]

The relevance of a properly functioning transplanted organ cannot be overemphasized and is clearly crucial for the success of transplantation of organs requiring immediate function such as the heart and lung. Temporary failure of the liver, kidneys, and pancreas may be tolerated with supportive measures such as hemodialysis and pharmacologic interventions. Early graft failure accounts for approximately 30% of all deaths of cardiac and lung recipients, and the deaths of 30% of liver and 5% of renal recipients.[4]

At a time when transplant surgeons are facing an increasing number of deaths on the waiting list, and as the size of the list continues to grow, there has never been a greater need to utilize a higher percentage of older or otherwise marginal donors, minimize the incidence of primary graft nonfunction, and develop organ donor management strategies that continue to increase the number of organs available for transplant.[3,4–6]

To increase the number of transplantable organs, UNOS created the Critical Pathway for the Organ Donor, a blueprint of an organ donor's treatment plan. The Critical Pathway is a concise, one-page document designed to help critical care staff and procurement coordinators understand and follow the steps required for effective donor management.[3]

After brain death has been declared in potential organ donors and consent is given for donation, donors need to be medically managed to keep their organs viable until organ recovery can occur. The Critical Pathway describes optimal care for the organ donor and maps the process to improve the outcome for successful organ transplantation. The Pathway promotes collaboration between organ procurement coordinators and critical care staff, and delineates roles to prevent duplication of effort or confusion.

Recent studies have shown that the Critical Pathway, which has been endorsed by four major transplantation associations, significantly increased the number of organs procured and transplanted from brain-dead donors.[3,5,6] There is no sacrifice in the quality of the transplanted organs or an increase in donor management time.

The two most limiting factors in organ donation today are: (1) failure to identify patients that are potential organ donors and lack of referral of those patients to the organ procurement organization, and (2) refusal of patients' families to consent to donation. A proactive donor detection program maintained by well-trained transplant coordinators, the introduction of systematic death audits in hospitals combined with a positive social atmosphere, appropriate management of mass media relations, and appropriate economic reimbursement for the hospitals are the measures advocated by the Spanish model, which has resulted in the highest continuous increase by far in cadaveric organ donation within a large country, reaching 32.5 organ donors per million population in 2001.[7]

Once a patient has been identified as a potential organ donor, the critical pathway should be initiated by contacting the local organ procurement organization to make the referral. Referral is critical; if this does not occur the opportunity for donation may be lost entirely. Organ procurement organization staff may wish to be notified as the condition of the patient deteriorates even before brain death occurs. Most often, the organ procurement organization can quickly do a preliminary assessment to determine whether the patient is a potential candidate for organ donation. If the patient is not a candidate, there is no need to discuss the option of donation with

the patient's family members, and the pathway is stopped. Furthermore, if family members broach the subject of organ donation, a clear answer can be provided as to why the patient is not a candidate for donation, and any confusion can be avoided. Even if a patient is not a candidate for organ donation, the family may have other options to consider, such as donations of eyes, skin, bone, and heart valves.[8]

Referral systems should be automatic and simple. Donors are lost when hospital staff with limited knowledge of the acceptance criteria for organ donors inappropriately rule out potential organ donors as medically unsuitable. Retrospective reviews of the records of patients who have died while in the hospital indicate that a surprising number of potential donors were never evaluated by organ procurement organization staff for this reason. The reasons given for the determination of unsuitability, if any reason is noted in the chart, are many, and include age, use of vasoactive drugs, disease (i.e., diabetes), cardiopulmonary resuscitation, and positive cultures. Any patient with a significant and potentially life-threatening injury to the head, whether caused by trauma, an intracerebral hemorrhage, or an anoxic event, should be referred to the organ procurement organization as early as possible for evaluation as a potential organ donor. This practice allows the organ procurement organization to evaluate the situation and apprise staff members early on about whether the patient is a potential donor or not. Currently, only a few medical contraindications to donation are absolute, including:

- Transmissible infectious disease that will adversely affect the recipient (i.e., human immunodeficiency virus (HIV) infection, active viral hepatitis B, encephalitis of unknown cause, prion disease, malaria, and disseminated tuberculosis)
- Active visceral or hematologic malignant neoplasm
- Characteristics that indicate the organ is unlikely to function

Indeed, the only typical feature of a potential donor today is brain death, and with the increased use of non–heart-beating donors in the United States, even brain death is not necessarily typical anymore.

Early referral is also key to success in recovering transplantable organs for potential recipients. If an organ procurement organization receives a referral from the critical care staff well after brain death has occurred, decreases in end-organ function will already have taken place. If the organ procurement organization is called in only well after the signs of brain death are present, the donor who might have had 5 to 7 organs suitable for donation and transplantation may by that time have only 1 or 2 suitable organs. It has been questioned whether it is reasonable to expect nurses and physicians to keep pace with all of the changes taking place in organ donation, and thus systems have been developed and implemented, sometimes required by law, that do not rely on hospital staff to screen potential donors.[9]

Declaration of Brain Death

The introduction of successful kidney transplantation in the 1950s led to the concept of the use of organs from "heart-beating cadavers." The clinical findings of "brain death" were first described by French investigators Mollaret and Gaulon in 1959, describing patients on ventilators who have loss of neurologic function after persistent deep coma and loss of spontaneous ventilation; they first called this condition "coma depassé" to denote neurologic damage beyond coma, but they did not equate this entity with death itself.[10] In 1968, the Ad Hoc Committee of the Harvard Medical School to Examine the Definition of Brain Death was created to standardize the definition of brain death and resolve some of the growing controversies surrounding organ procurement for transplantation from heart-beating donors. The resolutions from this committee are known as the Harvard Criteria of Brain Death. The reasons for this redefinition of death, according to the aforementioned Committee, were the need to bring relief to the families of the sick, free up beds in the intensive care units, and remove the grounds for objecting to the obtaining of organs for transplantation.[11]

Two criteria were considered for determining brain death: either the irreversible loss of all of the functions of the entire brain, including the brain stem, or the irreversible loss of the functions of the brain stem only.

The concept of brain death continues to be a topic of international debate among medical clinicians, anthropologists, philosophers, and ethicists. Much of this discussion is the result of the awareness of continuing technological advances, neurodiagnostic developments, and clinical insight. This ongoing dialogue can be viewed as a dynamically developing process of achieving a multidisciplinary consensus that is responsive to a continually changing technological environment.[11,12]

It has been argued that brain death, either when referring to the entire brain or to the brain stem alone, is a concept without a precise clinical or pathologic basis, and for this reason, the criteria employed in its diagnosis are somewhat arbitrary. It has also been said that it is difficult or almost impossible to have diagnostic standards for a condition that has never been adequately defined.[12]

Evidence-based guidelines for determining the brain-death criteria in the United States are based on the Report of the Medical Consultants on the Diagnosis of Death to the President's Commission on the Study of Ethical Problems in Medicine and Biomedical and Behavioral Research of 1981.

The President's Commission requires loss of brain stem function, loss of cortical function, and that the condition is irreversible. Although the guidelines reflect generic, scientifically based recommendations, adaptation of certain details may vary across practice settings and states according to variations in institutional policy and local legislation.[11–13] The full description of the diagnosis of brain death is explained further in chapter 67.

Request for Consent

Refusal by the family to provide consent for donation is the most common reason that organs of medically suitable potential donors are not recovered. According to estimates, 35% of the medically suitable organ donors do not donate because the family of the potential donor refuses to consent to donation. Hospitals with low donation rates were more likely to have staff members who perceived dealing with a potential donor as time-consuming and burdensome, and who were uncomfortable with how their hospital handled donation. The

role that personal attitudes play in the ability of staff members to handle donation is unclear. Staff members in hospitals with high donation rates have a more positive personal attitude toward donation than do staff members in hospitals with low donation rates; however, a positive personal attitude does not correlate with the ability to approach families about donation.[9]

Another situational variable that has a marked influence on donation rates is the timing of the request (i.e., when the request is made relative to when the family is informed of the death). Research clearly shows that inappropriate timing of the request (i.e., informing the family of the death and requesting donation at the same time) is a formula for family refusal. Families need time to acknowledge the death before they are approached about donation. Consent rates have been shown to increase from 18% to 60% if there was a delay between death and the request for donation. Ensuring that this delay occurs is referred to as "decoupling" of the request. The timing of the request has been evaluated in numerous studies, and all the researchers have reached the same conclusion: that decoupling the request leads to improved donation rates. However, despite vigorous attempts by the organ donation community to educate critical care staff, and by the health care community about the importance of decoupling the request, a significant number of requests are still "coupled."[9,14]

Unfortunately, current medical school curricula generally lack training on how to break bad news and inform of death. It is important that the word "dead" should be pronounced and not avoided. At the brain death declaration, the main task of the intensive care unit staff is not that of obtaining consent for organ removal, but rather counseling and helping the family to cope with the grieving process. Minimizing the family's distress is the focus of care and is an essential prerequisite for a subsequent organ donation request.[10]

Unrestricted visits to the potential donor should not only be permitted, but actively encouraged. All the family's questions about brain death must be answered unhurriedly by the staff, and the right words should be used in front of a warm cadaver with a heart that is still beating. For example, it is better to use terms which strengthen the certainty of the death, such as "no, he does not breathe, but the ventilator forces the air into the lungs," or "yes, the heart is still pumping the blood, and it will do so for some hours more because it is artificially stimulated and this is why the skin is warm." No mention about organ donation should be raised before the concept of brain death is comprehended and the death is accepted by the family. The staff should refer to the dead patient using the past tense; as soon as family members begin to talk of him or her using "was," the acceptance of death becomes clear. The physician who is in charge of the intensive care unit should only discuss brain death with the family. The discussion relating to organ donation should be introduced by the transplant coordinator so that there is a clear distinction between the two functions (i.e., treatment of the patient and preparation for donation). The request should be made by the transplant coordinator in a positive way. It should be proposed as an option that the hospital offers the family for helping other patients, rather than an apologetic or indifferent businesslike gesture. Those who have difficulty in requesting consent should delegate the task to more confident staff. The family must never be forced into making a hasty decision, and it is always advisable to let them take their time and discuss the matter among themselves and with other members of the family before asking again. Often an initial refusal turns into a convinced consent over the course of two or three meetings. While a firm refusal must be respected, hesitation can easily lead to authorization if the subject of the urgent need of organs for many patients, as a life-saving procedure or a dialysis-relieving therapy, is raised tactfully. The consent process for organ and tissue donation should not only be considered a necessity, but also a family's right.[9]

Obtaining consent for organ donation from families is enhanced by:

- Allowing time for families to accept death
- Having someone who is an expert in donation consent approach the family
- Approaching the family in a private, quiet area in an unhurried manner
- Involving nursing and the organ procurement organization staff in the coordination of the entire consent and donation process

Evaluation of a Potential Donor

Once consent for organ donation is given, a thorough evaluation is conducted. The organ procurement coordinator collaborates with the critical care nurse to obtain the necessary history and results of diagnostic tests. The donor's chart is reviewed for prehospital and emergency department entries for details of the events leading to admission. The duration of "downtime" (cardiopulmonary arrest) and cardiopulmonary resuscitation, vital signs, drugs administered, and obvious signs of chest and abdominal trauma are noted. If an old chart or the patient's primary physician is available, a pertinent medical history is obtained.

Completing a battery of laboratory tests in a timely manner will expedite organ placement and decrease the time required for donor management. A blood sample is also obtained from the donor, to perform bacteriologic and serological screening for infectious disease. This serological sample is usually sent to a central laboratory that performs such testing on a 24-hour basis; however, once the sample arrives at the laboratory, it usually takes about 6 hours for the results to be determined. Usually, the donation coordinator is aware of the serological results as the offers for organ-specific recovery are made.

The organ procurement coordinator reviews a comprehensive medical and social history with the appropriate family members or significant others. Donors are screened for a number of factors, including but not limited to, any history or treatment of heart disease, hypertension, chest pain, or diabetes; use of tobacco, drugs, and alcohol; and high-risk behaviors for transmission of human immunodeficiency and hepatitis viruses. Pertinent family history is reviewed also. The organ procurement coordinator does a complete physical examination of the donor, paying close attention to any finding that may influence organ integrity. The transplant surgeons determine the suitability of the donor with respect to the transplantable organs.[8–10]

SCREENING FOR INFECTIOUS AGENTS

Serological screening for HIV, human T lymphotropic virus (HTLV),hepatitis B virus (HBV), hepatitis C virus (HCV), and

cytomegalovirus (CMV) is routinely performed along with screening for *Treponema* antigen (syphilis) and for *Toxoplasma*.

The presence of an active viral infection in the form of encephalitis or meningitis, varicella-zoster virus infection, or HIV infection is an absolute contraindication to organ donation because of the hazard that each of these clinical situations pose to the allograft recipient.

Isolated hepatitis B surface antibody positivity usually implies previous vaccination. Hepatitis B surface antigen (HBsAg) positivity reflects the presence of viral DNA in the blood that is related to current hepatitis B infection or a remote infection that has not cleared. These donors have contagious hepatitis B and will transmit the disease to the recipients unless the recipient has neutralizing antibodies due to previous exposure or vaccination. Patients who have acute hepatitis infection develop antibodies to the core antigen early in the course of the disease. Donors who are core antibody–positive should be considered infectious because they may be convalescing from acute infection. If both surface and core antibodies are positive, then the patient has recovered from hepatitis B and demonstrates immunity. Nevertheless, liver recipients from these donors are at significant risk for the development of acute hepatitis B infection, as opposed to the recipients of the other organs. Organs from these core-positive donors are generally reserved for patients with a documented response to the hepatitis B vaccine.[15]

All hepatitis C antibody-positive donors should be considered infectious. The hazard of HCV transmission from a previously infected organ donor is a concern for all allograft recipients. Approximately 5% of all organ donors are positive for antibody to HCV. The presence of antibody to HCV is indicative of HCV infection, because antibody to HCV appears in peripheral blood within 2 months of HCV exposure. Most organ procurement organizations have adopted a policy of screening organ donors for antibody to HCV. IgG antibody to HCV does not protect against donor organ contamination; however, it is also important to emphasize that detection of antibody to HCV by serological screening of the donor is not predictive of HCV transmission.

Although a positive screening result does not necessarily rule out organ donation, a selective strategy of reserving organs from HCV-positive donors for recipients with previous HCV exposure and detectable antibody to HCV can be applied. Transplantation of a liver from a donor positive for antibody to HCV to a recipient positive for antibody to HCV does not appear to cause increased morbidity or mortality. Transplantation of an HCV-positive heart or lung allograft when a HCV-negative recipient's life is in danger may be the only alternative to immediate death.[16,17] Kidney recipients who are hepatitis C positive can shorten their time on the waiting list by accepting a kidney from a HCV-positive donor. Table 91-1 shows the relative risk of viral transmission for hepatitis B and C viruses.[17]

Transplantation of an organ from a CMV-positive donor can result in subsequent reactivation of latent virus and replication in the immunosuppressed host. The specific CMV serological status of the donor and recipient has implications for prophylaxis, the highest-risk group being CMV-seronegative recipients of CMV-seropositive donor organs (i.e., the so-called primary infection group).

Nevertheless, transplantation of organs from CMV-seropositive donors has not been considered an absolute contraindication for transplantation, because the high seroprevalence of the virus among the general population makes it impractical to rule out such donors. Furthermore, recent evidence suggests that even mismatches between CMV-positive donors and CMV-negative recipients can be successfully overcome by strategies aimed at prophylaxis for CMV infection.

Over 95% of potential adult donors are seropositive (IgG antibody) for Epstein-Barr virus (EBV); thus serological screening of organ donors for EBV is not routinely performed. However, primary EBV infection (i.e., transplantation of an organ from an EBV-seropositive donor to an EBV-seronegative recipient) is associated with an increased risk of

TABLE 91-1 Risk of Hepatitis Viral Transmission

Donor serology	HBsAb+ recipient	HBsAb−recipient
HBsAg+	Liver: Insufficient data Non-liver: Insufficient data	Liver: High Non-liver: High
HBcAb+	Liver: Low – Moderate[a] Non-liver: Very low	Liver: Moderate to High Non-liver: low
HCVAb+	HCVAb+ recipient Liver: High[b] Non-liver: Insufficient data[c]	HCVAb−recipient Liver: High Non-liver:High

[a] Data indicate that the risk of viral transmission may be lower for recipients who are immune from previous HBV infection (HBsAb+/HBcAb+) compared to recipients who are immune from vaccination (HBsAb+/HBcAb−).
[b] Although there is evidence that the donor virus is transmitted to the recipient, repopulation after liver transplantation occurs with approximately even frequency by donor or recipient strain. Available data indicate *no* increase in short (1-year) and medium (5-year) term mortality and morbidity (incidence, timing, or severity of liver disease) is associated with transplantation of a liver from a HCVAb+ donor vs. a liver from an HCV Ab−donor into a hepatitis C+ recipient.
[c] There are insufficient data regarding persistence of donor vs. recipient virus strains after transplantation to determine the true incidence of viral transmission. Available data indicate that transplantation of a kidney from an HCVAb+ donor has *no* adverse impact on graft and patient survival (5 years) or the recipient's HCV disease compared to a kidney from an HCVAb-donor.

posttransplant lymphoproliferative disease. Therefore, recognition of this mismatch in a potential allograft recipient known to be EBV-negative may be important prognostic information. Currently, there is no effective means of preventing this complication.

The detection of antibody to treponemal antigen is not a contraindication to organ procurement, but it is a contraindication to tissue procurement. A standard course of penicillin therapy would provide sufficient antibiotic coverage to prevent syphilitic complications in an allograft recipient.

The possible transmission of the protozoan *Toxoplasma gondii* is a concern, especially for heart allograft recipients, because of the predilection of this parasite for muscle tissue. Organ procurement from seropositive donors is not contraindicated; however, the detection of seropositivity means that the recipient may be placed at high risk. Fortunately, the use of trimethoprim-sulfamethoxazole as prophylaxis for *Pneumocystis carinii* infection prevents transmission of *T. gondii*.[16]

Regional directives will need to be implemented as necessary with regard to novel infectious agents carrying alarming epidemic/pandemic life-threatening potential. Recently regions of North America have been faced with two relatively new entities, West Nile virus and the severe acute respiratory syndrome (SARS). Organ donors should be tested for evidence of both West Nile virus viremia by polymerase chain reaction (PCR) and early antibody response (IgM) to West Nile virus. If either test is positive the potential donor is to be deemed ineligible for organ donation.

SARS screening is currently conducted by using a specifically directed series of questions on the donor medical and social history questionnaire. This investigates the donor institution's category of contamination as determined by the infection control officer at that institution; the donor's clinical history relative to the last 10 days prior to donor assessment with regard to signs or symptoms associated with SARS; and epidemiologic links related to direct contact with SARS risk or travel to an area listed in the current Travel Health Advisory.[18]

DONOR-RELATED MALIGNANCIES

Transmission of donor malignancies is rare, with 18 cases from 34,933 cadaver donors and 3 cases from 32,052 living donors being reported to UNOS from 1994 through 2001. Donors with past histories of certain types of cancers may be considered as donors, including certain types of primary central nervous system (CNS) tumors. Risks of cancer transmission from donors with a history of nonmelanoma skin cancer and selected cancers of the CNS appear to be small. When considering organ use from donors suffering from intracranial malignancies, there are a number of general guidelines. Most important is to consider the known biologic behavior of various CNS neoplasms and their propensity to spread outside of the cranial vault. Repeated craniotomies as well as ventriculoperitoneal or ventriculojugular shunts have been associated with increased risk of metastasis.[17,19–21]

Risks of tumor transmission with certain other types of cancer may be acceptable, particularly if the donor has a long cancer-free interval prior to organ procurement, while certain other cancers pose a high transmission risk. Tumors that pose a high transmission risk include choriocarcinoma, melanoma, lymphoma, and carcinoma of the lung, colon, breast, kidney, and thyroid.

A list has been developed outlining the relative risks of CNS tumor transmission from cadaver donor to allograft recipient (Table 91-2).

TABLE 91-2 Relative Risk of Central Nervous System Tumor Transmission

Lowest risk
Benign meningiomas
Pituitary adenomas
Acoustic schwannomas
Craniopharyngiomas
Astrocytoma (grade I)
Epidermoid cysts, colloid cysts
Low-grade oligodendromas
Gangliogliomas, gangliocytomas
Pineocytomas, ependymomas
Well-differentiated teratomas
Papillomas
Hemangioblastomas
Moderate risk
Astrocytoma (grade II)
Gliomatosis cerebri
Highest risk
Anaplastic astrocytoma (grade III)
Glioblastoma multiforme
Medulloblastoma
Anaplastic oligodendroglioma
Pineoblastomas
Chordomas
Malignant ependymomas
Primary cerebral lymphomas

CARDIAC EVALUATION

An initial electrocardiogram (ECG) should be obtained on every potential cardiac donor, and additional ECGs should be obtained when changes in heart rhythm occur. ECG changes may be temporary and related to alterations in sympathetic output. Nonspecific ST-segment and T-wave changes, prolonged QT intervals, and T-wave inversion are common. Tachycardia is common and may be caused by diabetes insipidus, diuresis, hemorrhage, vasopressor therapy, or electrolyte disturbances. ECGs are evaluated for signs of acute myocardial injury.[8]

A transthoracic or transesophageal echocardiogram may be obtained to evaluate motion of the heart wall and valve function, estimate ejection fraction, and to detect a pericardial effusion. Transient changes that do not preclude heart donation include a stunned myocardium or myocardial depression related to acidosis and hypoxemia. If the causes of the changes are reversible, the heart may still be successfully transplanted. Although echocardiography is effective in screening for anatomic abnormalities of the heart, the use of a single echocardiogram to determine the physiologic suitability of a donor is not supported by clinical evidence. An alternative approach, using a pulmonary artery catheter to guide the physiologic assessment and management of ventricular dysfunction, has been used with success in the United Kingdom.

TABLE 91-3 Heart Donor Criteria

Criteria	Modification(s)
Age	Donors >55 may be used selectively, though coexisting LVH and longer ischemic times may increase recipient mortality risks
Size	Despite an increased risk associated with small donors, a normal-sized adult male (>70 kg) donor is suitable for most recipients
LVH	Mild LVH (wall thickness <13 mm by echocardiography and no LVH by ECG criteria) does not preclude recovery, particularly with shorter ischemic times
Valvular lesions	Certain lesions, such as mild or moderate mitral or tricuspid regurgitation, or a normally functioning bicuspid aortic valve may be amenable to repair prior to transplantation
Congenital lesions	Certain lesions, such as a secundum type ASD, may be amenable to repair
Coronary angiography	a. Male donor age 35–45 years and female donor age 35–50 years: perform angiography if there is a history of cocaine use or ≥3 risk factors for CAD b. Male donor age 46–55 years and female donor age 51–55 years: angiography recommended c. Age >55 years: angiography strongly recommended
CAD	Donor hears with mild coronary artery disease should be considered for recipients with relatively urgent need

ABBREVIATIONS: ASD, atrial septal defect; CAD, coronary artery disease; ECG, electrocardiographic; LVH, left ventricular hypertrophy.

Assessment and management of donor left ventricular dysfunction offers the greatest potential to increase heart donor utilization. Strong evidence indicates that younger hearts with left ventricular dysfunction can recover normal function over time in the donor and after transplantation into a recipient. Metabolic abnormalities, anemia, and excessive doses of inotropes should be corrected prior to obtaining an echocardiogram. Aggressive donor management, including pulmonary artery catheterization and hormonal resuscitation, should be performed in donors with an initial left ventricular ejection fraction less than 45%. Table 91-3 shows the heart donor criteria recently modified to potentially expand the available pool of cardiac donors.[17]

PULMONARY EVALUATION

The suitability of donor lungs for transplantation is determined with several diagnostic tests. A chest radiograph should be interpreted by a radiologist or qualified physician. A complete history of the donor's treatment while in the hospital, including the use of vasopressors and results of arterial blood gas analyses, are shared with centers considering the transplantation of lungs. Smoking history should be reported, along with the results of Gram stains of sputum (a specimen for detection of yeasts and fungi is desirable), and a description of the sputum characteristics. In addition, a bronchoscopic examination is performed to assess for signs of aspiration, and to document evidence of a foreign body or presence of blood or other material entering the lower airways from above. It also allows assessment of the character and amount of secretions in the lung and provides microbiologic specimens. A bronchoscopic examination will also promote pulmonary stability in the donor by removing airway secretions that may have accumulated. Blood gases are repeated every 3 hours to assess the results of interventions and to determine trends. Repeat pulmonary recruitment maneuvers are performed to optimize ventilation-perfusion matching.

Wider application of broader criteria for donor selection and procurement is possible and can clearly increase the size of the donor pool. If uniform multidisciplinary donor management protocols were developed, increased lung utilization would follow. Table 91-4 shows the current criteria that are used to determine the suitability of a cadaver lung donor. The Lung Transplant Working Group proposed the new criteria to include virtually any donor up to the age of 65 years, in the absence of significant lung injury from smoking, and absence of cancer with metastatic potential.[8,17,22,23]

In an effort to augment the donor pool, criteria have been loosened with the retrieval of organs from donors with greater smoking histories, infiltrates on radiography, or marginal gas exchange. Because these previously-considered marginal donors, or more appropriately termed "extended" donors, are now being used *any* potential brain-dead patient without obvious contraindication to cadaveric donation should be referred to appropriate local organ procurement agencies for final determination of suitability.[17,23]

TABLE 91-4 Lung Donor Criteria

- P_{O_2}:$F_{I_{O_2}}$ ratio >300, $F_{I_{O_2}} = 1.0$, PEEP = 5 cm H_2O
- Clear chest x-ray
- Age <55 years
- Absence of major chest trauma
- Absent aspiration, sepsis, or purulent secretions
- Smoking history of <20 pack-years
- No history of malignancy

ABBREVIATIONS: $F_{I_{O_2}}$, fraction of inspired oxygen; PEEP, positive end-expiratory pressure; P_{O_2}, partial pressure of oxygen.

RENAL EVALUATION

The discard rate of kidneys procured from cadaveric donors in the U.S. has been increasing to an alarming level of more than 15% of those kidneys recovered for transplantation. Approximately 50% of kidneys from cadaveric donors over 60 years of age (older-age donors) are not transplanted due to donor quality.

The renal system in a cadaveric donor undergoes a number of physiologic changes that are influenced dramatically by both the medical therapies used to prevent brain death and by brain death itself. The results of basic renal function tests such as measurement of serum levels of creatinine and urea nitrogen and urinalysis should be reviewed to provide a profile of renal system function in the donor since admission. When kidney donors are evaluated, the effect of hemoconcentration on the results of these studies should always be considered. Elevated levels of serum creatinine and urea nitrogen and atypical urinalysis findings may suggest that renal function was compromised. The relative risk of dialysis after transplantation is 1.5 times greater in recipients of kidneys from donors >55 years of age vs. those who are <55. Table 91-5[17] shows the latest approved expanded kidney donor criteria, based on the relative risk >1.7 of having a graft failure for donors older than 50 years of age with at least two of the following factors: creatinine >1.5 mg/dL, a cerebrovascular accident (CVA) as a cause of death, and hypertension, as compared to a reference group of nonhypertensive donors between the ages of 10 and 39 whose cause of death was not CVA, and whose creatinine was <1.5 mg/dL.[1,8,17]

LIVER EVALUATION

The assessment of a donor liver before transplantation has been the subject of much research; however, clinically one still relies on a subjective interpretation of donor data and the macro- and microscopic appearance of the liver to decide whether to use the graft. More reliable predictors of graft function are required. Significant efforts have been made to try to assess donor grafts by evaluating different aspects of liver function, including the ability of the liver to synthesize proteins, metabolize drugs, secrete bile, produce high-energy phosphates, and by following the levels of markers of microvascular injury. To date, many donor organs that were previously not considered suitable for transplantation, "marginal" grafts, are now being used in selected circumstances. The marginal donors are identified based on demographic, clinical, laboratory, and histologic data. This includes donor age >70 years or <3 months, donor body weight over 100 kg, moderate or severe macrovesicular fat infiltration of the liver, and abnormal liver function tests. Serum aspartate aminotransferase (AST) >160 IU/L, serum sodium >160 mmol/L, donor stay in intensive care of more than 5 days, significant periods of hypotension (<60 mm Hg systolic BP for more than 30 minutes associated with a rise in serum AST), and significant systemic infection are all parameters considered to define marginal grafts. Important in the assessment of potential grafts is the presence of hepatic steatosis: increased donor age, obesity, and a history of high alcohol intake have all been associated with fatty infiltration.

Donor selection remains highly subjective, and in the absence of reliable laboratory tests the decision whether to use a marginal graft is left to the judgment of the transplant surgeon. The definition of what constitutes a "marginal" or "extended" graft will continue to vary between centers until reliable parameters are available for prospectively predicting early graft function.[17,24,25]

Donor Management

Specific donor management may only begin after the diagnosis of brain death has been firmly established. Brain death is a catastrophic event associated with significant disturbances to many organ systems (Table 91-6).[15] Table 91-7 summarizes the key points of donor management (which are discussed in the following paragraphs) based on the current recommendations.[3,17,27]

Understanding and management of these changes is essential for optimal preservation of organs for transplantation.[8,10,15] In general, there should be a shift in emphasis from more focused cerebral resuscitation, to optimization of oxygen delivery to other organs and tissues. This shift of management may only begin after consent has been obtained from the family. Routine care with frequent turning, protection of the eyes, frequent airway suctioning, physiotherapy to prevent atelectasis and pneumonia, gastric decompression, and limited exposure to prevent hypothermia are important aspects of this regimen. Intensive nursing care is needed, with a 1:1 or even 2:1 nurse:patient ratio.[10]

Successful transplantation of organs from donors is dependent on adequate resuscitation. Potential donors manifest profound hemodynamic and metabolic abnormalities, which can result in a loss of valuable organs. Autonomic instability and hypotension occur in approximately 80% of donors. Even with aggressive management as many as 25% of potential organ donors are lost due to hemodynamic instability. Even more organs are lost as a consequence of the high doses of vasopressors required to maintain adequate perfusion of the brain-dead organ donor.

Hypovolemia from osmotic agents given to treat high intracranial pressure, poorly treated diabetes insipidus, and traumatic blood loss all may contribute to hypotension. A sudden increase in intracranial pressure may cause hypotension and severe bradyarrhythmias because of

TABLE 91-6 Physiologic Changes Associated with Brain Death

Neurologic

parasympathetic stimulation from dural stretch, which is encountered after failure of the Cushing reflex, which causes severe systemic hypertension as a final effort to maintain cerebral perfusion in the face of drastically elevated intracranial pressure. As the vagal cardiomotor centers become ischemic, termination of parasympathetic activity occurs with resulting unopposed sympathetic stimulation. This marked increase in vascular resistance may lead to myocardial ischemia.[10,13]

Animal models have demonstrated profound systemic and pulmonary vasoconstriction with a massive systemic increase in catecholamine levels, termed the *autonomic storm*. This autonomic storm is followed by a transient shift of systemic intravascular fluid volume to the lungs. Cardiac output decreases and left atrial pressure may exceed pulmonary artery pressure. This may result in capillary wall disruption and leakage of protein-rich fluid into the pulmonary interstitium, resulting in pulmonary edema (also referred to as "neurogenic pulmonary edema").[10,13]

A second major injury is the derangement of the hypothalamic-hypophyseal axis, with the associated changes in circulating plasma hormones. The loss of hypothalamic influence and sympathetic tone is characterized by a progressive decrease in serum norepinephrine and a decrease in systemic vascular resistance. This is analogous to a high cervical spinal cord transection. As a result, most potential organ donors require vasoactive agents to maintain blood pressure. The hypothalamic-pituitary axis dysfunction leads to neurogenic diabetes insipidus and a marked decrease in levels of thyroid hormone and cortisol in animal models. In the clinical setting the role these endocrine abnormalities play in the status of donors may vary among donors.[4,8,10,13]

Since the most crucial factor in determining optimal organ viability is the maintenance of adequate systemic perfusion pressure, invasive monitoring is recommended given the complex physiologic changes that are associated with brain death. This is particularly true if the heart and lungs are being considered for donation. Cautious repeated fluid challenges are administered until 10 cm H_2O central venous pressure (CVP) is reached (assuming positive end-expiratory pressure [PEEP] = 5 cm H_2O), thereafter aiming for the lowest CVP that maintains urine output and adequate perfusion pressure maintaining the CVP at 6 to 8 mm Hg. Crystalloid, colloid solutions, and blood products may be infused as indicated. Systolic blood pressure should not be allowed to fall below approximately 90 mm Hg. Red blood cells must be used to maintain a hemoglobin of at least 10 g/dL. Severe coagulopathy should be treated before organ procurement using appropriate blood component therapy. Low doses of dopamine or dobutamine at 2 to 10 μg/kg per minute are traditionally used, although arginine vasopressin at 0.5 to 4.0 U/h is an increasingly favored alternative. The systemic vascular resistance should be kept between 800 and 1200 dynes/s per cm^2. If necessary, a combination of these drugs, each in the lower dosage range, often produce the best results, while maintaining at least 1 mL/kg per hour of urine output. Reduced diuresis despite adequate perfusion pressure can be increased by mannitol administration, at the dosage of 0.25 g/kg as an intravenous bolus. Fluid resuscitation therapy should be guided by data from a central venous catheter or a pulmonary artery catheter, with euvolemia (not hypervolemia) being the target of volume replacement therapy.

Dysrhythmias are quite common and should be treated aggressively. Persistent bradycardia is treated by isoproterenol infusion or even pacing. Minute ventilation should be adjusted to keep the CO_2 and pH in a mild respiratory alkalosis. It is better to reduce the frequency of ventilation rather than tidal volume in order to prevent the development of atelectasis. PEEP is optimized and is regulated to maintain 95% oxygen saturation, and if possible the F_{IO2} should be no higher than 50%. Peak inspiratory pressures (PIP) are also important because high pressure results in barotrauma and impaired venous return to the heart, thereby compromising cardiac output. Pressure control modes of ventilation may be preferable for the minimization of these risks. Ideally PEEP is maintained at <7.5 and PIP at <30 cm H_2O. Bronchoscopy may be necessary for pulmonary toilet, to collect samples for microbiology, and to reinflate atelectatic regions of the lung, thereby decreasing shunting. Bronchodilators should be administered. Continuous full monitoring is of course essential.

Maintenance of normal acid base balance in organ donors is often difficult. Partial pressure of arterial carbon dioxide (P_{CO_2}) should be maintained in the normal range and optimum pH is between 7.35 and 7.45. Glucose consumption is also decreased and parenteral or enteral nutrition must be decreased to around 50% to avoid hyperglycemia and unnecessary metabolic workload. Ongoing nutrition must be maintained, as it is associated with improved graft function, particularly for the liver graft. In the liver, glycogen stores are depleted within 12 hours of brain death, with suggested reduced resistance of the graft to ischemia. Persistent

TABLE 91-7 Important Aspects of Donor Management

1. The airway
Perform bronchoscopy
Use frequent suctioning and aspiration precautions
Use albuterol therapy for wheezing (may improve lung fluid clearance)

2. Mechanical ventilation
Adequate oxygenation:
P_{O_2} >100 mm Hg, $F_{IO_2} = 0.40$ or O_2 saturation >95%
Adequate ventilation:
Maintain tidal volume 10-12 mL/kg
PEEP + 5 cm H_2O
Keep peak airway pressures <30 mm Hg
Maintain a mild respiratory alkalosis (pH 7.35–7.45 and P_{CO_2} 30–35 mm Hg)

3. Monitoring
Central venous line
Arterial line and pulse oximetry
Pulmonary artery catheter desirable for rational use of inotropes, pressors and fluids

4. Fluid management
Judicious fluid resuscitation to achieve the lowest CVP/PCWP consistent with adequate urine output and blood pressure to ensure end-organ perfusion *(euvolemia not hypervolemia)*
Maintenance CVP 6–8 mm Hg, PCWP 8–12 mm Hg
Urine output 1 mL/kg per hour
Colloid as the fluid of choice for volume resuscitation
Albumin with normal PT, PTT; fresh frozen plasma with coagulopathy
Hemoglobin >10g/dL or hematocrit ≥30%
Electrolytes
Maintain Na^+ <150 mEq/dL
Maintain K+ >4.0 mEq/dL
Correct acidosis with sodium bicarbonate and mild to moderate hyperventilation (P_{CO_2} 30–35 mm Hg)

5. Hemodynamic management
Donor resuscitation as outlined above to attain:
BP ≥90 or MAP ≥60 mm Hg
SVR 800–1200 dyn/s per cm^2
Cardiac index 2.4 L/min per m^2
Dopamine or dobutamine dose <10μg/kg per minute
Arginine vasopressin: 1 unit bolus, then 0.5–4.0 U/h drip

6. Hormonal resuscitation
Methylprednisolone: 10–15 mg/kg bolus (repeat q24h prn)
Arginine vasopressin: titrate to BP
Insulin: drip at a minimum rate of 1 U/h (titrate blood glucose to 120–180 mg/dL)
Triiodothyronine (T_3): 4μg bolus; 3μg/h continuous infusion

7. Early echocardiogram for all cardiac donors
Insert pulmonary artery catheter to monitor patient management (placement of the PAC is particularly relevant in patients with an EF <45% or on high-dose inotropes)
If EF <45%, need to optimize hemodynamic and hormonal management and then reassess

ABBREVIATIONS: CVP, central venous pressure; EF, ejection fraction; F_{IO_2}, fraction of inspired oxygen; MAP, mean arterial pressure; PEEP, positive end-expiratory pressure; P_{CO_2}, partial pressure of carbon dioxide; PCWP, pulmonary capillary wedge pressure; P_{O_2}, partial pressure of oxygen; PT, prothrombin time; PTT, partial thromboplastin time; SVR, systemic vascular resistance.

hyperglycemia despite reduced glucose administration can be treated with insulin. Loss of the hypothalamic-pituitary axis can result in diabetes insipidus. Associated electrolyte abnormalities are hypernatremia, hypocalcemia, hypokalemia, hypophosphatemia, and hypomagnesemia. In addition, the variety of strategies used to treat intracranial pressure may exaggerate the hypernatremic state. Aggressive correction of the electrolyte state should be performed and levels should be checked every 4 hours in order to prevent development of lethal dysrhythmias, myocardial dysfunction, and rhabdomyolysis. Sodium levels should be kept <155 mEq/dL, as liver primary graft nonfunction has been associated with hypernatremia. The diagnosis of central diabetes insipidus is easily made when more than 4 mL/kg per hour of dilute urine is produced while the serum sodium is above 145 mmol/L. Hypotonic fluids can be used to restore intravascular volume with a simple volume-for-volume replacement of the urine. Development of hyperglycemia may be caused by the

dextrose or glucose in the hypotonic intravenous fluids; but on the other hand, it will help restore glycogen liver reserves in a setting of inadequate nutritional support. More practical is to use desmopressin (DDAVP) in a loading dose of 8 ng/kg, followed by an infusion of 4 ng/kg per hour and a reassessment and titration up or down every 30 minutes; alternatively, a 1-μg bolus every 2 hours can be used as long as the urine output remains >300 mL/h. DDAVP has a longer half-life and minimal vasopressor activity (2000:1) as compared to arginine vasopressin. Arginine vasopressin is particularly useful in hypotensive patients in a continuous infusion of aqueous vasopressin at the dosage of 0.5 U/hr, which can be titrated as necessary by monitoring the urine output. A relatively small percentage of organ donors are resistant to aqueous vasopressin. In these cases desmopressin acetate should be considered.

Warmed intravenous fluid, heated humidified oxygen, and warming blankets may need to be used to limit hypothermia. The core temperature should be maintained above 35°C. Hypothermia contributes to donor hemodynamic instability, myocardial depression, severe dysrhythmias, and coagulopathy, and may even cause cold diuresis and also predispose to sepsis. It is much better to prevent hypothermia, because once it has occurred it may be difficult to correct.

The recognition of the metabolic derangements following brain death, including autonomic storm and hypothalamic-pituitary axis dysfunction, has highlighted the need for hormonal resuscitation as an integral part of the donor management protocol.[3–6,8,26–29]. The recommended hormonal resuscitation consists of methylprednisolone in a 10–15 mg/kg bolus; triiodothyronine in a 4-μg bolus followed by a continuous infusion of 3 μg/h; arginine vasopressin in a 1-unit bolus, then a continuous infusion at 0.5 to 4 U/h, titrated to a systemic vascular resistance of 800 to 1200 dynes/s per cm^2; and insulin 1 U/h titrated to maintain blood sugar at 120 to 180 mg/dL.[6] The use of steroids is based on the intensive effort to increase the number of usable lungs given the low recovery rate of lungs from potential donors. Retrospective studies have repeatedly showed that high-dose steroid administration improved oxygenation in the brain-dead donor and was associated with increased rates of successful donation.[30,31]

Though initial evidence showed that vasopressin used with epinephrine maintains hemodynamic stability and tissue viability, its implementation was not adopted universally. Rather DDAVP was used, with the assumption that the effectiveness of arginine vasopressin was related to its treatment of the diabetes insipidus that is commonly found in organ donors. DDAVP is an analogue that is highly selective for the vasopressin V_2-receptor subtype that is found in the renal collecting ducts, and has no vasopressor activity in humans, which is mediated by V_1-receptors on vascular smooth muscle. Arginine vasopressin was in fact abandoned due to concerns that the vasoconstrictive effect could be harmful for donor organs. This resulted in unnecessarily excessive fluid resuscitation with crystalloid, colloid, and blood products, along with higher doses of vasopressor agents with widely recognized adverse effects. Many transplant centers consider a donor heart to be unsuitable if dopamine requirements exceed 10 to 15 μg/kg per minute, because at such doses it can also affect both kidney and liver.[27]

Hemodynamic instability has also been suggested to be a consequence of diminished levels of circulating thyroxin, leading to reduced myocardial energy stores and a shift from aerobic to anaerobic metabolism, with the subsequent accumulation of lactate. These observations were initially described in animal studies, and the administration of thyroid hormone replacement to human brain-dead donors has shown improvement in the cardiovascular status of donors, with reduction in the inotropic support, particularly in hemodynamically unstable organ donors. This benefit is most pronounced in cardiac transplantation and heart graft function.[26]

Considerable debate is ongoing regarding the role of thyroid hormone therapy in the management of organ donors. Several studies have shown no correlation between thyroid hormone levels and hemodynamic status. Some observed no beneficial effect and a trend toward worsening metabolic acidosis following thyroid hormone administration. Contrarily, the implementation of the three-hormone resuscitation therapy, with methylprednisolone, arginine vasopressin, and triiodothyronine or levothyroxin, has been associated with an increased number of transplanted hearts and improved short-term graft function.[26,27] The selection of donors who are predicted to benefit from hormonal resuscitation has been outlined. After conventional management to adjust volume status, anemia, and metabolic abnormalities, the recommendation is that an echocardiogram be obtained to rule out structural abnormalities and document the ejection fraction. If the ejection fraction is <45%, a pulmonary artery catheter is placed and hormonal resuscitation is instituted. Subsequent cardiac function can be monitored using the pulmonary artery catheter.

Chapter 92

PRIORITIES IN MULTISYSTEM TRAUMA

JAMEEL ALI

KEY POINTS

- *To improve survival, injury management must be prioritized in the multiply injured patient.*
- *The order of priority among injuries is related to time and degree of life threat posed by each injury.*
- *Immediate priority is given to airway control and to maintenance of ventilation, oxygenation, and perfusion.*
- *Cervical spine protection is crucial during airway intubation.*
- *A trauma team leader is important to coordinate management in the multiply injured patient.*
- *Complete familiarity with techniques for airway control, chest decompression, and the establishment of intravenous access is essential in management of multiple trauma.*
- *Complete in-depth assessment of the multiply injured patient is required only after immediately life-threatening injuries have been treated.*
- *Repeated assessment is necessary to diagnose and treat injuries that are not obvious on initial presentation.*

Mortality from multiple injuries follows a trimodal distribution.[1,2] The first peak represents death occurring at the scene and results from such injuries as cardiac rupture or disruption of the major intrathoracic vessels, and severe brain injury that is incompatible with survival. Death from such injuries occurs within minutes of the traumatic event and medical intervention is usually futile. The second peak in mortality following multiple injuries occurs from minutes to a few hours after the event. Mortality during this phase is related to injuries that are immediately life-threatening, such as airway compromise, tension pneumothorax, and cardiac tamponade. This is also a period during which simple appropriate resuscitative measures can significantly affect the outcome. The third peak occurs as a result of complications of the injury, such as sepsis or multiple-system organ failure.[3] However, mortality in this third phase can also be significantly affected by the type of intervention during the second phase. The intensivist dealing with the multiple trauma patient is very likely to be involved in the institution of resuscitative measures during the second phase as well as the management during the third phase of the complications of the injury or complications arising from inadequate treatment. Many of the chapters in this text deal with the complications of trauma, such as sepsis and multiple organ failure. This chapter will deal with treatment priorities during the second peak of the trimodal distribution of trauma-related mortality.

Blunt trauma from motor vehicle collision is the most frequent cause of injuries in general. This type of impact usually results in injuries to many different parts of the body simultaneously. Figure 92-1 shows the distribution of motor vehicle driver injuries over a 2-year period at Sunnybrook Health Science Centre in Toronto, Canada, where 338 drivers with 2566 injuries were treated. Head and neck injuries were the most frequent, occurring at a frequency of 1.88 per patient, and the overall frequency of injuries was 7.6 per patient.

When faced with multisystem injury, the intensivist must prioritize treatment according to the threat to the patient's survival.[4] Prioritization of assessment and intervention requires a coordinated team approach. Where personnel are available from different specialties, it is of paramount importance that the entire resuscitative effort be coordinated through an identified team leader. This very simple decision should be made prior to institution of therapy and can be critical to the outcome in the patient with multisystem trauma. The team leader, who may be an intensivist, must be completely familiar with a wide variety of injuries and the relative threat they pose to life in order to prioritize intervention and direct personnel appropriately.

Certain fundamental concepts underlie the approach to resuscitation of the multiply injured patient. The most important of these is that immediately life-threatening injuries should be treated as they are identified. Therefore, assessment and resuscitation must proceed simultaneously. The initial goal in managing the trauma patient is to provide adequate oxygenation and perfusion. This goal is achieved by approaching assessment and treatment so that abnormalities in the injured patient that affect oxygenation and perfusion take top priority. It is also of prime importance to recognize findings that suggest a need for emergent surgical intervention.

Priorities

The order of priorities is a key feature for successful management of the multiply injured patient and should adhere to the following sequence:

1. Establishment of the airway and of oxygenation and ventilation with cervical spine control
2. Control of hemorrhage
3. Maintenance of adequate perfusion
4. Identification and correction of neurologic abnormalities
5. Total exposure of the patient to allow complete assessment while preventing hypothermia by minimizing the duration of this exposure
6. Temporary stabilization of fractures
7. Detailed systematic assessment and provision of definitive care

In the Advanced Trauma Life Support (ATLS) course for physicians,[1] steps 1 to 5 constitute the Primary Survey, during which immediately life-threatening injuries are identified by adhering to the sequence ABCDE, where A stands for *a*irway, B for *b*reathing, C for *c*irculation and hemorrhage control, D for neurologic *d*isability, and E for *e*xposure.

The basis for this order of priorities is the degree to which abnormalities in the different systems threaten the life of the patient. Adherence to this order allows assessment and resuscitation to occur simultaneously, because injuries will be identified in the order in which they are likely to threaten the patient's life. Although the patient with multiple fractures

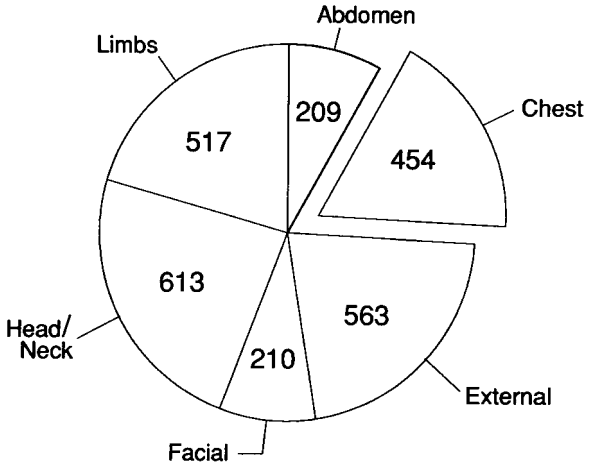

FIGURE 92-1 Injuries in 338 motor vehicle drivers (total = 2566 injuries). As indicated in the text, most of these patients had injuries to the head and neck area, and the average number of injuries per patient was 7.6.

requires treatment of these fractures, apart from hemorrhage control associated with the fractures, such treatment should take lower priority compared to treatment of abnormalities affecting the airway or respiratory status.

Complete evaluation requires assessment of the entire front and back of the patient, necessitating full exposure. Once this assessment is completed, the patient should again be covered to minimize heat loss and the risk of hypothermia.

AIRWAY, OXYGENATION, VENTILATION, AND CERVICAL SPINE CONTROL

The most frequent cause of airway obstruction in the multiply injured patient is loss of tone of the muscles supporting the tongue, either because of hypoperfusion of the brain from hypovolemic shock or because of central nervous system (CNS) injury. As outlined in Chaps. 15 and 35, the simple maneuvers of chin lift and jaw thrust move the mandible forward. Because the tongue muscles are attached to the mandible, these actions move the tongue anteriorly and open the upper airway. It is essential in the trauma victim to inspect the oropharynx to ensure that there is no foreign material (including vomitus) in the pharynx that will occlude the airway. Quick observation of the patient's nares and mouth and listening for unobstructed passage of air through the upper airway, together with inspection for the presence of foreign objects in the oropharynx, are all very simple maneuvers that should be undertaken in the initial care of the multiply injured patient. The patient who is fully conscious, vocalizing and breathing adequately, and who is not in shock does not require an artificial airway.

The underlying principle of establishing an airway in the trauma victim is to institute the simplest technique that allows effective oxygenation and ventilation. Over 90% of patients do not require endotracheal intubation. Measures short of endotracheal intubation include the insertion of oropharyngeal or nasopharyngeal tubes. However, when endotracheal intubation is necessary, it should be performed promptly and expeditiously. Prolonged unsuccessful attempts at endotracheal intubation without oxygenation and ventilation should be avoided. Mask ventilation with oxygen and an oropharyngeal airway should be performed intermittently to avoid hypoxia during prolonged attempts at endotracheal intubation. All multiply injured patients should have oxygen administered by the most appropriate means as early as possible. A pulse oximeter should be attached to monitor O_2 saturation, which should be maintained at 95% or greater.

In very rare circumstances, the patient's airway may not be patent and it may be impossible to establish an airway nasally or orally. In such situations, cricothyroidotomy is required. This procedure should only be done when an airway cannot be established by other, nonsurgical means. The landmarks for the cricothyroid membrane are indicated in Fig. 92-2. A cricothyroidotomy may be done using a large-bore needle or scalpel, the former method being preferable in children under 8 years of age because the cricoid cartilage is essential to the stability of the upper airway of infants and young children. A 14-gauge needle and cannula may be inserted through the cricothyroid membrane for temporary oxygenation, but this is not a very efficient means of ventilation. To maximize oxygenation and avoid hypercapnia, the needle cricothyroidotomy should be followed by tracheostomy in an operating room under ideal circumstances if a surgical airway is still required. The placement of the cricothyroidotomy needle allows approximately 30 to 45 minutes of adequate oxygenation without severe hypercapnia. The surgical cricothyroidotomy is preferable and more effective in adults. A transverse skin incision is made directly over the cricothyroid membrane, and after the subcutaneous structures are reflected, the cricothyroid membrane is identified and incised transversely. A pair of forceps is then inserted to spread the opening, and a tube of appropriate caliber, usually a 6F or 7F tracheostomy or endotracheal tube, is inserted through the opening and secured.[5]

Many techniques for establishing an artificial airway are associated with risks of cervical spine injury. Awareness of these risks during airway intubation is crucial in preventing spinal cord injury in the multiply injured patient. Inappropriate manipulation of the cervical spine during airway intubation could convert an unstable cervical spine injury without neurologic deficit into one with permanent neurologic deficits, including paraplegia, quadriplegia, and even

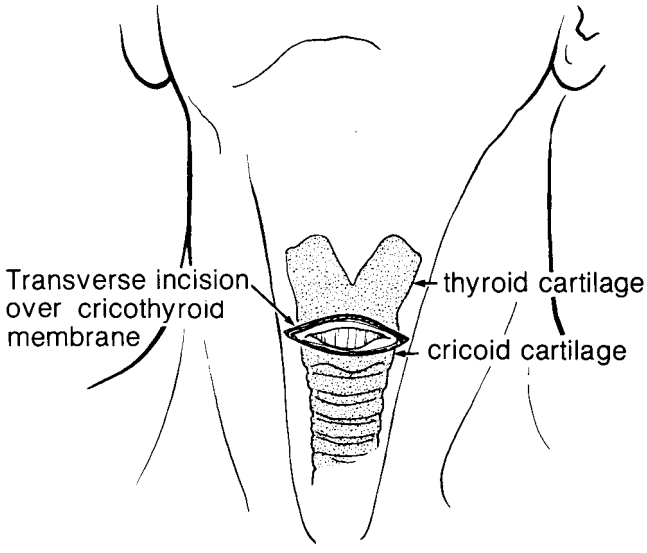

FIGURE 92-2 Landmarks for cricothyroidotomy.

death. In a patient who is unconscious or who is suspected of having a cervical spine injury, the neck should not be flexed, extended, or rotated. In-line immobilization with the neck in the neutral position should be maintained while the airway is secured. If the patient is conscious and breathing, then a blind nasotracheal intubation may be attempted with cricoid pressure anteriorly. If the patient is apneic, then orotracheal intubation with in-line cervical immobilization will have to be attempted. Failure or inability to secure the airway by nonsurgical means in a patient who requires a definitive airway necessitates cricothyroidotomy. Where fiberoptic bronchoscopy is immediately available, it may be used to facilitate endotracheal intubation. All unconscious patients or patients suspected of cervical spine injury should have a lateral cervical spine x-ray done as a minimum, and all seven cervical vertebrae and the superior aspect of the first thoracic vertebra should be clearly visualized. Failure to visualize all these vertebrae should necessitate other views of the spine, including a swimmer's view. An open-mouth anteroposterior odontoid and anteroposterior x-ray view of the cervical spine should also be done. If there is doubt as to the presence of a cervical spine injury, the neck should be immobilized with a semirigid cervical collar and computed tomography (CT) is performed to assess the integrity of the cervical spine. If the patient is awake and alert and has no cervical pain or tenderness or other abnormality on physical examination, then the cervical collar may be removed after adequate cervical spine x-rays. In the presence of clinical signs of spinal cord injury, the cervical spine is considered to be abnormal even if the cervical spine x-ray appears normal. In selected patients who have not had a period of unconsciousness or another painful distracting injury, and are alert and have no clinical evidence of cervical spine injury, x-rays of the cervical spine may be omitted and the cervical collar removed.[6,7]

Adequacy of ventilation is quickly assessed by observation of the chest for asymmetrical or paradoxical movement, followed by quick auscultation and percussion to determine whether there is any hyperresonance or dullness to suggest pneumothorax or hemothorax. Deviation of the trachea suggests the presence of a pneumothorax or hemothorax, but this finding is not always evident. Although one may confirm the diagnosis of a simple traumatic pneumothorax with an upright chest x-ray, suspicion of a tension pneumothorax requires immediate decompression, without prior x-ray confirmation. Further examination of the chest should be conducted to determine the presence of other life-threatening thoracic injuries, such as cardiac tamponade, open pneumothorax, flail chest, ruptured thoracic aorta, and massive hemothorax (see Chap. 95).

ADEQUACY OF PERFUSION

After airway control, oxygenation, and adequate ventilation have been secured, the next priority is maintenance of adequate perfusion. The most common source of hypoperfusion in the multiply injured patient is hemorrhage. Its clinical presentation will depend on such factors as the patient's age, as well as the duration and magnitude of the hemorrhage. The presence of a normal or even elevated blood pressure, particularly in the young patient, does not rule out blood loss. The physiologic response to hypovolemia includes sympathetic discharge with vasoconstriction and tachycardia, which will tend to maintain the blood pressure. Older patients tend to manifest hypotension much earlier in the course of hypovolemia. Therefore, other signs of hypoperfusion should be sought in assessing the trauma patient. The location and character of the pulse, the skin color, and capillary refill time are all signs that are immediately accessible to the examining physician and should be used in determining adequacy of perfusion. Failure to palpate a radial pulse may signify hypotension of the order of 70 to 80 mm Hg. Tachycardia with cool extremities suggests hypoperfusion from hemorrhage until proven otherwise. Hemorrhage may be subdivided into classes I to IV,[1] each class having an associated clinical response, as indicated in Table 92-1. The patient who has a normal heart rate with a strong, bounding radial pulse, warm skin, and a capillary refill time of less than 2 seconds would be considered not to have lost any significant volume of blood, and the degree of deviation from these clinical parameters would correlate with the magnitude of blood loss.

Although the most common cause of hypoperfusion in trauma patients is hemorrhage, other causes, such as tension pneumothorax, cardiac tamponade, myocardial contusion, open pneumothorax, and flail chest must be considered. Hypoperfusion in the trauma patient first requires a search for a source of hemorrhage, which should be immediately controlled. Any external source of hemorrhage should be controlled by direct pressure, without resorting to blind application of clamps or tourniquets. Improving the hemodynamic status should be the next goal. This should be accomplished by appropriate fluid replacement through at least two large-bore intravenous catheters (14 to 16 gauge minimum). It is very helpful to establish multiple IV catheters, not only to facilitate rapid volume infusion, but to ensure that an IV line will still be available if one of the catheters becomes disconnected, plugged, or otherwise nonfunctional. In the adult, the preferred peripheral percutaneous intravenous site is in the forearm or the antecubital vein. Failure to establish intravenous access through these routes should prompt establishment of intravenous access by other routes such as the internal jugular or subclavian vein in the neck or femoral vein in the groin using the Seldinger technique. Venous cutdown of the saphenous vein at the ankle or the antecubital vein or the femoral vein at the groin are other approaches, but are now seldom necessary because of the success in establishing access through the other nonsurgical routes. The route will depend on the experience and skill of the physician. Placement of central lines should always be followed by a chest x-ray as soon as feasible, not only to confirm proper location of the catheter, but also to check for the presence of pneumothorax or hemothorax. Because these lines are placed under less than ideal conditions, the risk of septic complications is high, and the lines should be replaced later under more sterile conditions. In children under age 6 years, the intraosseous route should be attempted before proceeding to the central venous routes. With specially designed devices the intraosseous route is also possible in adults but is seldom required.[8] As a rule, it is best to avoid placing IV catheters in limbs that have major soft tissue or bony injuries. The intensivist must be completely familiar with the usual sites for venous access and also be prepared to proceed to venous cutdown where percutaneous techniques are not successful. Venous access should be achieved promptly, since cannulation

TABLE 92-1 Clinical Classification of Shock in a 70-kg Male

Criterion	Class I	Class II	Class III	Class IV
Blood loss (mL)	Up to 750	750–1500	1500–2000	≥2000
Blood loss (% blood volume)	Up to 15	15–30	30–40	≥40
Pulse rate (beats per minute)	<100	>100	>120	≥140
Blood pressure	Normal	Normal	Decreased	Decreased
Pulse pressure (mm Hg)	Normal or increased	Decreased	Decreased	Decreased
Capillary refill test	Normal	Positive	Positive	Positive
Respiratory rate	14–20	20–30	30–40	>35
Urine output (mL/h)	≥30	20–30	5–15	Negligible
CNS (mental status)	Slightly anxious	Mildly anxious	Anxious and confused	Confused or lethargic
Fluid replacement (3:1 rule)	Crystalloid	Crystalloid	Crystalloid + blood	Crystalloid + blood

NOTE: The clinical signs of shock are very subtle for class I and II hemorrhage, but it is crucial to make the diagnosis at this stage before deeper levels of shock ensue. This is ensured by prompt fluid resuscitation. When crystalloid is used to replace estimated blood loss, a very rough guide is the 3:1 rule, according to which the estimated amount of blood lost should be replaced by three times as much crystalloid to produce a similar effect on vascular volume. This rule is only a guideline, however, and the adequacy of perfusion should be the end point for determining adequacy of fluid resuscitation.
ABBREVIATION: CNS, central nervous system.
SOURCE: Reproduced from the Committee on Trauma, American College of Surgeons.[1]

of the veins becomes more difficult as shock continues, owing to venoconstriction and venous spasm.

In the course of establishing IV access, blood is drawn for complete blood count, cross-matching of blood, coagulation, and toxicology screens. Prior to the availability of blood products, it is essential to maintain adequate perfusion, as judged by clinical indicators, including blood pressure, pulse, status of the neck veins, and urinary output. In most circumstances, there is sufficient time to obtain the patient's blood type. However, if after approximately 2 to 3 L of crystalloid have been given, the patient's vital signs do not normalize or normalize only temporarily, and typed blood is not available, then emergency blood (group O) will be required for resuscitating the patient. Packed cells in the amount of anywhere from 4 to 10 U should be ordered for resuscitating the patient with major hemorrhage.

If there is no obvious external source of hemorrhage, bleeding from pelvic or extremity fractures should be sought. Failure to demonstrate blood loss in these areas suggests that the blood loss is in either the thorax or the abdomen. Most sources of thoracic hemorrhage can be identified by a combination of physical examination and chest x-ray. Therefore by a process of elimination it is usually possible to determine the source of the hemorrhage. If the areas identified earlier do not represent the source of hemorrhage, the most likely source is intra-abdominal. If the patient shows signs of continued hemorrhage with only a transient response or failure to respond to volume infusion, laparotomy may be required for the identification and control of intra-abdominal hemorrhage. In some cases in which there is an obvious source of blood loss such as an extremity fracture, there may still be uncertainty regarding possible concurrent intra-abdominal hemorrhage. In these situations, ultrasonography, diagnostic peritoneal lavage, or CT of the abdomen (see Chap. 95) is helpful in determining whether or not there is an intra-abdominal source of hemorrhage.[9,10]

As indicated earlier, other causes of hypoperfusion should be sought in the trauma patient by assessing for such signs as those of cardiac tamponade, myocardial contusion, and tension pneumothorax, with prompt institution of corrective measures.[11] These intrathoracic causes of hypoperfusion are discussed in Chap. 95.

In patients sustaining major blood loss, end points of resuscitation and the volume of infused fluids should be based on the rapidity with which such patients can be taken to the operating room for definitive control of hemorrhage. In patients without major head injury, particularly those with penetrating torso trauma, borderline hypotension in the range of 90 mm Hg systolic should be the goal in preparation for the operating room, since massive volume infusion towards normalization of the hemodynamic status could aggravate blood loss.[12,13]

In evaluating the patient's response to volume infusion, it is important to recognize that massive blood loss may trigger a vagally mediated bradycardia, and that in these circumstances the absence of tachycardia does not represent adequate volume resuscitation.[14] When one is judging the amount of fluid required and the requirement for blood, a useful guideline is that if blood pressure has not approached normalcy after infusion of 50 mL/kg of crystalloid, then blood administration should be considered.[15] As indicated earlier, if type-specific blood is not available, then emergency type O packed red blood cells may be used. Because one of the most common causes of hypothermia and its complications is the rapid infusion of cold solutions in the resuscitation of trauma patients, techniques for warming both the patient and the infused fluid must be employed.[16,17] In addition to electrocardiographic monitoring and continued assessment of vital signs, core temperature monitoring is therefore important, using a device that is capable of reading temperatures at hypothermic levels.

Although volume deficit is the major cause of hypoperfusion in the trauma patient, failure to respond to adequate volume infusion may represent cardiovascular decompensation. If such causes as cardiac tamponade or tension pneumothorax have been ruled out as the cause of this cardiovascular decompensation, consideration should be given to the use of inotropes and vasoactive agents to support the circulation in these circumstances. Such intervention is accomplished with close hemodynamic monitoring, as outlined in earlier chapters.

In situations in which the hypoperfused patient fails to respond to massive fluid infusion and there is no obvious nonhemorrhagic source of the hypoperfusion, emergency

thoracotomy[18,19] may be required. This allows (1) identification and treatment of pericardial tamponade, (2) internal cardiac massage, (3) identification and control of intrathoracic hemorrhage, and (4) cross-clamping of the thoracic aorta to maintain cerebral perfusion and coronary blood flow while decreasing bleeding from a subdiaphragmatic source. Emergency thoracotomy also allows the diagnosis and treatment of air embolism, which is discussed in Chap. 95.

NEUROLOGIC STATUS

Following control of the respiratory and circulatory status, attention is directed at assessment and management of the neurologic status. The hallmark of CNS injury is a change in the level of consciousness. Therefore it is essential that the level of consciousness be defined, so that repeated assessment will detect any changes over time. The Glasgow Coma Scale score (GCS; see Chaps. 67 and 93) is the generally accepted means of establishing this level of consciousness in the trauma patient.

The brain is very sensitive to hypoxia and hypoperfusion, and one of the most common causes of a depressed level of consciousness in the multiply injured patient is uncorrected hypovolemia resulting in hypoperfusion and cerebral hypoxia. Therefore, overall resuscitative measures aimed at maintaining vascular volume and arterial oxygenation are of prime importance in the treatment of a patient with a possible head injury. Volume restriction as a primary goal, with the aim of decreasing intracranial pressure and cerebral edema, is inappropriate in the hypovolemic head-injured patient. In fact this approach is more likely to aggravate the head injury and increase cerebral edema and intracranial pressure. The key features of initial assessment and resuscitation of the brain-injured patient are to prevent secondary brain injury due to hypoperfusion and hypoxemia, control of cerebral edema, and identification and evacuation of significant mass lesions based on careful clinical and CT scan assessment under the guidance of a qualified neurosurgeon. The detailed assessment and management of such patients is discussed in Chap. 93.

FRACTURE STABILIZATION

Although the most dramatic injury in the multiply injured patient is frequently the mangled limb resulting from major fractures, fractures as such do not pose an immediate threat to life, and therefore are generally lower in our list of management of priorities. However, the secondary effects of fractures may have high priority. For instance, massive hemorrhage associated with a fracture will require direct control of the hemorrhage where possible, aggressive early fluid resuscitation, reduction of the fracture, and in the case of massive hemorrhage from pelvic fractures, the use of such techniques as external fixation. Time is also of the essence in the management of fractures when there is interference with the blood supply to the limb, as from spasm of the blood vessels or direct injury to the blood vessels adjacent to the fracture. Early assessment of neurovascular integrity and the correction of any abnormality are essential in the management of fractures to ensure limb salvage and to prevent rhabdomyolysis and compartment syndrome. Limb ischemia associated with the fracture should be initially treated by reduction of the fracture and immobilization. If this maneuver fails to restore perfusion, early angiographic assessment should be undertaken. To improve the chances of saving the limb, the period of limb ischemia should be less than 4 to 6 hours. Therefore all efforts should be made to obtain early angiography and definitive repair of the vascular injury associated with a fracture. The possibility of compartment syndrome should be kept in mind, particularly after perfusion has been re-established to a previously ischemic limb. Definitive management of the fracture itself is discussed in Chap. 96.

DETAILED SYSTEMATIC ASSESSMENT AND DEFINITIVE CARE

Once the initial rapid assessment and resuscitation of the patient has been completed, a more in-depth assessment is conducted systematically, beginning with the head and ending with the lower extremities. The multiply injured patient must be completely undressed so that a complete physical examination can be done. This includes assessment of the back and requires careful log-rolling of the patient to visualize the back while protecting the spinal column. X-rays of the thoracolumbar spine should be considered in unconscious patients or those with major torso trauma with or without neurologic deficit, and in those in whom the mechanism of injury suggests the possibility of spinal column injury. Until adequate radiologic assessment is complete, these patients should be moved with caution by log-rolling, and any rotation, flexion, or extension of the thoracolumbar spine should be avoided.

All multiply injured patients should have (1) large-bore intravenous access, (2) a nasogastric tube to decompress the stomach and monitor for evidence of upper gastrointestinal hemorrhage (unless contraindicated, as discussed below), and (3) a transurethral Foley catheter for monitoring urine output, unless contraindicated by the presence of a urethral injury. Patients in whom urethral injury may be present include those with a major pelvic fracture, perineal and scrotal ecchymosis, or bleeding through the urethral meatus, and those in whom a high-riding, boggy prostate is found on rectal examination. If these signs are present, a urethrogram should be performed; only if the results are normal should the Foley catheter be inserted per urethra. The presence of a cribriform plate fracture is a relative contraindication to insertion of a nasogastric tube.[20,21] Gastric decompression in this situation should be achieved by orogastric intubation.

If a rectal examination has not already been conducted to rule out a urethral injury prior to the insertion of a urethral catheter, it should be done as part of the complete assessment. The rectal examination not only assesses the integrity of the rectum, but provides information on the presence of blood in the gastrointestinal tract, the possibility of extrarectal pelvic injury (bony as well as soft tissue, e.g., injury of the prostatic urethra), and the presence of rectal sphincter tone, which may be abnormal in patients with spinal cord injury. During this phase of the assessment, potentially life-threatening injuries or injuries that are likely to produce morbidity and require correction on a nonurgent basis are detected. If the techniques of inspection, percussion, palpation, and auscultation are used appropriately, injuries such as simple pneumothoraces, uncomplicated fractures, and soft tissue wounds are detected and managed.

Reduction and stabilization of uncomplicated fractures are conducted once the life-threatening injuries have been

treated. The tetanus immunization status of the patient should be determined, and appropriate prophylactic measures instituted. The trauma flow sheet should be completed, and the use of agents such as tetanus toxoid should be clearly documented and must be available for continued reference during the patient's stay in the ICU. It is at this point that subspecialty services such as plastic surgery and otolaryngology may be consulted.

Repeated examination of the trauma patient is important so injuries that are not obvious at presentation may be diagnosed and treated appropriately. The mechanism of the injury should be carefully noted in the history, and a high index of suspicion is required so that occult injuries are not missed. Patients who are relatively stable but who have been involved in a collision in which there is an associated fatality must be monitored very carefully in an ICU setting, since it must be assumed that they were exposed to the same force and energy transfer as the dead victim. Such patients may have temporarily contained hematomas in the spleen, liver, or retroperitoneum or around major vascular structures. These patients can decompensate abruptly with sudden spontaneous hemorrhage. Slowly progressive tachycardia, hypotension, a fall in hemoglobin concentration, or any worsening of abdominal findings, such as increasing pain or signs of peritoneal irritation, should warrant aggressive investigation and consideration of intervention, including surgical exploration. For these high-risk patients, approximately 4 to 6 U of blood should be available at all times in the early phase of treatment. An unexplainable fall in hemoglobin concentration must be considered a sign of continued hemorrhage, and any sudden increase in heart rate or decrease in blood pressure must be considered signs of major hemorrhage. The source of this hemorrhage should be identified promptly and treated appropriately. A more subtle sign of impending hemodynamic instability is a progressive decrease in urine output despite volume replacement that appears to be adequate in relation to the recognized injuries. Deterioration in the respiratory status should prompt assessment for the presence of a pneumothorax, lung contusion, or another type of subtle injury, such as a ruptured esophagus with pleural effusion that may present later in the patient's course. Delayed cardiac decompensation without obvious blood loss should warrant investigation for myocardial contusion, cardiac tamponade, or tension pneumothorax. The latter condition may develop on institution of positive pressure ventilation in a patient who sustained a simple pneumothorax which was not treated by tube thoracostomy. As discussed in Chaps. 42 and 95, the clinical presentation and operative findings may suggest the possible development of traumatic abdominal compartment syndrome in the ICU, prompting decompression of the abdominal cavity to improve the patient's cardiorespiratory and hemodynamic status.[22] Respiratory deterioration may also occur in spontaneously breathing patients who sustained a rupture of the diaphragm and in whom the abdominal viscera at first remained in the abdominal cavity but later migrated above the diaphragm, causing respiratory compromise. For these reasons, continuous close monitoring in an ICU setting is crucial to improving survival of the multiply injured patient.

X-rays are obtained as indicated. In most multiply injured patients, these will include cervical spine x-rays if there is any suggestion of cervical spinal injury, a chest x-ray, and an x-ray of the pelvis. Other radiologic investigations will be undertaken as indicated by the assessment, such as the presence of deformity in an extremity warranting x-ray to confirm a fracture.

Deciding on Surgical Intervention

One of the most important decisions to be made in the emergency management of the trauma patient is whether or not surgical intervention is necessary. If the decision based on the initial assessment is that surgery is not warranted, then continued observation in an intensive care setting is necessary for most multiply injured patients. This approach, combined with a high index of suspicion, will minimize the risk of overlooking occult injuries, such as a subcapsular hepatic hematoma in a patient who is stable initially, which carries the potential for major sudden hemorrhage and hypovolemic shock.

In considering the need for surgical intervention, the common emergency indications are for thoracic, abdominal, and intracranial injuries. For thoracic injuries, this includes an uncontrollable pneumothorax representing a major airway laceration, a massive hemothorax usually representing laceration of a systemic artery (e.g., intercostal or internal mammary) or central pulmonary vessel, a widened mediastinum or other sign of aortic disruption, or signs of a ruptured esophagus, cardiac tamponade, or air embolism. The hypovolemic patient who suddenly becomes asystolic or suffers electromechanical dissociation is also a candidate for emergency thoracotomy. The details of assessment and management of these indications for thoracic surgery are considered in Chap. 95. The indications for laparotomy in the multiply injured patient are signs of peritoneal penetration, perforation, or hemorrhage in general; these are discussed in more detail in Chap. 95.

The indication for surgical intervention in head injuries is usually a change in level of consciousness in the presence of a mass lesion requiring evacuation or placement of an intracranial pressure monitoring device (see Chap. 93).

Chapter 93

HEAD INJURY AND INTRACRANIAL HYPERTENSION

RICHARD J. MOULTON
LAWRENCE H. PITTS

KEY POINTS

- *Secondary brain injury from hypoxia and ischemia should be prevented by appropriate airway ventilatory and fluid management in all comatose patients.*
- *In appropriately selected patients aggressive monitoring and treatment of intracranial pressure is warranted.*
- *Early identification and evacuation of operable intracranial hematomas can be life-saving.*
- *Change in the level of consciousness is one of the hallmarks of brain injury. Its recognition through careful history, physical examination, and close monitoring is therefore essential.*
- *Prophylaxis and aggressive treatment of seizures following head injury must be instituted.*
- *Maintenance of normal fluid and electrolyte balance and early provision of enteral nutrition is necessary.*
- *Risk of central nervous system infection is reduced by surgical débridement and restoration of dural integrity in cases of open cranial injury.*
- *Systemic sepsis often complicates recovery and should be diagnosed and treated aggressively.*

Epidemiology and Etiology of Head Injury

The incidence of head injury in the United States is approximately 200 to 400 per 100,000 population per year. Similar incidence rates have been documented for other countries. Male-to-female incidence ratios vary between 2:1 and 3:1, and incidence peaks in the second and third decades of life.[1] Patients with severe head injuries—i.e., those admitted in coma, with a Glasgow Coma Scale score (GCS) of 8 (Table 93-1)[2,3]—constitute a minority of head-injured patients admitted to hospital, but account for most of the morbidity and mortality (Fig. 93-1). Hospitals with a large primary care population see relatively fewer severely head-injured patients than do those functioning primarily as tertiary referral centers.

The most common cause of closed head injury is road traffic collisions. These include injuries to vehicle occupants, pedestrians, motorcyclists, and bicyclists. Falls are the next most common cause of injury. Gunshot injuries are a major cause of penetrating head injury in the United States and account for up to 44% of head injuries in some series.[1] Etiology varies considerably with local patient demographics and proximity to major highways, among other factors, and the resulting case mix will vary from center to center in terms of intracranial hematoma incidence, mean patient age, and consequently outcome from injury. Younger adults are more often involved in vehicular trauma, and there is a lower incidence of intracranial mass lesions in this patient population. Older patients are more often injured as a result of falls and have a higher incidence of mass lesions. At an equivalent depth of coma, both increasing age and presence of intracranial hematomas predispose patients to a poorer outcome.

Intoxication with alcohol or other agents is a significant factor in all causes of injury and across virtually all age groups except the very young and very old. Depending on etiology, 10% to 50% of our patients were obviously intoxicated at admission (Fig. 93-2).

The social and economic costs of head injury are enormous. Severe injury carries a high mortality, and patients who survive severe and moderate injuries may remain substantially disabled for years after the injury. The persistent effects of head injury on personality and mentation may be devastating for both patients and their families.

Pathophysiology of Craniocerebral Trauma

ACCELERATION-DECELERATION INJURY

Injury to the brain is produced by energy transfer to the cranium and its contained structures. In blunt injury, angular acceleration-deceleration forces cause shear strains within the cerebral parenchyma, which in turn are responsible for the characteristic diffuse axonal injury. The force may be applied directly to the head (i.e., impact injury) or indirectly via the body (i.e., impulse injury). The physiologic hallmark of diffuse injury to the brain is loss of consciousness. *Concussion* is a brief loss of consciousness without obvious sequelae. *Coma* is defined as a state of unconsciousness in which the patient does not open the eyes, follow commands, or utter any recognizable words. The severity of diffuse brain injury may be gauged by the depth and duration of coma or the duration of posttraumatic amnesia. The duration of both coma and posttraumatic amnesia can be judged only in retrospect, so the depth of coma as quantified by the GCS has been widely

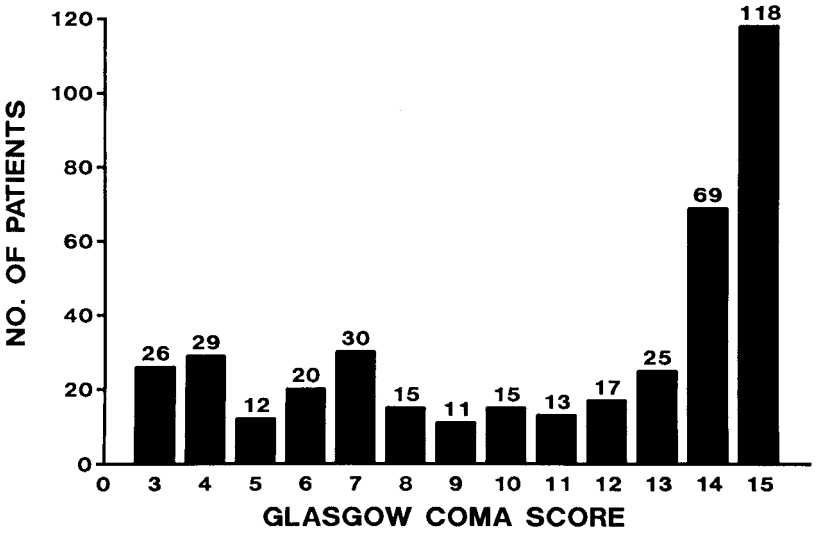

FIGURE 93-1 Distribution of head injury severity (measured by the Glasgow Coma Scale score at admission) in 400 consecutive admissions to a tertiary care hospital neurosurgical unit.

adopted as the most convenient measure of injury severity. With severe and prolonged coma, the patient may reach a state characterized by observable periods of eye opening and sleep without appreciation of the environment or of people or objects in it. This has been called the *persistent vegetative state.*

Acceleration-deceleration injury occurring as a result of impact or impulse mechanisms may produce gross disruption of brain tissue (laceration and/or contusion), diffuse axonal injury, or both. The characteristic histologic findings of diffuse injury consist of axon retraction balls (the pathologic marker of axonal separation) and microglial stars. Experimental evidence, and more recently human postmortem material, have shown that axon retraction balls develop over hours from initially intact axons.[4] Hemorrhagic lesions of the anterior corpus callosum may be seen on careful postmortem examination or may be apparent on computed tomography (CT) scans, as may small punctate hemorrhages deep in the hemispheres or small amounts of blood in the ventricular system (Fig. 93-3). For a given force, the greatest degree of injury occurs in the white matter of the hemispheres, and the brain stem is less severely injured.

Laceration/contusion of the brain surface may underlie the site of a blow (coup contusion), but more typically is found on the orbitofrontal surface of the frontal lobes and/or the anterior portion of the temporal lobes, remote from the site of the blow (contrecoup injury; Figs. 93-4 and 93-5). To-and-fro motion of the brain over the uneven surfaces of the anterior and middle fossae has been postulated as the underlying mechanism of contrecoup contusion. Cavitation of the brain

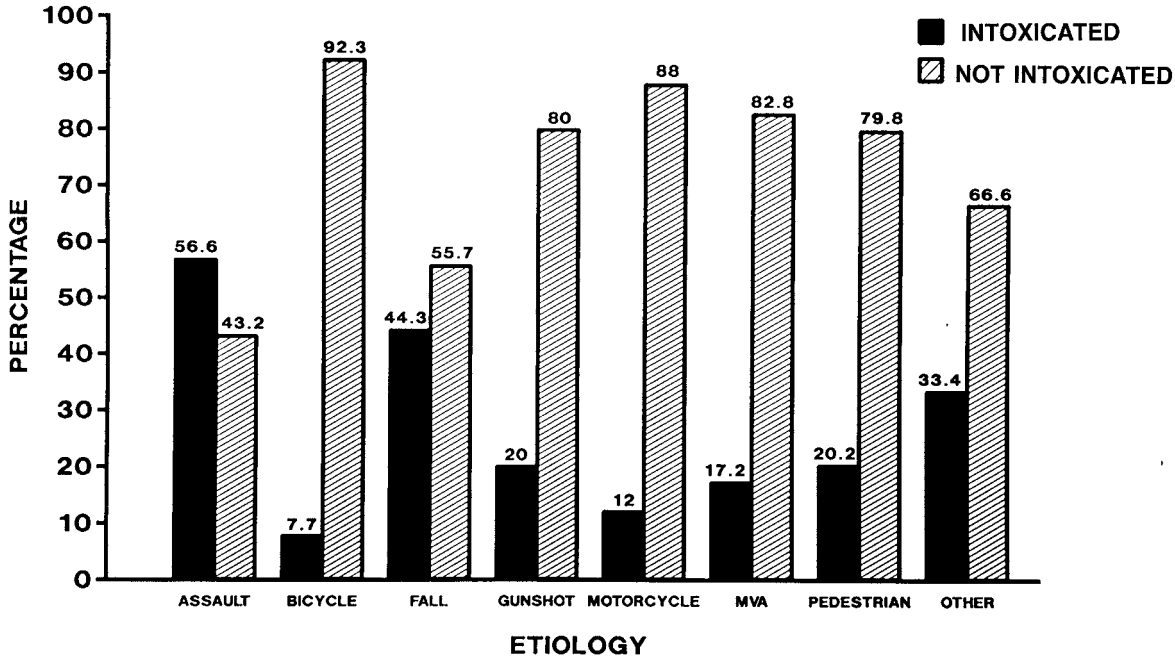

FIGURE 93-2 Proportional incidence of alcohol intoxication by injury etiology in 400 consecutive head injury patients. MVA, injuries to motor vehicle occupants.

FIGURE 93-3 CT scan of a 16-year-old patient with a typical diffuse head injury. The patient's GCS at admission to hospital was 4. There is a small amount of blood in the trigone and occipital horn of the right lateral ventricle (*lower arrow*). There is a small punctate hemorrhage in the left internal capsule (*upper arrow*).

FIGURE 93-4 CT scan of a 50-year-old man injured in a fall. There is a large mixed-density lesion in the left temporal lobe (*lower arrow*) and a similar, smaller lesion in the left orbitofrontal cortex (*upper arrow*). The appearance is typical of cerebral contusions.

produced by the rapid acceleration of the skull away from the brain at contusion sites is an alternate hypothesis. Both cerebral parenchyma and blood vessels are disrupted at the sites of contusion, and the bleeding may be sufficient to produce a subdural hematoma, a large confluent intracerebral hematoma, or both.

In addition to the disruption of cerebral parenchyma, direct impact injury may disrupt the skull and meninges or their blood vessels. Skull fractures are of importance primarily because they may trigger epidural bleeding, provide a portal of entry for infective organisms if compound (either directly or indirectly via the middle ear or paranasal sinuses), or lacerate the meninges and underlying brain if depressed fragments are present. Cranial nerves may be injured as they exit the skull base, and fractures involving the petrous temporal bone may injure the auditory and/or vestibular end organs, or disrupt the ossicles of the middle ear.

PENETRATING INJURY

Penetrating injury produces direct disruption and laceration of brain tissue. In low-velocity injuries (stab wounds or impalements), damage is confined to the directly disrupted tissue. There is often no loss of consciousness. In missile injuries, cavitation occurs along the track of the missile, and depending on the size and velocity of the missile, disruption of surrounding cerebral tissue is often widespread and severe. Both high- and low-velocity penetrating injuries disrupt the overlying skin, skull, and meninges of the brain, thereby allowing contamination of cerebrospinal fluid (CSF) or brain with infective microorganisms.

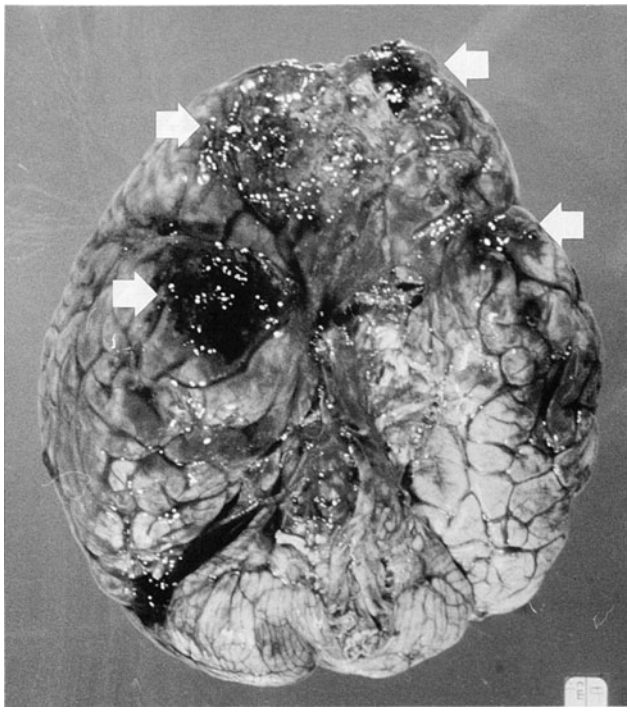

FIGURE 93-5 Pathologic specimen showing asymmetric hemorrhagic contusions of both temporal lobes (*lower arrows*) and both frontal poles (*upper arrows*). These are the usual locations of cerebral contusions.

SECONDARY INJURY TO THE BRAIN

Direct and immediate disruption of the brain tissue by blunt or penetrating trauma constitutes primary injury. Unfortunately, despite encouraging results in the elucidation of the mechanism of primary impact injury and the development of potential neuroprotective therapies in the experimental laboratory over the last decade and a half, effective treatment for primary impact injury still eludes us. Large multicenter trials of pharmacologic agents (including antioxidant drugs and excitatory amino acid antagonists) and hypothermia have failed to yield positive clinical results.[5] Clinical management of patients with traumatic brain injury continues to be grounded in the successful prevention, detection, and treatment of secondary insults to the injured brain. These secondary processes may be initiated at the time of injury or at any subsequent time, and these may aggravate existing injury to the brain. Secondary injuries include intracranial bleeding, hypoxia, ischemia, raised intracranial pressure (ICP), infection, and electrolyte and metabolic disturbances.[6] The incidence of secondary injury generally increases with the severity of the primary injury, although the relationship is not completely congruent. Patients with devastating primary injuries may initially have very little secondary injury. Conversely, patients with little primary injury may die or be crippled as a result of an enlarging intracranial hematoma. Clinically, the neurologic disturbance produced by primary injury is maximal at onset and then lessens or remains stable. By contrast, secondary injuries produce worsening of the patient's clinical neurologic status as their effects are added to those of the primary injury. Of considerable importance is the fact that secondary injuries are treatable and/or preventable.

Intracranial hematomas occur between the skull and dura mater (epidural; Fig. 93-6), between the dura mater and brain (subdural; Fig. 93-7), or within the substance of the brain (intracerebral; Fig. 93-8). As intracranial hematomas enlarge, they produce compression and shifting of the adjacent brain. This enlargement produces rapid and large increases in ICP as the volume-buffering capacity of the cranial contents is exhausted (see below). Hypoxia may occur as the result of central depression of respiration consequent to loss of consciousness, chest injury, aspiration of gastric contents, neurogenic pulmonary edema, or any combination of the above.

Evidence of ischemia is frequently found at autopsy following blunt head injury.[7] Focal ischemia may occur at the site of contusions or may be the result of vasospasm induced by traumatic subarachnoid hemorrhage. Global ischemia may be induced by systemic hypotension or reduction in cerebral perfusion pressure secondary to increased ICP.[8] Systemic hypotension at the time of admission to hospital has been shown to increase the mortality from severe head injury by approximately 150%.[9]

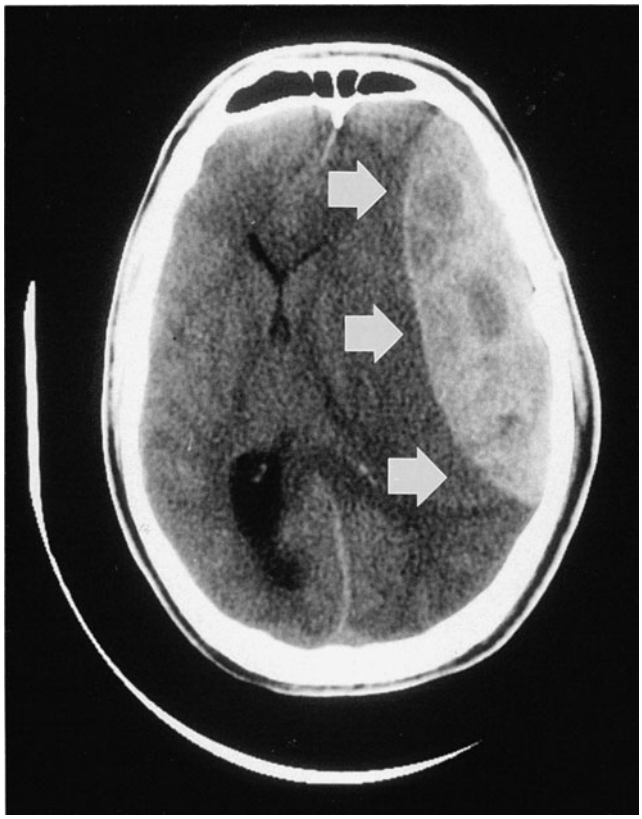

FIGURE 93-6 CT scan of a large acute epidural hematoma (*arrows*). Epidural (or extradural) hematomas have a convex medial border, which produces the lens shape that distinguishes epidural from subdural hematomas.

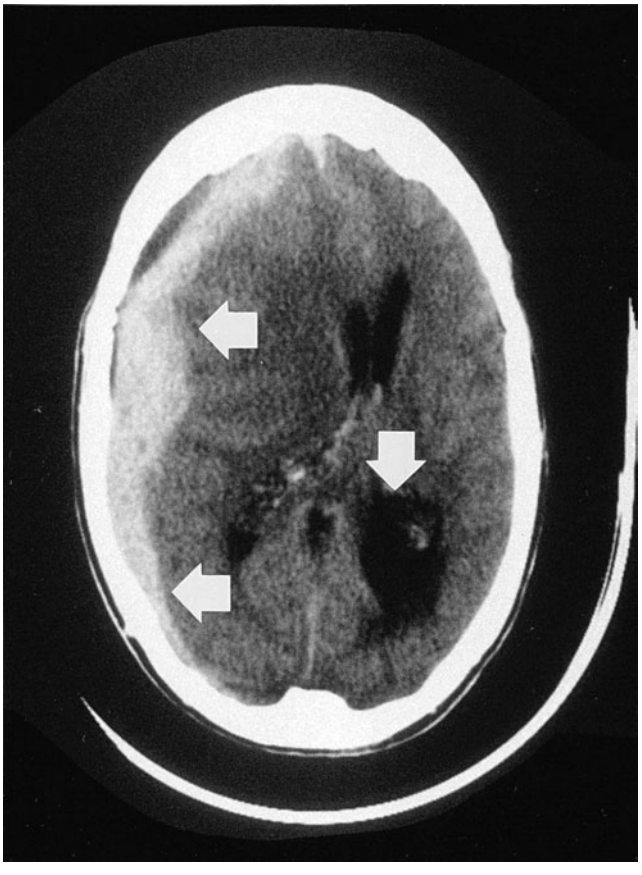

FIGURE 93-7 CT scan of a large acute subdural hematoma (*horizontal arrows*). The hematoma spreads over the entire convexity of the hemisphere, so that the medial border of the hematoma is concave. Note also the large amount of midline shift. The occipital horn of the left lateral ventricle is acutely enlarged as a result of trapping of CSF by ventricular distortion and obstruction of CSF flow (*vertical arrow*).

FIGURE 93-8 CT scan of a confluent traumatic intracerebral hematoma in the left frontal lobe of a patient struck by a motor vehicle (*lower arrow*). There is overlying scalp swelling and contusion at the site of the blow to the head (*upper arrow*).

Infection may be local (e.g., meningitis or brain abscess) or systemic. The former occurs when the integrity of the meninges is compromised as a result of penetrating injuries or compound fracture of the vault or skull base. Meningitis or ventriculitis may be iatrogenic, as a result of insertion of ICP-monitoring apparatus. Systemic infection typically involves the lungs or genitourinary tract. Systemic sepsis often causes neurologic deterioration that may improve with resolution of the infection. The accompanying hyperthermia often aggravates existing ICP problems.

Electrolyte disorders are common in patients with moderate and severe head injuries. The most frequent is the syndrome of inappropriate antidiuretic hormone secretion (SIADH). Serum sodium may fall significantly, and deterioration in patients' neurologic status usually occurs at levels below 120 to 125 mEq/L. Diabetes insipidus usually occurs in more severe injuries, often as a preterminal event in patients with progressive rostrocaudal neurologic deterioration caused by uncontrollable ICP elevation. In a much smaller number of patients, diabetes insipidus may be the result of focal injury to the hypothalamic-pituitary axis.

Severe head injury induces a state of catabolism with net excretion of nitrogen similar to that seen in other injuries. Catecholamine-induced tachycardia, increased blood pressure, and increased cardiac output are common. Myocardial ischemia may occur as a result of closed head injury.[10]

Abnormalities of blood coagulation are known to occur as a result of brain injury and are predictive of a poor outcome.[11] The reported incidence of coagulopathy depends to a certain extent on the diligence with which this entity is sought; its presence is often obscured by that of other potential causes of coagulation disturbance, such as massive transfusion in the multiply injured patient. Delayed and recurrent hematomas, including those related to placement of ventricular catheters, have been described in patients with disseminated intravascular coagulation.[12] In patients in whom a bleeding diathesis is known or suspected, it is preferable to use a subarachnoid bolt or epidural transducer rather than a ventricular catheter for ICP monitoring when there is a high likelihood of increased ICP (e.g., in the presence of a mass lesion). In patients who are known to have a low risk of raised ICP (i.e., those with normal CT scans), monitoring can be deferred until the coagulation abnormality is reversed.

INTRACRANIAL PRESSURE

Over the past 15 years, monitoring and control of ICP have been hallmarks of aggressive management of traumatic brain injury, and their use has been increasingly common in management of other cerebral disorders such as subarachnoid hemorrhage (SAH), intracerebral hematoma (ICH), brain tumors and liver disease. ICP monitoring and control are routine features of intensive care in most major neurosurgical centers and are done commonly in community hospitals. Although level one evidence of their efficacy is lacking, there is a substantial body of data to support their use and growing application.[13–16] Consensus guidelines derived by a panel of experts in the care of neurotrauma patients recommend the use of ICP monitoring in severely head-injured patients.[17] In this chapter, ICP monitoring will be discussed in the context of traumatic brain injury, but the techniques of monitoring and treatment are equally applicable to other conditions.

Since Lundberg[18] described ICP monitoring in 1960, its use in adults has been mainly in patients with severe head injury, both because of the large number of such patients and because intracranial hypertension is common when the injury is severe. We cannot tell whether a bad outcome in an individual patient results directly from the head injury, with brain swelling and increased ICP being epiphenomena, or whether it stems from secondary brain injury caused by cranial hypertension. In the first case, no remedy is possible. Most neurosurgeons assume and hope that the second case is actually present—i.e., that intracranial hypertension is adding to brain injury—and believe that ICP elevations should be detected and controlled. Any experienced neurosurgeon can relate anecdotes of cases in which detection and treatment of elevated ICP reversed neurologic deterioration and contributed to a good outcome. For example, detection of a delayed expanding intracranial hematoma by observation of rising ICP can lead to more prompt, and possibly life-saving, clot removal.

ICP is the pressure measured from some intracranial site and is generally recorded in millimeters of mercury. The site of measurement is usually in the cerebral ventricles or in the subdural or epidural space, or rarely in the brain parenchyma. While the brain is reasonably plastic, and the ICP measured at one place within the skull reflects fairly well the pressure at any other place, pressure gradients may develop across semirigid dural partitions in the skull when pathology is localized in one compartment (e.g., supratentorial vs. infratentorial). The combination of brain shift from focal masses, high intracranial pressure, and pressure gradients across dural and bony partitions (i.e., falx cerebri, tentorium, and foramen

magnum) causes brain tissue to herniate from compartments with higher pressure to compartments with lower pressure. The most important of these cases is transtentorial herniation, signaled by the presence of an ipsilateral dilated and fixed or sluggishly reactive pupil. Intracranial hypertension is clearly potentially injurious. While the precise point at which ICP should be considered abnormal is not agreed upon and undoubtedly varies among different pathologies, ICP levels above 20 or 25 mm Hg that have been present for 10 to 15 minutes generally are considered pathologic and treatment is recommended.[17]

Cerebral perfusion pressure (CPP) represents the difference between mean arterial pressure (MAP) and ICP (CPP = MAP − ICP). In normal brain, cerebral blood flow (CBF) remains fairly constant at around 50 mL/100 g brain tissue per minute as long as cerebral autoregulation is intact—i.e., cerebral vessels change their diameter and resistance with pressure changes, so that a constant CBF is maintained as long as CPP is about 50 to 150 mm Hg. If MAP falls substantially or ICP rises substantially, then CPP falls too low to be corrected by autoregulation, and cerebral ischemia results. In cases of uncontrolled ICP, the terminal event is usually an increase of the ICP to a level at or slightly above the MAP. In severe head injury, there is some evidence of an autoregulatory breakpoint at a perfusion pressure of about 70 mm Hg.[19] In the case of marginal CPPs of around 50 to 60 mm Hg, one must remember that the focal CPP can be lower than the overall CPP if there are focal brain lesions, and a more generous CPP of 70 to 80 mm Hg may be necessary to prevent focal ischemia. A treatment protocol has been proposed (supported by uncontrolled data) wherein the emphasis on treatment resides primarily on elevating and maintaining the CPP above 70 mm Hg, often with systemic vasopressors with less emphasis on managing ICP in isolation.[20] A more recent review of ICP and CPP data from a large clinical trial in head injury suggests that it is ICP alone, rather than CPP, that is the more critical variable in determining outcome.[21] A randomized prospective trial of ICP- vs. CPP-targeted treatment showed a reduction in episodes of jugular venous oxygen desaturation (a surrogate measure for cerebral ischemia), but failed to show any beneficial effect on overall neurologic outcome. Furthermore, there was a fivefold increase in the incidence of acute respiratory distress syndrome in the CPP-targeted treatment group.[22]

One particularly dangerous situation for patients with severe head injury is when the hemisphere subjacent to a large subdural or epidural hematoma undergoes massive swelling after the hematoma is removed. The mass effect of the hematoma undoubtedly causes severe unilateral ischemia, but this effect is dramatically worsened by the hypoxia or hypotension that are present in about half the patients who develop this particularly severe postoperative complication. Even if ICP is normal shortly after the initial operative procedure, intracranial hypertension occurs in virtually all of these patients and may be uncontrollable and fatal in a high percentage.[23]

A small percentage of patients with intracranial hematomas develop delayed traumatic hematomas not seen on the initial CT scan, some after previous surgery for extracerebral hematomas and sometimes more than a day after injury.[24] ICP monitoring and recognition of intracranial hypertension can lead to earlier repeat CT and earlier identification and removal of clots than can reliance on the neurologic examination alone,[25] although earlier clot removal has an uncertain effect on outcome.[26]

Management of Acute Head Injury

As may be inferred from the discussion of pathology and pathophysiology presented earlier, the management of head injury during the acute period is based primarily on the timely diagnosis and treatment of secondary insults to the injured brain. In the continued absence of effective drugs or other treatment strategies to reverse the pathophysiologic changes of diffuse axonal injury, management of the primary injury consists of providing the best possible physiologic milieu to permit unimpeded recovery of sublethally injured neurons.

DIAGNOSIS

Diagnosis in closed head injury is based on history, physical examination, and radiologic investigation. The relevant facts to be ascertained from the history are the mechanism of injury, whether there was any initial loss of consciousness, and whether the level of consciousness has improved or deteriorated since the injury. This last item is of paramount importance, since worsening of the patient's neurologic state subsequent to injury always implies the presence of secondary injury to the brain. Patients who have talked at some point after injury and who subsequently lapse into unconsciousness almost invariably are harboring an intracranial hematoma. One should determine whether or not there has been any witnessed seizure activity, since seizures may produce transient profound deterioration in the level of consciousness that may mimic that induced by an expanding intracranial hematoma.

Neurologic examination consists of two components: determination of the level of consciousness and identification of any focal deficits to aid in lesion localization and the measurement of severity. Determination of the level of consciousness is the single most important measure to be taken following traumatic brain injury and is best accomplished by use of the Glasgow Coma Scale (GCS). Although the scores in the three response categories of the GCS are frequently summed for convenience, more information is conveyed by reporting them separately. The motor score from the patient's "best" side is used if there is a discrepancy in response between sides. Intubation may be designated by a "T" for the verbal response score. In patients with a disturbed level of consciousness, the scope of the traditional neurologic examination is severely limited because of its considerable dependence on patient cooperation. In unconscious patients, crude localization may be achieved by observing discrepancies between sides in the patient's motor response to pain. Evidence of brain stem dysfunction should be sought; the common measures are pupillary reaction to light, oculocephalic responses (doll's-eye movements) or oculocaloric responses, and corneal reflexes. Doll's-eye testing should be deferred until the cervical spine is known to be intact, and oculocaloric testing should not be carried out in the presence of a ruptured tympanic membrane. Unless there has been local ocular trauma, the presence of unilateral pupillary dilation and unreactivity implies the presence of a mass lesion, and urgent diagnosis and evacuation of the mass are essential. This is particularly important in cases of unwitnessed

unconsciousness, and investigation of metabolic causes of coma should be deferred until a CT scan has been obtained.

Another relevant aspect of the physical examination is examination of the head for signs of trauma. These include bruising or laceration of the face and scalp; open skull fractures; hemotympanum and bruising over the mastoid process (Battle sign), indicating fracture of the petrous temporal bone; and periorbital hematoma (raccoon eye), indicating fracture of the floor of the anterior fossa. One should also look for signs of CSF leakage from the nose or ears. CSF may be mixed with blood; if the draining fluid forms a target shape on a piece of filter paper, the presence of CSF is indicated. Biochemical determination of the presence of CSF is usually not possible because of the difficulty in collecting a sufficient volume of the draining fluid.

CT is essential to the proper management of unconscious head-injured patients. It makes it possible to diagnose all types of intracranial hematoma and to determine their location and the extent of the mass effect they produce (measured by the displacement of the septum pellucidum from the midline). The scan should be obtained as soon as the patient is stable and any more urgent management priorities have been addressed. It is occasionally necessary to forego CT to deal with life-threatening injuries to other systems or because there would be an unacceptably long wait for a scan in a patient with a high likelihood of having an intracranial surface clot. Unconscious patients should have radiologic assessment of the cervical spine to the level of T1 to rule out cervical fracture. In the absence of x-ray evidence of an intact cervical spine, one must presume there is a fracture and continue to immobilize the head and spine until appropriate x-rays are obtained and the necessary treatment instituted.

Magnetic resonance imaging (MRI) has been used on a limited basis with head-injured patients. MRI is better than CT at detecting some types of small extra-axial fluid collections and parenchymal injuries. However, it offers no advantage in detecting hematomas requiring surgical treatment, and the difficulties inherent in having to exclude metallic objects from the scan environment render the technique somewhat impractical in the acute posttrauma setting. A potential application is the improved identification of parenchymal changes following mild and moderate head injury that have been shown to correlate with the neuropsychologic sequelae of head injury.[27,28]

PREOPERATIVE MANAGEMENT

In the initial phase of head injury management, the usual diagnostic and treatment priorities for the management of trauma patients are followed. Establishment of an adequate airway is of paramount importance in unconscious patients. All patients with a GCS $\leq$8 should have endotracheal or nasotracheal intubation and mechanical ventilation, regardless of whether other indications for intubation are present or not. Direct laryngoscopy can raise ICP dramatically, potentially worsening cerebral ischemia. Intubation should be performed by experienced personnel and after appropriate premedication (see Chap. 35).[29] Nasotracheal intubation should be avoided in patients with signs of basal skull fracture. Patients should be hyperventilated to a modest degree (partial pressure of carbon dioxide [P_{CO_2}] 30 to 35 mm Hg) to reduce raised ICP. Patients with a clear-cut deterioration in neurologic status should be given mannitol in a dose of approximately 1 g/kg body weight. Contraindications to the use of mannitol are hypotension, anuria, and severe congestive heart failure. Corticosteroids are of no benefit in reducing ICP in head injury, and their use has been abandoned in most centers. As soon as other management priorities have been dealt with, the patient should undergo CT.

Mild therapeutic hypothermia was first proposed as a treatment for brain trauma in the late 1950s. Hypothermia can lower ICP, alter chemical pathways that could contribute to injury, and modulate apoptosis. In 2001 the results of a large multicenter trial were published, demonstrating that hypothermia (target = 33°C) was not effective in improving functional outcome at 6 months, even though ICP was better controlled.[30] A more recent study raises again the possibility that hypothermia may confer benefit. Patients with severe head injury (GCS score $\leq$8) who continued to have intracranial hypertension (ICP >20 mm Hg) despite standard resuscitation, attention to the adequacy of CPP, surgery (when indicated), sedation, mannitol, therapeutic paralysis, and pentobarbital infusion, were cooled to 32°C.[31] Hypothermia was maintained for at least 24 hours or until slow rewarming did not cause the ICP to rise (mean duration of cooling = 4.8 days). Hypothermic subjects were less likely to die (62% vs. 72%), but only a small subgroup of patients with a GCS of 5 to 6 accounted for the majority of the response difference (12/25 hypothermia subjects survived vs. 6/25 control subjects). Given these conflicting data, as well as the fact that hypothermia is potentially harmful, leading to hypovolemia, hypotension, and electrolyte disturbances, this intervention should be considered investigational.

OPERATIVE MANAGEMENT

INTRACRANIAL HEMATOMA

The cornerstone of acute head injury management is the rapid diagnosis and prompt surgical evacuation of intracranial hematomas. Twenty-five to fifty percent of patients rendered comatose as a result of acute head injury have an operable intracranial hematoma.[3,6,14,32,33] Approximately 20% of patients with intracranial hematomas have an extradural hematoma, and the rest have hemispheric acute subdural hematomas, significant brain contusions, or both.[6,32,33] Traumatic hematomas in the posterior fossa are unusual. The diagnosis is ordinarily made by CT. Surgical evacuation is then accomplished via craniotomy, with wide exposure and evacuation of the hematoma and coagulation of sources of hemorrhage. Rarely, when there is clear-cut evidence of neurologic deterioration with progression to signs of uncal herniation (i.e., pupillary dilation), it is necessary to proceed directly to operation, bypassing CT. The other circumstance in which exploratory burr holes may be necessary is in comatose patients with signs of brain stem compromise who must be taken to the operating room for life-threatening systemic injuries without benefit of a CT scan. An alternate strategy in these patients is twist-drill air ventriculography in the operating room. The standard landmarks are used for cannulation of the frontal horn of the lateral ventricle. Once the ventricle is cannulated, 4 to 8 mL of air is introduced into the ventricles, and a brow-up anteroposterior skull film is obtained. The presence of a mass lesion is inferred from shift of the ventricular system (Fig. 93-9).

The frequent coexistence of acute subdural hematomas and temporal and/or frontal cortical laceration/contusion dictates

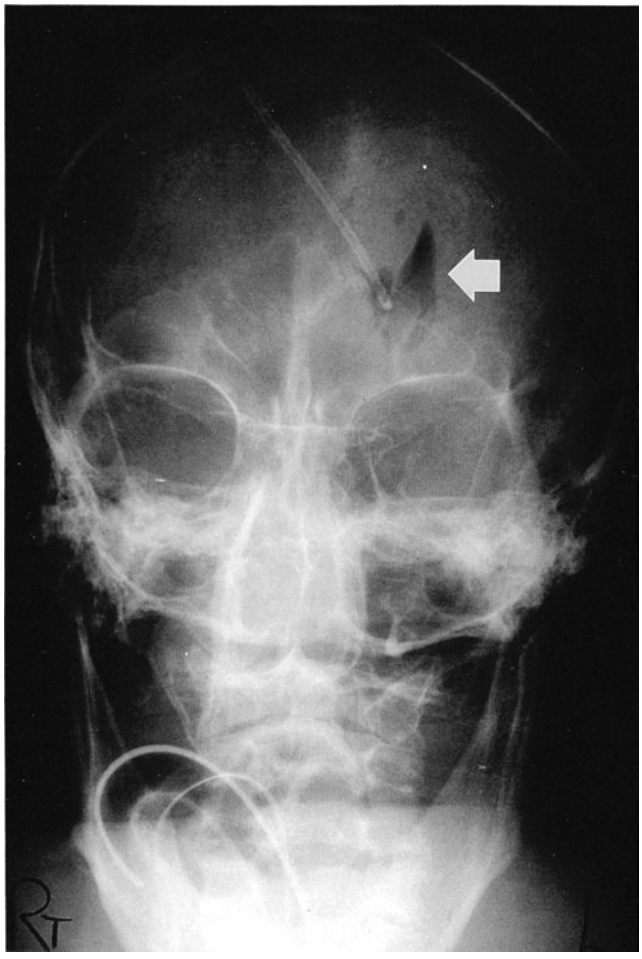

FIGURE 93-9 Air ventriculogram done in the operating room in a multiply injured patient. Air (4 mL) was injected into the ventricular catheter and an anteroposterior skull film obtained. The displacement of the frontal horns of the ventricles (*arrow*) away from the midline toward the left side indicates a mass lesion on the right side. Subsequent craniotomy revealed a large right frontal intracerebral hematoma.

the necessity of a wide operative exposure, allowing access to both the frontal and temporal lobes, as well as the medial convexity adjacent to the sagittal sinus, where there may be torn bridging veins (Fig. 93-10). The operative approach to an isolated extradural hematoma may be more circumscribed. Contusions of the frontal and temporal lobes, or confluent blood clots producing a midline shift greater than 5 mm, should be evacuated operatively through the standard large flap. Often, removal of the contused brain must be accompanied by formal frontal or temporal lobectomy to provide adequate internal decompression in the face of a traumatized, swollen brain. In this circumstance, the question of whether or not to leave out the craniotomy bone flap (or remove it later) to provide more room for the swollen brain has engendered some controversy. The prevailing view is that this measure does not improve the functional outcome. It is probable, however, that poor outcomes with this procedure are usually due to the fact that the patient had overwhelming primary injury, and that decompressive craniectomy may be useful in patients in whom the degree of primary injury is compatible with a reasonable neurologic outcome.

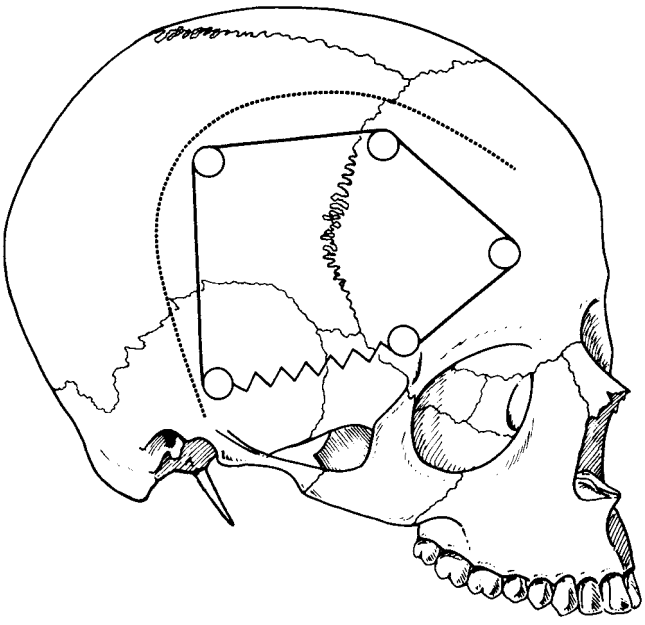

FIGURE 93-10 Diagram of the operative exposure for the removal of a traumatic intracranial hematoma. The skin incision is shown with the dotted line. The skull flap is outlined with a solid line. The exposure permits access to the major portion of the hemisphere convexity, as well as sufficient access for débridement/lobectomy of the frontal or temporal lobes.

At the conclusion of the evacuation of a hematoma, an ICP monitoring device is placed in almost all cases. The exceptions are patients whose level of consciousness was only mildly depressed preoperatively (GCS >10), and in whom the brain is not significantly contused or swollen at the time of operative exposure. The techniques and indications for ICP monitoring will be discussed.

PENETRATING INJURY

The same principles of prompt evacuation of intracranial hematomas and débridement of contused brain apply to penetrating injuries. The other indication for operating on compound lesions is the restoration of the integrity of the dura and overlying tissues to prevent bacterial infection of CSF (i.e., meningitis) or cerebral parenchyma (brain abscess). Accessible indriven bone fragments should all be removed, as well as underlying hematoma and devitalized brain. It is not necessary to attempt to remove inaccessible missile or bone fragments from the depths of the missile tract. Prophylactic antibiotics are used to reduce the incidence of delayed infection in cases of penetrating injury. Broad-spectrum coverage with antibiotics capable of crossing the blood-brain barrier should be used.[34]

BASAL SKULL FRACTURE

A special case of compound injury is the basal skull fracture with leakage of CSF through the paranasal sinuses or into the mastoid air cells, middle ear, and external ear or pharynx. CSF otorrhea almost always stops spontaneously, and surgical repair of the leak is rarely necessary. Rhinorrhea is more likely to continue, and the continued presence of a CSF fistula will eventually lead to meningitis. Surgical repair of an anterior fossa fistula may be undertaken early when there is an obvious bony disruption of the anterior fossa floor, often

coincident with complex facial fractures. In this case, repair of the CSF leak is undertaken at the time of facial reconstructive surgery. In cases of persistent CSF leak without obvious bony disruption, the site of the fistula may sometimes be localized with coronal CT cuts through the anterior fossa following the instillation of water-soluble radiographic contrast material into the CSF. Investigation of persistent CSF leakage should be deferred until the patient is stable with respect to both ICP and coexisting systemic injuries. Occasionally, bilateral anterior fossa exploration is necessary in the face of persistent CSF rhinorrhea for which the site cannot be identified radiologically.

There is considerable debate about the merits of prophylactic antibiotics for CSF rhinorrhea and otorrhea. Unfortunately, there are no good clinical studies to support either their use or their abandonment, and this remains largely a matter of personal preference. We do not use prophylactic antibiotics for CSF leakage in our unit for fear of selecting for multiply resistant organisms. When there is established infection, the diagnosis and treatment are the same as for meningitis of any cause. Operative repair of the dural fistula should not be undertaken until the infection has been cleared with appropriate antibiotic therapy.

CRITICAL CARE MONITORING

Monitoring of the head-injured patient is designed to detect and treat secondary injuries before they further compromise the injured brain. Ideally one would like to monitor neurologic function, cerebral blood flow and cerebral metabolism, intracranial pressure, and those systemic parameters required for the maintenance of adequate perfusion and oxygenation of the brain. Measurement of all these parameters is possible, but cerebral blood flow and cerebral metabolism are difficult to measure, and the ideal situation described here is rarely practiced.

CLINICAL EXAMINATION

Monitoring of neurologic function is most commonly and simply carried out by means of hourly repetition of the abbreviated version of the neurologic examination described earlier, in the section on diagnosis. Any deterioration in the patient's neurologic status should trigger an investigation for treatable causes. Neuromuscular blocking agents used to treat raised ICP or respiratory problems make it impossible to conduct a meaningful neurologic examination. In addition, these drugs are associated with numerous complications and may be associated with a worse outcome in head-injured patients.[35] When neuromuscular blocking agents are given, only the pupillary responses are available as a means of assessment. Because significant deterioration in the patient's neurologic function may occur before pupillary changes are evident, ICP monitoring becomes essential to provide some information about the status of the patient. Although ICP is not a measure of neurologic function per se, many of the pathologic processes that endanger the head-injured patient in the early phase after injury manifest themselves with raised ICP in addition to neurologic deterioration. In a patient who is pharmacologically paralyzed for ICP control, paralysis should be allowed to wear off at intervals of 12 to 24 hours so that a neurologic assessment may be carried out. Occasionally the effects of reversal of ICP are intolerable, and reversal is not possible. A potential alternative to clinical neurologic monitoring is electrophysiologic measurement of neurologic function. The common techniques are electroencephalography (EEG) and evoked potentials (EPs).

Electroencephalography

EEG recordings in comatose patients typically show slowing of the background frequencies; in most cases there is a correlation between the degree of slowing and the depth of coma. Conventional strip-chart EEG is impractical because of the amount of data generated. Various methods of data compression have evolved, the most common being fast Fourier transformation of the EEG. Fourier transformation yields quantitative frequency and amplitude data from the EEG, and is well suited to detecting long-term trends in the background frequencies and to performing quantitative analysis of such trends. Recognition of specific patterns (e.g., seizure spikes) is sacrificed. Survival from head injury has been correlated with a return of higher-frequency activity in the first week after injury.[36]

Evoked Potentials

EPs have been demonstrated to be particularly useful in predicting outcome from head injury. The single most useful measure is the somatosensory evoked response,[37] although combinations of EPs (somatosensory, auditory, and visual) yield the highest prognostic accuracy.[38] Deterioration in serially measured EPs, occurring as a result of secondary injury to the brain, have been shown to correlate with poor patient outcome.[39] In the past, EPs have been used primarily in an intermittent manner for determination of prognosis. With further technologic improvements and increased automation of data collection, these techniques may see more widespread use for continuous monitoring in an ICU setting.

ICP Monitoring

Numerous reports suggest a beneficial effect of ICP monitoring and treatment of intracranial hypertension, although there are no controlled trials to support this. In a group of patients with GCS scores of 3, 4, or 5, the mortality rate was 39% when ICP was monitored and 67% when it was not; however, the patients were not randomly allocated to the two groups.[40] In another series, using patients evaluated in sequential time periods with slightly different treatment protocols, the mortality rate fell from 46% to 33% when ICP was rigorously controlled below 15 mm Hg.[14] In as many as 75% of patients who die after head injury, there is pathologic evidence of intracranial hypertension as measured by medial temporal lobe necrosis, secondary brain stem damage, or cerebral ischemic changes.[41] These and other reports have convinced most neurosurgeons that ICP monitoring is appropriate in patients with traumatic coma.

Elevated ICP clearly correlates with a poor outcome in head-injured patients. In one series of patients with severe head injury, 74% of the patients whose ICP remained below 20 mm Hg had a satisfactory outcome, while only 55% of the patients who required therapy to control ICP to this level had a similar outcome. Of the patients whose ICP could not be controlled, 92% died, and only 3% had a satisfactory outcome.[32] In another series, the number of patients who died or remained institutionalized more than doubled when ICP was higher than 15 mm Hg (57% versus 23%) than when it remained

below that level.[42] In addition to its effects on survival, intracranial hypertension affects brain function in survivors. Neuropsychologic assessment done 1 year after severe head injury revealed that hyperemia during the acute phase correlated better with poor intellectual and memory function than did low-flow states, and that patients who had experienced intracranial hypertension had more memory deficits than those whose ICP had remained normal.[43]

A variety of monitoring techniques have been used over the past 30 years. Lundberg first used a ventriculostomy coupled to a fluid-filled manometer.[18] This system was cumbersome and carried a considerable risk of causing infection. As electronic transducers became available, closed monitoring systems came into use. Although a few implantable transducers have been used experimentally, they are not in regular clinical use today. The two most common ICP monitoring systems used now are fluid-filled catheters and rigid bolts[44] attached to an electromechanical transducer or a fiberoptic system that detects deflection of a sensing mirror to measure ICP.[45] The former devices are generally less expensive, but are prone to blockage and may require more experience on the part of the clinician to keep them functioning optimally. The latter may provide more accurate data for longer periods without the need for intervention by doctors or nurses. The fluid-filled systems may be more appropriate in hospitals where ICP monitoring is common and is applied in several patients simultaneously; in such settings, medical personnel become familiar with the system and can recognize and correct problems as they arise. The fiberoptic systems may be more appropriate for facilities where fewer patients require ICP monitoring.

We currently use either subdural or intraventricular catheters for monitoring ICP, which we place either in the operating room at the time of surgery or at the bedside in the ICU (Fig. 93-11). We prefer an intraventricular position, so that CSF can be drained when necessary to lower ICP. An intraventricular catheter can be placed through a craniotomy opening in the operating room or by twist-drill ventriculostomy in the operating room or ICU when the ventricles seem to be large enough to permit entry. When the ventricles are compressed by brain swelling, we prefer to use a subdural catheter, which can only be placed in the operating room. (Because a twist-drill hole is perpendicular to the skull and brain, it precludes catheter insertion parallel to the inner table of the skull over the brain surface.) Placement of an ICP device requires meticulous sterile technique; if any part of the system is contaminated during insertion or attachment, it must be discarded and replaced. Intracranial infection is a devastating complication when added to the brain dysfunction for which monitoring is required. ICP monitors should be placed by neurosurgeons, since they are most familiar with manipulating brain tissue and are least likely to induce brain hemorrhage, a risk that is always present and that can be fatal. Epidural catheters must be placed through a burr hole in the operating room and are used less frequently than subdural or intraventricular monitors.

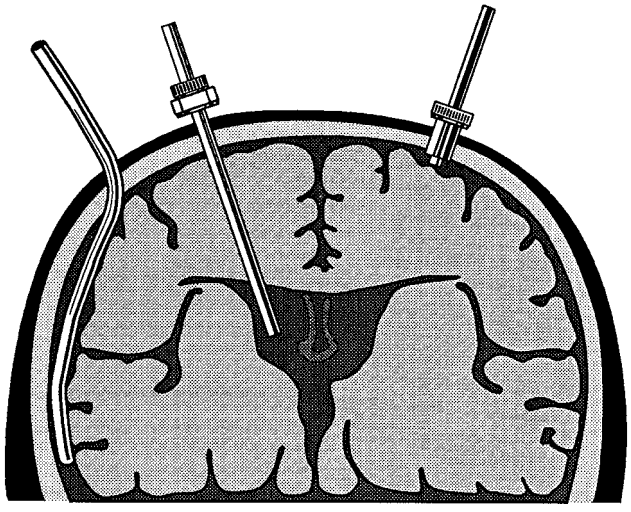

FIGURE 93-11 Schematic drawing of a coronal section of the brain, showing (left to right) the placement of a subdural flexible catheter, an intraventricular catheter, and a rigid subarachnoid bolt.

We attach the ICP catheter to pressure transducers connected to monitors, which provide continuous digital and waveform displays of ICP as well as of arterial, central venous, or pulmonary vascular pressures as needed in either the operating room or the ICU. The data can be sampled by a central ICU computer so that these and other parameters can be analyzed over a few hours or days. Usually a good pressure tracing is easily recognized, having a regular pulse pressure of 3 to 7 mm Hg (the pulse pressure can be greater at elevated ICP). The ICP baseline gently drifts up and down with respiratory or ventilatory excursions as intrathoracic pressure changes cause slight alterations in the intracranial venous pressure and ICP. A flat ICP tracing cannot be interpreted; a grave error in ICP monitoring is accepting a meaningless digital readout number as the actual ICP when the tracing clearly does not reflect a valid waveform. A flat tracing usually is due to blockage by blood or brain occluding the catheter tip or to a kink somewhere along the catheter. After the extracranial portion of the monitor is inspected for proper placement, it may be necessary to inject a small amount (0.25 mL initially) of an irrigating solution to clear the catheter tip; a larger amount, even only 1 mL, can markedly increase ICP when the brain is tight. It is helpful to turn the system stopcock from the injection position back to the monitoring position *while the irrigant is being injected.* If the stopcock is turned after the injection is completed, brain under pressure may immediately occlude the catheter tip when the injection pressure is stopped. Even if a catheter reoccludes and produces a flat waveform, a valid estimate of the ICP usually can be made. After a small amount of irrigant is injected, the ICP will be briefly elevated and have large pulse pressures, but will drift asymptotically toward the true ICP before becoming a flat line again.

The ICP catheter and transducer are filled with an antibiotic solution containing gentamicin, 1 mg/mL, which is stable in solution for 4 to 6 days and has wide antibacterial activity. It is important to maintain a closed system as much as possible; this requires tight connections throughout the monitoring system. It is imperative that no CSF leak around the catheter; any such leakage greatly increases the risk of infection. If leakage is noted, a new purse-string suture must be placed around the catheter's exit from the scalp. If the monitoring device is sufficiently flexible, it should be brought out through a stab wound a short distance from the incision made to insert it to further reduce infection risk. Our intracranial infection rate

for treatment of a variety of open or penetrating brain injuries is <2%, so the infection rate attributable to ICP monitoring is extremely low. Infection rates vary from 0.7% to 6.3% in other series using different devices.[46,47] In 378 patients, several different fluid-filled systems for monitoring ICP were compared regarding their tendency to become blocked or infected. The rigid Richmond bolt[42] became occluded 16% of the time; subdural or intraventricular catheters became blocked only 3% of the time, but the intraventricular catheters were associated with complications of infection or intracerebral hemorrhage, and led the authors to recommend the subdural catheter as the best of the methods.[48] However, intraventricular catheters allow withdrawal of CSF, which can be a critical method of ICP control. Some prefer to measure the change in ICP produced by withdrawal of a measured volume (ΔV) of CSF to determine the intracranial compliance ($\Delta V/\Delta ICP$); we have not found this additional measurement to provide a sufficient increment in useful data to warrant the time and risk involved.

Blood Flow and Metabolic Rate

Cerebral blood flow and cerebral metabolism have been measured in a number of units engaged in clinical research. The common techniques rely on measurement of washout curves from the brain of nitrous oxide or radioactive xenon. The equipment and techniques for conducting CBF measurements are complicated and expensive, and this fact has discouraged widespread adoption of these methods. Furthermore, in the case of xenon CBF measurement, the number of studies that can be carried out in a given patient is limited by radiation safety concerns. The incidence of ischemic levels of blood flow is highest within 12 hours of severe injury, and blood flow usually increases to normal levels by 24 hours.[49] Knowledge of CBF may be useful in identifying patients in whom hyperemia is contributing substantially to increased ICP, and thus to determine if treatment with hyperventilation may be used safely. CBF, the cerebral metabolic rate for oxygen (CMR_{O_2}), and the arterial-jugular oxygen content difference (AVD_{O_2}) are related by the following equation:

$$CMR_{O_2} = (AVD_{O_2} \times 3\ CBF)/100$$

When CMR_{O_2} is relatively constant, AVD_{O_2} varies inversely with CBF; therefore, it has been suggested that AVD_{O_2} could be used as an index of the adequacy of cerebral blood flow.[50] The jugular oxygen content may be measured by advancing a central venous catheter rostrally in the internal jugular vein upward to the base of the skull. The normal AVD_{O_2} is 4 to 9 vol%. Higher values indicate increased oxygen extraction and potential ischemia. More recently, fiberoptic catheters have been developed that will give a continuous readout of jugular venous oxygen saturation. Episodes of desaturation have been correlated with a poor outcome.[51,52]

Hemodynamics

Hemodynamic monitoring in the acute phase of head injury management should include arterial pressure monitoring and detailed measurement of fluid input and output. When repeated large doses of mannitol are administered, invasive hemodynamic monitoring may be necessary to maintain an accurate assessment of intravascular volume status in the face of massive diuresis and consequent fluid replacement (see below).

MEDICAL MANAGEMENT

MANIPULATING INTRACRANIAL PRESSURE

The medical management of acute head injury focuses primarily on the detection and treatment of raised intracranial pressure. Although the ICP is less than 10 mm Hg in normal individuals, 20 to 25 mm Hg is generally accepted as the point at which ICP requires treatment in head injury patients. Transient elevations above this level are common when patients are restless or coughing; therefore, persistence of the ICP elevation for 5 to 10 minutes in a nonagitated patient should be observed before treatment is initiated. In all cases, a cause for the elevation should be sought. There may be a problem with ventilation or obstruction of jugular venous return. Unless contraindicated by other injuries, patients should be positioned head-up 30° with the neck neutral between flexion and extension. If the ICP elevation persists after adequacy of ventilation and unimpeded jugular venous return have been assured, it is incumbent on the physician to rule out a surgically treatable cause of the ICP elevation with a CT scan. In cases of unoperated cerebral contusion, an increase in ICP may signify the need for surgical evacuation of the contused brain.[53]

Once it has been determined that the ICP increase has no surgically treatable cause, management depends on pharmacologic reduction of ICP and manipulation of the patient's P_{CO_2}. If the patient is not ventilated, intubation and mechanical ventilation should be instituted with moderate hyperventilation (i.e., P_{CO_2} 30 to 34 mm Hg). Hyperventilation to levels of 25 mm Hg or below has been shown to have an adverse effect on outcome.[54] If the patient is already ventilated, sedation with morphine or an analog should be given. The anesthetic agent propofol has come into increasing use for this indication. A recent randomized clinical trial has shown that it is safe and efficacious for sedation of intubated and ventilated head-injured patients.[55] If this measure is insufficient to reduce the ICP, then pharmacologic paralysis should be induced. In patients who are febrile, reduction of the core temperature to 37°C or lower by means of a cooling blanket frequently results in reduction of raised ICP. Often these measures alone are sufficient.

If the ICP elevation persists, and there is a ventricular drain in place, intermittent drainage of CSF may be instituted. It may be necessary to repeat drainage several times an hour. Continuous drainage should not be used, because drainage will often cease as the ventricles undergo progressive compression, and during ventricular drainage the ICP is not being measured. One is then in the unfortunate situation of not reducing the ICP and not being aware of the true ICP. If ventricular drainage is not feasible or effective, then mannitol must be used.

Mannitol, an osmotic diuretic, is the single most useful pharmacologic agent in the management of raised ICP following head injury. The dosage is 0.5 to 1.0 g/kg of a 20% solution infused as a bolus. Typically, the effects of mannitol on ICP will last from 2 to 6 hours, depending on the severity of the underlying pathologic process. Mannitol may be administered repeatedly as long as the serum osmolarity does not exceed 320 mOsm/L. At osmolarities greater than

this, the effectiveness of the drug is reduced, and there is an increasing risk of renal toxicity.[56] With frequent repeated doses of mannitol and the consequent diuresis, the patient may become systemically dehydrated, resulting in hypotension and increased serum osmolarity. Systemic dehydration is not necessary to achieve reduction in ICP. Therefore, the excess urine loss caused by mannitol should be replaced. The amount and type of replacement fluid should be calibrated to maintain high normal intravascular volume, a serum osmolarity of <320 mOsm/L, and normal serum electrolytes. With this regimen, it may be possible to give mannitol at intervals of 2 hours for several days at a time using aggregate volumes of 2 to 3 L of mannitol per day.

Furosemide can be used to reduce intracranial hypertension and probably works by inducing diuresis, increasing intravascular oncotic pressure, removing brain water, and possibly reducing CSF production.[57] The combination of mannitol and furosemide may be more effective in lowering ICP than either drug alone. This synergistic effect is not from an altered renal excretion of mannitol; furosemide may help to sustain the elevated serum osmolarity induced by mannitol, or may sustain the osmotic gradient across the blood-brain barrier induced by mannitol.[57] However, some caution is advised, since the combined use of mannitol and furosemide can cause rapid dehydration, hypotension, and a reduced CPP with the risk of brain ischemia.

In situations in which the combination of measures listed above is insufficient to control ICP, or where mannitol can no longer be used because of extant or incipient renal failure, pentobarbital may be a useful adjunct in the management of ICP.[58] It is not a first-choice agent, since it is clearly less effective than mannitol in lowering raised ICP,[59] may cause harmful cardiovascular side effects, and has no demonstrated protective effects on the brain when administered prophylactically to head-injured patients with or without raised ICP.[60] The dose regimen varies in the published literature, and pentobarbital may be given by bolus infusion or by drip. A typical approach is to administer a bolus of 10 mg/kg over 30 minutes, followed by a continuous infusion at 1 to 3 mg/kg per hour. The end point of administration is reduction of ICP or an unacceptable decrease in arterial blood pressure. Adequate hemodynamic monitoring (i.e., an arterial line and central venous catheter) must be in place before pentobarbital is given, and adequate intravascular volume should be assured prior to administration. Infusion of norepinephrine or other vasoactive agents is often necessary to maintain an adequate arterial pressure. Administration of high doses of pentobarbital will result in pupillary dilation and unreactivity, so that no clinical neurologic examination is possible. Brain stem auditory evoked responses (BAEPs) are preserved, and their recording may be a useful adjunct to the management of patients in barbiturate coma.[61]

The medical management of intracranial hypertension after head injury is generally successful in the vast majority of patients with severe head injury.[58,62,63] In one series, when standard medical management was unsuccessful, pentobarbital coma was induced, but it only controlled intracranial hypertension in about 30% of these patients. A subtemporal decompression was then performed, resulting in a significant further reduction in ICP and a 60% survival, compared with <20% survival when subtemporal decompression was not done.[62] Other surgical options available for the treatment of refractory ICP include subfrontal decompressive craniectomy, removal of an existing bone flap, or internal decompression by removal of a swollen or damaged frontal or temporal lobe. The controversy surrounding decompressive craniectomy has been alluded to above. These surgical adjuncts perhaps deserve consideration for a very small number of head-injured patients who do not respond to other avenues of ICP control. We have used surgical management in young patients with refractory ICP who have a reasonable potential for neurologic recovery (i.e., GCS ≥7).

MANAGEMENT OF SEIZURES

Seizures may aggravate an existing brain injury; therefore, their prompt treatment is essential. Factors that increase the risk of late epilepsy include severe injuries, intracranial hematomas, and the presence of seizures early after injury. Ordinarily, patients in these risk categories are given prophylactic phenytoin at the time of admission, and the medication is continued for 6 to 12 months, depending on the injury type and on whether or not any seizures have occurred. Prophylactic anticonvulsants have only been shown to be effective in the early posttraumatic period.[64] A discussion of acute seizure management is provided elsewhere in this text (see Chap. 64).

NUTRITION

The caloric requirements imposed by a head injury are comparable to those of a burn covering 20% to 40% of the body surface area. The requirements are increased by motor posturing and reduced by barbiturate coma or muscle relaxants. Enteral feeding via nasogastric tube is usually possible and is certainly desirable early after injury, unless there has been major abdominal trauma, in which case parenteral alimentation may be used. Although the nitrogen loss resulting from a severe head injury may be mitigated by early feeding, it may not be possible to reverse it consistently.[65]

FLUID AND ELECTROLYTES

SIADH is usually successfully managed by restricting free water intake to 1 liter or less per 24 hours. Demeclocycline may be a useful adjunct when the syndrome persists beyond a few days. Hypertonic saline (3%) is occasionally necessary to correct profound hyponatremia in the presence of serious neurologic symptoms (e.g., seizures). Diabetes insipidus may be managed with desmopressin acetate (DDAVP). The dosage is 1 to 2 μg (0.25 to 0.5 mL) intravenously two to four times daily as necessary to control urine output. Serum and urine osmolarity and electrolyte measurements are necessary to distinguish true diabetes insipidus from excessive diuresis caused by mobilization of fluids used during resuscitation or as a result of the use of mannitol for control of ICP.

REHABILITATION

Attention to the rehabilitation needs of the patient should begin on or shortly after admission to the critical care unit. In the early days after admission, this consists of proper positioning, regular turning, skin care, and movement of patients' limbs through their full range to minimize or prevent late joint contractures and skin decubiti, either of which may significantly retard recovery; more active rehabilitation begins once consciousness has been regained. Sensory stimulation programs to facilitate the return of normal consciousness are attractive

in theory, but they have not been tested by randomized clinical trials. As the patient's level of consciousness improves, the goals of rehabilitation therapy change from maintenance of normal limb posture and movement to the retraining of simple and then progressively more complex physical and mental activities. Although at this time the patient will normally be out of the ICU, it is important that these measures be initiated in the ICU.

Outcome from Traumatic Brain Injury

The mortality from severe head injury varies from 30% to just over 50% in most published series.[3,6,14,32,33,40] Factors associated with a decreased likelihood of survival are low GCS, advanced age, the presence of significant intracranial hematomas, and the presence of significant systemic injuries in addition to the head injury. Approximately 50% of patients dying from head injury do so from uncontrollable ICP, and this occurs early in the patient's course. In 30% to 60%, there is a good outcome or moderate disability. In contrast, the number of patients with a good outcome or moderate disability following hypoxic-ischemic coma was 13% in one large series.[66] In addition to those patients who die, small numbers will be left in a persistent vegetative state or alert but totally dependent. The numbers of such patients have not been increased in those series of patients in which mortality was reduced by early aggressive management of head injury.[6] Recovery may continue for up to 18 to 24 months after head injury, although the most significant gains are made during the first 6 months.[3]

Chapter 94
SPINE INJURIES

G. E. JOHNSON

KEY POINTS

- *Management of life-threatening injuries takes priority over management of spinal injuries.*
- *In the multiple-trauma setting, spinal injury should be assumed to be present pending appropriate assessment.*
- *Spinal injuries must be considered unstable until they are evaluated thoroughly.*
- *Vertebral injuries must be assessed in terms of the potential to create early neurologic injury or late deformity.*
- *Spinal cord injury is minimized or prevented by limiting the secondary ischemic phase and maintaining appropriate spinal immobilization.*
- *Complete spinal cord injuries have no potential for functional recovery. Incomplete injuries have recovery potential, which must be maximized.*
- *Considerations in rehabilitation must be initiated at the outset.*

Severely injured patients frequently require ICU admission preoperatively and more commonly postoperatively for monitoring and assessing for change that may require intervention, including surgery. It is estimated that approximately 20% of patients sustaining multiple injuries have associated spinal column trauma that may be the prime reason for ICU admission. More commonly, ICU admission is necessitated by the more immediately life-threatening injuries, and the spinal injury then could be missed or management delayed, leading to significant morbidity or even death. The intensivist plays an important role in determining outcome in these injuries by having a high index of suspicion based on awareness of the mechanisms of spinal injuries and their clinical features. This chapter reviews (1) the mechanism, classification, and clinical picture of spinal injuries and (2) the principles of management of vertebral and spinal neurologic injuries to enable the intensivist to optimize ICU management and recognize the need for early orthopedic and/or neurosurgical consultation.

It is extremely important in the management of multiply injured patients that longer-term rehabilitation considerations not be forgotten because this may result in serious chronic disability. The possibility of cervical spine injury must be considered in anyone who has suffered significant injuries to the face or head, especially those who are unconscious from trauma.[1] However, patients who are at risk on the basis of preexisting abnormalities of the cervical spine (e.g., ankylosing spondylitis and congenital anomalies) may suffer serious neck injury as a result of what might appear to be trivial trauma. Knowledge of the mechanism of injury is helpful in considering the possibility of spinal injury (e.g., fractures at the thoracolumbar junction associated with falls from a height).

Anatomy

The vertebral column consists of three components (Fig. 94-1)[2]:

1. The anterior column, consisting of the anterior two-thirds of the vertebral body, disk, and annulus and the anterior longitudinal ligament
2. The middle column, consisting of the posterior one-third of the vertebral body, disk, and annulus and the posterior longitudinal ligament
3. The posterior column, consisting of the pedicles, laminae, facets, capsule, and the interspinous and supraspinous ligaments

An injury is considered to be stable if only one of the columns is involved and if the injury does not pose a risk of damage to neural structures. Any injury resulting in damage to two or more columns or risking neurologic injury (i.e., damage to the middle column) is considered to be unstable. A great variety of forces or combinations of forces may be applied to the vertebral column (e.g., flexion, extension, flexion-rotation, shear, axial load). The effect of the application of these forces to the vertebral column depends on (1) the magnitude and direction of the force and (2) the underlying anatomy.

A flexion force applied to the cervical spine may result in a pure soft tissue ligamentous injury and dislocation because of the relatively horizontal alignment of the facets. A similar force applied to the lumbar spine most commonly would result in fracture because of the vertical orientation of the facets. An exception is ankylosing spondylitis, where the force is dissipated across the vertebral column, much as it would be in a long bone.[3]

Classification of Vertebral Injuries

CERVICAL

UPPER CERVICAL SPINE

Because of the unique anatomy of the occipital-atlantoaxial complex, applied forces result in characteristic injury patterns, as described below.

Jefferson's Fracture

This is a four-part fracture of the ring of the atlas (C1) caused by axial loading (e.g., a fall on the vertex of the skull). If the combined lateral displacement of the lateral masses exceeds 7 mm, disruption of the transverse ligament has occurred, indicating a greater degree of instability[4] (Fig. 94-2*A*). This injury must be differentiated on a lateral x-ray view from a stable fracture involving only the posterior arch of C1 caused by extension (see Fig. 94-2*B*).

Atlantoaxial Instability (C1 and C2)

SAGITTAL A gap greater than 4 mm between the anterior arch of the atlas and the odontoid is due to insufficiency of the transverse ligament. This condition may result from trauma or inflammatory erosion (e.g., rheumatoid arthritis).

ROTATIONAL This injury is a subluxation of variable degree, recognized by asymmetry of the gap between the lateral

aspect of the odontoid and the lateral mass of C1 on each side and also a decreased joint space between the lateral masses of C1 and C2.

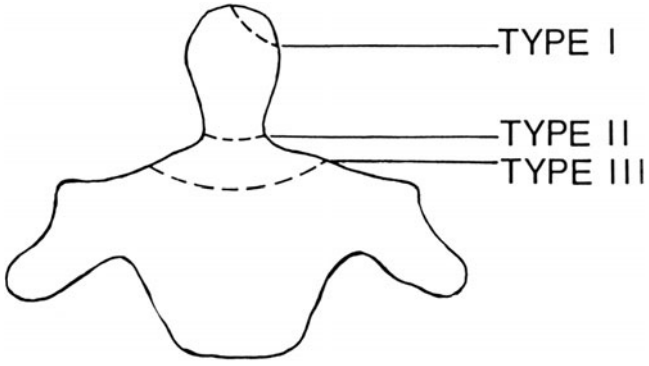

FIGURE 94-3 Fractured odontoid. ***(Used with permission from Anderson and D'Alonzo.[5])***

Fractures of the Odontoid

Shear forces in the sagittal plane cause these fractures. The level of the fracture is variable and has been classified by Anderson and D'Alonzo[5] into three types (Fig. 94-3).

Hangman's Fracture

This injury is a traumatic spondylolisthesis of C2–C3. It is a bipedicle fracture of C2, usually from an extension force, with anterior displacement of the body of C2 on C3. There is a low incidence of neurologic injury.

LOWER CERVICAL SPINE

These injuries are classified on the basis of the force applied to the neck, as described below.[5]

FIGURE 94-2 ***A.*** **AP tomogram confirming an unstable Jefferson's fracture with avulsion of the transverse ligament from the lateral mass of C1.** ***B.*** **Lateral view showing fracture of the posterior arch of C1 (*arrow*).**

A

B

Flexion
The applied force may be either compressive or distractive.

COMPRESSIVE The force acting through the anterior column results in fracture of the vertebral body. The extent of the injury varies from stable minor wedging of the anterior vertebral body only, with no neurologic loss, to marked intrusion into the neural canal, with frequent severe neurologic loss. There is usually associated facet subluxation and instability (e.g., teardrop and quadrangular fractures).

DISTRACTIVE The applied force begins posteriorly, involving the posterior ligamentous complex and, if severe, may involve all three vertebral column components. The extent of the injury varies from relatively stable subluxation through unilateral and bilateral facet dislocations to a complete vertebral body dislocation. The extent and frequency of neurologic injury usually are in proportion to the vertebral injury, but the initial displacement of the vertebrae may have been much more severe than that seen on x-ray.

Extension
The applied force may also be compressive or distractive.

COMPRESSIVE This type of force results in fractures through the laminae, which may be sheared off. These fractures can be unilateral or bilateral, and at the extreme, there may be displacement of the vertebral body anteriorly and severe instability. However, since the laminae are sheared off, there may be little intrusion into the neural canal, so the extent of neurologic injury may be less severe than the vertebral injury (Fig. 94-4).

FIGURE 94-4 Compressive extension fracture dislocation of C6–C7. There is dislocation of the facets, but since the spinous process and lamina were sheared off (*arrow*), there was minimal neural canal encroachment, and the patient suffered only bilateral C7 root injury.

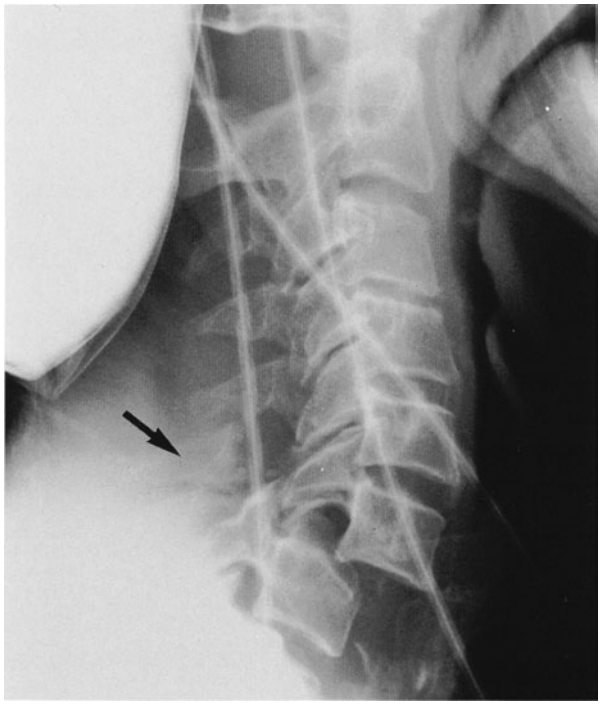

FIGURE 94-5 Distractive extension injury with severe preexisting osteoarthritis of the cervical spine. The disk space is opened anteriorly (*arrow*). Posterior osteophytes encroach on the neural canal, and there is a myelographic block (*arrow*).

DISTRACTIVE There is failure of the anterior column (anterior longitudinal ligament and disk) in tension, and therefore, the anterior column is usually stable in flexion. In young individuals, this condition may be missed easily clinically and radiologically and is associated with a low incidence of neurologic involvement. However, in the elderly with associated preexisting degenerative changes, there may be avulsion of bony spurs from the anterior vertebral body. The cervical spinal cord may be pinched between osteophytes on the posterior vertebral body and infolded ligamentum flavum posteriorly, typically resulting in incomplete injury (usually central cord syndrome; Fig. 94-5).

Vertical Compression
Axial load causes centrifugal displacement and intrusion into the neural canal and subsequent serious neurologic injury.

Lateral Flexion
This results in compression and fracturing of the lateral mass and also frequent contralateral ligament disruption. It is usually associated with nerve root injury on the compression side.

THORACOLUMBAR

Since the underlying anatomy in the thoracic and lumbar spine is similar, the mechanistic classification proposed by Denis[2] is helpful.

COMPRESSION
This is usually stable and only involves the anterior column, so there is a low incidence of neurologic injury.

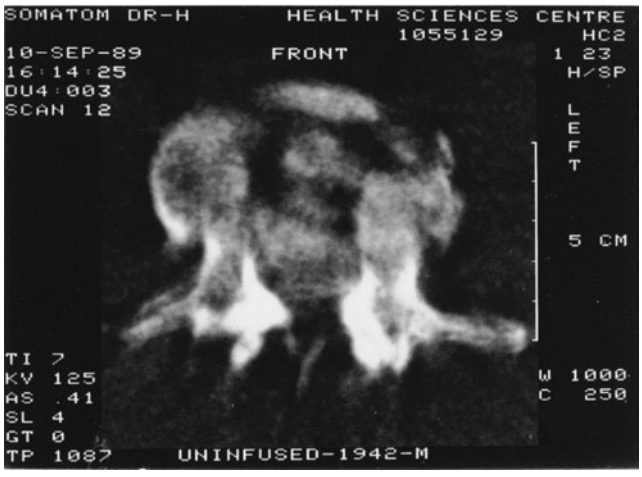

FIGURE 94-6 CT scan showing nearly total encroachment on the neural canal.

BURST

This condition results from axial load forces and results in major injury to the centrum of the vertebral body and intrusion of bone into the neural canal (Fig. 94-6), often associated with lateral displacement of the pedicles and a vertical fracture of the laminae. There frequently is associated neurologic injury.

SEAT-BELT TYPE (CHANCE FLEXION-DISTRACTION)

This injury is caused by a severe flexion force with the axis of rotation anterior to the vertebral body, resulting in failure of all three columns in tension. The pattern can involve various combinations of bony and ligamentous injury. There is minimal encroachment into the neural canal, and the most common neurologic injury involves the nerve root exiting beneath an involved pedicle and may be unilateral or bilateral.

FRACTURE DISLOCATIONS

These injuries usually are caused by a combination of forces (flexion, rotation, and shear) and result in translation of the vertebrae and severe neurologic loss.

The Neurologic Injury

Nerve tissues can be injured by stretching, compression, and laceration. Physical disruption of the spinal cord results in complete, irreversible loss of function. However, autopsy examination of the spinal cord in patients who clinically had a complete injury showed the spinal cord frequently to be structurally intact but to exhibit fibrous and cystic degeneration resembling end-stage ischemic changes.[6] Experimentally, in drop-weight tests, the initial finding is hemorrhage into the gray matter of the central cord, which may coalesce and form a central hematomyelia, surrounding edema, and increased interstitial pressure and local ischemia, as evidenced by a severe decrease in oxygen tension and an increased lactic acid concentration.

A second ischemic phase begins shortly afterward and may persist for more than 24 hours, involving both gray and white matter and spreading both proximally and distally from the site of injury.[7,8] The mechanism for this secondary vascular injury may be local high concentrations of norepinephrine[10–12] or other vasoactive amines. In addition to vascular injury, direct axonal injury would result in permanent functional loss due to the limited ability of central axons to recover.

It has been shown clearly that the effect of injury is directly related to the magnitude of the force and the duration of its application.[13,14] Since the initial force cannot be changed, we can only prevent further force application first by immobilizing the unstable area and then by relieving the continued compression through early reduction of displaced bony fragments and disks.

SPINAL SHOCK AND SPINAL CORD INJURIES

The direct force applied to the spinal cord results in a physiologic block to conduction (called *spinal shock*), which is recognized clinically as complete cessation of all neurologic function—motor, sensory, and autonomic—below the level of the injury. In slight injuries, this phase lasts only minutes, but in more severe injuries, it may last weeks. During this phase, predictions of neurologic recovery should be avoided.

The *pattern of spinal cord injury* is determined clinically when the patient is out of spinal shock.

COMPLETE CORD INJURY

Clinically, in cases of complete cord injury, there is no voluntary movement and no sensation, but spinal reflexes are present or exaggerated.

INCOMPLETE CORD INJURY

Some recognized forms of incomplete cord injury are listed below.

Anterior Cord Syndrome

This syndrome is characterized by complete motor loss below the level of injury and loss of light touch sensation but preservation of position, vibration, and deep touch sensation. This pattern is caused by anterior compression of the spinal cord, which injures the lateral corticospinal and spinothalamic tracts but spares the posterior tracts.

Central Cord Syndrome

Clinically, this injury is marked by disproportionate loss of motor power in the upper extremities, with less severe loss in the lower extremities. Sensation is variably altered. This pattern is caused by central hemorrhage in the cord, which affects the lower motor neurons and decussating tracts but spares the lateral corticospinal tracts.

Brown-Séquard Syndrome

Rarely, this syndrome is seen as a pure injury with blunt trauma, but it also may be seen in penetrating injuries. Motor power is lost on the ipsilateral side, and pain and temperature sensations are lost on the contralateral side, up to one or two segments below the level of the injury.

POSTERIOR CORD SYNDROME

This rare condition results in loss of position sense.

CAUDA EQUINA SYNDROME

The degree of neurologic loss with this syndrome varies greatly, depending on the extent of nerve root damage. The motor and sensory loss is symmetric, and there may be loss of bladder and bowel control.

ROOT LOSS

A few specific vertebral injuries are associated with loss of function of individual nerve roots. For example, a C5–C6 unilateral facet dislocation may cause ipsilateral C6 root injury. In a seat-belt injury, it is not uncommon that the nerve root exiting below the affected pedicle either unilaterally or bilaterally may be injured.

CLINICAL ASSESSMENT

Assessment of patients specifically for possible spinal injury begins after general assessment and resuscitative measures have been carried out. The patient must have an intact airway, adequate ventilation and circulation, and control of hemorrhage.

A history of the mechanism of injury is helpful in anticipating the type of injury. Other important information includes a history of previous neurologic abnormalities. Observations by the patient, witnesses, or the primary care giver of the occurrence of transient or persistent weakness or sensory changes or loss of bladder function related to the injury are very helpful.

On examination, any evidence of head or facial trauma, such as bruises, lacerations, or abrasions, can suggest the direction of an applied force. Especially important is any asymmetry of head position and tenderness along the sternomastoids. In a patient with an injured cervical cord, the arms may be held in the typical position of shoulder abduction and elbow flexion of a C5 quadriplegic. An ominous sign of neurologic loss is the presence of a paradoxical pattern of respiration. Priapism in a male patient with an injured cervical cord indicates loss of thoracolumbar sympathetic outflow. Examination of the trunk may show bruises or abrasions of the shoulders, the periscapular area, or the buttocks, suggesting a rotatory or flexion force to the spine.

A detailed neurologic examination then should be performed; it is recorded on a flow sheet to allow for serial examinations. Standardized methods of scoring for neurologic deficits have been developed that are extremely useful making neurologic assessments more consistent and reliable.[15,16]

The patient, wearing a cervical collar and held with gentle manual traction, may be carefully logrolled to allow examination of the back for tenderness, malalignment of the spinous processes, or a boggy gap in the supraspinous ligament, suggesting disruption of the posterior column (Fig. 94-7). While the patient is turned, sensation in the perianal area and rectal examination to include resting tone and voluntary contraction should be performed, along with testing of the bulbocavernosus reflex (Fig. 94-8).

RADIOLOGIC EXAMINATION

In multiple-trauma patients, the initial films are the scout lateral cervical spine film and an anteroposterior (AP) view of the chest and pelvis. Other, more detailed films are obtained on the basis of the clinical findings. In addition to the configuration and alignment of the vertebral bodies, the general alignment of the facets, the posterior vertebral bodies, and the interspinous distances, the specific points to observe on each film are listed in Table 94-1.

Following these x-rays, further detail may be required, and the following techniques are helpful. Since they require movement or turning of the patient, they should be done only when no instability has been demonstrated on plain films.

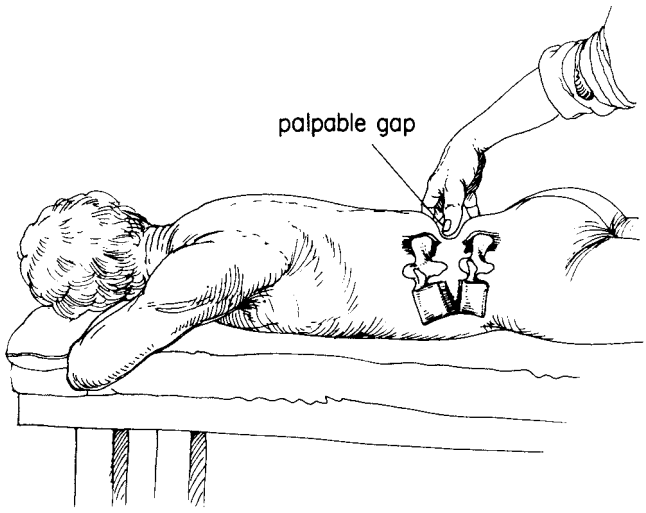

FIGURE 94-7 A palpable gap between the spinous processes indicating complete disruption of the supraspinous and infraspinous ligaments and severe posterior column injury. ***(Used with permision from Hoppenfield S: Orthopaedic Neurology. Philadelphia, Saunders.)***

CERVICAL SPINE

Swimmer's View

This view helps to visualize the cervicothoracic junction but is difficult to interpret and may show only gross malalignment.

Oblique and Pillar Views

These views are used to show the facets and lateral masses, respectively, and can be obtained with minimal movement of the patient.

FIGURE 94-8 Bulbocavernosus reflex produced by stimulation of the dorsum of the glans penis resulting in anal sphincter contraction. ***(Used with permission from Hoppenfield S: Orthopaedic Neurology. Philadelphia, Saunders.)***

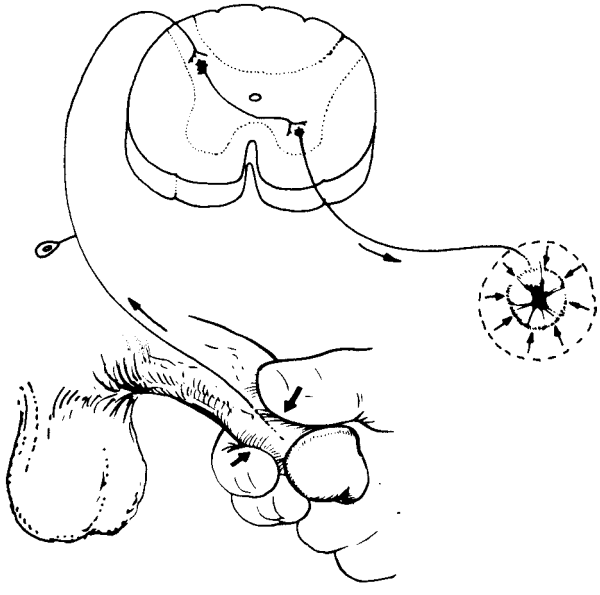

TABLE 94-1 Radiologic Evaluation of Spine Injuries

Location of Injury	Lateral	Anteroposterior
Cervical spine	Adequacy of the film (top of T1 should be visible) Retropharyngeal swelling at C3 (>3 mm) and C6 (>15 mm)	
Upper	Odontoid Gap from anterior arch to odontoid <4 mm	(Through-mouth) Odontoid Interval between odontoid and the lateral mass of C1 General alignment occipital condyle to the lateral mass of C1, and C1–C2 C1–C2 Joint space
Lower (C3–C7)	Disc space height Compression or avulsion of the anterior vertebral body Widening or asymmetry of interspinous distance	Fracture of lateral mass Abrupt change in alignment of the spinous processes
Thoracic and lumbar spine	Vertebral body configuration especially of the posterior wall Pedicles	Vertebral body height H-shape of the lamina Interpedicular distance Interspinous distance

Oblique Lumbar View
This view shows the lamina, pars interarticularis, and facets.

Conventional Tomography
This technique considerably improves detail and helps to show difficult areas (e.g., the cervicothoracic junction). It always should be done in two planes (AP and lateral) and requires turning of the patient; therefore, this technique is being replaced by computed tomography.

Computed Tomography
Computed tomography (CT) is a very valuable modality and requires only a single transfer of the patient, which can be done on the spine board or patient mobilizer. Routine, coronal, and sagittal reconstructions should be obtained. It is important that this examination be coordinated with other disciplines so that the patient with known or suspected spinal injury can have the appropriate areas examined at the same time as examination for other injuries (e.g., head, intrathoracic, intraabdominal).

Myelography
Myelography is indicated only under the following conditions:

1. The extent of the neural injury cannot be explained on the basis of the findings from plain films or CT.
2. Progressive neurologic loss occurs in the absence of severe encroachment on the neural canal, suggesting that the loss is ischemic in nature.
3. It is necessary to demonstrate possible dural defects or avulsed nerve roots.

Magnetic Resonance Imaging (MRI)
MRI has been used to assess the degree of soft tissue and ligamentous injury in the spine, looking for potentially unstable injury, particularly in the cervical spine. Overall, the results have not shown much advantage compared with conventional films and CT. There is a tendency to overcall significant injury. MRI does have a very high negative predictive value for significant soft tissue injury but is of uncertain positive predictive value and specificity.[17] This modality offers clear imaging of the acute injury to the spinal cord as well as of late changes, such as the development of traumatic syringomyelia. Rizzolo and colleagues[18] emphasized its usefulness in the unconscious or uncooperative patient in whom disk material must be removed before reduction is attempted.

CLEARING OF THE CERVICAL SPINE
Occasionally, when routine films are negative and a ligamentous injury to the cervical spine is suspected, flexion and extension films are indicated. They must be done only actively and, therefore, in an awake patient with medical supervision. Other methods for assessing the potential for unstable skeletal injuries in the unconscious patient include passive flexion extension using the image intensifier.[19] This can be done by experienced personnel when good visualization of the entire cervical spine can be obtained by passively flexing and extending the patient through an arc of about 30 degrees of flexion and extension.[20] MRI, when performed within 48 hours, also may be helpful.

Pitfalls in the Assessment of Spinal Injuries

ANKYLOSING SPONDYLITIS

The fracture may not be seen initially. The patient should be managed as having an unstable injury until further investigations (tomograms, bone scan) are performed.[3]

MULTIPLE NONCONTIGUOUS INJURIES

It is becoming more common for patients to have more than one spinal fracture at nonadjacent levels, especially in high-velocity injuries. The primary injury is considered to be the one associated with neurologic deficit. This is most often in the upper thoracic level. When a fracture in the spine is diagnosed, the entire spine should be x-rayed.[21]

UNCONSCIOUS OR HEAD-INJURED PATIENTS

The absence of symptoms and/or a compromised neurologic examination in these patients makes assessment very difficult.

Management of Spinal Injuries

IMMEDIATE

PREHOSPITAL

Multiple-trauma victims and patients with spinal injuries, especially spinal injuries involving neurologic loss, should be taken directly to a level 1 tertiary care center if they are physiologically stable and if the transport time is reasonable. Major trauma-receiving centers must have a formal team designated for the management of spinal injuries.[22]

PRIORITIES

The presence of a spinal injury, although serious and carrying a risk of severe late disability, does not alter the priorities of ensuring a clear airway, adequate ventilation, and adequate circulation.

OTHER TREATMENT MEASURES

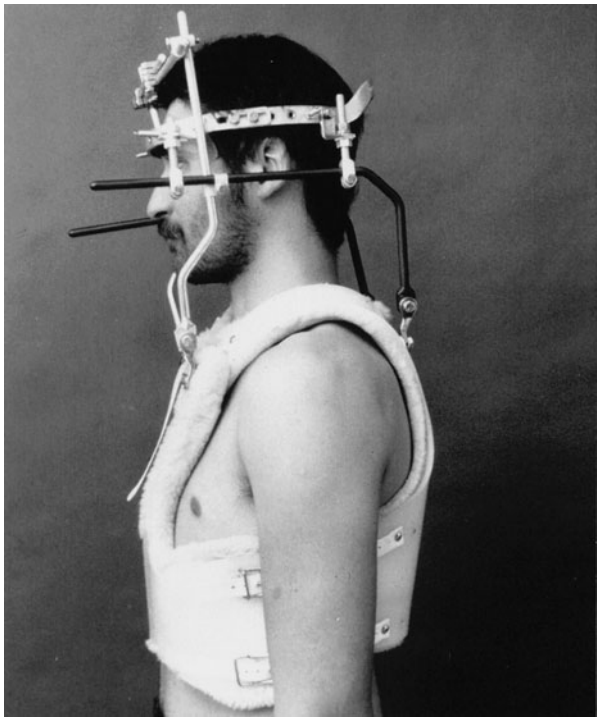
Trauma patients with suspected or proven spinal injuries must continue to be immobilized or logrolled as indicated until definitive care is instituted. Temporary immobilization of the cervical spine is accomplished by appropriate application of a cervical collar. A long spine board should be used for transporting the patient. It is important that this initial assessment and resuscitation be expedited to avoid prolonged pressure on areas such as the occiput, sacrum, and heels.

It is imperative that adequate perfusion with well-oxygenated blood be maintained to the injured spinal cord, and therefore, supplemental oxygen is given by facemask to maintain a Pa_{O_2} of at least 100 mm Hg. Other measures, as outlined below, are used to maintain a blood pressure of at least 100 mm Hg systolic.

Other general measures that should be instituted in the emergency department include insertion of intravenous lines, a nasogastric tube, and a Foley catheter.

As soon as the patient arrives in the emergency department, the spine injury team should be notified. That team then may supervise the spinal aspects of overall patient management and participate in decision making. Patients requiring manipulation for reduction of the spine should be managed where they can be monitored carefully and have easy access to x-ray facilities for serial films. Spine injury patients with other multiple trauma, all patients with high spinal cord injuries (above C5), and patients who have low cervical or thoracic cord injury as well as with significant preexisting disease are best treated initially in the intensive care setting until stabilized.[23]

Management of Complications of Spinal Injuries



NEUROGENIC SHOCK

Patients with neurogenic shock, particularly those with injuries above the level of T6, will be hypotensive and bradycardic owing to the combination of (1) loss of thoracic sympathetic outflow, vasodilatation, and pooling of blood and (2) relative predominance of vagal stimulation to the heart. In the absence of associated hypovolemia, the patient should be given a maintenance crystalloid infusion. If tissue perfusion is inadequate and/or the response to infusion is unsatisfactory, the patient should be investigated for concealed bleeding. Central lines are indicated, and monitoring of central venous pressure is used to gauge further fluid resuscitation. Extremes of crystalloid administration to maintain a normal pressure should be avoided, and colloids should be given as a volume expander, as repeated challenges. A persistently low perfusion pressure despite adequate fluid resuscitation warrants consideration of small doses of vasopressors.[24,25]

RESPIRATORY

Respiratory complications after cervical spinal cord injury occur in 60% of patients. The single most significant determining factor is the severity of the spinal cord injury.[26] Respiratory complications[27] are greatest in cervical cord injuries in which the patient has lost intercostal function and the abdominal muscle function needed to support a vigorous cough. The phrenic nerve is involved in lesions above C5. In lesions below C5, with a functioning diaphragm and accessory muscles and in the absence of lung injury or preexisting disease, most patients can support satisfactory ventilation. There is a tendency, even with good general care, for ventilatory function to deteriorate by the third or fourth day because of fatigue and retained secretions, and intubation and ventilation may be required early. While the patient is being ventilated, the position of the cervical vertebrae can be maintained by traction, giving access to the chest for therapy. Once the respiratory compromise has stabilized and weaning can begin, it is advantageous to immobilize the cervical spine in a halo vest (Fig. 94-9). The vest restricts access to the chest and increases chest wall stiffness.

FIGURE 94-9 Halo vest.

However, the upright or semiupright position facilitates diaphragmatic excursion, improving functional residual capacity,[28] especially in patients lacking intercostal function. While the patient is in neurogenic shock, postural hypotension will not allow maintenance of the upright position.

CARDIAC

Acute spinal cord injury may be associated with pulmonary edema. This usually occurs early, possibly owing to massive sympathetic outflow, increased afterload, and a predisposition to dysrhythmia.[29,30] A persistent feature following acute spinal cord injury above the T6 level is hypotension and bradycardia, even after administration of enough fluid and colloid to fill the venous capacitance vessels. These problems may respond to atropine (0.2 to 0.4 mg); if hypotension persists, vasopressors may be required.

GASTROINTESTINAL

Almost every patient with spinal cord injury and most patients with significant fractures of the thoracic or lumbar spine in the absence of neurologic injury will have a transient ileus, and a nasogastric tube should be inserted.

THROMBOEMBOLIC PREVENTION

Approximately 50% of patients with spinal cord injuries develop deep vein thrombosis.[31] Prophylaxis with low-dose heparin appears ineffective. Better methods include adjusted-dose heparin, low-molecular-weight heparin, low-dose heparin plus electrical stimulation of the calf, and low-dose heparin plus graduated stockings plus intermittent pneumatic compression; these measures should be continued for 6 to 12 weeks.[32]

SKIN CARE

Avoidance of decubitus ulceration depends on meticulous attention to frequent turning and protection of pressure points. This regimen is made easier by the use of special mechanized beds for turning (e.g., Stoke-Mandville bed).

NUTRITION

Following acute spinal cord injury, the patient becomes catabolic.[33] To minimize this effect and encourage early rehabilitation, early alimentation is encouraged as soon as the ileus resolves. If the gut cannot be used for a long period, then parenteral nutrition should be considered.

MANAGEMENT OF THE NEUROLOGIC INJURY

Decision making is based on accurate neurologic assessment initially, serial examinations, and accurate documentation. In the presence of neurologic injury, the two fundamental principles of management are

1. *Provision of an adequate perfusion pressure and well-oxygenated blood.* The patient must not be allowed to become hypotensive or hypoxic.
2. *Decompression.* The degree of injury and, conversely, the ability of the spinal cord to recover vary according to the magnitude of the applied force and the duration of compression. Decompression of the injured cord must be achieved as quickly as possible, usually by reduction of displaced fracture fragments by either closed means (e.g., halo traction, postural reduction on bolsters) or open ones. The adequacy of decompression must be proven radiologically.

Principles of Surgical Management

1. Decompression should be performed from the direction of encroachment on the neural canal (anterior or posterior).
2. The adequacy of decompression should be proven intraoperatively by direct visualization or myelography or postoperatively by CT.
3. Following decompression, a stable construct must be achieved by internal stabilization.[34]

Indications for surgical decompression of spinal cord and cauda equina or root injuries are as follows:

1. *Progressive neurologic loss.* This development is seen clinically as either an ascending level of neurologic loss or progression from incomplete to complete injury. Not infrequently, the neurologic level rises by one segment in the very early stages following injury. This event is due to ischemia, and subsequently, the neurologic loss usually recedes to the original level.
2. *Failure or anticipated failure of nonoperative decompression* (owing to retained bone or disk fragments). Generally, the reduction seen on plain x-rays represents the residual encroachment on the neural canal. Only in 3% of cases is there residual soft-tissue compression.
3. *Incomplete cord and/or cauda equina lesions with residual compression.*

In the following situations, surgical decompression will be of no benefit or may even be harmful:

1. A complete spinal cord lesion in a patient out of spinal shock
2. Progressive neurologic loss due to ischemia, with no blockage or significant residual compression, as seen on myelography

TECHNIQUES OF SPINAL CORD DECOMPRESSION

Anterior decompression of the cervical spinal cord[35] is the technique of choice in the following injuries:

1. Axial load (burst) fractures
2. Cervical disk injuries
3. Distractive extension injuries with residual neural canal encroachment by posterior vertebral body osteophytes

Extremely complex patterns of fractures and fracture dislocations (e.g., quadrangular,[36] teardrop,[37] compressive extension) may be treated by a combination of anterior and posterior approaches.

The most common type of injury to the upper thoracic spine that may require decompression is a fracture dislocation that is extremely unstable and difficult to reduce nonoperatively. When decompression is indicated, the reduction can best be performed posteriorly, followed by stabilization using a segmental spinal instrumentation technique. New developments in instrumentation such as hook rods, pedicle screws, cages, and anterior plating systems have made it possible to achieve

neural decompression, as well as a high degree of stability and correction of deformity, while also limiting the extent of the fusion.

For fracture dislocations, surgical decompression can be performed by laminectomy, clearing residual bone from within the neural canal followed by reduction and stabilization using pedicle screw or hook rod systems.

Burst fractures of the thoracolumbar spine usually can be decompressed posteriorly by pedicle screw distraction (ligamentotaxis) if done within 4 to 5 days of the injury. Anterior corpectomy and reconstruction are another option in the situation of severe canal encroachment or if residual neural compression persists after a posterior procedure.[38]

ADJUNCTIVE TECHNIQUES TO REDUCE SPINAL INJURY

The secondary ischemia following initial spinal cord injury is a major contributor to further neurologic damage and functional loss. Attention has been paid to understanding the pathophysiology of this process in order to identify ways to minimize its effect.[39] Despite initial enthusiasm, many modalities, such as spinal cord cooling, hyperbaric oxygen, mannitol, and dimethylsulfoxide (DMSO), have not been shown to be effective.

STEROIDS

The glucocorticoids (e.g., dexamethasone) are presumed to act by decreasing the effect of norepinephrine, stabilizing cell membranes, preventing release of lysosomal enzymes, inhibiting complement activation, and reversing the sodium and potassium electrolyte imbalance that results from tissue edema and necrosis.[40] Experimentally, controversy exists regarding the effectiveness of steroids. Clinically, Bracken and colleagues[41] have indicated that the administration of methylprednisolone, 30 mg/kg within 8 hours of injury, followed by infusion of 5.4 mg/kg per hour for 23 hours resulted in improvement in neurologic function. A further study[42] suggested that there was improved motor outcome when methyprednisolone was initiated earlier than 3 hours and for 24 hours or between 3 and 8 hours for 48 hours. However, functional outcome was not improved. Review of the data leaves unsolved issues.[43–45]

Since complications may be associated with the use of steroids,[46] administration of these agents on an ad hoc basis is discouraged. The spine injury team should adopt a policy with respect to the use of steroids, standardizing dosage, time of administration, and duration of treatment.

Management of the Vertebral Injury

When considering the bony injury, the principles of fracture management (reduction, maintenance, and mobilization) apply. These goals may be accomplished nonoperatively. With failed closed reduction, inability to maintain position, or the desire for early mobilization, an open reduction and internal stabilization are indicated. Stable fractures of the cervical or thoracolumbar spine can be mobilized early with limited use of an orthosis for pain relief.

In the cervical spine, unstable fractures that do not require reduction may be managed in an orthosis only (e.g., a nondisplaced type III fracture of the odontoid), but careful monitoring is necessary to demonstrate that the position is maintained. When a reduction is necessary, halo traction should be used so that once the fracture is reduced, the patient can be mobilized in a halo vest (see Fig. 94-9). The initial enthusiasm regarding the ability of the halo vest to control unstable cervical injuries has been challenged.[47] Patient selection criteria for halo vest management are outlined in Table 94-2.

TABLE 94-2 Halo Vest Management of Cervical Injuries

Suitable	Unsuitable
Fracture of the odontoid of types II and III	Axially unstable fractures (e.g., Jefferson's)
Hangman's fracture	Primarily ligamentous injuries (e.g., distraction flexion causing unilateral and bilateral facet dislocations)
Minimal compression-flexion injuries	Obesity
Fracture of the lateral mass	Noncompliant patient
	Multiple-level injuries

When open reduction and internal stabilization are indicated, the fracture pattern must be analyzed carefully in preoperative planning to make sure that the force causing the injury will be neutralized so that sufficient stability will be achieved that minimal, if any, external support will be required. Using modern implant techniques, this result is for the most part achievable.[48,49]

In fractures of the thoracic and lumbar spine, similar principles may be applied. Unstable fractures not requiring reduction may be treated with bed rest and logrolling for 2 to 3 weeks, followed by a well-fitted, rigid polypropylene brace. Closed postural reduction of some minimally displaced thoracolumbar fractures can be achieved by positioning the patient on corrective bolsters and careful logrolling until sufficient bony healing has occurred to allow mobilization in an orthosis. However, this approach requires skilled personnel in specialty units. With the advent of much-improved techniques of stabilization, there is an increased emphasis on health care costs and earlier mobilization, and thus there is an increasing trend toward early surgical stabilization.[50,51] However, careful attention must be given to achieving sufficient stability to allow early mobilization.[52–54]

Pitfalls in the Management of Spinal Cord Injury

HYPOTHERMIA

Hypothermia is a particularly important problem in patients with cervical or high thoracic cord injuries. The patient is unable to produce vasoconstriction because of loss of the thoracic sympathetic outflow and also is unable to shiver to maintain core temperature. This results in hypotension and bradycardia. The temperature must be monitored carefully, and the patient must be kept covered or warmed by radiant heaters.

AUTONOMIC DYSREFLEXIA

This potentially dangerous complication occurs in patients with spinal cord injuries above the T6 level at any time after

the stage of spinal shock. The presenting symptoms are quite variable, the most consistent being hyperhidrosis, headache, and vasodilatation above the level of the neurologic loss with nasal stuffiness. Paroxysmal hypertension is the cardinal sign; bradycardia is present inconsistently. The usual precipitating events are distention or manipulation of the bladder or rectum or intraabdominal pathology. These stimuli result in massive reflex sympathetic outflow, causing hypertension and reflex bradycardia and vasodilatation in the part of the body above the level of the spinal cord lesion. Immediate management should consist of placing the patient in an upright position and removing the stimulus, e.g., by bladder decompression. Vasodilator therapy may be required for severe hypertension.[55]

THE SWOLLEN LIMB

The neurologically impaired patient may present at any time after the injury with a painless swollen limb. The differential diagnosis includes fracture, venous thrombosis, and myositis ossificans. Myositis ossificans is a frequent occurrence in association with spinal cord injury. In total joint arthroplasty, the use of indomethacin may decrease the occurrence and severity of this complication, but the usefulness of this agent is unproven in spinal injuries. Physiotherapy to maintain range of motion should be reduced but probably not discontinued.

Considerations in Rehabilitation

Many assessment tools are available for documenting neurologic status after acute spinal cord injury, such as the Frankel scale and the American Spinal Injury Association (ASIA) scale. A practical method of determining function is incorporated in the Functional Independent Measure (FIM), which is a combination of a neurologic assessment and an assessment of the ability to perform various self-care activities. Restoration of the highest possible level of function in the patient with a spinal injury begins with initial management. Since function is related directly to the level of neurologic injury, preservation of even a single nerve root or segment, especially in the cervical cord, may make the difference between independence and the need for attendant care. For example, a C7 quadriplegic with strong active elbow extension can do transfers from bed to chair and chair to toilet and can live independently with some assistance at home. A C6 quadriplegic with good shoulder muscles and some active wrist extension is capable of independent feeding and grooming because of a fairly strong tenodesis grip. The patient can turn independently in bed, assist with transfers, operate a regular wheelchair, and even operate a car with hand controls. By contrast, a patient with a C5 injury is capable of very limited self-care, cannot turn in bed, and can only use an electric wheelchair.

Maintaining range of movement of joints that can be moved actively is essential to achieving maximum function. This is also important in joints that have lost active movement because flexion contractures of hips and knees interfere severely with independent transfers.

In some instances, it may be advantageous to leave an imbalance of certain muscle groups in order to facilitate function. For example, some tightness of the long finger flexors will improve the grip in patients dependent on the tenodesis effect for grasping objects.

Active therapy must begin during the phase of spinal shock and continue as the patient passes into the stages of spasticity.

Chapter 95
TORSO TRAUMA

JAMEEL ALI

KEY POINTS

- *Consideration of abdominal and thoracic injuries as one complex torso trauma is a useful treatment strategy.*
- *Prioritization of intervention in torso trauma is based on the relative threat to life from specific injuries.*
- *In managing torso trauma, the surgeon must be prepared to explore the chest and/or abdomen because the source of instability frequently is not obvious.*
- *The major decision in assessing the traumatized abdomen is to recognize the need for surgical exploration.*
- *In general, indications for surgical intervention in abdominal trauma are perforation, penetration, and hemorrhage.*
- *An organ-specific diagnosis is not necessary to establish the need for laparotomy in trauma.*
- *Ultrasound, peritoneal lavage, and computed tomographic (CT) scan are important tools in assessing the traumatized abdomen when physical examination alone is unreliable.*
- *Most thoracic injuries can be managed appropriately by simple measures aimed at correcting thoracic sources of hypoperfusion and hypoxemia.*
- *Emergency thoracotomy should be considered in the unstable patient who has a potentially correctable source of instability in the thorax.*

Injuries involving the chest and abdomen may be considered as a single complex torso trauma. The rationale for this point of view is based on several factors. The configuration of the diaphragm and its attachment to the rib cage result in marked variability in its position with respiration and thus in demarcation of the thoracic and abdominal cavities. It is not unusual for the diaphragm to traverse distances of over 15 cm between the inspiratory and expiratory phases of respiration. The diaphragm may be at the level of the nipple line during full expiration and well below the costal margin during full inspiration, with corresponding shifts of the abdominal and thoracic contents (Fig. 95-1). This phenomenon, together with the variable trajectory of objects or forces after penetrating the torso, makes it virtually impossible in many instances to determine on the basis of the external point of impact or penetration whether intrathoracic or intraabdominal injury has been sustained. The concept of torso trauma ensures that injuries in one cavity will not be overlooked while injuries in the other are being managed.[1,1a,1b]

As outlined in Chap. 92, the initial approach in trauma management is to secure the airway, to maintain respiration, and to identify and control hemorrhage and institute immediate fluid resuscitation as required. Definitive management of intraabdominal or thoracic injury may be necessary as part of this resuscitative phase, particularly if the source of instability is major hemorrhage in the thoracic or abdominal cavity. Although it may be possible to identify a specific source in the thorax or abdomen for the abnormal hemodynamics in the trauma patient, it is frequently impossible to be absolutely certain of such a source. Therefore, a decision has to be made to approach the hemodynamically abnormal patient through either a laparotomy or a thoracotomy if a source outside the thorax or abdomen has been ruled out. With this approach, one must be prepared to stop exploration of one cavity when it becomes obvious that the source of the hemodynamic abnormality is in the other.

Classification of Torso Trauma

Generally, torso trauma may be classified into two broad groups: penetrating and blunt. As indicated earlier, any penetrating missile entering inferior to the nipple line can produce diaphragmatic, intrathoracic, or abdominal injuries. Similarly, blunt injuries may disrupt intrathoracic contents as well as intraabdominal contents either directly or indirectly through fractures of the lower ribs, which then puncture intraabdominal organs such as the spleen, liver, and stomach.

A more clinically applicable method of classifying torso trauma involves two categories. The first category consists of injuries that are immediately life threatening and thus require immediate intervention because of cardiorespiratory or hemodynamic compromise. The other category includes injuries in a relatively hemodynamically normal patient. These latter injuries are considered to be potentially life threatening because, if left unattended, they eventually may threaten the patient's survival.

Occasionally, neck injuries, particularly the penetrating type, may involve intrathoracic structures. In addition to causing vascular injury (which may present with hemorrhage or ischemic sequelae), injury to the thoracic duct (resulting in chylothorax), or violation of the pleura (resulting in pneumothorax), penetrating neck wounds may affect any of the intrathoracic structures, depending on the trajectory of the offending weapon.

The neck traditionally is divided into three anatomic regions for the purposes of categorizing penetrating wounds. Zone I extends from the cricoid to the clavicle, zone II from the cricoid to the angle of the mandible, and zone III lies between the angle of the mandible and the base of the skull.

Penetrating wounds of the neck should be explored in the operating room under sterile conditions with adequate anesthetic support. A preoperative plain x-ray of the neck if the patient is stable could provide information such as depth of penetration and the presence of air in the tissues, hematoma, airway deviation, etc. Impaling objects should be removed only in the operating room with vascular equipment available and a securely controlled airway in place. Although there is reasonably good agreement that zone III injuries should be investigated with angiography, the use of angiography and other diagnostic modalities in zone II injuries is controversial because this area can be assessed thoroughly and more easily through direct surgical exploration in the operating room. Diagnostic modalities include angiography, endoscopy, contrast radiography, and computed tomography (CT).[2]

A nasogastric tube should be inserted in the operating room, preferably after the airway is securely controlled by

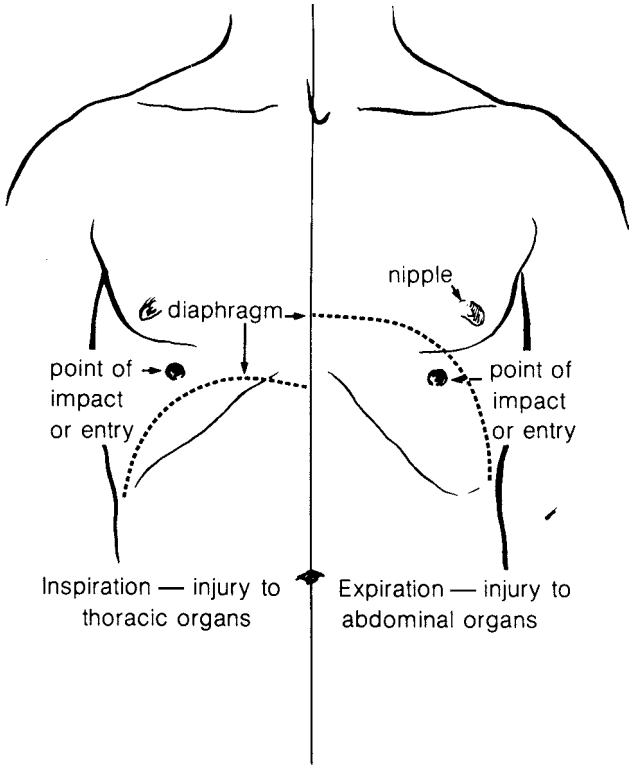

FIGURE 95-1 The rationale for regarding torso trauma as a unified entity. A blunt or penetrating impact at a given level of the chest wall may cause either intraabdominal or intrathoracic injury depending on the trajectory of the missile and/or the position of the diaphragm.

endotracheal intubation, because retching during the insertion of such a tube could lead to clot dislodgment, hemorrhage, and airway compromise. The possibility of intrathoracic injury always should be considered in patients with penetrating neck wounds. The chest therefore should be prepared and draped adequately in the event that thoracic exploration is necessary for repair of intrathoracic injury or possible vascular control for vascular injuries in the neck.

Thoracic Injuries Requiring Immediate Intervention

Although thoracic injury frequently is associated with trauma-related deaths, less than 10% of blunt chest injuries and only 15% to 30% of penetrating chest injuries require open thoracotomy.[3] Lifesaving skills for dealing with thoracic trauma generally are within the scope of most practicing intensivists. Of the injuries that require open surgical intervention, most do not require the expertise of a trained thoracic surgeon. From the intensivist's standpoint, resuscitative measures are aimed at correcting hypoxemia and maintaining normal hemodynamic status. These two aims are achieved by techniques for establishing patency of the airway[3,4] (see Chap. 35), chest decompression for evacuating fluid or air, pericardiocentesis, and vascular access for fluid administration.

In addition to upper airway obstruction, which is discussed in Chap. 34 and poses an immediate threat to life, the following thoracic injuries require immediate intervention[4–6]:

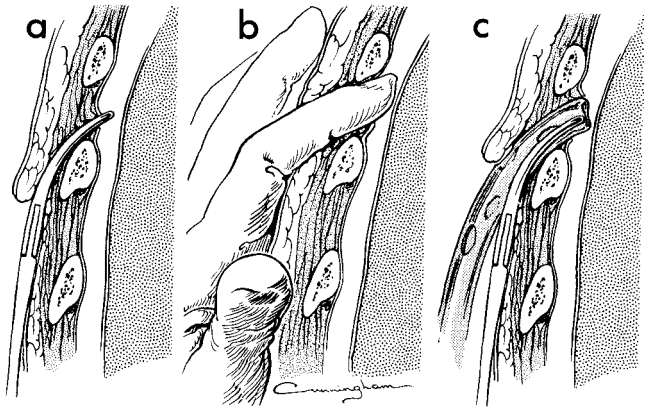
1. Tension pneumothorax
2. Open pneumothorax
3. Cardiac tamponade
4. Massive hemothorax
5. Massive pneumothorax
6. Traumatic air embolism
7. Flail chest

Since all of these conditions require immediate intervention, the intensivist who sees such patients must be prepared to institute therapy before any other physician is available. To guide appropriate intervention, a brief description of the pathophysiology, diagnosis, and treatment principles for each of these conditions follows. In all cases, the airway must be secured and adequate intravenous (IV) access established.

TENSION PNEUMOTHORAX

This lesion arises when a one-way valve mechanism exists after chest wall or lung injury. Gas enters the pleural space but has no escape, and with each subsequent respiratory cycle, there is increased intrapleural pressure and gas accumulation. This increased tension causes the ipsilateral lung to be compressed and displaced to the opposite side. With the resulting mediastinal shift, there is not only compromise of ventilation and gas exchange but also kinking of the major veins at the thoracic inlet of the neck and at the diaphragmatic entrance of the inferior vena cava, thus compromising venous return to the heart. Continued shift of the mediastinum eventually compresses the contralateral lung as well, producing further ventilatory compromise. This combination of hypoperfusion and hypoxemia can be lethal, and immediate treatment is required. The diagnosis is suspected in a patient who presents with chest trauma, tachypnea, severe dyspnea, decreased air entry, and hyperresonance on the affected side and, sometimes, a clinically detectable shift of the trachea to the opposite side with hypotension.

The treatment is immediate decompression of the pleural space, which is accomplished initially by inserting a large-bore needle or incising with a scalpel down through the chest wall into the pleural space at the second intercostal space in the midclavicular line or the fourth to fifth intercostal space just anterior to the midaxillary line. If a plunger syringe is used with the needle, an immediate spontaneous rise of the plunger in the barrel will be seen. Similarly, when the scalpel enters the pleural space, there is a massive loud decompression of the pleural space, followed by immediate respiratory improvement. Either procedure should be followed by formal insertion of a chest tube. Briefly, the technique of chest tube insertion requires an incision down to the pleura in the fourth to fifth intercostal space just anterior to the midaxillary line. The large-bore chest tube (F32 to F36) is inserted directly with a clamp after verification with finger palpation that the pleural space has been entered and there are no pleural adhesions (Fig. 95-2). When needle decompression is performed prior to insertion of the chest tube, the needle may be inserted through the finger portion of a glove so that air may exit but not enter



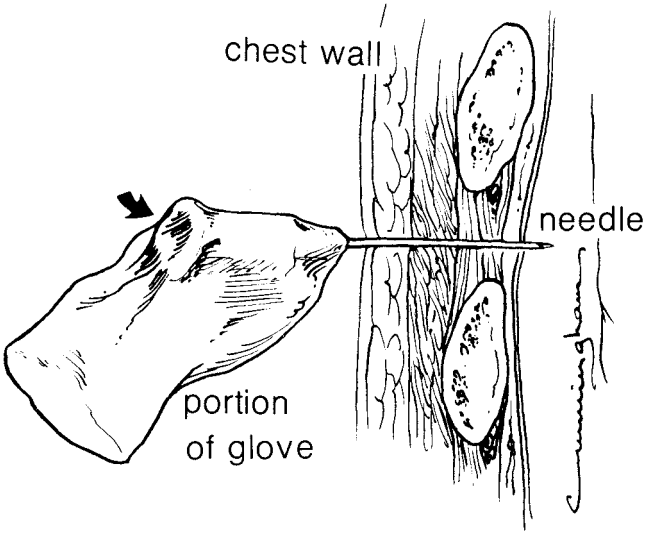


FIGURE 95-2 Technique of chest tube insertion. The incision is made 2 cm below the chosen interspace, and the clamp (*A*) followed by the finger (*B*) is inserted into the pleural space above the upper border of the rib. The tube is inserted and directed with the Kelly clamp (*C*). The tube is then gently directed posteriorly and toward the apex.

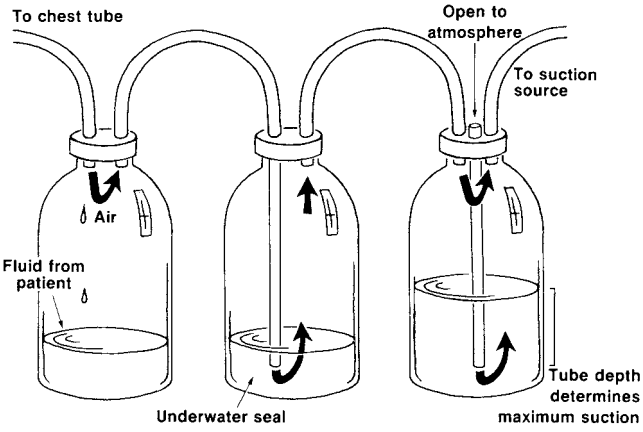
the pleural space from the atmosphere (Fig. 95-3). Once the chest tube is inserted, it is connected to an underwater seal system with the option of applying suction. Figure 95-4 illustrates the classic chest tube drainage system. However, commercially available prepackaged chest tube drainage systems are available that operate on the same principles.

OPEN PNEUMOTHORAX

In open pneumothorax, there is free communication through a chest wall wound between the pleural space and the atmosphere. Entry of air with each respiratory cycle results in progressive collapse of the ipsilateral lung. The larger the defect in the chest wall, the greater is the rate at which pleural air accumulates, and the more rapid is the collapse of the ipsilateral lung. This pathophysiology is similar to that in tension

FIGURE 95-3 Needle decompression of the pleural space. Use of the finger portion of a glove prevents air from entering the pleural space.



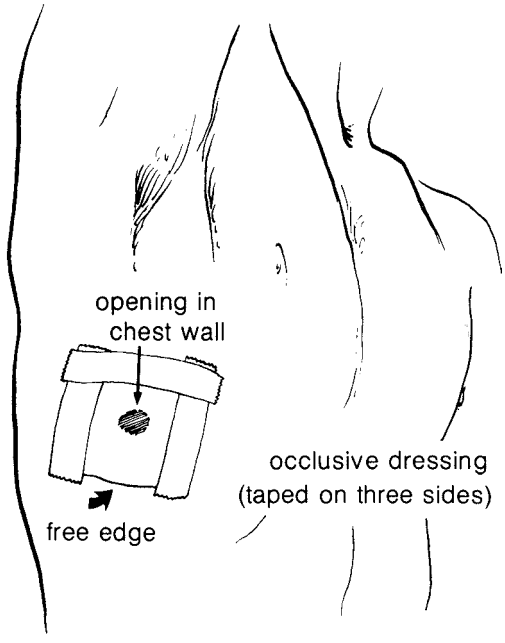


FIGURE 95-4 Chest drainage collection systems.

pneumothorax because collapse of the lung and shift of the mediastinum to the opposite side will cause hypoxemia and decreased venous return. The diagnosis usually is obvious, with a visible open wound in the chest wall and a characteristic loud noise created from atmospheric air entry into the pleural space.

The first principle in treating this injury is occlusion of the open wound. This usually can be accomplished with an occlusive gauze dressing (Fig. 95-5). Larger defects will require much larger dressings, and major defects that cannot be occluded readily by dressing technique will require support of the patient with endotracheal intubation and positive-pressure ventilation until formal surgical repair of the chest wall defect can be accomplished. After the opening in the chest wall is occluded, a chest tube should be inserted through a separate opening, as indicated earlier. Figure 95-5 shows a

FIGURE 95-5 Temporary occlusive dressing for open pneumothorax. This dressing allows egress of air but prevents entry of air into pleural space.

technique whereby an occlusive dressing can be applied that allows decompression of the pleural space as well as occlusion of the opening. The nonpermeable dressing is applied over the opening and secured on all but one side. This allows egress of air from the pleural space but prevents air from entering the pleural space.

CARDIAC TAMPONADE

Cardiac tamponade occurs when fluid accumulation in the pericardial sac interferes with cardiac filling. Elevated pericardial pressure decreases transmural filling pressures of the cardiac chambers, resulting in diminished filling and stroke volume of the right and the left side of the heart. Cardiac output falls, with an attendant decrease in systolic blood pressure and pulse pressure.

The diagnosis of cardiac tamponade is one that requires a high index of suspicion and should be considered in any patient who has blunt or penetrating trauma to the chest and is hypotensive without any obvious signs of blood loss. The classic triad described by Beck of hypotension, elevated venous pressure, and muffled heart tones is not always present or easily discernible.[7] The status of the neck veins is particularly important in distinguishing hypotension caused by hypovolemia from that caused by cardiac tamponade. In the former case, the neck veins are flat, whereas in the latter, they are distended. However, a struggling or straining patient may produce misleading bulging of the neck veins, which must be taken into consideration. An increase in pulsus paradoxus (the difference in systolic blood pressure between inspiration and expiration) above 10 mm Hg suggests the diagnosis of cardiac tamponade. However, in the emergency setting it may be difficult to quantitate the degree of pulsus paradoxus. During arterial pressure transduction in the ICU, it is possible to measure pulsus paradoxus accurately. The physician should note the difference between systolic blood pressure during inspiration and expiration. The pressure waveform will exhibit a lower peak level in inspiration, with higher peak levels in expiration. The difference between the two peaks is the pulsus paradoxus. The degree of pulsus paradoxus may be determined at the bedside by listening for the first set of sounds with the sphygmomanometer slowly deflating. The first set of sounds represents the systolic blood pressure on expiration. As the pressure in the cuff is slowly released, the gaps in systolic blood pressure sounds between inspiration and expiration disappear, and there is an increased frequency of sounds heard with the stethoscope. The difference between the initial pressure and the pressure when the gaps in sounds have disappeared is the degree of pulsus paradoxus. Since distended neck veins and hypotension are present in both tension pneumothorax and cardiac tamponade, differentiation between these two conditions is important but at times difficult. The physician must rely on evidence of hyperresonance and decreased breath sounds that will suggest tension pneumothorax. If a search for these signs still leaves doubt, the patient should be treated first for possible tension pneumothorax by insertion of a needle in the pleural space. This step can be performed quickly and will give the diagnosis as well as be therapeutic for a tension pneumothorax. Once tension pneumothorax is ruled out, one should proceed to treatment for cardiac tamponade if signs of circulatory compromise persist. If immediately available in the emergency setting, epigastric placement of an ultrasound probe is also helpful in diagnosing hemopericardium.[8]

Although performance of a subxiphoid pericardial window in the relatively stable patient is acceptable, the initial treatment of cardiac tamponade consists of prompt pericardiocentesis.[9] This usually is performed with a 16- to 18-gauge needle that is at least 6 in long, incorporates a catheter, and is attached to a 50-mm empty syringe with a three-way stopcock. If time permits, the skin below the xiphoid process is anesthetized, and an electrocardiographic lead is attached to the hub of the needle as the needle is inserted below the skin at roughly a 45-degree angle and advanced cephalad toward the tip of the left scapula.[3,9] Gentle aspiration is maintained as the needle is advanced. A sense of "give" may be noted as the needle enters the pericardial sac. Nonclotting blood aspirated at this time confirms a pericardial position of the needle. If the needle is advanced into the myocardium, an injury pattern is seen on the electrocardiogram (ECG) monitor. If this is noted, the needle should be withdrawn slightly and then aspirated coincident with return to the previous baseline ECG tracing. Other ECG patterns, including premature ventricular contractions, may occur when the needle contacts the myocardium.

Although the pericardial sac can accommodate large volumes of fluid when the fluid accumulates chronically, in acute pericardial tamponade, a volume as small as 100 mL can compromise cardiac function significantly. Similarly, withdrawal of as little as 20 to 50 mL of blood from the pericardial sac results in significant improvement in hemodynamic status.[10] Apart from the signs noted earlier that suggest successful aspiration of the pericardial sac, recovery of blood that immediately clots in the syringe, particularly if the patient's hemodynamic status does not improve, should raise the concern that the needle has penetrated the heart and that intracardiac rather than pericardial blood is being aspirated. As pericardiocentesis is being conducted, the operating room (OR) should be prepared; whether pericardiocentesis fails or succeeds and results in stabilization of the hemodynamic status, it should be followed by formal thoracotomy and repair of the lacerated heart.[10–13] This usually is conducted through an anterolateral thoracotomy incision in the fifth intercostal space. However, a median sternotomy is an alternate route. When the thoracic cavity is entered, the pericardium is identified, and a longitudinal incision is made in it, care being taken to avoid transection of the phrenic nerve. Blood is aspirated, and the laceration in the heart is identified and controlled quickly by digital pressure. With finger control of the bleeding point, interrupted sutures are placed and secured with Teflon pledgets to repair the laceration, and the pericardium is then resutured, with a small opening (approximately 1 cm) left to prevent reaccumulation of blood in the pericardial sac. Other reported techniques for repair of the cardiac laceration include temporary Foley catheter insertion into the cardiac wound, followed by inflation of the balloon of the catheter and repair of the laceration. Skin staples also may be used to close the cardiac wound. In very rare circumstances, the laceration involves the coronary arteries. Formal repair of the artery will require heart-lung bypass and may be accomplished in the acute setting if the resources are immediately available. If the patient's condition stabilizes and the bleeding and laceration have been controlled, then definitive therapy for the coronary artery laceration may be pursued

subsequently on a semielective basis. In placing sutures for the cardiac repair, care should be taken to avoid incorporating and ligating coronary arteries.

MASSIVE HEMOTHORAX

Although most patients with traumatic hemothorax are relatively stable and do not require immediate surgical intervention, a few present with massive intrathoracic hemorrhage. This condition requires prompt diagnosis and immediate treatment to ensure survival. The mechanism of injury may be blunt or penetrating and generally involves disruption of a major central vascular structure or laceration of a systemic artery such as an intercostal artery or internal mammary artery. Intrathoracic hemorrhage usually arises from parenchymal lesions of the lung and stops spontaneously, particularly with reexpansion of the lung. The patient with massive intrathoracic hemorrhage presents initially with severe hypotension from blood loss and later with hypoxemia from collapse of the lung caused by the mass effect of the blood in the involved thoracic cavity.[14] Apart from severe hypotension and tachycardia, these patients demonstrate dullness to percussion and decreased air entry on the involved side and a shift of the mediastinum to the opposite side. The central venous pressure or jugular venous pressure is usually low, but it may be elevated in the unusual circumstance that a mass effect from the blood contained in the thorax produces a mechanical obstruction to venous inflow into the chest.

The diagnosis is confirmed and treatment instituted by insertion of a large-bore chest tube, through which a large volume (frequently close to 2000 mL) of blood drains immediately, to be followed by a continuous drainage of blood at rates approximating 100 mL/h. If either of these conditions is present, the patient is considered to have a massive hemothorax requiring surgical intervention. These should not be considered absolute indications for thoracotomy but merely guidelines. The most important indicator of whether or not surgical intervention is necessary is whether the patient's hemodynamics improve significantly and remain so after chest decompression and with fluid resuscitation. If bleeding continues at a rapid rate, or if the patient's hemodynamic status cannot be normalized with rapid infusions of blood and crystalloid, surgical intervention is warranted. The involved chest is opened through a posterolateral incision. Once the blood has been evacuated from the pleural space, a search is made for the bleeding point. It is frequently necessary to clamp the hilum of the lung temporarily and to release it intermittently in order to identify the area of bleeding, which is repaired by direct suture. Occasionally, massive hemorrhage necessitates resection of the involved lung, which should be accomplished quickly using staple devices. Very occasionally, the bleeding is from a ruptured thoracic aorta. Usually patients with free bleeding into the thoracic cavity from a ruptured aorta exsanguinate at the scene or immediately thereafter. However, in certain instances, it is possible to salvage some of these patients by clamping the aorta proximal and distal to the laceration and expeditiously repairing the laceration or inserting an aortic graft prosthesis.[4,15,16] If available, a preheparinized shunt may be of use in these circumstances to bypass the lacerated area of the aorta and maintain perfusion of the distal aorta and spinal cord while the repair is undertaken.[17] Occasionally, access to the bleeding source will require extension of the unilateral thoracotomy incision into the opposite chest by transection of the sternum and ligation of the internal mammary arteries.

The Massively Bleeding Patient

As indicated previously, it is not always possible to determine precisely whether massive bleeding arises from a thoracic or an abdominal source. Therefore, it is crucial that the entire abdomen and chest be prepared and draped for exposure in the OR. In these circumstances, if the bleeding is into the right chest and the apparent site of impact or penetrating injury is in the lower right chest below the nipple line, laparotomy through an upper midline incision should be conducted because the source of the hemorrhage is usually a liver injury with penetration of the right hemidiaphragm. Where ultrasound assessment is immediately available, this may allow more precise location of the source of the hemorrhage and thus guide the location of the incision in the abdomen or thorax. Failure to reveal an abdominal source of hemorrhage at laparotomy will necessitate an anterolateral thoracotomy on the right side, which usually will reveal lacerated intercostal arteries, which should be identified and ligated. As indicated earlier, injuries to the low-pressure pulmonary vasculature usually are not associated with massive hemorrhage, and the bleeding stops spontaneously, particularly with reexpansion of the lung and decompression of the pleural space. If the impact is to the right upper chest or to any portion of the left chest, then massive hemorrhage should be treated by anterolateral thoracotomy on the bleeding side, and the incision should be extended as necessary to obtain control of the bleeding site. Occasionally, bleeding into the chest arises from a penetrating injury to the base of the neck. In these circumstances, the chest should be opened through a median sternotomy, with the option of extending laterally into the chest as well as above the clavicle to convert the incision to a trapdoor type of exposure. The median sternotomy under these circumstances allows better exposure of the vascular structures of the base of the neck than would be available through an anterolateral thoracotomy.[18]

MASSIVE PNEUMOTHORAX AND AIRWAY INJURY

Most patients with traumatic pneumothoraces present with signs characteristic of a pneumothorax but without any major degree of hemodynamic compromise, and the pneumothorax responds very promptly to chest tube insertion. Occasionally, however, the pneumothorax persists despite adequately functioning large-bore chest tubes and is accompanied by massive subcutaneous emphysema and continued hypoxemia and respiratory instability. The patient usually also has some degree of hemoptysis, which may be evidenced by blood draining through the endotracheal tube if the patient has been intubated, as is often the case. This scenario suggests the presence of a large airway laceration and requires immediate surgical intervention.

The patient is immediately placed on 100% oxygen. If time allows, bronchoscopy should be performed to identify the level of the lacerated airway. However, thoracotomy is warranted even if the lesion is not identified or there is insufficient time to perform bronchoscopy. It is essential that one

be certain that the chest tubes are functioning adequately in these circumstances, and if mechanical problems are ruled out, the patient should be taken to the OR promptly. Occasionally, for a right-sided bronchial leak, insertion of a balloon-tipped catheter down the right mainstem bronchus may allow ventilation of the normal left lung after the right bronchus is occluded by inflation of the balloon. This measure temporarily stabilizes the patient by decreasing the air leak on the involved side. It is technically very difficult to accomplish, however, and should not take priority over getting the patient to the operating room as quickly as possible. For a left-sided bronchial tear, the endotracheal tube may be directed into the right mainstem bronchus and the cuff of the endotracheal tube inflated. This would allow ventilation of the right lung until the left lung lesion has been repaired.[19] In the OR, a double-lumen tube, if available, will allow selective ventilation of the normal lung. At surgery, the lesion is identified and repaired directly. If there is massive destruction of the airway with failure to achieve an anastomosis or a high risk of subsequent stenosis of the airway, lung resection should be considered.[20]

TRAUMATIC AIR EMBOLISM

The exact incidence of this entity in patients with multiple injuries is not known. However, to make the diagnosis, a very high index of suspicion must be maintained, and this diagnosis should be suspected in any patient with sudden cardiovascular collapse who demonstrates a neurologic deficit after chest injury, especially if these signs occur with the initiation of positive-pressure ventilation.[21] In most cases, the diagnosis of traumatic air embolism is made at thoracotomy that is conducted on the basis of sudden collapse of a patient who has sustained major chest trauma. Occasionally, these patients may be quite stable initially, only to develop a focal neurologic deficit suddenly with cardiovascular collapse immediately after being placed on positive-pressure ventilation. Another sign suggestive of the diagnosis is the presence of bubbles within arterial blood drawn by arterial puncture, usually for blood gas analysis. It must be recognized, however, that the most common cause of air bubbles in the syringe is a loosely fitting syringe connector; this must be ruled out prior to making the diagnosis. Occasionally, air may be seen in the retinal arteries on funduscopic examination as well.

An anterolateral thoracotomy should be performed on the side of the penetrating injury or on the left side if no penetration is apparent. On entry into the thoracic cavity, prevention of further embolization is accomplished by cross-clamping of the pulmonary hilum. An 18-gauge needle should be used for venting the most anterior surfaces of the left atrium, left ventricle, and ascending aorta. This maneuver is followed by compressing the root of the aorta between the thumb and index finger, which are placed in the transverse sinus. Massaging the heart should drive air bubbles out of the coronary microvasculature. Maintenance of a high systemic blood pressure, with α agonists if necessary, should help to force trapped air from the heart and brain through the microvasculature into the venous circulation. With reestablishment of cardiac activity, the left-sided chambers and the aorta should be vented once more. Attention is then directed to the pulmonary lesion, which will require repair by direct suture, lobectomy, or pneumonectomy as necessitated by the nature of the injury.

FLAIL CHEST

This condition arises whenever a portion of the chest wall becomes completely discontinuous from the rest of the rib cage. It usually results from blunt chest trauma in which several adjacent ribs are fractured on both sides of the sternum or, at least, at two locations on each of the ribs involved. This leads to a free-floating segment of the chest wall that positions itself in response to changes in pleural pressure rather than to the mechanical positions of the rest of the chest wall. The result is paradoxical movement of this portion of the chest wall. During spontaneous breathing, the flail segment moves inward with the negative pleural pressure of inspiration and moves outward with expiration. The diagnosis frequently is missed initially if one relies entirely on the detection of paradoxical movement of the chest wall because muscle spasm and pain restrict movement of the chest wall and make it very difficult to detect the paradoxical movement. This is particularly true in injuries involving the posterior thorax, where the muscle mass makes it even more difficult to detect paradoxical movement. Also, if the patient has been intubated and positive-pressure ventilation is instituted, paradoxical movement of the chest wall will not be seen. The presence of multiple adjacent rib fractures involving the same rib in different segments on chest x-ray would suggest the presence of flail chest even if it is not apparent clinically. The degree of pulmonary and hemodynamic disability that arises is related to the extent of the flail, the degree of underlying lung contusion, and the restrictive effect of chest wall pain from the multiple fractures. There is, therefore, a wide spectrum of presentation of patients with flail chest.

In the severely hypoxemic patient with a large flail and/or hemodynamic instability, immediate endotracheal intubation and positive-pressure ventilation are indicated, with prompt chest tube insertion on the involved side to prevent a tension pneumothorax from developing on institution of positive-pressure ventilation. Patients who are able to maintain adequate oxygenation and ventilation with supplemental oxygen may be maintained without mechanical ventilation and endotracheal intubation, particularly if adequate pain control can be achieved. This may require frequent or continuous intravenous analgesia in the form of titrated fentanyl, morphine, or other agents. In other circumstances, epidural or, less preferably, intercostal blockade with long-acting local anesthetic agents may be used to control the pain. With adequate analgesia, it is possible to avoid endotracheal intubation and mechanical ventilation in most patients with flail chest.[22]

Emergency thoracotomy is not required for treating flail chest. Also, mechanical fixation of the rib fractures usually is not necessary. There is still controversy as to whether formal thoracotomy and mechanical fixation of the fractured ribs should be considered at all in these patients.[23] However, in situations where thoracotomy is required for other reasons, it may be appropriate to reduce and plate the fractures involved.

If a decision is made to ventilate the patient with a flail chest, the timing of weaning will not necessarily depend on disappearance of the paradoxical movement of the chest wall. Rather, weaning from the respirator may be initiated when the gas exchange abnormality associated with the underlying lung contusion is resolved. In fact, frequently these patients are weaned completely off respiratory support (with adequate pain control) when the lung contusion clears, even

when residual paradoxical movement remains apparent for several weeks. A potential disadvantage of the nonsurgical and conservative nonventilating approach to flail chest is the acceptance of a high degree of ultimate chest wall deformity. However, these chest wall abnormalities are of questionable significance in terms of producing a long-term restrictive defect in these patients.

Other Chest Injuries

Although the following chest injuries do not immediately threaten life, early diagnosis and treatment are essential to prevent significant morbidity and later mortality:

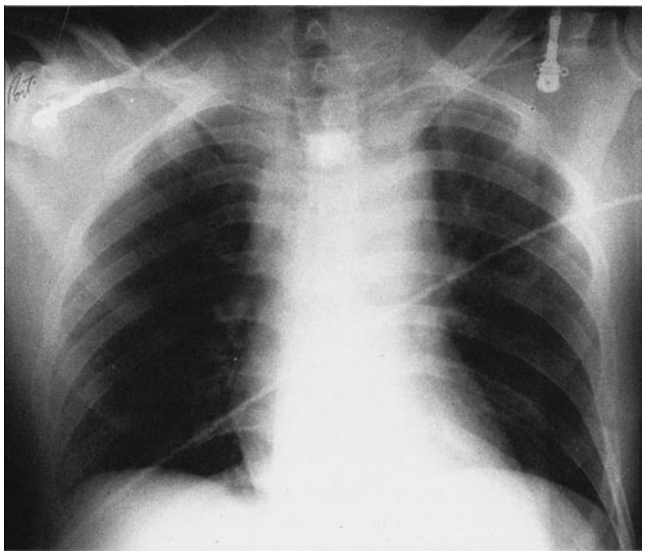
1. Lung contusion
2. Blunt cardiac injury
3. Aortic rupture
4. Esophageal disruption
5. Diaphragmatic rupture
6. Rib fractures
7. Simple hemopneumothorax

A very brief discussion of the pathophysiology, diagnosis, and treatment of these entities follows.

LUNG CONTUSION

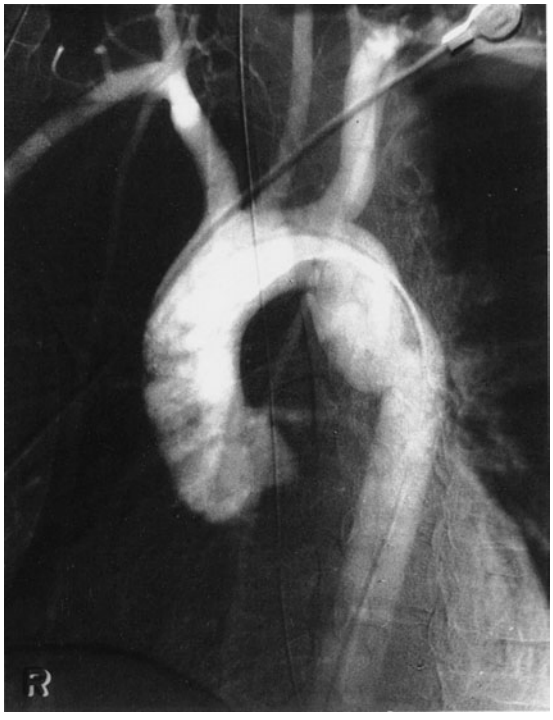
This lesion results from direct trauma to the lung parenchyma, usually by a blunt mechanism, although it can occur from penetrating injuries as well. There is a wide spectrum of severity, ranging from very minor localized hemorrhage into the lung parenchyma to complete obliteration of an entire lung or even bilateral involvement. This injury is missed often because the respiratory failure that develops is not immediately evident, and indeed, chest films may be completely normal initially. It is essential, therefore, that the diagnosis be considered whenever there is significant direct injury to the chest wall. Initially, there may be chest pain and minimal dyspnea or hypoxia. However, within hours there may be slow deterioration in gas exchange and a progressive development of radiologic densities on chest x-ray. As pointed out earlier, there may or may not be an associated flail chest.

The treatment is selective and is based on the degree of respiratory impairment.[24] When the gas exchange abnormality is minimal and oxygenation and ventilation can be maintained without endotracheal intubation, close attention to fluid balance is required. However, fluid should not be restricted in a patient with lung contusion if fluid resuscitation is required in a hemodynamically abnormal patient. Close, continuous monitoring of the hemodynamic and respiratory status is essential; if there is no major hemodynamic or respiratory compromise, the patient will not require mechanical ventilation. The criteria for initiation of mechanical ventilation are outlined in earlier chapters, but certain associated disorders increase the likelihood that mechanical ventilation will be needed. These include preexisting chronic respiratory failure and associated abdominal, thoracic, or central nervous system injuries.



BLUNT CARDIAC INJURY

This lesion probably occurs much more commonly than was suspected previously because of the subtle nature of its presentation among other associated injuries.[4,25] It usually results from blunt trauma to the sternum, most commonly caused by steering wheel impact. In fact, whenever a fractured sternum is diagnosed in chest trauma, one must assume an underlying myocardial contusion. The patient's symptoms frequently are clouded by associated chest wall contusion and other causes for chest wall discomfort and cardiorespiratory dysfunction. The diagnosis is suggested by the presence of ECG abnormalities, serial elevations in the level of the creatine kinase MB isoenzyme, or abnormalities found by two-dimensional echocardiography. However, myocardial enzymes do not contribute significantly to the diagnosis or management in this injury.[26] Although cardiac troponins usually are helpful in the diagnosis of myocardial infarction, the levels obtained following trauma are too inconclusive to allow a diagnosis of blunt cardiac injury and provide no additional information beyond that available by electrocardiography. ECG abnormalities may vary from few to multiple premature ventricular contractions, persistent tachycardia, dysrhythmias such as atrial fibrillation, bundle branch block, ST-segment changes, or even changes indistinguishable from those of acute myocardial infarction. None of these tests is specific for blunt cardiac injury.



Because of the nature of this entity and its propensity for certain life-threatening dysrhythmias, consideration should be given to monitoring these patients in an ICU environment. Oxygen should be administered, pain should be treated with parenteral analgesics, and the patient should be treated in the same way as for myocardial ischemia, as outlined in other chapters of this book. The indications for inotropic agents, vasoactive drugs, and other forms of cardiac support are comparable with those for any patient with myocardial ischemia. Most patients with minor degrees of contusion do not require ICU admission.

AORTIC RUPTURE

Traumatic disruption of the thoracic aorta frequently is lethal.[16] In patients who reach the hospital alive, the rupture tends to be located at the point of fixation of the aorta just distal to the origin of the left subclavian artery at the ligamentum arteriosum, which represents the junction between a relatively fixed and mobile portion of the vessel. Therefore, the mechanism is a shear force, commonly seen with acceleration-deceleration injuries, although a sudden increase in intraluminal hydrostatic pressure may play a role in its pathogenesis. Aortic rupture at other sites near the root of the aorta usually results in death at the scene. In patients who survive the initial injury, the hematoma is contained by an intact adventitial layer. Because of the possibility of free rupture and exsanguination whenever this diagnosis is suspected, investigations and treatment should be prompt. Although several radiologic signs are described (such as widened mediastinum, fractures of the first and second ribs, obliteration of the aortic knob, deviation of the trachea to the right, presence of a pleural cap, elevation and rightward shift of the right mainstem bronchus, depression of the left mainstem bronchus, and obliteration of the space between the pulmonary artery and the aorta), frequently the only suggestive sign is a widening of the mediastinum on the plain chest film (Fig. 95-6). Other suggestive signs are the presence of a thoracic bruit or a discrepancy in blood pressure between the upper and lower limbs or between the right and left upper limbs. Placement

A

B

FIGURE 95-6 Ruptured thoracic aorta. *A*. Chest film showing widened mediastinum. *B*. Aortogram from the same patient showing lacerated aorta.

of a nasogastric tube may highlight the degree of esophageal deviation and hematoma size on the chest film. Since most chest x-rays in traumatized patients are done in the supine position, the size of the mediastinum is exaggerated, and consequently, this diagnosis is considered in a large percentage of patients who do not actually have a traumatic aortic rupture. However, because of the lethal nature of this disease, it seems justified to pursue further imaging whenever aortic rupture is seriously suspected.[27]

Spiral computed tomography (CT) is recommended in the presence of suspected mediastinal widening, and if this is totally normal, then further imaging is not warranted.[28,29] If the CT scan is questionable or suspicious, then an aortogram should be obtained. In any event, most surgeons still insist that angiography be performed prior to surgery.

The use of transesophageal echocardiography[30,31] also has given excellent results in the diagnosis of aortic rupture, and in some centers it has virtually replaced angiography because of its accuracy and relative noninvasiveness, but there still remains a worrisome incidence of false positivity with this diagnostic tool.

The approach to management of the patient with aortic rupture is early surgical repair unless contraindicated by significant associated life-threatening injuries such as major head injuries. Resection with placement of a prosthetic graft frequently is necessary, although direct repair without the use of a prosthetic graft is sometimes possible. As soon as immediate life-threatening injuries have been addressed, the aortic lesion should be treated surgically. If surgical treatment is delayed because of associated major injuries, then treatment and close monitoring in the ICU with afterload reduction, β blockade, and maintenance of borderline hypotension are appropriate.[32]

ESOPHAGEAL DISRUPTION

The most common cause of esophageal rupture is iatrogenic injury during endoscopic maneuvers. However, this injury may result from both penetrating and blunt injury. A severe blow to the upper abdomen in the presence of a closed glottis can result in a sudden increase in intraesophageal pressure with rupture. The resulting tear allows leakage of gastric contents into the mediastinum, causing severe mediastinitis.

The patient presents with severe retrosternal chest pain and very soon develops profound hypotension and tachycardia. Frequently, pneumothorax or hemothorax is evident without a rib fracture, and if a chest tube is inserted, particulate matter may appear in the drainage. The drainage of pleural fluid with a very low pH and a high amylase content also should suggest the diagnosis. Other radiologic signs include the presence of mediastinal air. The diagnosis may be confirmed by gastrograffin swallow or esophagoscopy.

Treatment consists of massive infusion of crystalloid to maintain euvolemeia, antibiotic coverage, and early thoracotomy with repair of the lesion. If the diagnosis is made late in the onset of the disease, direct repair of the laceration may not be possible, and esophageal diversion techniques may become necessary as part of the surgical therapy. This may require the formation of an esophagostomy in the neck, as well as a gastrostomy, pleural drainage through chest tubes, and parenteral nutrition and antibiotic therapy.[33]

DIAPHRAGMATIC RUPTURE

Lacerations of the diaphragm may occur from blunt and penetrating injuries, and the injury may originate from either the thorax or the abdomen. The injury is diagnosed most frequently on the left side but may occur with equal frequency on the right side. Penetrating injuries tend to be small and sharply demarcated, whereas blunt injuries often result in large, irregular lacerations with herniation of intraabdominal contents into the chest.[34]

The diagnosis is missed frequently because of misinterpretation of the chest film, often thought to represent an elevated

left hemidiaphragm, gastric dilatation, or loculated hemopneumothorax or hematoma. The placement of a nasogastric tube with its location above the diaphragm after entry into the stomach suggests the diagnosis.

Depending on the degree to which abdominal contents herniate into the thoracic cavity, the symptoms may be very minimal or very significant.[35–37] A patient with blunt chest or abdominal trauma who exhibits sudden deterioration in respiratory status when intraabdominal pressure is increased should be considered as having a ruptured diaphragm. This was noted frequently when the abdominal compartment of the pneumatic antishock garment was used in the past. During peritoneal lavage, drainage of lavage fluid through a chest tube that is in place also indicates that diaphragmatic rupture is present.

The urgency of treatment depends on the degree to which the patient's hemodynamic and respiratory status is compromised. In most instances, an isolated diaphragmatic hernia can be repaired within several hours of admission, after the patient is resuscitated. Repair is done through a midline upper abdominal incision. This approach allows complete examination of the abdominal cavity. The hernia can be reduced quite easily and the repair conducted from within the abdomen. Associated injuries, such as splenic rupture, also can be treated easily during the laparotomy. If the diagnosis is made several weeks after the injury, then it is preferable to approach the lesion through a thoracotomy because any intraabdominal injury would have declared itself already; also, it will be much easier to reduce the hernia from within the thoracic cavity. Although laparoscopy increases the risk of tension pneumothorax in the presence of a diaphragmatic rupture, recent reports have suggested that this technique may be employed cautiously in the diagnosis and treatment of diaphragmatic rupture when the laparoscope is used in assessment of the traumatized abdomen.[38–40]

RIB FRACTURES

Rib fractures are very common with chest injuries. Frequently they are missed on x-ray examination unless special rib views are taken. However, the diagnosis is suspected when there is localized chest wall pain. The diagnosis is also suggested when one is able to elicit crepitus over the fracture site or auscultate a "click" with inspiration over the fracture site. Tenderness on compression of the chest wall is also suggestive of rib fractures.

The treatment of rib fractures consists of analgesics, which may be administered orally, parenterally, or epidurally, depending on the degree of discomfort and the number of ribs involved. In the ICU setting, parenteral analgesics or regional blocks are preferable. Generally, the fractured ribs do not require any specific treatment. However, in the setting of a patient with preexisting pulmonary dysfunction, the restriction produced by fractured ribs can make the difference between normal gas exchange and severe respiratory failure. Maintenance of adequate respiratory function therefore is the mainstay of treatment in these patients.

SIMPLE HEMOPNEUMOTHORAX

In contrast to a tension pneumothorax, the simple hemopneumothorax usually is diagnosed by a combination of physical examination and chest x-ray. Although it has been suggested recently that small pneumothoraces may be treated by close monitoring in the ICU without chest tube insertion, generally, if a hemothorax or pneumothorax is noted following trauma, a chest tube is inserted regardless of the size of the air or blood collection. This measure allows decompression of the pleural space, as well as monitoring of the drainage from the pleural space. It is particularly important that chest tube decompression of the pleural space be secured before mechanical ventilation is instituted or a general anesthetic administered.

Abdominal Injuries

GENERAL PRINCIPLES

Apart from patients with pericardial tamponade or traumatic air embolism, any hemodynamically compromised patient with torso trauma in whom adequately functioning chest tubes demonstrate no free pleural blood or continued major air leakage must be considered to have an intraabdominal source of blood loss until another cause is proven. Hence, when the decision is unclear in an unstable patient with torso trauma, the combination of physical examination, chest x-ray, and chest tube insertion frequently will allow one to determine whether the lesion is located in the chest. With a negative chest film and no chest tube drainage in the absence of cardiac tamponade or air embolism, laparotomy frequently is required in the unstable patient with torso trauma.

In the OR, all such patients should have the entire abdomen and chest prepared and draped. They also should receive preoperative antibiotics that will cover aerobic gram-negative and anaerobic organisms. It is crucial that the antibiotics be administered before the incision is made in order to minimize septic complications.[41] If there is no fecal contamination in the peritoneal cavity, the antibiotics may be stopped within 24 hours. However, in the presence of contamination, antibiotic administration should be continued until the temperature is normal and there is no leukocytosis. An increase in the temperature and white blood cell (WBC) count after antibiotics are stopped suggests residual sepsis, which often is in the form of an undrained intraabdominal abscess.

A generous upper midline incision extending from the xiphoid process to just below the umbilicus is the exposure of choice because most of the lesions producing instability arise from injuries to the upper abdominal contents. This incision can be extended easily up into the chest through lateral thoracotomy or a median sternotomy or extended into the lower abdomen for lower abdominal injuries. Occasionally, the history suggests an isolated lower abdominal injury, and in this circumstance, a lower midline incision beginning at the umbilicus may be undertaken.

Prior to laparotomy, the surgeon need only decide that surgical intervention is necessary; a specific diagnosis is not necessary. In deciding on laparotomy, one looks for the signs of penetration, perforation, or hemorrhage. Penetration of the peritoneum in stab wounds is diagnosed by exploration of the abdominal wound under local anesthesia with good lighting; if it is determined that the peritoneum has been violated, in most instances laparotomy is performed. This approach has been questioned, and peritoneal lavage has been conducted in conjunction with exploration of the wound to determine

the need for laparotomy on a more selective basis.[42,43] In these circumstances, demonstration of violation of the peritoneum and positive peritoneal lavage are used as indications for laparotomy. All bullet wounds to the abdomen are treated by laparotomy,[44] although a selective approach based on careful scanning of the abdomen to identify tangential nonpenetrating wounds has been reported. The signs of perforation are abdominal pain, tenderness, guarding, and rigidity. Signs of hemorrhage also may present with signs of peritoneal irritation, shoulder tip pain, or variable degrees of hemodynamic instability.

On entry into the peritoneal cavity, the presence of dark blood usually suggests a liver injury, whereas bright red blood suggests an arterial source of bleeding. Rapid evisceration of the small intestine and liberal use of packs wherever blood is accumulating allow identification of the source of blood loss. Concentration on the first site of bleeding should be avoided. The lesions should be approached in order of severity; i.e., the areas that are bleeding most briskly should be treated first.

In general, findings on physical examination determine the need for surgical intervention. There are situations, however, in which the signs may be equivocal or impossible to elicit in the unstable patient. In these circumstances, ultrasound,[45] peritoneal lavage, and CT[46] are all very helpful in determining the need for laparotomy.

Massive intraabdominal hemorrhage may require thoracotomy to allow clamping of the supradiaphragmatic aorta for temporary control of intraabdominal hemorrhage and the maintenance of perfusion to the brain and myocardium.[47,48] Prompt laparotomy after aortic clamping would allow identification and control of intraabdominal hemorrhage before release of the aortic clamp. In many instances, aortic clamping also may be achieved through a laparotomy with compression and/or clamping of the infradiaphragmatic abdominal aorta.

ROLE OF PERITONEAL LAVAGE, CT, AND ULTRASOUND IN ASSESSING ABDOMINAL TRAUMA

Diagnostic peritoneal lavage, ultrasound, and CT are all useful diagnostic tools in assessing the traumatized abdomen. These modalities are all very sensitive for the detection of hemoperitoneum. Of the three modalities, CT is the most specific.[46] However, it requires transporting the patient to the CT suite and is relatively costly and time-consuming. Its main use, therefore, is in relatively stable patients, particularly those who are already having CT for another indication, such as possible head injury. The main advantages of ultrasound are its rapidity, sensitivity, noninvasiveness, and portability. Where emergency ultrasound assessment is available (focused assessment for the sonographic examination of the trauma patient [FAST]), this is preferred and superior to diagnostic peritoneal lavage, but like all imaging techniques, is not sufficiently sensitive to be used in isolation to make judgments regarding the need for surgery.[48a] With proper training of personnel, FAST can be very accurate in detecting hemoperitoneum, even when conducted and interpreted by nonradiologists.[45,49] Like other investigative tools, peritoneal lavage, ultrasound, and CT should be used only if the results will affect the decision on whether to perform a laparotomy. If there is an obvious need for laparotomy, then these modalities are not indicated.

INDICATIONS

1. When there are equivocal abdominal findings. Certain conditions, such as fractures of the lower ribs, pelvis, or lumbar spine, may produce abdominal signs that are difficult to separate from those injury due to intraabdominal structures.
2. When abdominal findings are impossible to elicit (e.g., when pain perception is abnormal, such as with severe head injury, drug intoxication, or spinal cord injuries).
3. When there may be long periods during which the patient is unavailable for repeated physical examination and observation, such as during lengthy surgical procedures.
4. When there is an obvious source of hemorrhage, such as a pelvic or extremity fracture, which could account for hypotension, but when simultaneous intraabdominal bleeding is also a possibility.

CONTRAINDICATIONS

An absolute contraindication to diagnostic peritoneal lavage is an already identified indication for laparotomy. Relative contraindications to diagnostic peritoneal lavage include previous abdominal operations with scars in the abdomen, morbid obesity, a preexisting coagulopathy, and advanced pregnancy. An incision may be made above the umbilicus in advanced pregnancy or distant from prior surgical wounds, and the open technique may be used if necessary. Otherwise, the closed Seldinger technique for insertion of the peritoneal catheter is acceptable.[50] There are virtually no contraindications to ultrasound assessment of the traumatized abdomen except an obvious need for laparotomy on the basis of clinical examination alone. The relative contraindication to CT is instability of the patient that makes transfer to the CT suite unsafe.

TECHNIQUES FOR CT, ULTRASOUND, AND DIAGNOSTIC PERITONEAL LAVAGE

CT

Whenever possible, CT of the abdomen should be conducted with oral, intravenous, and rectal contrast agents to enhance specificity. This approach allows assessment not only for solid-organ injury and hemoperitoneum but also for injury of hollow organs.

Ultrasound Examination for Fluid

The ultrasound probes are placed in four locations[45]:

1. Right upper quadrant—Morison's pouch
2. Epigastric area (pericardial)
3. Left upper quadrant (perisplenic)
4. Suprapubic area—pouch of Douglas

FAST detects blood in the pericardial sac as well as the perihepatic, splenoral, and pelvic regions of the abdomen.

Open Peritoneal Lavage

The urinary bladder and stomach should be decompressed by urinary catheter and nasogastric tube, respectively. The abdomen should be surgically prepared with an antiseptic solution, and local anesthetic should be infiltrated below the umbilicus in the midline if the patient perceives pain. The skin is incised in the midline, and an opening is made that permits visualization of the subcutaneous tissue and fascia. After hemostasis in the skin and subcutaneous tissue has been

ensured, the fascia is incised, and the peritoneum is grasped with clamps. A purse-string suture is then inserted in the peritoneum, and an opening is made for insertion of the peritoneal dialysis catheter into the peritoneal cavity. The catheter is directed toward the pelvis, connected to a syringe, and aspirated. If no gross blood or obvious enteric contents are aspirated, 10 mL/kg of Ringer's lactate or normal saline is allowed to drain by gravity into the peritoneal cavity. The abdomen is palpated and agitated gently to distribute the fluid throughout the peritoneal cavity. After approximately 5 to 10 minutes, the fluid is siphoned off and examined.

Closed Diagnostic Peritoneal Lavage (Seldinger Technique)

In the closed technique[50] of diagnostic peritoneal lavage, preparation of the patient is similar. After a puncture wound is made through the skin with a scalpel, a needle with a guidewire is inserted into the subcutaneous tissue, fascia, and peritoneum. A peritoneal lavage catheter then is introduced over the guidewire and directed toward the pelvis, after ensuring that bowel has not been penetrated by the needle by aspirating and examining for bowel liquid contents or gas.

Semiclosed Peritoneal Lavage Technique

In this technique, an incision is made down to the fascia, which is grasped and then punctured. The catheter is then introduced through the opening in the fascia.

Interpretation of Diagnostic Peritoneal Lavage

1. Aspiration of more than 5 mL of gross blood or obvious enteric contents signifies a positive peritoneal lavage.
2. A positive result is also suggested when newsprint cannot be read through the IV tubing containing the drained fluid.
3. The fluid is sent for microscopic analysis, and the following criteria are used for positivity: more than 10^5 red blood cells (RBCs) per microliter, more than 500 WBCs per microliter, or the presence of bacteria, vegetable fibers, etc. on Gram stain. Lower counts also are used in special circumstances, such as the selective approach to laparotomy in penetrating wounds.[51]

With use of these criteria, the peritoneal lavage findings are falsely negative in approximately 2% of patients, and these patients usually have isolated injuries of the pancreas, duodenum, diaphragm, small bowel, or bladder.[52] Retroperitoneal injuries are missed frequently by peritoneal lavage.

SELECTING THE DIAGNOSTIC MODALITY IN BLUNT ABDOMINAL TRAUMA

Hemoperitoneum is the major indication for laparotomy in blunt abdominal trauma. Therefore, a diagnostic technique other than physical examination that detects hemoperitoneum accurately, quickly, noninvasively, and with minimal cost, such as ultrasound, appears most attractive. However, there is still a role for other modalities, such as diagnostic peritoneal lavage and CT,[53] in the assessment of the patient sustaining blunt abdominal trauma. If the ultrasound examination is negative, the patient may be followed clinically without the need for CT or diagnostic peritoneal lavage. With an equivocal ultrasound examination in a stable patient, CT should be done. An unstable patient with an equivocal ultrasound examination should either have a diagnostic peritoneal lavage or be taken directly to the OR. When the ultrasound examination in a stable patient is positive for hemoperitoneum and a more specific diagnosis is desired, CT should be conducted. CT is particularly useful in patients who have hemoperitoneum with solid-organ injury that may be treated nonoperatively. Use of this approach significantly reduces the frequency with which CT is necessary as a screening tool for hemoperitoneum. The unstable patient in whom ultrasound examination is positive for hemoperitoneum generally requires laparotomy.

Specific Abdominal Injuries—Diagnosis and Management Principles

Although the nonsurgeon intensivist does not need detailed knowledge of the surgical management of specific intraabdominal injuries, some familiarity with the diagnostic and management principles to be applied in the surgical treatment of specific intraabdominal organ injuries is likely to improve the confidence with which these patients are managed in the ICU.

Penetrating abdominal injury differs significantly from nonpenetrating injury. Penetrating injury may result from stab wounds or wounds from other sharp objects or from bullet or shotgun wounds. Stab wounds tend to be the least serious, in that they involve organs only within the short trajectory of the weapon, and unless the stab wound impales a major vessel directly, major hemorrhage is not as likely as in other forms of penetrating or blunt abdominal injury. Patients with stab wounds require exploration of the wound to determine whether the peritoneum has been violated. If the peritoneum has been violated, a decision has to be made to proceed with formal laparotomy unless one is prepared to use peritoneal lavage as an adjunctive test in determining whether laparotomy should be conducted.[42] Although a selective approach using imaging such as CT and MRI to identify tangential nonpenetrating wounds that would not require laparotomy is suggested, generally, all bullet and shotgun wounds to the abdomen require laparotomy.[44] These missile injuries usually result in damage to more than one organ. Since kinetic energy transfer is affected most significantly by missile velocity ($K = 1^1/_2 MV^2$), low-velocity missiles tend to produce limited surrounding injury, whereas high-velocity missiles produce greater damage. Organ involvement, therefore, is very unpredictable because of the variable trajectory and wide variable area of dissipated energy. A straight line joining the points of entry and exit usually does not represent the pathway of the missile. In shotgun injuries, much less damage is inflicted when the injury occurs from far range rather than close range.

The crushing force produced by blunt injuries results in very irregular lacerations. Multiple injuries are also common. Diagnosis and therapy are more challenging and should be more aggressive with blunt injury. Hemorrhage, devitalization of tissue, morbidity, and mortality are all increased in blunt injury compared with penetrating injuries of the abdomen.

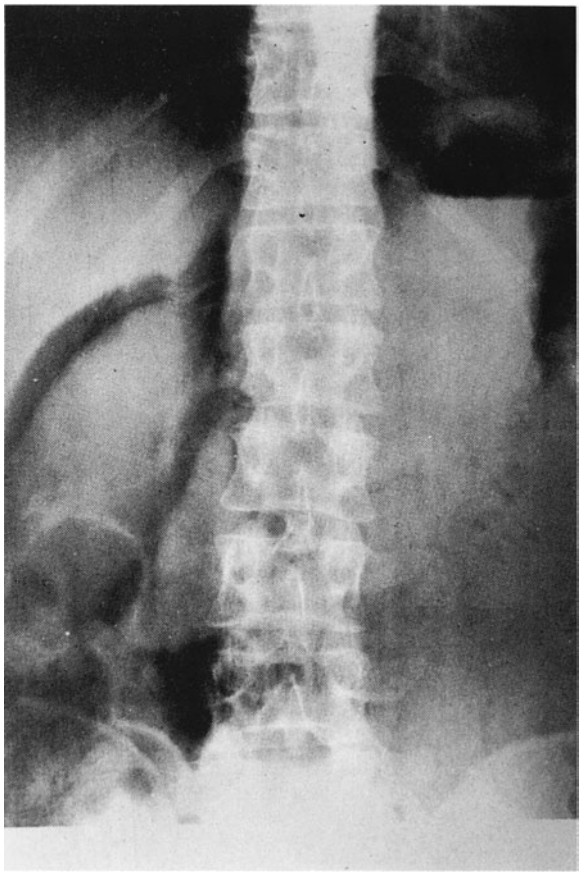
The frequency of organ involvement in penetrating trauma is also different from that in blunt trauma to the abdomen. In penetrating trauma, the organs involved, in order of frequency, are the liver, small bowel, stomach, colon, major vessels, and retroperitoneum. In blunt injuries, the solid

organs—the spleen, kidney, and liver—are damaged most often, followed by the intestines.[54]

STOMACH INJURIES

The diagnosis of stomach injury is suggested by epigastric pain and pain at the shoulder tip if there is free perforation. Usually there is very minimal hemorrhage, and the patient's hemodynamic status is not particularly affected. Upright chest x-ray reveals free air under the diaphragm. The diagnosis also may be suggested by bloody aspirate from the nasogastric tube.

The surgical treatment of stomach injuries is straightforward and involves débridement of devitalized tissue and usually primary suture or anastomosis if resection is required for wide areas of devitalization. It is essential that the entire stomach, including the posterior wall, is visualized to minimized missed injuries.



DUODENAL INJURIES

These injuries are seen often in association with other injuries, and the second portion of the duodenum is involved most commonly. Because the duodenum is a retroperitoneal structure, frank peritonitis is a very late sign, and the diagnosis is made only with a very high index of suspicion based on the mechanism of injury. A useful sign is the identification of retroperitoneal air on a plain film of the abdomen (Fig. 95-7). Occasionally, a free perforation of the first portion of the duodenum produces pneumoperitoneum and can be identified on an upright chest film.

In the surgical treatment of injuries to the duodenum, complete mobilization and visualization of the entire duodenum are crucial. Patients with intramural hematomas of the duodenum may present with vomiting and symptoms of gastric outlet obstruction; radiologic examination of the stomach and duodenum with contrast agents reveals the presence of an intramural hematoma. If this is the only injury, treatment can be conservative, with nasogastric suctioning and intravenous fluids until the hematoma resolves. If the lesion is found at laparotomy, the hematoma is evacuated easily through an incision in the duodenal wall.[55] The principle of treatment is to débride the area of injury, removing all devitalized tissue. If, after this is accomplished, the edges of the duodenum can be approximated without undue tension, primary suture closure is appropriate. The defect also may be closed by a serosal patch from adjacent small bowel or a resection and end-to-end anastomosis. When these techniques are not possible, then roux-en-Y anastomosis between the duodenal ends and the small bowel needs to be conducted. When there is concern about the duodenal closure, it is wise to place a duodenal catheter, brought out as a tube duodenostomy. If the anastomosis is not secure, the resulting duodenal fistula will be controlled and can be treated by observation and parenteral nutrition until the fistula tract matures, after which the duodenal tube is removed.[56,57] Severe duodenal injuries require pyloric exclusion procedures in which the gastric contents are diverted through a gastrojejunostomy.[58]

PANCREATIC INJURIES

Injuries to the pancreas usually result from blunt trauma and are caused by impact of the pancreas against the vertebral column. Diagnosis is often difficult because the retroperitoneal

A

B

FIGURE 95-7 Ruptured duodenum. ***A.*** **Plain radiograph showing retroperitoneal air around the right kidney.** ***B.*** **Transected duodenum found at laparotomy on the same patient.**

position of this organ prevents early physical signs of peritoneal irritation. Frequently, the diagnosis is made at laparotomy for other associated conditions. However, the diagnosis is suggested by an increase in the serum amylase level. If the diagnosis is suspected and findings on physical examination are minimal, upper gastrointestinal radiographic studies with gastrograffin may demonstrate a widening of the duodenal loop. CT of the abdomen allows assessment of the retroperitoneum and pancreatic area for evidence of retroperitoneal hematomas or even ductal injury. Peritoneal lavage frequently is negative in the presence of severe retroperitoneal pancreatic injuries.

Treatment of these injuries depends largely on whether or not the pancreatic duct has been violated. In simple contusions of the pancreas, drainage of the area is all that is required after mobilization of the pancreas and full inspection to rule out any associated ductal injury. Any devitalized area should be débrided, and bleeding points should be controlled by direct suture ligations combined with cautery.

Ductal injury usually is identified during laparotomy. However, in exceptional circumstances where endoscopic retrograde pancreatography (ERP) is immediately available in an otherwise stable patient, this may allow assessment of ductal integrity prior to the laparotomy.[59] When the duct has been injured, there is often a mixture of pancreatic fluid and blood over the surface of the pancreas, which should be exposed for complete inspection. Although ductal injury involving the body and tail of the pancreas may be treated by transection and anastomosis of the ends of the duct to the small bowel, this injury is treated more appropriately by distal pancreatic resection without an enteroanastomosis. When the head of the pancreas is involved, a roux-en-Y anastomosis of the distal pancreatic segment is advisable.[60] This type of injury usually is a combined pancreaticoduodenal injury and may require a Whipple procedure (pancreaticoduodenectomy). This procedure carries a high mortality and should be conducted only when more conservative measures are unsuccessful.[61,62] An alternative approach to combined pancreaticoduodenal injury is the diverticulization procedure, in which the pylorus is closed internally, and a gastrojejunostomy is constructed with an added option of drainage of the duodenum through a tube duodenostomy after repair of the duodenal injury and wide drainage of the pancreas. The entire area is drained, with drains placed around the peripancreatic and duodenal area and exiting posteriorly.[63] It should be emphasized that pancreaticoduodenal resection should be a last resort because of the high associated mortality. Less aggressive treatment should be instituted initially if possible.[39] Even though this approach is more likely to result in complications such as pancreatic abscess, the overall mortality is still less with drainage than with resection.

Postoperatively, patients with pancreatic injury are at risk for development of complications such as pancreatic abscess and pseudocyst. The former is suggested by a continued septic course with the development of a peripancreatic mass, which is identified by CT. This lesion requires drainage and antibiotic coverage.

The complication of pancreatic pseudocyst results from pancreatic secretions and debris in the lesser sac. Symptoms may be those of a mass effect and may include gastric outlet obstruction with vomiting. The presence of a symptomatic mass in these patients requires decompression of the pseudocyst. However, if the pseudocyst is not symptomatic, it may be observed for up to 6 weeks, at which time, if there are no signs of spontaneous decrease in size, it should be drained. There is much controversy as to whether drainage should be conducted internally or externally. If the external route is chosen, percutaneous drainage may be done under ultrasound or CT guidance. In any event, if this technique is attempted and the catheter is incapable of draining the very thick secretions, internal drainage should be performed via pseudocystgastrostomy or cystenterostomy.[64] Apart from the mass effect of the pseudocyst, these patients require frequent monitoring of the serum amylase level, which often remains elevated during the active phase when the pseudocyst is enlarging. Percutaneous drainage also is unlikely to be effective when the pseudocyst is multiloculated.

INTESTINAL INJURIES

Acceleration-deceleration injuries are most likely to occur at points of fixation of the bowel, e.g., the ligament of Treitz, the ileocecal junction, and the rectosigmoid area. Blowout perforations of the small bowel, however, can occur at any site. Another mechanism for bowel perforation and injury is related to the lap seat belt. The presence of contusion on the abdominal wall from a lap seat belt often makes it difficult to assess the abdomen for signs of peritoneal irritation. In these circumstances, ultrasound or CT examination of the abdomen is quite helpful in determining whether or not there is a seat belt type of related intestinal injury. The presence of peritoneal signs will necessitate laparotomy. A high index of suspicion and aggressive investigation using ultrasound and CT are required to minimize missed small bowel injuries because these injuries occur frequently in the setting of other associated injuries.[65–67]

Treatment of injuries to the small bowel involves débridement of devitalized tissue and control of any associated bleeding points with primary suture. Devitalized areas may require formal resection of segments of bowel; this is usually followed by primary anastomosis with excellent results. The treatment of injuries to the colon depends on the time elapsed between injury and surgery, the degree of contamination, the stability of the patient, and the presence of associated injuries. If there is minimal gross contamination, the operation is being performed within 3 to 4 hours of the injury, and the patient is not in shock, primary anastomosis may be conducted safely. Devitalization of a large portion of the right colon often necessitates resection of the ileum and ascending colon with an ileocolic anastomosis. Left colonic lesions are more likely to be associated with frank fecal spillage. However, if there is very minimal spillage and no evidence of continued hemorrhage or associated injury, even these injuries may be treated by primary closure.[68] Whenever there is doubt, however, the safest technique for treating left-sided colonic injuries is the fashioning of a colostomy together with repair of the laceration and irrigation of the peritoneal cavity. In situations where the lacerated bowel can be exteriorized, the resection may be performed and the ends of the bowel brought out as a proximal defunctioning colostomy and a mucous fistula. This technique is preferable to a defunctioning colostomy and Hartmann's procedure (oversewing of the rectal stump in the pelvis), which is associated with greater difficulty in subsequent reanastomosis of the large bowel.

Injuries to the rectum should be assessed in the operating room and frequently require general anesthesia with a proctosigmoidoscopic (preferably flexible) assessment to determine whether or not the anorectum has been perforated. Because of the propensity for major septic complications, particularly in the multiply injured patient, patients with possible perforating rectal injuries should be treated by a proximal defunctioning colostomy and the fashioning of a mucous fistula through which a catheter can be inserted for performing complete rectal washout.[69] The irrigation of the rectum is conducted with the anus being held dilated. The perirectal space is then drained with appropriately placed drainage tubes. Once the gross fecal contents have been irrigated, the rectal mucosa and major lacerations should be repaired and the sphincter muscles reapproximated with interrupted sutures. This approach in the acute phase prevents retraction of the transected sphincter muscles, which makes later repair and maintenance of continence very difficult. Failure to adhere to the system of drainage, irrigation, and proximal defunctioning colostomy can lead to a protracted septic course with multiorgan failure and death from rectal injuries. A patient with a rectal injury with gross fecal contamination in the perineal area may require reexploration if the he or she continues to run a septic course in the ICU.

As indicated in Chapter 89, the abdomen remains a frequent source of sepsis in surgical patients in the ICU setting. These complications arise primarily after operations on the bowel, so any traumatized patient who has had bowel lesions treated surgically and who remains septic should be considered as having an intraabdominal source for that sepsis. This requires intensive investigation using modalities such as CT scan and ultrasound; drainable lesions may be treated by percutaneous techniques under CT or ultrasound guidance. When such techniques are contraindicated or are likely to be ineffective, or when the source is not obvious despite investigations, laparotomy may be necessary to identify and treat septic complications. With the availability of sophisticated technology in the form of CT and ultrasound investigations, it is usually possible to make a diagnosis prior to laparotomy, and only under very unusual circumstances is the lesion not identified prior to laparotomy.

One of the common areas of sepsis in patients with a perforated bowel is wound infection. Although the incisions in these patients frequently are left packed and open, in some instances the wound is closed primarily. The possibility of suppuration in the wound always should be considered at the first sign of sepsis, and the wound should be opened for diagnosis as well as treatment.[70]

LIVER INJURIES

Although liver injuries may occur from both blunt and penetrating trauma, patients with blunt injury to the liver tend to have a higher morbidity and mortality because of the irregular type of laceration and the involvement of an entire lobe or frequently both lobes of the liver. The signs of liver injuries are very nonspecific, and the diagnosis frequently is made only at laparotomy, the patient presenting with signs of intraabdominal hemorrhage. Liver hemorrhage is sometimes the chief cause of a patient presenting in hemorrhagic shock. Although diagnostic peritoneal lavage for hemorrhage may suggest liver injuries, it is not as specific as CT or ultrasound and is indicated in the hemodynamically compromised patient when FAST is not available or the patient cannot be transferred safely to the CT suite. Otherwise, these injuries are very clearly outlined by CT or ultrasound examination of the abdomen. Other signs that suggest the possibility of liver injuries include bruising of the lower chest, particularly on the left side; contusions over the upper abdomen; fractured lower ribs: an elevated hemidiaphragm; and increased size of the liver shadow on plain films of the abdomen. The usual indication for surgery in a patient with liver injury is intraabdominal hemorrhage.[71]

Although reported mortality rates from major liver trauma vary from 20% to 60%, most of the deaths are due to severe associated injuries, particularly of the head and thorax. When death is attributed to the liver injury itself, it is usually secondary to uncontrollable hemorrhage and later in the course is due to sepsis and multiorgan failure. Careful surgical technique and postoperative management of these patients will decrease the morbidity and mortality. The objectives of surgical management of liver injuries are (1) control of hemorrhage, (2) removal of nonviable tissue, and (3) provision of adequate drainage.

Exposure must be adequate, which necessitates a midline upper abdominal incision with the ability to extend into the chest. The liver itself should be mobilized completely by transection of the triangular ligaments, as well as the falciform ligament, with care taken to secure the inferior phrenic artery. The operative strategy should allow exposure of all structures that are likely to be injured or have an impact on management of the injury, including the vena cava and other retroperitoneal structures, and the surgeon must be prepared to perform the Kocher maneuver, right medial visceral rotation (Cattel and Braasch maneuver)[72] and left medial visceral rotation (Mattox maneuver).[73]

CONTROL OF HEMORRHAGE

In most instances, once the peritoneal blood has been aspirated, a nonbleeding hepatic laceration is identified. Such lacerations require drainage and no further surgical exploration. If hepatic bleeding is still active at the time of laparotomy, then the initial maneuver is to pack the liver area very tightly with dry gauze and continue with the remainder of the laparotomy for approximately 15 minutes. This allows time for stabilization of the patient's hemodynamic status, as well as time for replacement of fluid deficits. If, on removal of the pack, the bleeding has stopped, as is frequently the case, then the treatment is drainage of the perihepatic space. Failure to control bleeding by this technique necessitates clamping the portal triad, examining the wounds to determine the source of hemorrhage, and direct suture ligation of the bleeding points. Intermittent release of the clamp will allow examination for hemostasis. Hepatic artery ligation may be of benefit in some patients, although its effectiveness has been questioned.[74] When bleeding arises from the retrohepatic vena cava, as evidenced when clamping of the portal triad fails to control the bleeding, it is necessary to rotate the liver medially and visualize the retrohepatic vena cava. Earlier reports have suggested the use of intracaval shunts to assist in preserving a dry field so that the injured hepatic veins and retrohepatic vena cava may be identified and repaired.[75] However, recent data have shown a very high mortality associated with the use of the intracaval shunts, and aggressive hepatic packing has been

an alternative that results in a better outcome.[76,77] In extreme circumstances, complete vascular isolation of the liver by also clamping the suprahepatic and infrahepatic vena cava may be successful, although this maneuver frequently results in cardiac arrest in the already hypovolemic patient. Bleeding from through-and-through penetrating wounds of the liver also can be tamponaded by insertion of inflatable devices directly into the hepatic wound.[78] In some instances, formal resection of liver tissue is required to control hemorrhage, particularly when there is major devitalization of liver tissue. This measure usually does not require formal anatomic lobectomy but instead consists of resectional débridement of the bleeding, devitalized liver tissue as demarcated by the edges of the laceration itself. The bare area of the liver is then treated with suture ligature, cautery, and the application of microfibrillar collagen or other types of topical hemostatic agents. In some instances, the patient may lose several units of blood as well as have other injuries that require attention. In addition, with the massive blood transfusions, the patient may show signs of coagulopathy. In such instances, it is advisable to pack the liver temporarily, close the abdominal wound, and correct the coagulopathy in the ICU with the hope of stabilizing the patient. The patient may then be taken back to the OR in 48 hours for removal of the pack, after which the bleeding will have either ceased or decreased considerably, allowing formal treatment of the bleeding source.[79]

DAMAGE-CONTROL SURGERY

Patients presenting with major liver injury frequently sustain other intraabdominal, thoracic, extremity, and head injuries. Such patients pose a great challenge to the surgeon and anesthetist. Massive blood transfusions with hemodynamic and respiratory compromise are seen in such patients, who become hypothermic, hypocoagulapathic, acidotic, and hypoperfused. These responses are not entirely confined to the patient with major liver injuries but also accompany other injuries to the chest and abdomen. In these circumstances, operative strategy should be directed at temporarily controlling hemorrhage and contamination by the most expeditious means and allowing the patient to return to the ICU setting, where the cardiorespiratory, renal, metabolic, hypocoagulable, and hypothermic states can be monitored and corrected before returning the patient to the OR for more definitive surgical care. In the setting of abdominal injuries, this involves control of hemorrhage by packing and ligation of vessels without attempts at formal repair, as well as ligation and temporary stapling of injured bowel ends with evacuation of intestinal contents by suction, followed by temporary rapid skin closure of the abdomen. Similar damage-control techniques for thoracic injuries, including tractotomy and quick stapling of vascular and bronchial structures, allow the patient to return to the ICU environment for correction of these immediately life-threatening abnormalities before being returned to the OR for formal, definitive surgical repair of the injuries.[79–82]

RESECTION OF DEVITALIZED TISSUE

Formal hepatic lobectomy is seldom necessary for trauma. Resection usually is confined to removal of frankly nonviable tissue. The area for resectional débridement usually is well demarcated by the nature of the liver laceration itself. Manual compression is maintained on the liver while the resection is conducted to control hemorrhage. Intermittent packing and compression of the liver are required to allow volume resuscitation of the patient during the procedure.

DRAINAGE

The lacerated liver continues to drain bile, blood, and tissue fluid for a considerable period postoperatively. Accumulation of this fluid in the peritoneal cavity is prevented by appropriately functioning peritoneal drains. T-tube drainage of the common bile duct is not required unless there is a central ductal injury requiring surgical repair or unless the common bile duct is enlarged because of previous pathology.

During the postoperative period, these patients frequently run a febrile course, which makes it difficult to determine whether or not there is underlying sepsis. Therefore, antibiotics frequently are administered in the immediate perioperative period. With major hepatic resection, glucose infusions are required to treat hypoglycemia, and hypoalbuminemia needs to be treated temporarily with plasma and albumin infusions until the nutritional status of the patient is improved. Coagulation defects are treated with fresh frozen plasma, vitamin K supplements, and platelets when indicated. Most of these patients also develop some degree of jaundice, which usually is transient but may last from several days to several weeks. Because many of the signs indicated earlier are common in uncomplicated liver injuries, the presence of septic complications may go unnoticed. Frequent radiologic investigation and monitoring of the WBC count are necessary, and baseline estimate of these parameters would allow one to determine whether the patient is progressing satisfactorily or not. A patient whose bilirubin level and WBC count are decreasing but who suddenly shows an increase in serum bilirubin level or has a spike in temperature should be investigated carefully for a source of sepsis in the abdomen. Another complication that may arise in hepatic injury is hemobilia, which may present with upper gastrointestinal hemorrhage, as evidenced by hematemesis or blood-stained nasogastric drainage. This lesion requires immediate investigation in the form of hepatic angiography and CT or ultrasound examination. Once the source of the intrahepatic hemorrhage is identified, hepatic artery embolization or balloon tamponade is a viable option for controlling the hemobilia[83] before formal hepatic resection is considered.

SPLEEN INJURIES

Injuries to the spleen should be suspected in patients who present with left upper quadrant pain, especially in the presence of left lower rib fractures. There may be associated shoulder tip pain on the left side. A frequent mode of presentation, however, is a patient with signs of massive intraperitoneal hemorrhage requiring immediate laparotomy for hemorrhagic shock. In situations where the signs are equivocal, ultrasound examination may be diagnostic. CT of the abdomen in an otherwise stable patient also will identify splenic injury. Most patients who are able to maintain adequate hemodynamics with minimal requirements for blood transfusions, particularly children, can be treated conservatively without the need for laparotomy.[84] Such patients should be monitored very closely in the ICU setting for signs of continued blood loss and requirement for continued fluid infusions. Although imaging techniques have been attempted to identify splenic injury patients that will require surgical

intervention, the most important determinant of the need for surgical intervention remains the hemodynamic status of the patient and the requirement for continued fluid infusion.[85] Where the patient's condition allows, angiography can identify bleeding vessels that may be embolized to control bleeding from the traumatized spleen.[86] Currently, nearly all children and 50% to 80% of adults with blunt hepatic or splenic injuries are treated without laparotomy.[87] Whenever there is a suggestion of associated injury or there is an acute splenic injury in an adult who is severely compromised hemodynamically, laparotomy is advised.

At laparotomy, the aim should be to control hemorrhage, with splenic salvage if possible. In order to assess the splenic injury adequately, complete mobilization and delivery of the spleen into the wound are necessary. Superficial supcapsular tears of the spleen may be treated by initial packing for approximately 15 minutes. Failure to control the hemorrhage by this means will necessitate such techniques as the application of microfibrillar collagen or fine sutures. Identifiable bleeding points are coagulated as well as suture ligated, particularly when bleeding points occur near the hilum of the spleen. Ligation of the short gastric vessels in certain instances also will arrest splenic hemorrhage. In some instances, a lacerated portion of the spleen may be excised, with suturing of the remainder of the spleen with large chromic sutures with Teflon pledgets for securing the sutures. When multiple lacerations are evident, it is possible to control the hemorrhage by placing the spleen in a net of Dexon mesh, which can be tightened to produce compression and control of hemorrhage.[88] If control of hemorrhage by a combination of these techniques is impossible, then splenectomy should be conducted. Also, if the patient remains unstable from other major injuries and bleeding from the spleen is a major problem, splenectomy should be conducted most expeditiously to decrease the operating time and improve the patient's chances of survival.

Postsplenectomy patients are very prone to septic complications, particularly from infections associated with the encapsulated pneumococcous, *Haemophilus influenzae,* and *Neisseria meningitidis.* Prior to discharge from the unit, these patients should be vaccinated against these organisms. Patients also should be warned that any infective process is cause for seeking medical attention because of the increased risk of overwhelming sepsis in splenectomized patients.[89] One of the areas of concern in monitoring patients after splenectomy in the ICU is the frequent occurrence of leukocytosis and thrombocytosis. This situation makes monitoring for intraabdominal sepsis difficult, and one has to follow the WBC count until it plateaus. A deviation or a sudden increase from a plateau high WBC count could be considered evidence of occult sepsis. In patients who are in the ICU for prolonged periods with platelet counts above $10^6/\mu$L, consideration should be given to prophylactic anticoagulation to prevent thrombotic complications.

INJURIES TO THE EXTRAHEPATIC BILIARY TRACT

These injuries are relatively infrequent. Common bile duct injuries commonly involve the other structures in the porta hepatis, with frequently associated injury to the liver, duodenum, or other structures in the abdomen. Vascular injuries isolated to the porta hepatis are relatively rare and carry a very high mortality rate. If a porta hepatis injury is suspected, the Pringle maneuver would allow better identification of the injury with dissection of the structures of this area. Vascular injuries take priority over duct injuries because of the immediate threat to survival posed by massive hemorrhage. If the portal vein is the source of the hemorrhage, then attempts should be made to repair this by lateral venorrhaphy, resection, and anastomosis or interposition grafting. Portal systemic shunting usually results in severe encephalopathy in previously healthy patients with normal hepatic flow and should be avoided if possible. Common hepatic artery injury should be repaired where possible; otherwise, ligation may be performed as a last resort.[90,91]

Common bile duct injuries that involve less than 50% of the circumference of the duct should be treated by débridement and primary closure with a stent (a ureteric stent or T-tube) exiting away from the anastomosis. If more than 50% of the circumference of the bile duct is involved, then there is an over 50% rate of late stricture that diminishes to about 5% if a biliary enteric anastomosis is performed.

Injuries to the gallbladder should be treated by cholecystectomy unless the patient's hemodynamic status is precarious, when a cholecystostomy may be performed as a temporizing measure.[92,93]

RETROPERITONEAL HEMORRHAGE

Frequently, hemorrhage in the retroperitoneal space is identified at laparotomy. This problem can be very difficult to treat, and when possible, preoperative investigation including x-ray of the pelvis, CT scan, or angiography will allow consideration of specific diagnostic possibilities and a more directed surgical approach. When the patient is taken to the OR prior to any of these investigations because of instability, however, a decision needs to be made regarding proper treatment of the retroperitoneal hemorrhage.

Division of the retroperitneum into three zones may be used to guide therapeutic decisions (zone 1, central; zone 2, lateral; zone 3, pelvic). In general, hemorrhage that is associated with a major pelvic fracture and confined to the pelvis or originating in the pelvis should be treated without exploration unless either there is a penetrating injury that is likely to involve the iliac vessels or the hematoma is pulsatile.[94,95] Exploration of such retroperitoneal hematomas usually results in massive uncontrollable hemorrhage when the source is the pelvic fracture. This type of hemorrhage often is best treated by external fixation of the fractured pelvis and blood transfusions. Angiography is required when hemorrhage is continuing with a view to embolizing any identifiable bleeding artery. The mainstay of controlling hemorrhage from pelvic fractures, however, is immediate stabilization of the pelvis to prevent undue motion of the fracture fragments, and this is accomplished most expeditiously by external fixator application.[96]

Apart from hematomas arising from the pelvis, hematomas that are not pulsatile or expanding and that are located in the lateral retroperitoneal spaces (zone 2) also should be left unexplored, and further investigation should be done postoperatively in the form of contrast-enhanced CT scan and angiography as indicated. If the lesion is expanding or pulsatile, the retroperitoneal space has to be explored to identify the bleeding source and control it. Temporary control of an infradiaphragmatic source of hemorrhage can be achieved by

thoracotomy and clamping of the supradiaphragmatic aorta.[47] However, when the hematoma or bleeding does not extend to the aortic hiatus, temporary control may be achieved within the abdomen by compressing the aorta at the diaphragmatic crura. This compression can be done by an assistant's hand, an aortic compressor, or a sponge stick. By incising the peritoneum and mobilizing and displacing the esophagus, a clamp also may be applied directly to the aorta to achieve temporary control of intraabdominal hemorrhage.[97]

A retroperitoneal hematoma that is centrally located (zone 1) in the midabdomen represents possible injury to the pancreas and major retroperitoneal vessels. These hematomas require exploration with a view to determining the extent of the injury and, in the case of the pancreas, to determine whether the pancreatic duct has been violated. The lesion is then treated as outlined earlier for pancreatic trauma. Surgical exposure strategies are as outlined previously to allow adequate visualization of retroperitoneal structures as well as vascular control.

Occasionally, retroperitoneal hemorrhage, particularly in the pelvis, cannot be controlled by surgical means, and one has to resort to packing of the retroperitoneal space and closure of the abdomen with a view to exploring the patient within 48 hours, hopefully after cessation of the bleeding. These patients require very close observation in the ICU with correction of any coagulopathy, acidosis, hemodynamic derangement, and hypothermia.[66]

GENITOURINARY INJURIES

Although hematuria is absent in 5% to 10% of patients with genitourinary trauma,[98] it still is a most important sign of genitourinary injury. The patient frequently has sustained blunt or penetrating injury to the flank or diffuse transfer of force to the abdomen. Occasionally, there is a direct penetrating injury into the bladder or kidney. Penetrating injury resulting in ureteric lacerations is very rare, and where possible, these injuries are repaired by débridement, primary repair, and stenting. Although in the past traumatic hematuria of any degree has been investigated with IV pyelography, a more selective approach is more appropriate. This change in approach has resulted from the low yield of IV pyelography in all patients with trauma; also, in the presence of hematuria, the yield in terms of positive lesions identified varies from 15% to 60%.[99] Most of the injuries discovered (65% to 70%) are considered minor, involving a parenchymal laceration or contusion that does not require surgical intervention. Major parenchymal laceration through the corticomedullary junction and often into the collecting system usually causes gross hematuria and represents 10% to 15% of renal injuries.[100] The remainder of renal injuries are associated with a shattered kidney or renal pedicle injury. These considerations, together with the cost of the procedure, as well as the incidence of allergic reaction (5.7%), including anaphylaxis, renal failure, and death (0.0074%), have led to a change in the approach to hematuria in the assessment of genitourinary trauma. In most instances, the major cause of death from genitourinary trauma is the associated injuries, and the investigation using IV pyelography has had very little effect on management or outcome in general.

Microhematuria without shock has not been shown to be associated with lesions requiring surgical intervention, whereas gross hematuria or microhematuria with shock or a major abdominal injury has been associated with lesions requiring surgery in up to 10% of cases.[99,100] Penetrating renal injuries are associated with lesions requiring surgery both with and without hematuria.[100] On the basis of these observations, IV pyelography should not be routine in abdominal trauma.[101] Also, if the patient is having a CT scan of the abdomen for another reason, or if there is only microhematuria without shock or any evidence of severe injury, IV pyelography is not recommended. The IV pyelogram, however, is helpful in the following circumstances: (1) if a CT scan is not being done and there is gross hematuria or microhematuria with shock, (2) if there is hematuria in the presence of a major abdominal injury, or (3) if there is a penetrating injury and the trajectory suggests the possibility of renal injury, even without hematuria. One other relative indication for IV pyelography is if the patient is unstable but hematuria is present; if time allows, a one-shot IV pyelography may be conducted to assess the functioning of both kidneys in the event that nephrectomy may be required during laparotomy.

The main indication for surgical intervention in renal trauma is an injury with major hemorrhage such that the patient's hemodynamic stability cannot be maintained with rapid transfusion of crystalloid and blood. Otherwise, most patients with renal trauma are treated nonoperatively (Fig. 95-8) at first. They should be observed very closely in an ICU setting for any deterioration in hemodynamic status suggesting continued major hemorrhage that requires surgical intervention. If there is failure to visualize both kidneys on IV pyelography, then contrast-enhanced CT or angiography should be conducted to determine the extent of the injury producing nonfunctioning of the kidneys.

The main principle in surgical treatment of kidney injury is to control hemorrhage while preserving kidney function; this is best achieved by exploring the kidney only in selected patients in whom there is an expanding of pulsatile hematoma or signs of urine extravasation. In order to ensure adequate hemorrhage control, the renal vascular pedicle should be isolated first and secured to allow occlusion if this becomes necessary. If after attempts at repair or partial nephrectomy there is still massive bleeding after release of renal pedicle occlusion, then nephrectomy becomes necessary, especially in the unstable patient who is known to have a contralateral normal kidney.

Hematuria also may result from injury to the bladder, and the suspicion of bladder injury should be investigated by cystography, at least three views being taken with the bladder both filled and emptied to determine whether or not there is any extravasation of bladder contents. Retrograde cystography has been reported to be more accurate in diagnosing bladder injuries than the spiral CT.[102] Extraperitoneal bladder rupture may be treated by catheter drainage alone, whereas intraperitoneal bladder rupture usually warrants open laparotomy with débridement and formal repair of the laceration.[103,104]

Although in most multiply injured patients urinary catheterization per urethra is routine for monitoring the urine volume and consistency as a reflection of the hemodynamic status, there are certain contraindications to catheterization per urethra. Blood at the urethral meatus or the presence of scrotal or perineal hematomas with a large, high-riding, boggy prostate may signal injury to the urethra; these findings

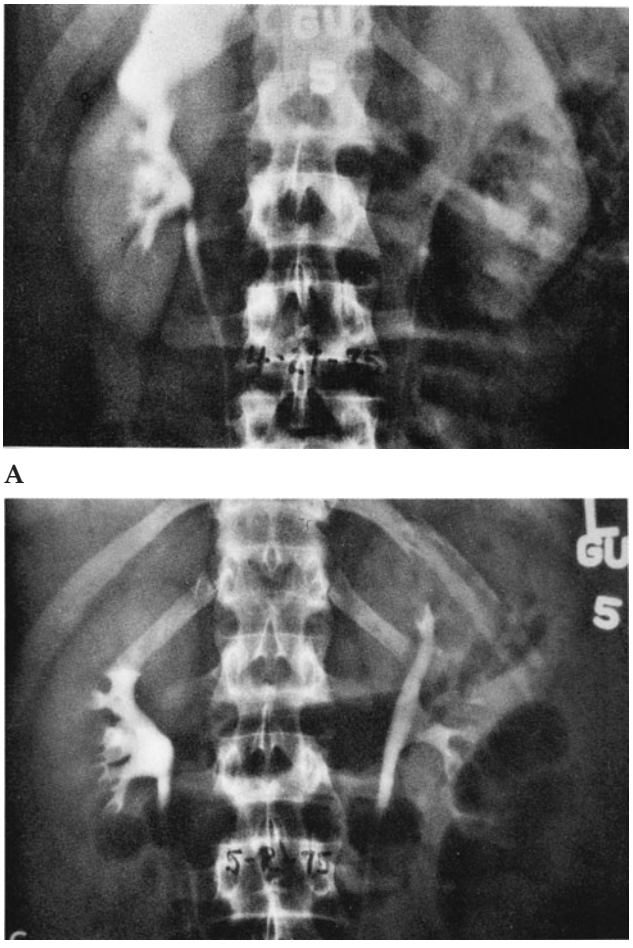


FIGURE 95-8 Spontaneous resolution of renal injury. ***A.*** **Intravenous pyelogram showing extravasation of contrast material immediately after blunt trauma with hematuria.** ***B.*** **Repeat intravenous pyelogram after 5 days of observation shows no extravasation.**

necessitate a urethrogram to exclude urethral laceration prior to transurethral placement of a Foley catheter. Urethral rupture necessitates urologic consultation and treatment.

Postoperative care of these patients requires maintenance of renal perfusion; thus careful attention to maintenance of hemodynamic stability is important. In addition, maintenance of good urinary output and close monitoring of the degree of hematuria, as well as the volume of urine, are required in the ICU setting. An occult injury to the genitourinary tract with extravasation of urine that is left undiagnosed is another means by which a multiple-trauma patient may develop septic complications in the ICU. This type of complication is diagnosed by ultrasonography or CT and is treated by drainage of the urinoma with or without repair of the source of the urinoma.

TRAUMATIC ABDOMINAL COMPARTMENT SYNDROME

Although the deleterious effects of increased intraabdominal pressure have been identified prior to the twentieth century,[105] improvements in prehospital care and the rapidity with which multiply injured patients are taken to the OR room have led to an increased recognition of the syndrome caused by acute increases in intraabdominal pressure (see Chap. 42) because this syndrome is more likely to occur in the presence of multiple major intraabdominal injuries resulting in severe blood loss, massive fluid requirements, and prolonged surgery. Previously, most of these patients would not survive to reach the operating room. The *traumatic abdominal compartment syndrome* may be defined as the adverse clinical consequences of an acute increase in intraabdominal pressure following trauma. The generally accepted parameters for defining this syndrome include an increase in intraabdominal pressure above 20 cm H_2O, peak airway pressure of greater than 40 cm H_2O, oxygen saturation of less than 90% on 100% oxygen, and oxygen delivery index of less than 600 mL/m^2 per minute, as well as oliguria of less than 0 .5 mL/kg per minute.[106] The condition is diagnosed usually at the end of a surgical procedure when attempts are made to close the abdomen or early in the postoperative period of the massively injured patient, although it may occur in patients with major intraabdominal hemorrhage or retroperitoneal hemorrhage prior to surgical intervention. The source of the increased intraabdominal pressure is usually edema, blood accumulation, or distention of the hollow viscera. Prevention of this syndrome therefore is achieved by minimizing intraabdominal edema through decreasing the period of hypotension, minimizing manipulation of the bowel, limiting the duration of surgical procedures, adequate control of hemorrhage, and appropriate decompression of the gastrointestinal tract.[107]

In the setting of hemodynamically compromised patients requiring massive blood transfusions leading to hypocoagulability states, acidosis, and hypothermia, major definitive surgical procedures should be postponed in order to eliminate factors that predispose to increases in intraabdominal pressure. The concept of damage-control laparotomy is therefore an important consideration in this setting.[79–81]

The increase in intraabdominal pressure affects virtually all systems in the body,[108,109] including a decrease in cardiac output from the decrease in venous return arising from compression of the vena cava, decreased renal perfusion, decreased myocardial perfusion, and increased airway pressure resulting in inability to mechanically ventilate and maintain oxygenation of the patient—all of which are associated with a poor outcome unless the increase in intraabdominal pressure is treated promptly by abdominal decompression. In the OR, apart from the practice of damage-control laparotomy, if on attempting formal closure of the abdomen there is major increase in intraabdominal pressure, as reflected by an extraordinary increase in airway pressures with difficulty in ventilating the patient, the formal closure should be aborted. In these circumstances, the abdominal contents are contained by using temporary devices such as plastic bags sutured to the edges of the skin. In some instances, skin closure without fascia closure may be possible without a major increase in intraabdominal pressure. The patient is returned to the ICU for stabilization, monitoring, and correction of associated abnormalities. With improvement in these parameters and signs of reduction in the intraabdominal pressure, the patient is returned to the OR for further surgical intervention, which may allow either primary closure of the fascia with skin closure or the use of mesh for closing the fascia followed by skin closure

or skin grafts later on. Other more elaborate techniques of abdominal wall closure are required in the long term for these patients.[110,111]

Apart from recognition of this entity in the OR, it may develop slowly or abruptly without previous surgery (e.g., the patient with major retroperitoneal hemorrhage from a pelvic fracture) or in the postoperative period during the patient's ICU stay. In a patient in whom this syndrome is likely to develop, close monitoring of airway pressures, hemodynamics, renal perfusion, gas exchange, and intraabdominal pressure is required. A simple means of monitoring intraabdominal pressure is by attaching a three-way stopcock to the side tubing of a Foley catheter after instilling 50 to 100 mL of sterile saline into the bladder through the catheter. On clamping the Foley catheter tubing distal to the three-way stopcock, the stopcock is opened to a manometer that is zeroed at the level of the symphysis pubis.[112]

The mainstay of treatment of patients with this traumatic abdominal compartment syndrome is immediate abdominal decompression, which can be performed in the ICU. Without decompression, mortality is prohibitive and arises from the development of cardiopulmonary failure, renal failure, hepatic failure, and bowel ischemia.

Patients at particularly high risk of developing this entity include those with massive retroperitoneal hematomas from conditions such as pelvic fractures and those with major intraabdominal hemorrhage requiring prolonged operative procedures, the use of massive amounts crystalloids and blood transfusions leading to hypothermia and hypocoagulable states. Treatment should be directed at correction and prevention of these precipitating factors. A high index of suspicion should be maintained in order to predict the onset of this condition so that preventive measures and early diagnosis will result in prompt abdominal decompression.
