Chapter 96

PELVIC RING INJURIES AND EXTREMITY TRAUMA

A. S. L. LIEW

KEY POINTS

- *Hemorrhage from pelvic injuries is underestimated frequently, leading to delayed diagnosis and treatment.*
- *Pelvic ring injuries frequently are associated with other significant injuries resulting in major morbidity and mortality.*
- *Management of pelvic injuries initially requires hemorrhage control and volume resuscitation.*
- *Temporary external fixation is a key element in the initial control of hemorrhage from pelvic fractures.*
- *Extremity fractures, though frequently not life threatening, require accurate diagnosis and appropriate management to prevent significant morbidity.*
- *Complications of extremity injuries, such as compartment syndrome and neurovascular compromise, can best be avoided by a high index of suspicion, careful assessment, and institution of appropriate preventive measures.*
- *Knowledge of the mechanism of injury is crucial in predicting the type and severity of extremity injuries.*

Pelvic Ring Injuries

Patients sustaining major pelvic and extremity trauma frequently are managed in the ICU setting. These patients may present with significant hemodynamic abnormality owing to their associated injuries, and this can be compounded by inadequate resuscitation resulting from underestimation of the volume of blood loss associated with such injuries. The following information is provided to assist the intensivist in understanding extremity and pelvic ring injuries, thus allowing early diagnosis with prompt and appropriate management aimed at preventing major morbidity and mortality.

Significant force is required to sustain an injury to the pelvic ring. In various epidemiologic studies, mortality rates of up to 25% have been reported, depending on the pattern and severity of the pelvic injury.[1,2] While the direct cause of death is usually attributed to a head or thoracic injury,[3] pelvic bleeding significantly contributes to this high rate of mortality. There is an increased risk of mortality in association with open pelvic fractures, a high injury severity score (ISS), or concomitant head, thoracic, abdominal, or neurologic injury.[4]

When the body is subjected to such forces, other injuries are very common. On presentation to the hospital, 15% of patients with pelvic ring injuries are hemodynamically unstable, 66% have a closed head injury, 25% have a thoracic injury, 20% have an abdominal injury, 20% have a urologic injury, and 8% have a lumbosacral injury.[3] A team approach is required to treat trauma victims adequately, including the trauma team leader, surgical team (general, thoracic, orthopedic, and neurosurgery), and intensivist.

ANATOMY

The pelvis is composed of the two innominate bones (hemipelvis) and the sacrum joined anteriorly by the pubic symphysis and posteriorly by the anterior and posterior sacroiliac ligaments, as well as the interosseous sacroiliac ligaments. Within the pelvic floor, the pelvis is further reinforced by the sacrospinous and sacrotuberous ligaments, as well as the muscles and fascia of the pelvic floor (Fig. 96-1).

Running over the sacral ala and into the pelvis are the common iliac artery and vein, bifurcating to the internal and external iliac vessels above and below the pelvic brim, respectively. These vessels run close to the innominate bones, thus making them vulnerable to injury with any disruption of the pelvic ring. In particular, there is a plexus of veins running along the walls of true pelvis below the pelvic brim that is commonly disrupted by pelvic injuries, contributing to the rapid venous blood loss seen with these injuries (Fig. 96-2).

Arterial injuries are less common, accounting for 20% of pelvic exsanguinating deaths.[5] The arteries most at risk are the internal pudendal, superior gluteal, obturator, and lateral sacral arteries, usually as they exit the pelvis or at a branching or tethering point within the pelvis.

The bladder lies directly behind the pubic symphysis, with the urethra exiting inferiorly, making both these structures vulnerable to injury. Similarly, the sigmoid colon and rectum are vulnerable as they run along the posterior pelvis and through the pelvic floor.

The lumbar and lumbosacral plexi composed of the ventral nerve roots also lie against the posterior pelvis, and the resulting peripheral nerves, particularly the sciatic nerve, can be injured as they exit the pelvis. The sacral nerve roots are particularly vulnerable with injuries that involve a fracture through the sacral foramen.

MECHANISM AND INJURY CLASSIFICATION

The mechanism of injury is an important part of the presenting history in that it can be used to predict what type of pelvic injury has been sustained, as well as the pattern of associated head, thoracic, abdominal, and extremity injuries.[2] For example, in motor vehicle crashes, side impacts are more likely to result in a pelvic ring injury than a frontal impact.[6] Associated injuries that can be expected with a side impact include a closed head injury, cervical spine injury, rib fractures with pneumo- or hemothorax, splenic or liver laceration, lateral compression pelvic injury, and ipsilateral extremity fractures. A fall from a height has a pattern of injury including closed head injury, shearing injuries of the great vessels in the thorax, spinal burst fractures, vertical shear injuries of the pelvis, femoral neck fractures, and other lower extremity fractures.

Several pelvic fracture classifications exist to assist in deciding the appropriate treatment. The Young-Burgess classification stratifies the injury first by mechanism, i.e., anteroposterior compression (APC), lateral compression (LC), vertical shear (VS), and combined, and then subclassifies by severity of injury (Fig. 96-3). Higher grades of injury within each mechanistic subclass usually require operative fixation. The Tile classification stratifies the injury first by resulting stability,

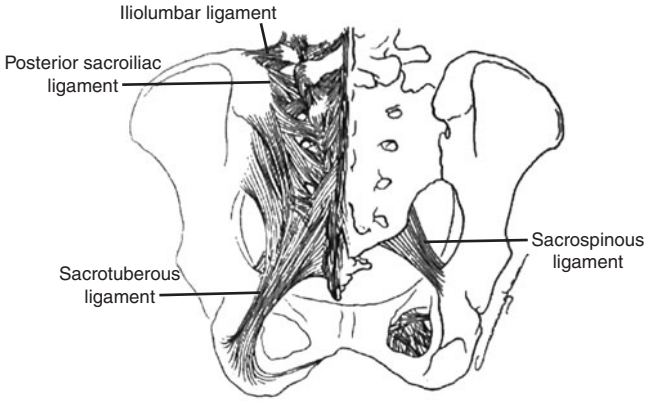

FIGURE 96-1 The bony and ligamentous anatomy of the posterior pelvis. (From Tile M, Hearn T: Biomechanics, in Tile M (ed): *Fractures of the Acetabulum*, 2nd ed. Baltimore, Williams & Wilkins, 1995, p 23.)

i.e. stable (A), rotationally unstable only (B), and vertically and rotationally unstable (C), and then subclassifies by pattern of injury (Table 96-1). Type B and C injuries usually require operative fixation. Both these commonly used classification systems have their merit, in that they communicate information about the pattern of injury, functional stability, and appropriate treatment.

Acetabular fractures are not uncommon in association with pelvic fractures. For the most part, they are also associated with similar visceral injuries as pelvic fractures. The classification system is descriptive in nature and also can be used to predict concomitant injuries; however, this is beyond the scope of this book.

CLINICAL ASSESSMENT

A pelvic ring injury should be suspected if there is any visible swelling, ecchymosis, or compound wounds around the pelvis. Scrotal or labial swelling and ecchymosis, i.e., bleeding from the urethral meatus, vagina, or rectum, are also good clinical signs of pelvic injury. Obvious rotational deformity or shortening of the lower extremities also may be indicative of injury.

The pelvis should then be assessed by manual palpation of tenderness anywhere around the pelvic ring. Next, the clinical stability should be tested by anterior compression of the pelvis at the anterosuperior iliac spines, followed by lateral compression of the iliac wings. Any gross motion that is felt indicates an unstable pelvic ring injury.

The peripheral pulses should be palpated, and a detailed neurologic examination of the lower extremities should be recorded to document the baseline function and to determine whether a peripheral nerve versus nerve root is involved in the injury.

RADIOGRAPHIC ASSESSMENT

The routine anteroposterior (AP) pelvis film obtained during the advanced trauma life support (ATLS) resuscitation is adequate to correctly identify 90% of pelvic ring injuries.[7] Virtually any clinically relevant pelvic instability can be identified. Indicators of instability include greater than 5 mm of displacement of the posterior elements in any plane and greater than 2.5 cm of widening of the pubic symphysis, avulsion fractures of the ischial spines or tuberosities, and avulsion fractures of the L5 transverse process. Additional inlet and outlet radiographs are helpful to assess AP displacement and superior migration of the hemipelvis, respectively.

For sacral fractures and subtle sacroiliac joint disruptions, the CT scan can further delineate fracture displacement.

MANAGEMENT

The most important aspect of management of the patient with a pelvic ring injury is the resuscitation as per the ATLS

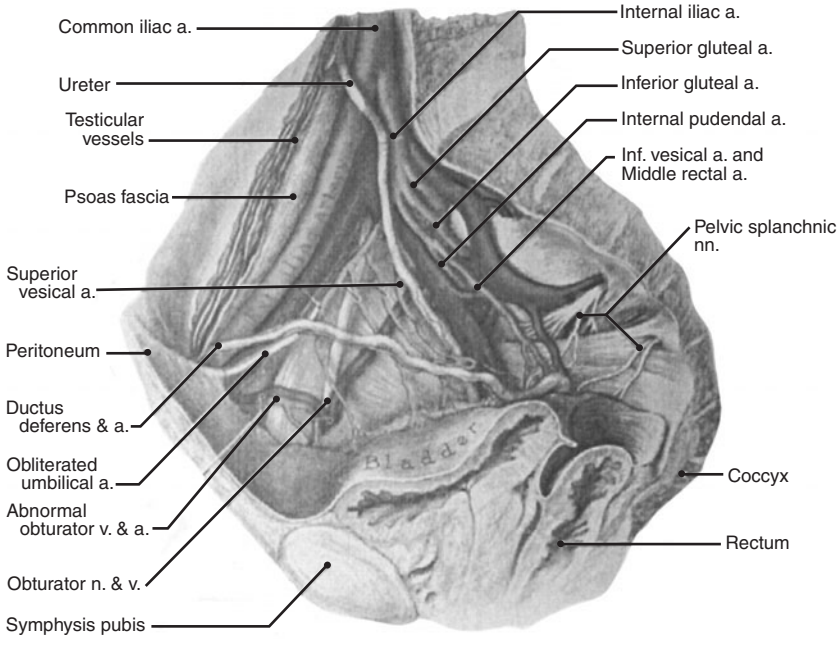

FIGURE 96-2 The vascular anatomy of the pelvis. (From Moore KL: *Clinically Oriented Anatomy*, 2nd ed. Baltimore, Williams & Wilkins, 1985, p351.)

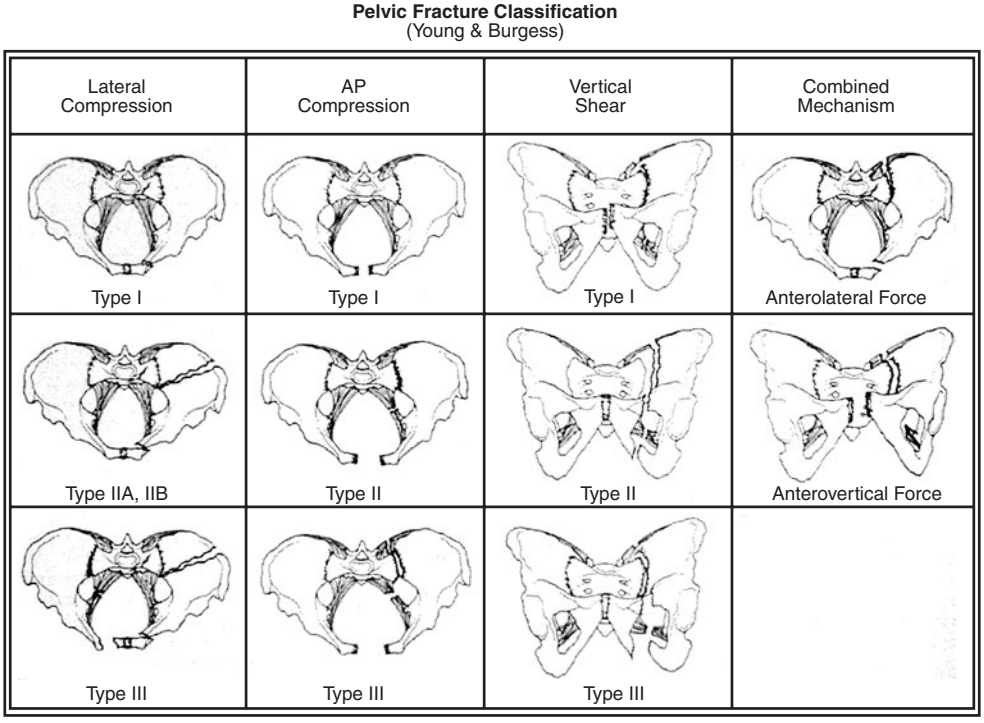

FIGURE 96-3 Young-Burgess pelvic fracture classification. (From Bosse MJ: The acute management of pelvic ring injuries, in Levine AM (ed): *Orthopaedic Knowldge Update Trauma,* 1st ed. American Academy of Orthopaedic Surgeons, 1996, p 220.)

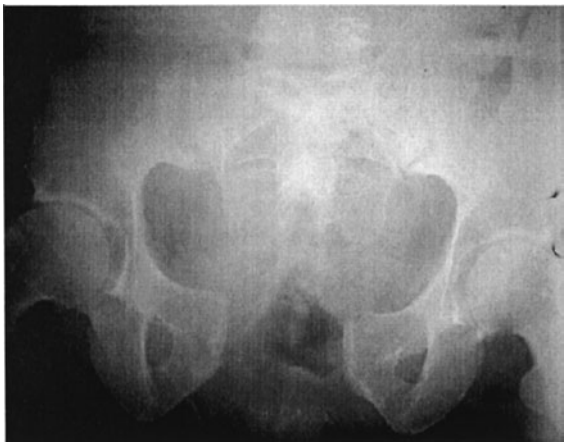
protocol.[8] During the circulatory assessment, the presence of other thoracic, abdominal, or extremity sources of blood loss should be ruled out. Massive fluid replacement, including transfusions, may be necessary.

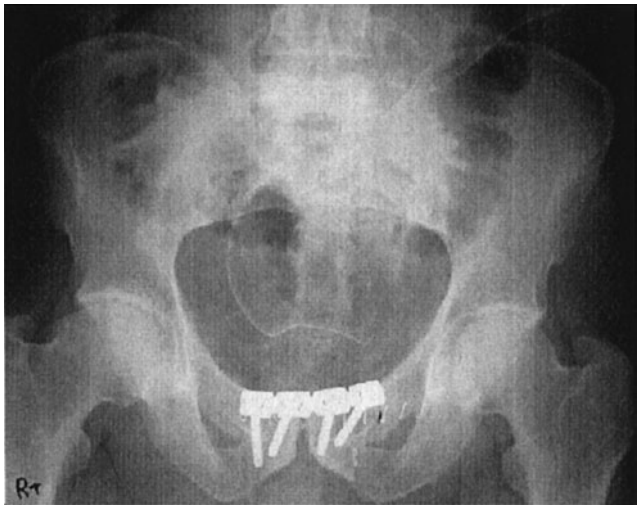
Initial stabilization of the pelvis is important to minimize or decrease bleeding from the pelvis and to stabilize intrapelvic vascular clots.[9,10] Historically, military antishock trousers (MAST) were used for this, but they have been found to contribute to decreased ventilatory ability and lower extremity compartment syndrome.[11] Recently, it has been found that simply wrapping and tying a sheet around the pelvis can effectively provide initial provisional stability.[12] A simple two-pin anterior external fixator or the pelvic C-clamp can be applied quickly to the anterior pelvis in the emergency room and provide adequate stability. Caution should be exercised in using the pelvic C-clamp posteriorly because improper pin placement can easily result in visceral, neurologic, or arterial injury. There is a greater margin of safety if the technique is applied using fluoroscopic assistance.[13,14]

The next priority is the identification and treatment of all significant sources of bleeding. If the patient is responding to the fluid resuscitation and becomes hemodynamically stable, other imaging, such as contrast-enhanced CT scanning, can be used to further delineate other sources of blood loss. Angiography for pelvic bleeding is indicated if there is ongoing unaccountable blood loss after provisional stabilization of the pelvis with an external fixator. It has been shown to be an effective way to rule out and treat arterial sources of hemorrhage in the pelvis.[15,16]



In the face of exsanguinating hemorrhage from venous pelvic bleeding not controllable by obtaining mechanical stability, open packing of the pelvis may be considered as a last resort; however, mortality rates are extremely high.

Provisional stabilization while the patient is being optimized in the ICU includes external fixation for unstable injuries, as well as skeletal traction on the lower extremity if there is associated vertical instability of the pelvis.[17]



Definitive stabilization usually requires internal fixation, provided there are no contraindications to surgery. The ideal time for this is when the patient is stable and systemically optimized. Fixation usually includes SI screws for posterior injuries[18] and open reduction and internal fixation or percutaneous screws for anterior injuries (Fig. 96-4). The use of external fixation and traction for routine injuries treatable with open reduction and internal fixation is not advised[19,20] because this usually compromises mobilization of the patient and increases the risk of associated problems of prolonged bed rest, including pneumonia, venous thromboembolism, and decubitus skin ulceration, as well as an increased mortality rate.

TABLE 96-1 Classification of Pelvic Fractures

Type A—stable
A1 Avulsion fractures
A2 Isolated fractures of the iliac wing, undisplaced ring fractures
A3 Transverse fractures of the sacrum and coccyx
Type B—vertically stable, rotationally unstable
B1 Open book injury
B2 Lateral compression injury
B3 Bilateral partially stable injuries
Type C—vertically and rotationally unstable
C1 Fracture of the ilium
C2 Fracture or fracture-dislocation of the sacroiliac joint
C3 Fracture of the sacrum

A

B

FIGURE 96-4 *A.* **46-year old man in motor vehicle accident sustains an APC type II pelvic injury with hemodynamic instability on presentation.** *B.* **Definitive fixation of the pelvis after provisional reduction and fluid resuscitation.**

COMPLICATIONS

Other complications may arise as a direct result of the pelvic ring injury. Massive blood loss and hemodynamic instability as described earlier are the most acute issues to be managed. Injuries to the gastrointestinal and urologic systems, vaginal tears, and skin degloving can cause significant problems if not managed properly in the acute setting.

Laceration of the colon or rectum results in fecal contamination of the peritoneal and retroperitoneal space. If left untreated, this results in abdominal or pelvic sepsis. The clinical diagnosis can be made with the finding of blood per rectum or on rectal examination. Rectal tears also can be palpated in the digital rectal examination and visualized by flexible proctosigmoidoscopy. Treatment consists of provisional external fixation of the pelvis, laparotomy with defunctioning colostomy, wide drainage and irrigation of the perirectal space, and repeated débridements until the pelvis and abdomen are clean. Definitive internal fixation may be considered at this time.

Injuries to the bladder and urethra are also very common, especially with high-grade anteroposterior compression or vertical shear injuries. The physical findings of blood at the urethral meatus and high-riding or mobile prostate with perineal ecchymosis suggest the diagnosis. This is confirmed with a retrograde urethrogram. Intraperitoneal bladder rupture should be repaired, whereas extraperitoneal ruptures may be treated by drainage only. Urethral tears should be stented, if possible, by a catheter. A defunctioning suprapubic catheter followed by delayed repair may be necessary with complete or complicated urethral tears. Once it is ensured that the pelvic contents are sterile, internal fixation of the pelvis may follow.

A laceration of the vagina should be suspected if there is blood in the perineum. This can occur with pelvic ring injuries with greater degree of displacement anteriorly. A bimanual and culposcopic examination to palpate and visualize the tear will confirm this. In general, these lacerations may be débrided and repaired and usually do not require a laparotomy. Timely repair has been seen to decrease the incidence of pelvic abscesses and infection.[21]

The soft tissue envelope around the pelvis is contused frequently; any laceration should be considered a possible open wound communicating with the pelvic ring injury. The Morel-Lavallee lesion is a closed lateral skin degloving injury that occurs most commonly with lateral compression injuries. This is apparent clinically by a large subcutaneous hematoma and lateral pelvic ecchymosis. There is an increased risk of cellulitis, as well as deep wound infection. They should be treated as open wounds, with serial débridements as necessary.[22]

The patient with a pelvic ring injury is at high risk of developing a deep vein thrombosis (DVT) owing to the injury itself, the often-accompanying lower extremity injury, immobilization, and altered coagulation profile secondary to transfusions of blood products. Prophylaxis is required, both mechanically and pharmacologically, in the absence of contraindications. Mechanical methods include intermittent pneumatic compression devices and graduated compression stockings if there are no extremity injuries that prevent the application of these devices. Pharmacologic prophylaxis, such as subcutaneous low-molecular-weight heparin, should be administered routinely, except when contraindicated by active bleeding or intracranial neurologic injury. The presence of a DVT in the lower extremities can be detected by venous duplex ultrasound. Intrapelvic DVTs are best detected by venography or magnetic resonance angiography; ultrasound is not a reliable modality in this situation.[23] There is a very high rate of embolism of intrapelvic clots; therefore, treatment is imperative. If anticoagulation is contraindicated owing to ongoing bleeding or upcoming major surgery, an inferior vena cava filter should be placed.

Extremity Trauma

Extremity trauma is very common, occurring in up to 75% of patients with multisystem and pelvic ring injuries.[1] Established patterns of injury are seen with common mechanisms, such as head-on and side-impact motor vehicle collisions, a pedestrian struck by a vehicle, and falls from a height. The

TABLE 96-2 Gustilo-Anderson Open Fracture Classification

Type I: Low-velocity injuries less than 1 cm long, usually compound from within, with minimal soft-tissue injury or comminution of the fracture.
Type II: Lacerations more than 1 cm long, with minimal to moderate soft-tissue crushing.
Type III: High-velocity injuries with severe crushing and the presence of skin flaps.
IIIA: No soft tissue loss
IIIB: Soft-tissue loss with periosteal stripping
IIIC:Associated vascular injury requiring repair

extremity injuries include injuries to the bones, joints, soft tissues, vascular system, and peripheral nerves.

Head-on motor vehicle collisions often result in a closed head injury, flexion-distraction injuries of the spine, intraabdominal injuries, posterior element acetabular fractures, hip fracture dislocations, bilateral femur and tibia fractures, and posterior knee dislocation with associated popliteal artery injury. Lateral-impact collisions and pedestrian injuries also have their own distinct patterns. Falls from a height frequently result in head injury; thoracic vascular shear injuries; abdominal visceral lacerations; spinal burst fractures; vertical shear injuries of the pelvis; and lower extremity fractures, including femoral neck and shaft fractures; tibial plateau, shaft, and pilon fractures; and calcaneal fractures. Although every patient should be examined thoroughly for all injuries, these patterns help to direct the focus of assessment to the most likely areas of injury.

FRACTURE ASSESSMENT

In general, all fractures need to be assessed for specific findings aside from the underlying fracture or dislocation. Excessive bleeding from fractures or vascular, neurologic, and soft tissue envelope injuries should be assessed, as well as the presence of compartment syndrome and open fractures.

Subtle injuries require palpation of each bone and motion of each joint. Even then, serial examinations several days after the initial injury may be required to detect all injuries. Any suspected areas should be imaged with radiographs in orthogonal planes.

Open fractures are graded by the system of Gustilo and Anderson[24,25] (Table 96-2).

TREATMENT

Although the initial fracture care usually is done in the emergency department, occasionally patients will be admitted to the ICU before any treatment can be initiated. After the initial assessment, any wounds should be flushed with saline and covered with a sterile dressing. Gross limb deformity and joint dislocations should be reduced and splinted and the neurovascular examination repeated. All musculoskeletal injuries should be imaged, and repeat fracture reductions or reductions of dislocations may be performed at this time as necessary. The patient should be prepared for operative intervention if a vascular injury, open fracture, irreducible dislocation, or compartment syndrome is detected.

In the case of open fractures, intravenous antibiotics should be administered, with gram-positive coverage for all compound fractures and with the addition of gram-negative and anaerobic coverage for contaminated wounds. The patient's tetanus status should be determined, and tetanus toxoid and immunoglobulin should be administered as required (Table 96-3).

All compound fractures should be treated with urgent irrigation and débridement within 8 hours, followed by provisional or definitive fixation, depending on the condition of the soft tissue envelope and the amount of wound contamination. Gustilo-Anderson type I, II, and IIIA fractures can be treated with irrigation and débridement and immediate definitive fixation, followed by serial débridements every 48 hours until the wound is clean. Type IIIB injuries usually require provisional external fixation and serial débridements until the wound is clean enough for definitive fixation and soft tissue coverage. For type IIIC injuries, the most pressing concern initially is reestablishment of perfusion to the extremity. After provisional fixation and vascular repair, serial débridements again may be required before definitive fixation can be performed, with soft tissue coverage as necessary. Prophylactic fasciotomies are frequently required to prevent reperfusion compartment syndrome. There is an increased risk of infection and nonunion with increasing grade of injury.

If the patient has not been optimized or there is some other delay postponing definitive treatment, provisional treatment of the fractures by splints, traction, or external fixation may be necessary. In addition, prophylaxis for DVT should be initiated, as discussed earlier. Attention to the skin, especially in dependent areas such as the sacrum, heels, and posterior

TABLE 96-3 Tetanus Immunization Schedule

History of Absorbed Tetanus Toxoid, Number of Doses	Non-Tetanus-Prone Wounds		Tetanus-Prone Wounds	
	Td[a]	TIG[b]	Td	TIG
Unknown or less than three	Yes	No	Yes	No
Three or more[c]	No[d]	No	No[e]	No

[a] Td: Tetanus and diphtheria toxoids absorbed—for adult use. For children under 7 years old, diphtheria and pertussis (dPT) (Td, if pertussis vaccine is contraindicated) is preferred to tetanus toxoid alone. For persons 7 years old and older, Td is preferred to tetanus toxoid alone.

[b] TIG: Tetanus immune globulin—human.

[c] If only three doses of fluid toxoid have been received, a fourth dose of toxoid, preferably an absorbed toxoid, should be given.

[d] Yes, if more than 10 years since last dose.

[e] Yes, if more than 5 years since last dose. (More frequent boosters are not needed and can accentuate side effects.)

scalp, should be maintained, with frequent log-rolling and skin care to avoid the development of decubitus ulcers.

Definitive fixation of most fractures allows greater ease of mobilization for general care and pulmonary toilet. Early mobilization and physical therapy also prevent the development of joint contractures and muscle atrophy, resulting in a faster recovery and reduced morbidity. DVT prophylaxis should be maintained during the postoperative period until the patient is mobilizing well independently.

COMPLICATIONS

Blood loss from fractures alone can be enough to cause hemodynamic instability. Even without a significant arterial laceration, femur fractures can result in blood loss of up to 2 units, tibia fractures 1 unit, and pelvic and acetabular fractures 4 units or more. Aggressive fluid resuscitation must be maintained while reassessing for other causes of hemodynamic instability. With increasing swelling of the extremities from fracture bleeding, there must be a high index of suspicion for compartment syndrome.

VASCULAR INJURY

The vascular status of each limb must be assessed by checking for the presence and quality of peripheral pulses, as well as the perfusion of the tissues distal to the zone of injury. Blunt or nonpenetrating vascular injuries often are associated with traction or avulsion injuries, fractures, and dislocations. It is important to assess the entire peripheral vasculature if there are multiple ipsilateral injuries, such as concomitant femur and tibia fractures. Knee dislocations and tibia fractures have the highest incidence of arterial injury, followed by femur fractures and traction injuries to the shoulder girdle. An abnormal vascular examination may be due to vascular spasm, external compression, intimal tear, or disruption of the artery itself. If the vascular examination is abnormal before or after gross realignment of fractures and reduction of dislocations, further investigation with an ankle-brachial index, angiogram, or magnetic resonance angiography is indicated to determine the nature of the injury. External compression of the artery usually can be relieved by reduction of the fracture or dislocation, and vascular spasm usually resolves after reduction as well.

Penetrating injuries such as gunshot and knife wounds also have a high incidence of vascular injury. All structures in the path of the projectile should be assessed from entry to exit wounds, including a generous surrounding area of collateral damage.

If the limb remains dysvascular, urgent operative intervention is required because muscle necrosis begins after 6 hours of warm ischemic time.[26] The sequence of events for vascular repair usually begins with provisional fracture stabilization with an external fixator or rapid internal fixation followed by the establishment of a provisional shunt to restore perfusion.[27] Definitive vascular repair, ideally with an end-to-end anastamosis or saphenous vein graft, if necessary, then can be performed, followed by definitive fracture fixation.[26] Reperfusion edema and compartment syndrome are common; thus a prophylactic fasciotomy usually is indicated. Wound coverage by skin graft or free flap can be achieved after the wound has undergone serial débridements to minimize the risk of wound infection and sloughing of the graft[28] (Fig. 96-4).

NEUROLOGIC INJURY

If the patient is awake and cooperative, a detailed neurologic examination of each extremity should be done, with particular attention distal to the zone of injury. If the patient cannot participate in the examination, general observations of gross limb movements and reaction to pain stimulus help to establish baseline function. Most peripheral nerve injuries are neuropraxias, which begin to recover spontaneously over 6 to 12 weeks. The progress of recovery can be monitored with serial nerve conduction studies. In the situation of penetrating injuries or dissection for open reduction and internal fixation of fractures, the nerve may be explored to assess for injury. If it is found to be lacerated, direct primary repair is indicated once the wound is clean.[29]

With or without nerve repair, it is important to splint the extremity in a functional position of rest, with occupational and physical therapy involvement to maintain motion of the affected joints. Muscle stimulators also may be beneficial to decrease the rate of atrophy of the affected muscles. If acute repair or grafting has been performed, the extremity should be splinted in a resting position temporarily (1 to 2 weeks) to allow the repair to begin to heal and then gradually mobilized to prevent arthrofibrosis and contractures.

COMPARTMENT SYNDROME

Increased compartment pressures result from intercompartmental edema and bleeding associated with fractures or vascular injury. The increase in pressure causes a compressive occlusion of capillary venules, stopping capillary flow and perfusion of tissues, the most sensitive of which are the muscles and nerves. Because the compressive phenomenon affects the microvasculature, distal pulses usually are maintained during this process.[30]

Clinically, compartment syndrome is manifested by the "five P's". In order of clinical relevance, these are pain out of proportion to the injury,[31] pain with passive stretching of the affected muscles, paresthesia (numbness) involving the nerves within and distal to the compartment, powerlessness (weakness) of the muscles within the compartment, and a pulseless extremity (which may not necessarily ever happen). If left untreated, the muscles and nerves undergo necrosis, resulting in ischemic contractures and loss of sensation or painful paresthesias, leaving the limb with very poor function.

The most common sites affected are the lower leg, in association with tibia fractures, and the forearm, in association with radius and ulna fractures. Compartment syndrome also can occur in the thigh, buttock, upper arm, hand, and foot.[32,33]

Early recognition is mandatory either clinically, as described earlier, or by compartment pressure monitoring. A compartment pressure greater than 30 mm Hg or within 30 mm Hg of the diastolic pressure is diagnostic for compartment syndrome. It may be necessary to rely on pressure monitoring if the patient is obtunded, there are significant distracting injuries, or the clinical examination is unreliable (psychiatric conditions, intoxication, etc).

The initial treatment includes elevation of the limb to the level of the heart and release of all circumferential or compressive dressings. If there has been no improvement within 1 hour, a fasciotomy is required. If in doubt, it is far better to perform a fasciotomy because the consequences of untreated compartment syndrome are extremely debilitating and usually permanent. Owing to the typical amount of swelling with

these injuries, the wound usually cannot be closed and requires coverage with a skin graft several days after release.[34]

FAT EMBOLISM SYNDROME

Fat embolism syndrome (FES) encompasses the respiratory, neurologic, and other systemic sequelae of the embolism of fat from the marrow space of long bones. It occurs in up to 2% of isolated long bone fractures and up to 10% of multiply injured patients. The most significant feature of FES is the potentially severe respiratory effects, which may result in adult respiratory distress syndrome (see Chap. 27). It usually occurs within 1 to 3 days following injury, and the clinical presentation includes the following: lethargy, disorientation, and irritability with the appearance of petechiae on the trunk and in the axillary folds, conjunctiva, and fundi in 50% of cases. Blood tests may demonstrate anemia and thrombocytopenia, and examination of the urine may show lipiduria.

The diagnosis of FES can be made on major and minor criteria. The major criteria include respiratory insufficiency, central neurologic impairment, and petechial rash. The minor criteria include tachycardia, fever, retinal fat emboli, lipiduria, anemia, and thrombocytopenia.[35]

Once the patient becomes hypoxemic, supportive measures are all that can be done, including positive end-expiratory pressure (PEEP) and lung-protective ventilation. The most significant treatment aspect of FES is prevention. Early long bone fracture fixation has been shown to be a key factor,[36] particularly with tibia and femur fractures. Aggressively fluid resuscitation and maintaining an adequate circulatory volume also have been shown to be protective. Despite aggressive management, the mortality rate of full-blown FES is up to 15%; thus the importance of early fracture fixation is critical.

Chapter 97
ELECTRICAL TRAUMA

LAWRENCE J. GOTTLIEB
RAPHAEL LEE

KEY POINTS

- *Aggressive and prolonged life support maneuvers should be performed as necessary on all electrical injury patients in the first few hours.*
- *All patients are to be considered to have multisystem injuries, including cervical spine fracture, until such injuries are eliminated diagnostically.*
- *Intravenous fluid resuscitation should not be underestimated.*
- *Most patients should be monitored for cardiac dysrhythmias for 24 to 48 hours after injury, particularly if electrocardiographic abnormalities were present or persist.*
- *The preservation of renal function depends largely on adequate volume resuscitation. If urine is visibly discolored by myoglobin, then renal function may depend on supplemental therapies.*
- *The neurologic examination should be monitored carefully for seizure activity, which should be treated if it develops.*
- *Early recognition and decompression of compartment syndromes are critical for maximizing extremity salvage and long-term function.*
- *Adequate wound care necessitates complete débridement of nonviable tissue followed by wound closure as expeditiously as possible.*

Electrical shock is one of the leading causes of work-related injury, comprising 7% of all workplace fatalities. Typical victims of high-voltage electrical injury are young industrial workers or linemen usually between the ages of 20 and 34 years, with 4 to 8 years experience on the job. Immediate death can result from cardiac dysrhythmia, central respiratory arrest, or asphyxia due to tetanic contraction of the muscles of respiration. If victims survive the initial cardiopulmonary or central nervous system (CNS) insult, they then may face potential limb- and life-threatening sequelae from cutaneous injury, internal tissue destruction, and organ system dysfunction. The distribution of the tissues and organs damaged depends on the path of the injury current. Frequently, the injury is complicated by associated blunt trauma when the patient falls from a height or is thrown by the force of the electric current.

When the voltage is less than 1000 V, direct mechanical contact usually is required for electrical contact. For high voltages (>1000 V), arcing usually initiates the electrical contact. Most electrical injuries are due to low-voltage (<1000 V) electrical shock. Whereas low-voltage shocks carry a significant risk of electrocution-induced cardiac arrest, high-voltage shock injury is characterized by extensive tissue damage rather than electrocution. Approximately 3% to 4% of all U.S. hospital burn unit admissions are for electrical injury, mostly a result of high-voltage (>1000 V) shocks.

The duration of contact with the high-voltage power source and the distribution of electric current are important factors in the magnitude of the injury. If the contact is brief (i.e., <0.5 s), cell damage can occur through nonthermal components of electrical injury, called *electroporation.*[1] If the contact is longer, both heating caused by electrical conduction (joule heating) and electroporation play important roles. Prolonged contact can lead to thermal burning of tissues in the current path. The electric current distribution across the tissues between the surface contact points depends on the electrical conductivity of the various tissues and on the variation in electrical field intensity. Usually, current density is greatest at the contact points. Once the current travels away from the contact points into the subcutaneous tissues, the tissues with the least electrical resistance, i.e., muscle, nerve, and blood vessels, will have the largest current densities and will experience the most rapid heating.[2]

Many cells, such as muscle and nerve cells, use electrical signals to control their function. The application of weak electrical fields from a nonphysiologic source can interfere with cell function and, if the field is strong enough, cause direct cell damage. Electricity at frequencies below 1 MHz may produce tissue injury primarily by permeabilizing cell membranes, electroconformational denaturation of cell membrane proteins, and thermal denaturation of tissue proteins. Factors that determine the anatomic pattern, extent of tissue injury, and relative contribution of heat versus direct electrical damage include the amount of current, the anatomic location, and the contact duration. The type of clothing, use of protective gear, and the power capability of the electrical source also contribute to the wide range of clinical manifestations observed in electrical shock victims.

At the commercial frequency of 60 Hz, the threshold for human perception of a current passed hand to hand is approximately 1.0 mA. As the current reaches 16 mA, the muscles in the arm develop involuntary spasms. Within 10 to 100 milliseconds of the onset of the current (the excitation-contraction response time of human skeletal muscles), muscles located in the current path will contract. If the hand is holding the conductor at that time, the strong forearm flexor muscles will contract, causing the victim to grasp the conductor strongly and thus maintaining contact uncontrollably with the current source. This is called the *no-let-go phenomenon.* Alternatively, if the victim is close to but not touching the conductor at the time of current passage, the strong muscle contractions generally propel the person away from the contact. Judging from eyewitness reports, the latter phenomenon may be more common. In addition, a very high-energy electrical arc can produce a strong thermoacoustic blast force leading to significant barotrauma.

When a current of 60 mA or greater traverses the mediastinum, there is enough depolarization of myocardial membranes to cause cardiac arrhythmias, particularly if induced during early myocardial repolarization. When the current amplitude reaches 1500 mA through the upper extremity, skeletal muscle and peripheral nerve cells are damaged by electrical forces, independent of heat. Smaller currents, in the range of 200 to 500 mA, can generate enough joule heating to cause tissue damage if the duration of current passage is sufficient. The rise in serum creatine phosphokinase (CPK) levels that results may be a useful prognostic indicator.[3]

While the spectrum of electrical injury ranges from minor cutaneous trauma to severe multisystem injury, the

TABLE 97-1 Criteria for Admission of Electrically Injured Victims to the ICU

Any the following qualify a patient for admission to an ICU:

1. Thermal injury (arc or flash) to greater than 20% of the body surface area
2. Thermal injury (arc or flash) to hands, feet, face, or perineum
3. Suspicion of inhalation injury or upper airway swelling
4. Evidence or suspicion of direct electrical contact with more than 100 V and more than 200 mA across the body (or at least one limb)
5. History of loss of consciousness
6. Abnormal neurologic examination findings (central or peripheral)
7. Cardiac dysrhythmia (at the scene or in the emergency room)
8. Abnormal electrocardiogram
9. History of cardiopulmonary arrest (at the scene or in the emergency room)
10. Evidence or suspicion of developing increased muscle compartment pressure
11. CPK level greater than 400 units/L
12. Pigments (hemochromogens) in urine
13. History of blunt trauma associated with electrical injury (e.g., a fall or being thrown from a power source)
14. Signs of visceral injury

victims of high-voltage electrical injury are usually the patients who are admitted to a critical care unit (Tables 97-1 and 97-2).

Initial Evaluation

On arrival at a critical care facility, the ABC's of trauma (airway, breathing, and circulation) are assessed, and appropriate therapeutic maneuvers are initiated. Cardiopulmonary resuscitation (CPR) is initiated or continued, as needed, and routine advanced trauma life support (ATLS) procedures and protocols are performed. Life support activities should be continued for a prolonged period because complete functional recovery after lengthy resuscitatory efforts has been well documented.[4] Precise time limits for the continuation of life support have not been elucidated.

After the patient is stabilized, a complete history should be obtained, if possible, and a careful physical examination should be performed. Witnesses and family members often give pertinent information regarding the accident, as well as significant medical history. On physical examination, particular attention should be paid not only to the sites of electrical contact but also to other areas of significant patient complaint. It is a misnomer to refer to electrical "entry" and "exit" sites. When the electrical source is an alternating current (e.g., a home 60-Hz electrical socket), any point of physical contact will carry the current in and out of the body at 120 times per second. The location of surface contact points, which usually are full-thickness burns, allows the physician to establish the most likely pathway of the current and the region(s) of potential tissue damage. Obvious cutaneous injury is usually only the tip of a large soft tissue injury (iceberg theory). During resuscitation, electrical trauma victims frequently require large volumes of isotonic intravenous fluids, in excess of calculated needs. These large fluid requirements are due to considerable third-space losses secondary to deep or occult tissue damage. Unlike purely thermal burn injuries, resuscitation formulas such as the Parkland formula are not helpful guides to fluid management. Isotonic fluids should be given liberally, with the initial goal of resuscitation being a urine output of between 0.5 and 1 mL/kg per hour. Any electrolyte abnormalities should be quickly corrected. If hemochromogens (such as myoglobin or free hemoglobin) are found in the urine, the rate of fluid administration is increased to achieve a goal of a urine output of 1.5 to 2.0 mL/kg per hour. Mannitol infusion may aid in maintaining high urine flow. The recommended dosage is 12.5 g administered as an intravenous bolus. If hemochromogens persist in the urine after mannitol bolus therapy, then a mannitol infusion should be started at the rate of 12.5 g/h continuously until the urine clears. Careful observation of electrolytes is required when a patient is treated with continuous mannitol infusion. Other therapies include alkalinization of the urine (to pH > 6.5) with bicarbonate to prevent precipitation of urine myoglobin in the renal collecting system. Loop diuretics rarely, if ever, should be used to improve urine output. Reliable large-bore intravenous access is essential, as well as arterial blood pressure monitoring and a urinary catheter. A pulmonary artery catheter is not essential in most patients, but it may be helpful in those with significant left ventricular dysfunction if the volume status cannot be ascertained on clinical grounds.

Victims of electrical trauma should be viewed as potentially having multiple traumatic injuries. A large percentage of high-voltage electrical trauma patients have either fallen from a height or been thrown by the force of the electric current. Cervical spine as well as other orthopedic injuries should be suspected and sought, and therapy should be initiated as appropriate. A falling hematocrit or hemodynamic instability must be investigated thoroughly. Changes found by the mental status examination must be explained. An unstable level of consciousness cannot be attributed to changes secondary to electricity until any systemic hypoperfusion or surgically correctable head trauma has been eliminated. The initial physical examination also should include a careful evaluation and documentation of both the central and peripheral nervous systems. A paralyzed ventilated patient may need electroencephalographic (EEG) monitoring to assess seizure control. The manifestation of neurologic deficits may be delayed, so these evaluations should be repeated daily.

Appropriate tetanus prophylaxis is provided, as delineated by the American College of Surgeons Committee on Trauma guidelines. Antistreptococcal and anticlostridial antibiotics

TABLE 97-2 Criteria for Transfer Out of the ICU

All the following criteria need to be met for safe transfer at 48 hours:

1. Thermal injury on less than 20% of the body surface area
2. No evidence of inhalation injury or upper airway edema
3. Neurologic stability
4. No cardiac dysrhythmia for 24–48 hours or cardiac rhythm stability documented by serial ECGs
5. Hemodynamic stability for 24–48 hours
6. Normal acid-base balance
7. Compartment syndrome diagnostically excluded or appropriately treated
8. Peak CPK serum level less than 400 units/L in first 48 hours[a]
9. Clearance of urinary pigments (hemochromogens)

[a] See Ahrenholz et al.[3]

should be administered prophylactically in patients with significant soft tissue injuries. Appropriate evaluation and management of corneal injury and tympanic membrane rupture should be instituted.

CARDIAC

Lethal ventricular dysrhythmias are a major cause of immediate death from electrical injury. If an initial dysrhythmia is corrected and the patient is stabilized hemodynamically, recurrence of a potentially fatal dysrhythmia is unusual unless a cardiac pathology exists. As stated earlier, it is important to remember that electrical injury victims who require CPR because of a dysrhythmia should be given prolonged ACLS because reports of complete functional survival after significant periods of CPR do exist.[4]

Close to 50% of patients exhibit electrocardiographic (ECG) changes or rhythm disturbances after injury. The most common ECG alterations are nonspecific ST-T-wave changes and sinus tachycardia, which usually revert with time. Most dysrhythmias are transient, and therapeutic intervention is rarely needed. The difficulty lies in identifying the existence of new myocardial damage and determining its physiologic significance. Some patients may suffer long-term damage to the conductive system.[4a]

The usual clinical diagnostic criteria for myocardial infarction include ECG changes and elevation of cardiac isoenzyme levels in a setting compatible with myocardial ischemia. These pieces of evidence are not reliable, however, in the circumstance of electrical injury. ECG abnormalities after electrical trauma are common, temporary, and usually physiologically insignificant. The levels of the CPK MB isoenzymes may be elevated owing to large-scale muscle damage and may give a false impression of myocardial damage.[5] Clinical symptomatology of cardiac ischemia, which is subjective at the best of times, usually is not helpful in the face of multisystem electrical trauma. The technetium-99m pyrophosphate scan also has been used to try to identify myocardial damage. However, transmural myocardial damage is rare, and this test does not assess nontransmural injury accurately. Since diagnostic tests are not helpful and significant myocardial injury historically is known to be unlikely, aggressive volume resuscitation and surgical intervention should proceed as required. The exception to this principle is the patient who has been hemodynamically unstable as a result of congestive heart failure, malignant dysrhythmia, or clinically obvious myocardial ischemia.

The evaluation of these patients includes daily ECGs for 3 days following injury, as well as serial cardiac isoenzyme determinations. The results of these tests are interpreted in light of the clinical situation. It has been suggested that not all patients need to have continuous cardiac monitoring after injury unless they have a history of (1) loss of consciousness, (2) recurrent dysrhythmia in the field or emergency room, (3) abnormal ECG on admission, or (4) other injuries that necessitate cardiac monitoring.[6]

RENAL

Renal dysfunction occurs in approximately 10% of patients who suffer high-voltage electrical trauma. The most frequent cause of renal dysfunction, and the most easily treated, is hypovolemia. A common mistake is to grossly underestimate the volume requirements in electrically injured patients. The extent of soft tissue damage and the resulting third-space losses are not always immediately apparent, so fluid resuscitation may be inadequate. Intravascular volume depletion can lead to a decrease in the renal blood flow, which leads to decreasing glomerular filtration rate, renal cortical ischemia, and acute tubular necrosis. Aggressive volume replacement is therapeutic by restoring the circulating plasma volume. The goal for urinary output is 0.5 to 1 mL/kg per hour.

The precipitation of intravascular hemochromogens in the renal tubules is another cause of renal dysfunction. Hemochromogens can be visualized in the urine in approximately 25% of patients with electrical injuries. The responsible pigments are myoglobin, secondary to rhabdomyolysis, and free hemoglobin, from lysed red blood cells. The detrimental effect of pigments deposited in the tubules is thought to increase with hypovolemia, which further underscores the need for adequate fluid resuscitation.

The best prophylactic and therapeutic regimen to prevent renal toxicity secondary to hemochromogen deposition is to maintain adequate intravascular volume and high urine output. This is accomplished with lactated Ringer's solution and mannitol infused hourly in 12.5-g increments. The resulting solute diuresis must be monitored carefully to prevent intravascular volume depletion and electrolyte abnormalities. In the presence of urine pigments, the goal is to create a flow of urine of at least 1 to 2 mL/kg per hour.

Myoglobin is much more soluble and less likely to be retained by the kidney when the urine is alkaline. Some contend that the provision of adequate resuscitation and a solute diuresis will automatically create a urine pH that is clinically therapeutic. However, others recommend maintaining a urinary pH of greater than 6.5 by adding sodium bicarbonate to the intravenous fluids. This treatment is continued until urinary myoglobin has cleared, which may take from 48 to 60 hours. There is evidence that bicarbonate also participates in the solute diuresis; hence its value may be twofold.[8] If the urine does not clear of hemochromogens within 24 hours and the serum levels of CPK isoenzymes continue to rise, then a source of undetected muscle ischemia or myonecrosis should be sought actively. Careful, repeated physical examination, specifically looking for areas of swelling and tenderness, should be performed. Technetium-99m nuclear scanning may be helpful in localizing areas of ischemic muscle, although its lack of specificity may lead to false-positive results.[8a] Xenon 131 scanning and arteriography have both been shown to be generally unhelpful in localizing areas of muscle ischemia or myonecrosis. Magnetic resonance imaging (MRI) provides a reliable method of evaluating edematous muscle. When occult muscle ischemia is discovered, surgical decompression or débridement may or may not lead to functional recovery of that muscle group but may alleviate the systemic problems related to toxic effects of injured or dying muscle.

PULMONARY

There are relatively few pulmonary complications that are characteristic of electrical injury. Acute ventilatory failure secondary to electrical injury is usually related to CNS injury or to chest wall impairment. Depressed respiratory drive due to CNS damage may lead to respiratory failure, necessitating mechanical ventilation. The chest wall and the muscles

of respiration may be injured directly, compromising neuromuscular efficiency and leading to the need for ventilatory support.

Long-term pulmonary sequelae such as pneumonia or effusion are treated as in any other injury. There are isolated reports of current-induced bronchopleural fistula, but in most cases the need for ventilatory support is not due to current injury to the pulmonary parenchyma.

When the transient path of the current passes through the pharynx, significant upper airway swelling may develop. All patients at risk should undergo serial examinations of the upper airway by fiberoptic endoscopy and should be intubated prophylactically if hypopharyngeal edema is found.

GASTROINTESTINAL

Abdominal complications following electrical trauma are relatively infrequent. Most often gastric atony and adynamic ileus are seen. These complications usually resolve with nasogastric suction, intravenous fluid administration, nutrition, and time. More serious complications, such as gastrointestinal bleeding, acalculous cholecystitis, and rupture of colon, gall bladder, and other organs, have been reported. It is difficult to know whether all these processes are due to electricity or to the stresses of severe shock and systemic illness. If a contact point on the abdomen has caused a full-thickness burn, the wound should be excised surgically. If this wound includes the posterior fascia of the abdominal wall, then formal exploratory celiotomy should follow. Intraabdominal pathology may be present even without abdominal wall injuries, however. Systemic signs of sepsis or changes on serial physical examination of the abdomen should alert the clinician to intraabdominal pathology. White blood cell counts, liver function tests, amylase and lipase determinations, and examination of the abdomen by ultrasound, computed tomography (CT), MRI, and peritoneal lavage may be required in making the correct diagnosis and directing therapy. Virtually any abdominal catastrophe can be caused by electrical current, and thus the physician must be alert and respond appropriately to subtle clinical changes in abdominal signs and symptoms.[9] If intraabdominal injury is not suspected, then enteral feedings should be instituted within 6 hours of admission, if possible.

NEUROLOGIC

It is possible for any aspect of the human nervous system to be affected by high-voltage trauma. Neurologic deficits may appear in either the central or peripheral nervous system. Evidence of injury may be immediate or delayed. Finally, the duration of neurologic deficit ranges from transient to permanent.[9a]

Neurologic changes often are poorly described and documented when they do occur, and hence evaluation of retrospective data is difficult. Immediate neurologic deficits occur in more than 40% of patients. The most common symptom is loss of consciousness. This occurs in up to 65% of symptomatic patients and usually resolves without permanent sequelae. However, long-term complaints include headache, dizziness, vertigo, and seizure activity, as well as psychosocial behavioral disorders such as impotence and personality changes.

Spinal cord injuries can have acute or delayed presentations. Acute neurologic deficiencies can demonstrate a frighteningly complete motor and sensory loss. Yet acute deficits have a tendency to resolve over hours or days. Delayed spinal cord symptomatology is much more ominous and less likely to resolve. The pathophysiology of these delayed findings is not well understood.[10]

Peripheral nerve injuries account for 5% to 23% of all posttraumatic neurologic sequelae. The most common injury is to the median nerve, followed by the ulnar, radial, and peroneal nerves. In the acutely damaged edematous arm and hand, immediate operative decompression of the carpal tunnel, cubital tunnel, and Guyon's canal is urgent if peripheral neuropathy develops. Following appropriate release, signs of acute peripheral nerve compression should dissipate if thermal injury to the nerve has not occurred.

EXTREMITY AND WOUND

Care of the extremity and the wound caused by electrical trauma will be discussed concurrently. The rationale behind this approach is that the attempted salvage of the extremity, particularly the arm and hand, best demonstrates the principles of maximal tissue preservation with optimal residual function.

After life-threatening emergencies are addressed, attention should be turned to assessing the soft tissue injury. The injury always should be suspected of being more extensive than it initially appears because visible cutaneous injury is only a portion of the total tissue destruction. Compartment syndromes are a common manifestation of the electrically traumatized extremity. Within minutes after injury, tissue edema begins to increase owing to increased vascular permeability and release of intracellular contents into the extracellular space. Pain with passive movement is an early finding. Tense compartments may be recognized by palpation, but compartment pressure should be documented.

Compartment fluid pressures in excess of 30 mm Hg are abnormal and indicate the need for decompressive fasciotomy. Measurement of pressure in smaller compartments such as that of the intrinsic muscles of the hand is notoriously unreliable. Exploration of the fascial compartments of the acutely swollen hand should be performed empirically whenever high-voltage trauma involves the hand and there is a high index of suspicion of compartment syndrome. Fasciotomy of any fascially bound muscle group may salvage an otherwise moribund muscle. Complete release may be facilitated by incising the epimysium of each muscle. All nonviable skin is débrided. Deciding which tissue is irretrievably injured and requires débridement is often a difficult problem. We define healthy muscle as that which is of normal color and contracts with electrocautery stimulation. All noncharred nerves and tendons are preserved, as is marginal muscle when intermixed with healthy muscle.

It is at this point in management that controversy exists. The most widely practiced surgical approach is to reinspect the wound and débride obviously necrotic tissue every 48 hours.[11] Between débridements, one must be careful to avoid tissue drying or desiccation. Typically, allograft is applied to decompressed exposed, viable muscle, and a topical antimicrobial is applied to marginal tissue. Closure is usually delayed until the wound is in bacteriologic balance and is free of all dead or marginal tissue. Whether a finding of additional nonviable tissue at each of the serial débridements represents

progressive necrosis or *progressive recognition* of fatally damaged tissue remains an unresolved question.

Based on the hypothesis that marginally viable tissue is potentially salvageable if covered acutely with well-vascularized tissue, another more aggressive therapeutic regimen exists for selected patients. After decompression of tense compartments, obviously nonviable muscle and skin is débrided. Exposed, devascularized tendons and nerves, as well as marginal muscle, are covered acutely with well-vascularized tissue. Consideration is given to replacement of injured major arteries and veins with healthy vein grafts before they rupture or thrombose. Owing to the limited availability of suitable local tissue, distant flaps or microvascular free tissue transfers are generally used for coverage.[12]

The decision to salvage an injured extremity must involve careful weighing of the potential morbidity and mortality. A cold, insensate, stiff extremity will be less useful to the patient than a functional prosthesis. This decision of whether to attempt salvage or to amputate should be made as soon as possible, thereby minimizing the risks as well as the physical and psychological efforts invested in salvaging an extremity that eventually will be amputated.

Lightning Injury

Injuries due to lightning are often fatal, and the pathophysiology is relatively complex.[12a] Lightning injury is a powerful manifestation of arc-mediated electrical contact. Arcing occurs when the voltage gradient in air exceeds 2 million V/m. The arc consists of a hot ionized gas of subatomic particles that is highly conductive. Peak lightning currents reach into the range of 30,000 to 50,000 A for a duration of 5 to 10 microseconds. Lightning arc temperatures reach up to 30,000 K, which generates thermoacoustic blast waves commonly called *thunder.* Peak blast pressures reach 4 or 5 atm in the immediate vicinity of a lightning strike and up to 1 or 2 atm 1 m away. Clearly, substantial barotrauma can result. Lightning produces a high transient electrical field and resulting magnetic field. Because of its high-frequency characteristics, the electrical field only penetrates the outer surface of the body, but the huge magnetic field can penetrate throughout. Victims of direct lightning strikes experience a multimodal injury. Superficial burns on the skin represent the current path along the skin surface. The intense brief shock pulse seems to arrest all electrophysiologic processes. The victim appears lifeless. Prolonged CPR may be necessary. Muscle and nerve necrosis is rare in survivors. Deeper injury results when the victim is in contact with a large conducting object such as a truck or fence that has been struck by lightning, which then will discharge over several milliseconds through the victim.

Hundreds of fatalities occur in the United States alone each year as a result of lightning injury.[13] Delay in resuscitation is the most common cause of death. Bystanders usually are afraid to touch the victim while precious minutes pass. However, unless the victim is on an insulating platform, there is no residual electric charge on the body after several milliseconds. When needed, CPR should be given without hesitation. Victims should be cared for in an ICU until life-threatening CNS and cardiac injuries are ruled out. Late neurologic and ophthalmologic sequelae often develop. Treatment of lightning injury should follow the guidelines given for major electrical trauma. In addition to the electrical effects, one may expect tissue injury from the electrothermal-acoustic shock waves that also occur.

Survivors of lightning injury are not likely to be the victims of a direct hit. Rather, they are likely to have been in the vicinity of the hit and to have experienced surface burns and arc effects.

Late Sequelae of Electrical Injury

The late sequelae of electrical injury generally result from the acute loss or damage of tissue. The extent of tissue damage may not be recognized acutely. Neuromuscular problems usually are due to muscle fibrosis and peripheral neuropathies coupled with loss of tissue from débridements and joint stiffness. Sensorimotor neuropathies, paresthesias, dysesthesias, and reflex sympathetic dystrophy may manifest long after the wounds have healed. Severely injured victims may require functional muscle and nerve reconstruction, as well as correction of scar contractures. Cold intolerance may persist for up to 2 to 3 years, and growth disturbances producing skeletal deformities in children are frequent long-term sequelae.

There are also late sequelae of electrical trauma in which the etiology is unknown. Cataracts occur in 1% to 2% of victims even though the current path did not necessarily involve the head and neck. A full spectrum of central neurologic disorders has been described as late sequelae of electric shock. Persistent peripheral neurologic, psychological, and neurocognitive problems often require detailed evaluation and therapeutic intervention. Although unusual, paraplegia and quadriplegia may manifest up to 5 years after the injury.

Rehabilitation into society and gainful employment are the ultimate objectives of the care of these patients. Subtle mental status and personality changes may have a severe effect on the patient's motivation and participation in the rehabilitation program that is crucial to optimal function.[14] Workforce reentry should be guided by consultation with the employer, the patient, coworkers, and an experienced occupation medicine and rehabilitation team.[14a]

Chapter 98

BURNS: RESUSCITATION PHASE (0 TO 36 HOURS)

ROBERT H. DEMLING
LESLIE DESANTI

KEY POINTS

- *A burn patient is a trauma patient; therefore, other injuries should be expected and sought.*
- *Endotracheal tubes should be large enough to allow ventilation and pulmonary toilet.*
- *Hypothermia is a major concern, and early, aggressive attempts at prevention are required.*
- *Modification of the standard lactated Ringer's resuscitation is often necessary in the massive burn or inhalation injury patient or in the very young and old. Additions of colloid, blood, and inotropes are often very useful in restoring hemodynamic stability. Fluid formulas should not be rigid.*
- *It is important to watch for local perfusion problems and chest wall restriction caused by the burn.*
- *The burn itself is a low priority for initial care.*

Care of the burn patient has improved dramatically over the past 10 to 15 years, resulting in a marked decrease in mortality and morbidity, as well as improved functional outcome. The major reason for this improvement is the multidisciplinary approach by a team that has the clinical decision-making skills, experience, and scientific background to render care in a manner that avoids the predictable pitfalls while also maintaining critical care monitoring. A burn center is the best environment to provide this care.

The burn patient's condition changes dramatically over the course of the injury. The initial postburn period is characterized by cardiopulmonary instability caused by fluid shifts and direct smoke injury to the airways. With the onset of intense wound inflammation, immunosuppression, and infection, physiologic and metabolic parameters change substantially from those seen initially. Treatment therefore must be based on a clear understanding of these changes over time.[1,2] This discussion thus will be divided into three time periods—the initial resuscitation period (0 to 36 hours; this chapter), the early postresuscitation period (2 to 6 days; Chap. 99), and the inflammation-infection period, which is usually most evident after the first week (Chap. 100).

Monitoring requirements are no different from those for any other ICU patient. However, vascular access is much more of a problem, and noninvasive measures are often all that are available. A typical burn unit has a procedure room for wound care and often an operating room, but wound care in the ICU is very feasible and actually essential in the unstable patient. Hyperbaric oxygen chambers are not a necessary component and are really only indicated in patients with such severe carbon monoxide exposure that the cytochrome system is saturated with carbon monoxide, which is not readily displaced with 100% oxygen alone (see Chap. 102). It is safe to say that 99% of patients with major burns and some degree of carbon monoxide inhalation do not benefit from hyperbaric oxygen. The secret to a successful patient outcome, however, remains in the knowledge base, judgment, and decision-making skills of the personnel, not in the external environment.[1,2]

Cardiopulmonary instability characterizes the resuscitation phase. Life-threatening airway and breathing problems are major concerns at this time, with carbon monoxide poisoning, upper airway edema, and the immediate effect of smoke inhalation injury being the most common. The initial phase is also characterized by hypovolemia because plasma volume is lost into the burn tissue. The burn itself is of less immediate concern, with initial treatment of pulmonary and circulatory abnormalities taking first priority. Any early management error will lead to a dramatic increase in morbidity and mortality during the subsequent injury phases. It is of critical importance to remember that the burn patient is a trauma patient with the potential for many other injuries. The standard approach to trauma resuscitation therefore must be followed, including assessment for cervical spine and head injuries, pulmonary and abdominal trauma, fractures, and so on.[2a] Management of these problems is the same as in the nonburn patient.

Airway and Pulmonary Abnormalities

Abnormalities of ventilation and oxygenation are common in the immediate postburn period.[2b] Several fairly distinct critical disease processes must be recognized and managed aggressively.[3] The first three are associated with the inhalation injury complex and are presented below in the approximate order in which symptoms will develop (carbon monoxide toxicity, upper airway obstruction, and chemical burn to the lung). These sections are followed by discussions of lung changes due to the skin burn and, finally, of the effects of impaired chest wall compliance.

SMOKE INHALATION INJURY COMPLEX

Pulmonary insufficiency caused by the inhalation of heat and smoke is the major cause of mortality among fire victims, accounting for over 50% of fire-related deaths.[4,5] The exposure time, concentration of fumes, elements released, and degree of accompanying body burn are critical variables in determining outcome.

CARBON MONOXIDE AND CYANIDE TOXICITY

Carbon monoxide, a by-product of incomplete combustion, is one of the leading causes of death in fires. Hydrogen cyanide is also a well-recognized cause of morbidity and mortality, especially with burning of synthetics such as polyurethane.

Symptoms of carbon monoxide toxicity usually are not present until the carboxyhemoglobin concentration exceeds 15%. Symptoms are those of decreased tissue oxygenation, with the initial manifestations being neurologic. Cyanide toxicity presents in a very similar fashion, with severe metabolic acidosis and obtundation. Diagnosis, however, is more difficult because measurement of cyanide levels is not always readily available or very reliable. Normal levels are less than

Copyright © 2005, 1998, 1992 by The McGraw-Hill Companies, Inc. Click here for terms of use.

0.1 mg/L (even in smokers). A level near 1 mg/L is lethal. Neurologic dysfunction also can be caused by factors other than carbon monoxide toxicity, such as alcohol or drug intoxication or blunt head trauma. A toxicology screen therefore is warranted. The indications for obtaining a computed tomographic (CT) scan of the head are the same as for other trauma patients.

The persistence of a metabolic acidosis in a patient with adequate volume resuscitation and cardiac output suggests that oxygen transport and use are being impaired by carbon monoxide or cyanide. Pa_{O_2} can remain relatively normal because the chemical alteration of hemoglobin by carbon monoxide will not affect the amount of oxygen dissolved in arterial plasma. A high carboxyhemoglobin level also indicates a significant smoke exposure and, therefore, a chemical burn to the airways. Treatment of carbon monoxide toxicity is covered more fully elsewhere in this text; briefly, it consists of the early displacement of carbon monoxide from hemoglobin by administration of 90% to 100% oxygen (see Chap. 102). Treatment of cyanide toxicity involves restoration of hepatic blood flow to clear the cyanide. In addition, sodium nitrite is given, followed by sodium thiosulfate. Hyperbaric oxygen is best used in patients who show severe neurologic compromise with a high carboxyhemoglobin level (>50%) but no major burns and who are not responding to high-flow oxygen. The vast majority of patients can be managed successfully using simply 90% to 100% oxygen.

UPPER AIRWAY OBSTRUCTION FROM AIRWAY EDEMA

Heat produces an immediate injury to the airway mucosa, resulting in edema, erythema, and ulceration. Although these mucosal changes may be present anatomically shortly after the burn, physiologic alterations will not be present until the edema is sufficient to produce clinical evidence of impaired upper airway patency. This may not occur for 12 to 18 hours. The presence of a body burn magnifies the effects of airway injury in direct proportion to the size and depth of the skin burn. The massive amount of fluid administered is in part responsible. A face or neck burn will accentuate these problems by producing marked anatomic distortion and, in the case of a deep neck burn, external compression of the larynx. The airway edema and the external burn edema have a parallel time course so that by the time symptoms of airway edema develop, external and internal anatomic distortion is extensive. The local edema usually resolves in 4 to 5 days.

Inspection of the oropharynx for soot or evidence of a heat injury should be routine in every burn victim. Numerous techniques have been used in further assessing the degree of injury and in determining the need for endotracheal intubation. Fiberoptic bronchoscopy or laryngoscopy will show whether physical evidence of pharyngeal or laryngeal mucosal injury is present. Laryngoscopy will demonstrate the presence of mucosal irritation at and above the cords and provide information about the need for endotracheal intubation.[4,5] Unfortunately, unless serial studies are performed, none of these tests can predict the severity of subsequent airway compromise accurately because the edema progresses during the first 18 to 24 hours. Repeated examinations for airway compromise are feasible in patients without facial burns. However, in the presence of a large burn, it is best to proceed with intubation if there is any concern.

An early decision regarding the need for airway intubation is crucial. When there is doubt, it is safer to intubate. A patient with a significant inhalation injury and deep facial burns usually should be managed by early endotracheal intubation. There are many other indications for intubation in burn patients besides airway edema, such as hemodynamic instability and impaired consciousness. A large orotracheal tube (at least 7 mm in internal diameter) should be used in adults because very thick secretions develop. If the initial tube is too small, it will be dangerous to change once massive facial

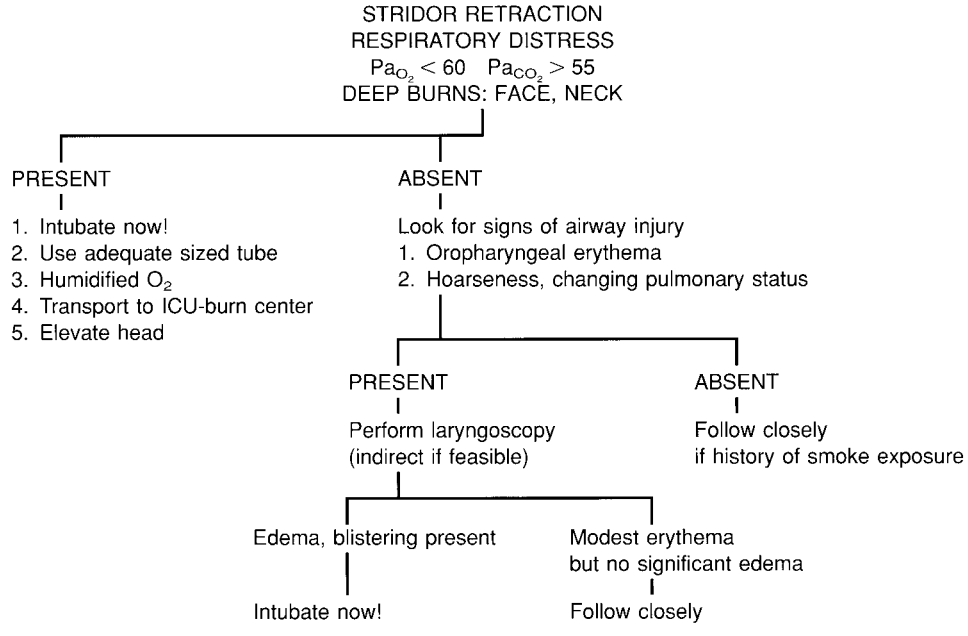

FIGURE 98-1 Initial assessment of airway (for the decision of whether or not to intubate).

TABLE 98-1 Toxic Elements in Housefire Smoke

Gas	Source	Effects
Carbon monoxide	Any organic matter	Tissue hypoxia
Nitrogen dioxide	Wallpaper, wood	Bronchial irritation, dizziness, pulmonary edema
Hydrogen chloride (from phosgene)	Plastics (polyvinyl chloride)	Severe mucosal irritation
Hydrogen cyanide	Wool, silk, nylons (polyurethane)	Headache, respiratory failure, coma
Benzene	Petroleum plastics	Mucosal irritation, coma
Aldehydes	Wood, cotton, paper	Severe mucosal damage, extensive lung damage
Ammonia	Nylon	Mucosal irritation

and airway edema develops. An algorithm for this approach is presented in Fig. 98-1.

CHEMICAL BURNS OF THE UPPER AND LOWER AIRWAYS

Toxic gases contained in smoke, as well as carbon particles coated with irritating aldehydes and organic acids, can injure both upper and lower airways (Table 98-1). The location of injury will depend on the duration of exposure, the size of the particles, and the solubility of the gases.

Breath holding and laryngospasm are protective mechanisms against excessive exposure in the conscious patient. The unconscious patient, however, loses this protection and sustains more severe injury to the lower airways. Information regarding loss of consciousness at the scene should be sought in the history.

Symptoms may well be absent on admission, with the true magnitude of injury becoming evident only after 24 to 48 hours. Early symptoms usually consist of wheezing and bronchorrhea. This intense initial bronchorrhea caused by irritation of the airway mucosa in combination with increased oral and nasal secretions can give the false appearance of fulminant pulmonary edema. Soot in the lung secretions is certain evidence of smoke exposure but is not always present.

Early bronchospasm and bronchiolar edema initiated by the irritant gases cause a marked decrease in dynamic lung compliance with increased work of breathing. Impaired clearance of secretions will accentuate this problem.

Impairment of gas exchange is due to ventilation/perfusion ($\dot{V}/\dot{Q}$) mismatching related to airway injury rather than to alveolar edema.[6–8] A body burn markedly potentiates the inhalation-induced lung dysfunction caused by chemical injury. The combination of a major burn and smoke inhalation is more lethal than either injury alone.

Initial treatment of this component consists of an aggressive approach to upper airway maintenance and pulmonary support that includes maintenance of small-airways patency and removal of soot and mucopurulent secretions. Careful, well-monitored fluid resuscitation is necessary to avoid accentuation of the process. The addition of positive end-expiratory pressure (PEEP) frequently is necessary to maintain small-airways patency and an adequate functional residual capacity (FRC), assisting in holding the edematous airway open until edema resolves. Endotracheal intubation and PEEP have been reported to decrease the rate of early pulmonary death after severe burns and smoke inhalation.[9]

Beginning about 18 to 24 hours after a burn, increasing airway resistance is often due to bronchiolar edema and airway plugging rather than to bronchospasm. The associated impairment of gas exchange often responds to further increases in PEEP in addition to bronchodilator administration. The injured airway mucosa frequently becomes colonized with bacteria. Prophylactic antibiotic administration only selects for resistant organisms and therefore is not indicated. Corticosteroids increase morbidity and mortality in the presence of a body burn and are, therefore, contraindicated.[10]

IMPAIRED CHEST WALL COMPLIANCE

Respiratory excursion can be impaired markedly by a burn to the chest wall, especially a circumferential third-degree burn.[11,12] The loss of chest wall compliance increases the work of breathing. Symptoms may not be evident until edema formation peaks. The first clinical evidence of chest wall restriction is often labored breathing, followed by rapid respiratory deterioration, particularly in the patient who is not receiving ventilatory support. Clearance of secretions can be impaired owing to the inability to generate enough hyperinflation to cough well.

Treatment involves surgical decompression or escharotomy of the chest wall. Longitudinal incisions placed in the midaxillary lines should be connected across the lower chest wall. Bleeding usually is controlled easily if the incisions stay within the margins of the third-degree burn because the dermal vessels are thrombosed. The incision must extend into the subeschar area to allow adequate chest wall expansion. Escharotomies usually are not required in a second-degree burn unless the edema is so massive that the burned skin is tight. (This approach is diagrammed in Fig. 98-2.)

Restoration and Maintenance of Hemodynamic Stability

Massive fluid shifts occur during the resuscitation phase of burn injuries and can lead to severe impairment in oxygen

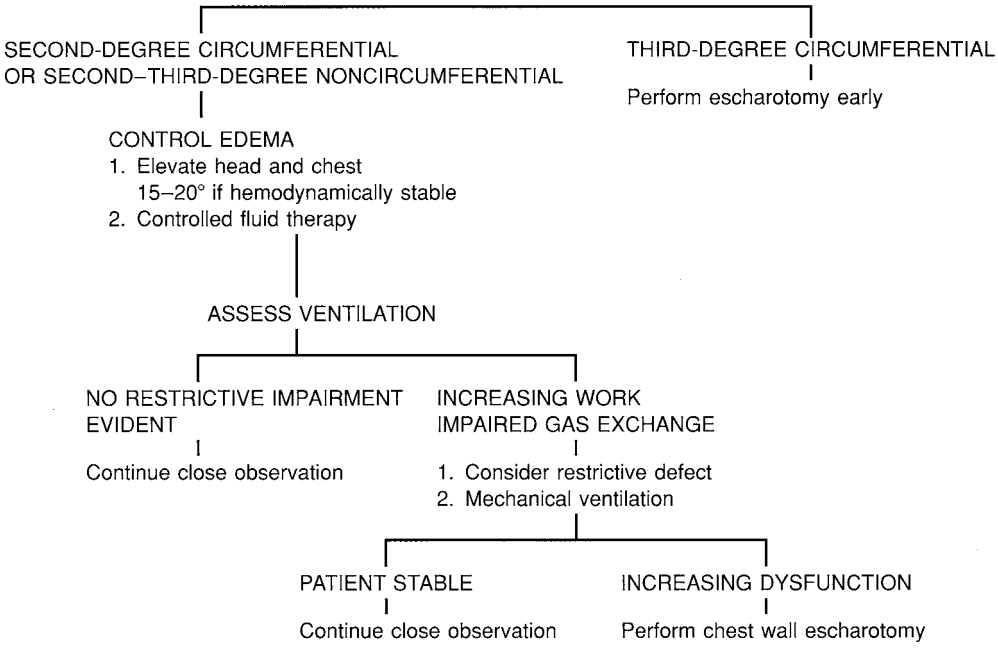

FIGURE 98-2 Treatment of chest wall burn.

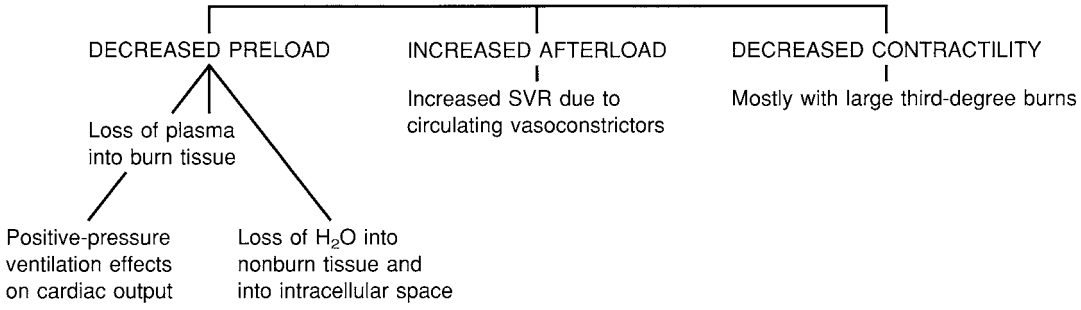
delivery to tissues. An understanding of these early fluid shifts is necessary to avoid hemodynamic instability and to initiate appropriate treatment.

PATHOPHYSIOLOGY OF BURN SHOCK

With a major burn, intravascular volume is lost into burned tissue as well as nonburned tissue. Increased vascular permeability, the increased osmotic forces in burned tissue, and cellular swelling contribute.[14] The most pronounced shift occurs in the first several hours as a result of the increased protein permeability and the apparent increase in burn tissue osmotic pressure.[15] The fluid and protein shifts are the greatest in the first several hours because of the combined effect of increased permeability and an imbalance of osmotic forces. Subsequently, the quantity of edema depends on the adequacy of the fluid resuscitation. Severe hypoproteinemia also occurs as a result of the loss of protein into the wound. The major protein losses occur in the first 6 to 8 hours, during the period of peak fluid loss. Plasma proteins can decrease to less than 50% of normal. Resolution of edema depends on restoration of lymphatic patency, which may take a number of days to weeks. Edema in deeper burns resolves more slowly than in superficial burns.

Generalized tissue edema in nonburned tissues is evident in patients with burns covering more than 30% of the total body surface area (TBS). The edema appears to be due, at least in part, to the low protein content.[16]



Cardiac output is depressed initially, primarily as a result of hypovolemia. Afterload is also increased owing to a marked increase in systemic vascular resistance (SVR) elicited by vasoactive mediators such as catecholamines. A decrease in cardiac contractility[17] is most evident in third-degree burns covering more than 40% of the TBS and is probably due to myocardial edema rather than to a circulating factor. All these contributors to impaired perfusion are summarized in Fig. 98-3.

MANAGEMENT OF THE CIRCULATION

INTRAVENOUS ACCESS

A peripheral vein catheter through nonburned tissue is the preferred route for fluid administration. A central line or

FIGURE 98-3 Causes of decreased oxygen delivery to tissues after a burn injury.

pulmonary artery line, preferably through nonburned tissue, is needed only occasionally to monitor the patient during the initial resuscitation period and is removed as soon as it is no longer needed.

Monitoring lines are required primarily for elderly patients or patients with severe heart disease. Because of the high infection rate, an intravenous catheter should not be placed through burn tissue unless no other possible route exists. Some centers rotate central line sites regularly (e.g., every 3 days) to minimize the risk of catheter sepsis, but any benefits may be offset by the risks of repeated procedures.

WHAT TO MONITOR

No one parameter of perfusion in a burn patient is a completely reliable indicator of tissue oxygenation (perfusion). The increased sympathetic tone characteristic of this early period makes arterial pressure an insensitive measure of volume status. However, a minimum perfusion pressure—e.g., a mean arterial pressure of more than 85 mm Hg—must be maintained.

Tachycardia is inevitable owing to hypovolemia and catecholamine release. In most patients, a pulse rate of less than 120 beats per minute usually indicates adequate volume, whereas a pulse rate of more than 130 beats per minute usually indicates that more fluid is needed.

Renal blood flow is another reflection of the adequacy of systemic perfusion during this early phase of injury. A urine output of 0.5 to 1 mL/kg per hour normally reflects adequate renal blood flow, assuming that there are no factors such as hyperglycemia, mannitol, or alcohol to alter the relationship between renal perfusion and urine output. A value greater than 1.0 mL/kg per hour usually means that too much fluid is being given and that excess edema therefore is being produced.

The measurement of base deficit is extremely useful for the assessment of tissue oxygenation. A base deficit during this phase usually reflects impaired tissue oxygenation due to hypovolemia or carbon monoxide (or cyanide) toxicity, and a progressive decrease in base deficit is a very sensitive indicator of the adequacy of restoration of perfusion.

Burn patients are very prone to hypothermia during this early period, especially with infusion of cool fluids. A decrease in temperature will lead to further hemodynamic instability and impaired perfusion. The external environment must be altered to allow for maintenance of a normal temperature (37 to 37.5° C) for this period.

The filling pressures in a large burn at this stage are usually low even with adequate fluid resuscitation because the rate of fluid loss increases markedly with small rises in capillary pressure. Use of an arbitrary filling pressure as an end point of resuscitation should be avoided.

Only older patients with massive burns or smoke inhalation are typically monitored with a central catheter. Hypoperfusion is almost always due to hypovolemia. Measurement of the mixed venous oxygen tension, however, can assist greatly in this determination.

CHOICE OF RESUSCITATION FLUID

In general, fluids that contain at least as much salt as is present in plasma are appropriate in resuscitation.[16a] Restoration of sodium lost into the burn is essential. Fluids should be free of glucose (except in the treatment of small children) because glucose intolerance characteristically is present. Blood volume can be restored more effectively as the leakage decreases at about 24 to 36 hours. Volume infusion above the amount necessary for adequate perfusion can accentuate edema-related complications markedly.

Crystalloid

Crystalloid, in particular lactated Ringer's solution, is the most popular resuscitation fluid in the United States. The amount of isotonic crystalloid required in the first 24 hours is adjusted on the basis of the parameters used to monitor the adequacy of resuscitation (see below). If a hypertonic solution is used, the serum sodium level should not be allowed to exceed 160 mEq/L.[15]

Colloid

Since nonburned tissue appears to regain normal permeability very shortly after injury, and since hypoproteinemia may accentuate the edema in nonburned tissue, protein restoration beginning at about 8 to 12 hours with 6% albumin seems appropriate if edema in noninjured tissue and total fluid requirements are to be minimized. The use of fresh frozen plasma should be reserved for correction of documented clotting abnormalities.

Hetastarch, a 6% starch solution, has colloid properties similar to those of a 6% protein solution and generates an oncotic pressure comparable with that of protein. The molecules are much larger than those of most dextrans, and vascular clearance therefore is much slower. As with dextran, volumes exceeding several liters can lead to clotting abnormalities and to the potential for immune dysfunction from reticuloendothelial blockade.

Blood

Because there is no early red blood cell deficit with a burn alone (unless severe hemolysis occurs), blood replacement usually is not needed.

RATE OF INFUSION

An initial rate can be estimated using the size of the burn (combined second and third degree) relative to the TBS and body weight:

$$\text{24-h volume in mL (of which half is given in the first 8 h)} = 4\ \text{mL} \times \%\ \text{TBS burned} \times \text{body weight in kg}$$

However, the volume of fluid required is that necessary to maintain perfusion. Any formula is only an initial guide. Approximately half the fluid requirements for the first 24 hours need to be given in the first 8 hours. Beginning at 8 to 10 hours, an attempt should be made to decrease the rate of fluid administration gradually to the lowest level that maintains adequate perfusion.

INDICATION FOR INOTROPIC SUPPORT

Inotropic support to supplement fluids is indicated if adequate perfusion cannot be maintained without excessive fluid administration. In contrast to nonburned patients, it is very difficult to increase preload to values above normal levels in order to increase cardiac output in burned

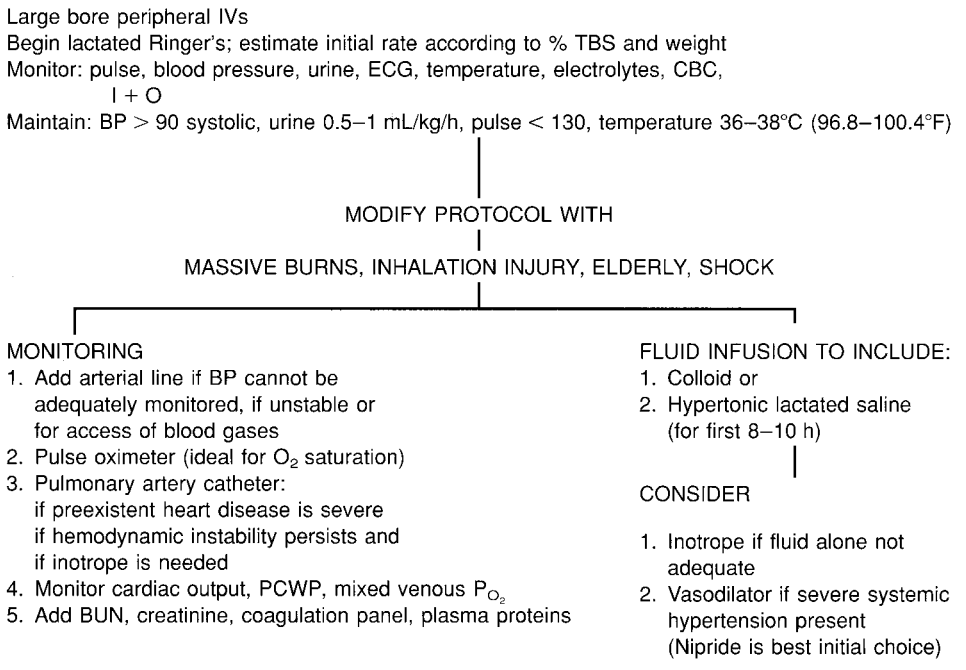


FIGURE 98-4 Treatment summary (0 to 24 hours) for maintaining hemodynamic stability. All patients had burns of more than 20% of the TBS.

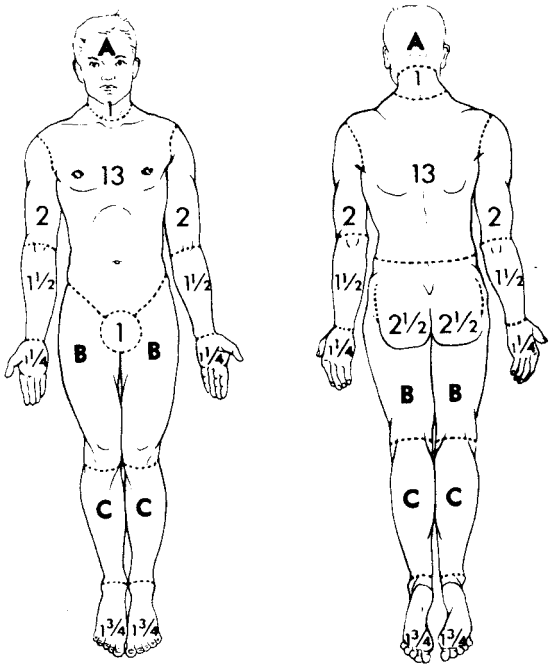
patients. Hemodynamic management is summarized in Fig. 98-4.

Hematologic Changes

A number of hematologic disorders are seen after major burns.[18] Hemolysis occurs commonly after deep third-degree burns or any prolonged exposure to a heat source. In addition, red blood cell fragility is increased markedly. Increased cell wall lipid peroxidation is evident, and fragmented cells are seen often on smears. The injured red blood cells will have a markedly shortened life span, leading to an anemia beginning in the first week. Red blood cell hematopoiesis is also markedly impaired and remains so until the burn is closed, resulting in a persistent anemia. A leukocytosis is also characteristic during this early phase. A marked consumption of platelets, fibrinogen, and plasminogen is seen in the burn wound, as well as a marked depletion of hemostatic components. A hypercoagulable state may be seen in the initial period in moderate burn injuries. A hypocoagulable state, resulting from depletion of clotting factors, is seen frequently with massive burns. Thrombocytopenia also will be evident in the latter group. It most likely results from the tremendous stimulus to clotting created by the large area of injured collagen tissue.

Assessment of the Burn Itself

ANATOMY AND FUNCTION OF THE SKIN



The skin is the largest organ of the body, ranging in area from 0.25 m^2 in newborns to over 2 m^2 in adults. It consists of two layers, epidermis and dermis (or corium). The outermost cells of the epidermis are dead cornified cells that act as a tough protective barrier against the environment. The second, thicker layer, the corium (0.06 to 0.12 mm thick), is composed chiefly of fibrous connective tissue. The dermis contains the blood vessels to the skin and the epithelial appendages of specialized function. The nerve endings that mediate pain are also found in the dermis. Partial-thickness injuries are extremely painful because the nerve endings are exposed. Full-thickness burns usually are anesthetic because the nerves have been destroyed by heat. The skin is also the barrier that prevents loss of body fluids through evaporation and limits the loss of body heat. In addition, the skin is the primary protective barrier against penetration of microorganisms into the subdermal tissues. Loss of this function results in increased risk of invasive infection.

DEPTH OF BURN INJURY

Traditionally, burn depth has been classified in degrees of injury based on the amount of epidermis and dermis injured. At present, depth is estimated by physical appearance, pain, and skin texture or pliability. A *first-degree burn* involves only the thin outer epidermis and is characterized by erythema and mild discomfort, healing rapidly.

Second-degree burns are defined as those in which the entire epidermis and variable portions of the dermis are destroyed. A *superficial second-degree burn* involves heat injury to the upper third of the dermis. The microvessels perfusing this area are injured, and permeability is increased, resulting in the leakage of large amounts of plasma into the interstitium. This fluid lifts off the thin, heat-destroyed epidermis, causing blister formation. Despite loss of the entire basal layer of the epidermis, a burn of this depth will heal in 7 to 14 days.

A *deep dermal* (or *deep second-degree*) *burn* extends well into the dermal layer, and fewer viable epidermal cells remain. Therefore, reepithelialization is extremely slow, sometimes requiring months. The wound surface usually is red, with white areas in deeper parts. Because the remaining blood supply is marginal, there is a high probability that the tissue damage will deepen with time.

Relative Percentages of Areas Affected by Growth

Area	Age		
	10	15	Adult
A = half of head	5½	4½	3½
B = half of one thigh	4¼	4½	4¾
C = half of one leg	3	3¼	3½

FIGURE 98-5 Lund and Browder method of calculating the percentage of the body surface area burned.

A *full-thickness* (or *third-degree*) *burn* occurs with destruction of the entire epidermis and dermis, leaving no residual epidermal cells to repopulate the burned area. The portion of the wound not closed by wound contraction will require skin grafting. The exact depth of many deep burns cannot be defined on first appearance. A zone of ischemia is present between the dead superficial tissue and the deeper living tissue. This marginally viable tissue can be readily converted to nonviable tissue by infection or a further decrease in blood flow.

SEVERITY OF INJURY

The size of the burn is defined as a percentage of the TBS. A useful initial guide is the *rule of nines,* which divides the body into areas that each represent 9% of the TBS. The head and each arm are considered 9% of the total, whereas the chest and abdomen, the back, and each lower extremity are considered to be 18% of the TBS. However, the Lund and Browder chart (Fig. 98-5) is more accurate and should be used for more precise calculation. The surface area of the body involved, the depth and location of injury, the patient's age, and the presence of associated injuries determine morbidity and mortality.[1] Age and the presence of associated injury appear to be the most significant parameters affecting the chance of survival (Table 98-2).

Treatment

The early treatment focuses on neutralizing the source of burn injury, avoiding excess heat loss, determining the extent of injury, cleaning and débriding the wound, controlling infection, and maintaining tissue perfusion.

AVOIDING EXCESS HEAT LOSS

With a deep burn, the barrier to evaporative water loss is markedly impaired. As a consequence, the barrier to heat loss is also impaired, a fact that is extremely important to recognize in the resuscitation period. Heat loss can be decreased by closing the wound under dressings, thereby limiting air movement and decreasing the air-to-wound temperature gradient. Therefore, the burn is only cooled initially to neutralize excessive heat and to control pain in superficial second-degree burns covering less than 15% of the TBS.[21] Patients with major burns must be placed in a warmed external environment to minimize heat loss. Wound débridement and washing should not be initiated on a large burn until the external temperature is controlled.[19]

TABLE 98-2 Data Obtained from Specialized Burn Facilities: Mean Survival Rate (%) According to Age and Burn Size

% TBS Burned[a]	AGE (YEARS)						
	0–1	2–4	5–34	35–49	50–59	60–74	>75
0–10	>95	>95	>95	>95	>95	95	90
10–20	95	>90	>95	>90	>85	80	50
20–30	90	90	95	90	75	50	25

[a] Combined second-degree and third-degree burns.

TABLE 98-3 Standard Burn Categorization

Critical burns
1. Second-degree burns involving >30% TBS
2. Third-degree burns involving >10% TBS
3. Burns complicated by respiratory tract injury or fractures or involving critical areas such as the face, hands, feet, or perineum
4. High-voltage electrical burns
5. Lesser burns in patients with significant preexisting disease

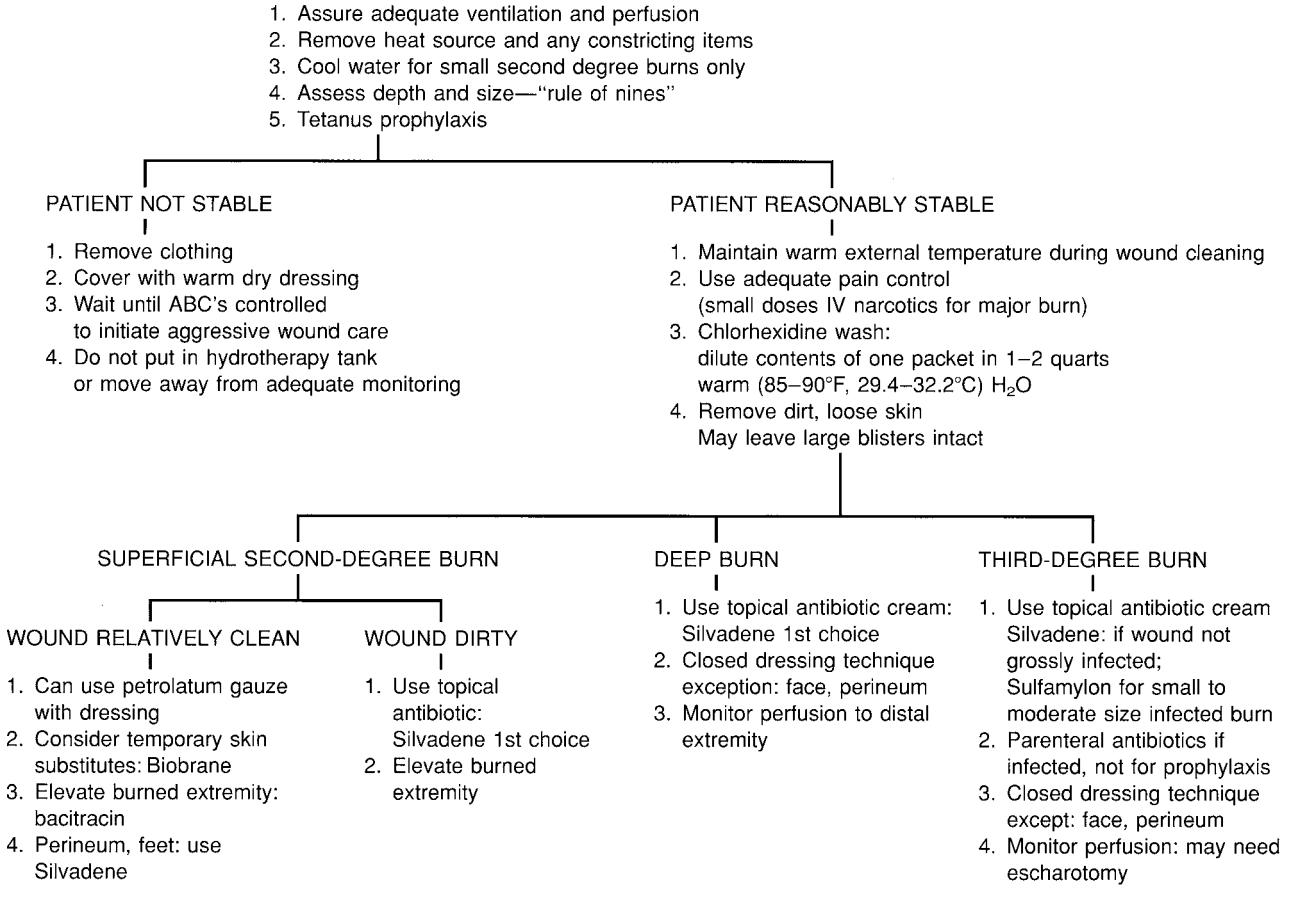
Moderate burns
1. Second-degree burns involving 15%–30% TBS (but not involving the face, hands, feet, or perineum)
2. Third-degree burns involving 2%–10% TBS (but not involving the face, hands, feet, or perineum)

Minor burns
1. Second-degree burn involving <15% TBS
2. Third-degree burns involving <2% TBS

DETERMINING THE EXTENT OF INJURY

The wound can be categorized on the basis of size, depth, age, and other complicating factors. Table 98-3 presents the standard categorization used by the American Burn Association.

CONTROLLING INFECTION



The management of the burn wound itself depends on the status of initial cardiopulmonary function. Adequate control of the airway, maintenance of adequate gas exchange, and restoration of fluid loss must precede attempts at wound cleaning and débridement. Initial débridement consists of the elimination only of superficial, easily removed dead tissue; once this is accomplished, control of potential infection in the injured tissue is the next priority. Tetanus prophylaxis is necessary. Numerous studies have demonstrated that prophylactic systemic antibiotics in patients with either minor or major burns are of no benefit in decreasing the rate of wound infection.[22]

The recommendation for the use of topical antibiotics is based on the fact that nonviable tissue is present and will act as a nidus for infection and on the lack of effectiveness of systemic antibiotics.

IMPAIRED DISTAL PERFUSION AND NEED FOR ESCHAROTOMY

As subeschar edema develops under the burn tissue, pressure increases. This development is of particular concern in extremities with a circumferential burn, where the increasing pressure cannot be dissipated by expansion of neighboring tissue. The pressure impedes blood flow. Perfusion to the distal extremity must be monitored closely. Pain and color are unreliable indicators of perfusion in the presence of a burn. The use of a Doppler flowmeter is the most practical means of assessing perfusion. Decreasing distal flow with a proximal deep burn is also an indication for escharotomy. Wound management is summarized in Fig. 98-6.

FIGURE 98-6 Treatment summary (0 to 24 hours). Wound management.

Chapter 99

BURNS: POSTRESUSCITATION PHASE (DAYS 2 TO 6)

ROBERT DEMLING
LESLIE DESANTI

KEY POINTS

- *Pulmonary problems must be controlled during this period to allow for an aggressive surgical excisional approach.*
- *Fluid management changes dramatically to a strategy of replacing evaporative water losses.*
- *Postburn anemia will develop and necessitate increased blood transfusions.*
- *Monitoring must be primarily noninvasive to avoid line sepsis.*
- *Nutritional support should begin at this point, using enteral alimentation.*
- *Controlled surgical excisions should begin as soon as the patient is hemodynamically stable, to avoid having extensive burns still in place when the infection-inflammation phase begins.*

The early postresuscitation phase is a period of transition from the ebb, or shock, phase to the flow, or hypermetabolic, phase. Major cardiopulmonary and wound changes occur that alter patient care substantially from that given during resuscitation. In general, cardiopulmonary stability is optimal during this period because wound inflammation and infection have not yet developed. Early wound excision and grafting are initiated during this period because operative risks, especially blood loss and septicemia, are substantially less than after inflammation and infection develop.

Pulmonary Abnormalities

Five major abnormalities impair pulmonary function during this period: (1) continued upper airway obstruction, (2) decreased chest wall compliance, (3) tracheobronchitis, (4) pulmonary edema, and (5) lung dysfunction induced by surgery (and anesthesia). Upper airway and facial edema caused by the heat-induced tissue and mucosal damage begins to resolve between days 2 and 4. The decision to extubate (Fig. 99-1) is a difficult one because there is no good test for determining the adequacy of airway patency.[1,2] Laryngoscopy to determine the presence of cord edema is helpful, as is deflation of the cuff to determine if air moves around the tube. The impaired compliance of the chest wall caused by deep burns is improved, but certainly not eliminated, by escharotomy. Early excision of the full-thickness wound can improve chest wall motion by removing both edema and noncompliant tissue.

The chemical burn to the airways results in a spectrum of clinical manifestations during this period. At the very least, mucosal irritation will persist for several days and cause bronchorrhea, cough, and increased mucus production. The damaged ciliary function of the airways leads to a high risk for infection, manifested first (in the next 3 to 4 days) by a bacterial tracheobronchitis that is often followed by bronchopneumonia. Bacterial colonization is inevitable. If infection can be controlled and secretions cleared, the acute process will resolve over the next 7 to 10 days. However, the risk of infection persists for several weeks, extending well into the inflammation period. The treatment of lung dysfunction during this phase is summarized in Fig. 99-2. The clearance of soot, mucopurulent exudate, and sloughing mucosa is essential to avoid progression of the lung injury.

Infection surveillance is crucial during this early period in order to detect bacterial bronchitis before pneumonia develops. Unlike typical bronchopneumonia, presenting with a localized infiltrate, the entire tracheobroncheal tree becomes colonized with pathogens, and the resulting infection is often a diffuse bronchopneumonia. Sputum smears and monitoring of the character of the sputum are useful as early guides. Systemic antibiotics are not given prophylactically but are initiated when a bacterial tracheobronchitis becomes evident. This approach is summarized in Fig. 99-3.

Repeated excision and grafting procedures, especially on large body burns, usually result in a situation in which the patient either is recovering from an inhalational anesthetic or is awaiting surgery. Most general anesthetics cause deterioration in an already marginal respiratory status and put the patient at further increased risk for pneumonia and respiratory failure during the subsequent phase of injury. Muscle relaxants compound this problem.

Maintaining Hemodynamic Stability

PATHOPHYSIOLOGIC CHANGES

FLUID LOSSES

Evaporation from the surface of the burn becomes a major source of water loss that persists until the wound is closed. This loss is related to the water vapor pressure at the surface.[4] A reasonable estimate of loss can be obtained from the following formula, where TBS is the total body surface area:

$$\text{Evaporative water loss in mL/h} = (25 + \%\ \text{of TBS burned}) \times (\text{TBS in m}^2)$$

Red blood cell mass can decrease markedly during this period because of breakdown and decreased production of red blood cells.[5,6] Lipid peroxidation of the red blood cell membrane after burn injury is well described. The hematocrit characteristically falls to between 30% and 35% or lower several days after the burn injury. Besides increased red blood cell breakdown, there is decreased red blood cell production by the bone marrow—an effect characteristic of any chronic injury state. Red blood cell production does not return to normal until after the wound is closed.

FLUID GAINS

Intravascular fluid is gained during the postresuscitation period as a result of absorption of edema. Edema resorption is much more rapid in the case of superficial burns where lymphatics are intact and begins at about day 2 or 3. Edema

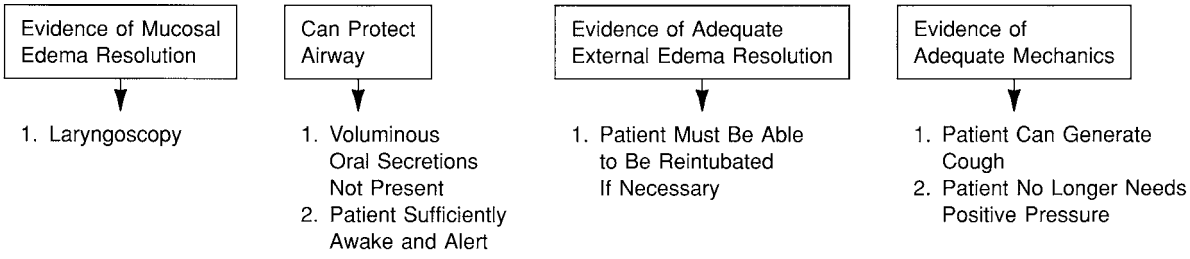

FIGURE 99-1 Criteria for deciding when to extubate a patient. All these criteria should be met to ensure safe extubation.

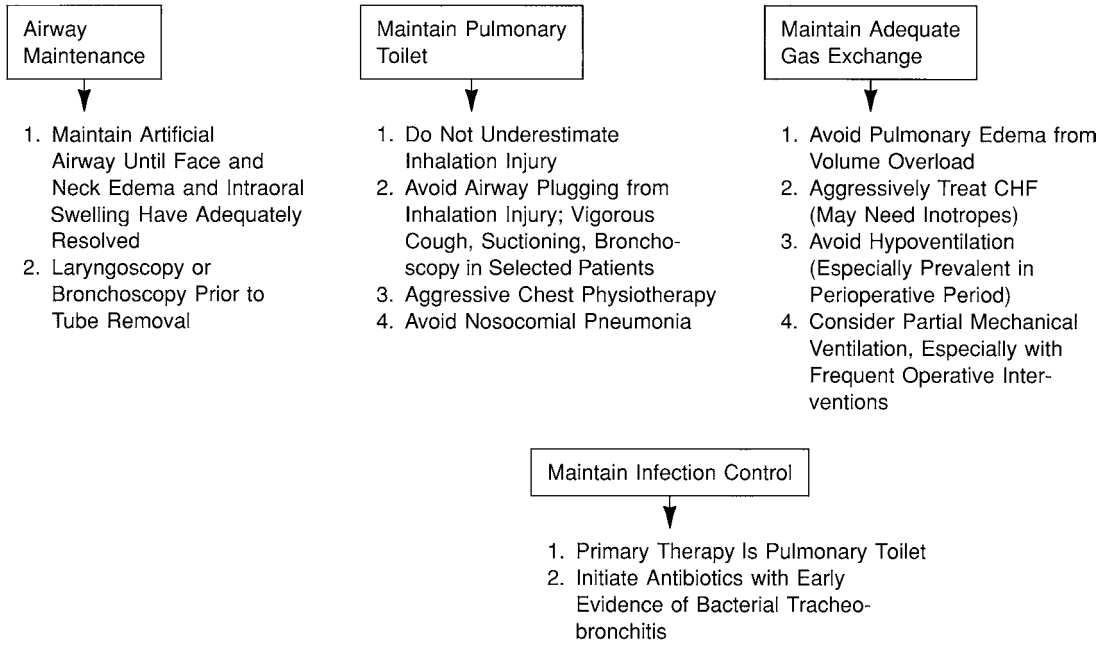
resorption is much slower after full-thickness injury because of the lack of local lymphatics and venules. However, the magnitude of tissue edema is not a valid reflection of the circulating volume and never should be used to judge the correct rate of fluid replacement.

SYSTEMIC METABOLIC CHANGES AND CIRCULATORY RESPONSES



The ebb, or hypometabolic, phase characteristic of the initial burn shock period begins to change into the flow, or hypermetabolic, phase over the next 3 to 5 days.[7,8] Tachycardia, ranging from modest to significant (100 to 120 beats per minute), is seen frequently and results partly from persistent elevation of catecholamine levels. Systemic vascular resistance begins to decrease. The vasodilatation results in an increase in the capacity of the vascular space and, therefore, an increased need for colloid and red blood cells.

Oxygen consumption usually peaks 5 to 7 days after the burn.[7] The transition to the flow state also initiates an increase in body temperature, which increases further with the release of pyrogens from the burn wound. The characteristic increase in body temperature by 1 to 2°F makes it more difficult to diagnose infection. Patients with subclinical glucose intolerance (typically obese or elderly patients) may develop hyperglycemia, especially with a large burn. Increased catabolism leads to increased urea production, especially if inadequate glucose calories are being provided. The rate of body protein loss is massive as a result of the increased levels of catecholamines and cortisol, as well as inflammatory cytokines, which markedly stimulate gluconeogenesis using protein as a substrate.[9,10] Decreased levels of human growth hormone and testosterone amplify the catabolism.[11] A total of 20% to 30% of calories come from proteins, as opposed to the protein sparing, which occurs in starvation, where fat is the main fuel. Loss of the amino acid glutamine is particularly pronounced because it is used heavily as a fuel source by the gut as well as a precursor for the antioxidant glutathione.[12] Muscle losses of a kilogram a day are common with large burns. Over a 10-day period, 10% to 15% of body protein stores can be lost, resulting not only in muscular weakness, including weakness of the intercostal muscle and diaphragm, but also in decreased wound healing and immune function. Because of the large increase in oxidant release due to inflammation, the levels of endogenous antioxidants fall rapidly, increasing the risk of further oxidant injury and generalized organ dysfunction.[13]

HEMODYNAMIC MANAGEMENT

Understanding the physiologic and metabolic changes during this period is the key to successful management. The major decisions relate to fluid therapy and the ongoing assessment of the adequacy of perfusion.

FIGURE 99-2 Summary of treatment of pulmonary abnormalities from 36 hours to 6 days after the burn injury.

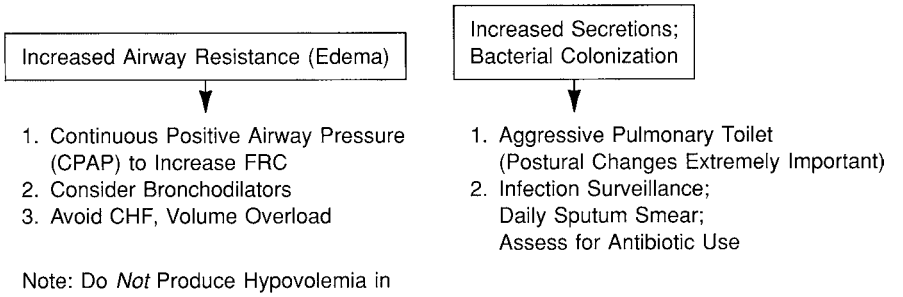


FIGURE 99-3 Treatment of tracheobronchial injuries.

SELECTION OF FLUID

A common error is continued infusion of isotonic crystalloid during a period when major losses of sodium do not occur. A 5% glucose-containing solution with a low sodium content and an increased potassium content is the primary replacement fluid for evaporative and urinary losses during this period. Initiation of nutrition is also essential, preferably by the enteral route. To restore blood volume and maintain the protein binding required for predictable pharmacokinetics, protein losses should be replaced. A serum albumin level of 2.5 g/dL is a reasonable goal. It is also frequently necessary to replace red blood cells. The hematocrit should be kept at least at a level of 30% to optimize delivery of oxygen to tissues. Hemodynamic management is summarized in Fig. 99-4.

WHAT TO MONITOR

Assessment of the adequacy of perfusion, tissue oxygenation, and fluid and electrolyte balance can be difficult during this period of evolving hemodynamics. Oxygen consumption increases gradually with the transition from the ebb state to the flow state. The absolute value of body weight cannot be used to reflect blood volume during this transition. However, if weight is increasing, excess fluid (and salt) is probably being given. One should anticipate a gradual increase of 1 to 2°F in body temperature over normal; this increase is due to hypermetabolism. Further increases are common with wound manipulation.

Care of the Burn Wound

The wound undergoes dramatic changes during this period as inflammation develops. In addition, wound colonization and the potential for wound infection increase. This process of deepening of the burn (called *wound conversion*) is seen most commonly in deep second-degree burns and can occur even with optimal management. Processes such as wound

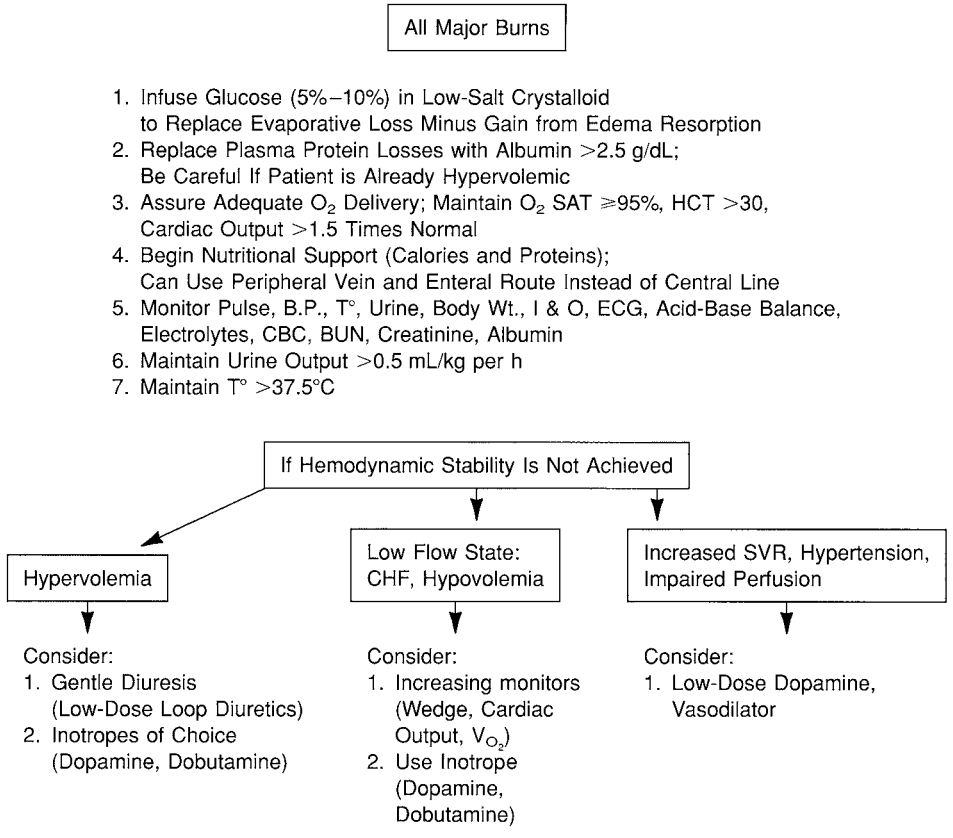

FIGURE 99-4 Maintenance of hemodynamic stability from 36 hours to 6 days after the burn injury.

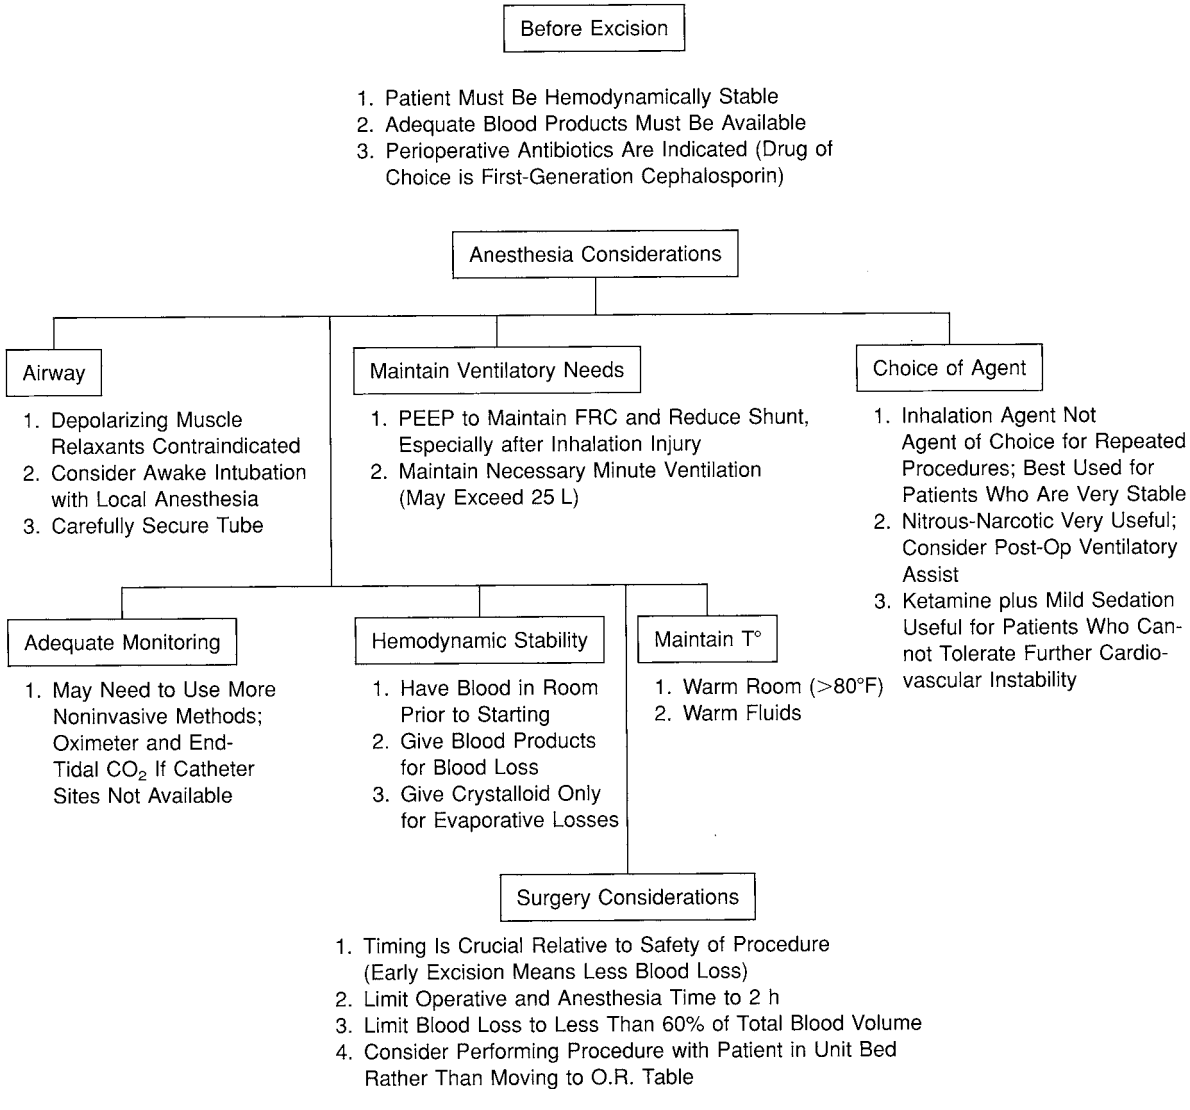
desiccation, hypovolemia, increased tissue pressure, and hypothermia all can accentuate the potential for conversion. The most common cause, however, is local infection.

PATHOPHYSIOLOGIC CHANGES IN THE BURN WOUND

Intense inflammation is seen at about 7 to 10 days in deep burns. The rate of onset of inflammation depends on the blood flow to the wound, with inflammation occurring more rapidly in more superficial burns. A marked increase in wound vascularity is also seen. As wound blood flow increases, so do water loss and heat loss. Heat and water losses are further accentuated by the increase in core temperature that develops with the onset of hypermetabolism.[14]

MANAGEMENT OF BURN WOUND INFECTION



PATHOGENESIS OF BURN WOUND INFECTION

With loss of the outer skin barrier, bacteria can populate the burn wound.[15] Most of these early colonizing bacteria are endogenous, originating from the heat-injured skin (especially hair follicles, glands, and so on), the nares and oropharynx, and the perineal and stool microflora. In addition, systemic host defenses are significantly impaired after a major burn[17] (Table 99-1). Movement of organisms via hand contact,

TABLE 99-1 Effects of a Major Burn on the Immune System

Effects of impaired cell-mediated immunity:
Altered skin test reactivity (anergy)
Increased allograft survival
Decreased T cell response to mitogen
Decreased T cell numbers and response to antigen
Increase in suppressor relative to helper T cells
Effects of impaired neutrophil function:
Decreased chemotaxis
Decreased phagocytosis
Decreased bacterial killing
Effects of alterations in humoral defenses:
Decreased immunoglobulins
Decreased fibronectin
Decreased primary antibody response

FIGURE 99-5 General principles of burn excision.

by patient and by personnel, from area to area on the patient—or between patients—is the major factor leading to bacterial contamination of the wound.

USE OF TOPICAL ANTIBIOTICS

The mainstay of infection control is the use of topically applied antibiotics. Silver sulfadiazine is the most common and least toxic. Mafenide is more potent and is reserved for the treatment of deep infections because of its toxicity (carbonic anhydrase inhibitor).[14,15]

DIAGNOSIS OF WOUND INFECTION

In order to assess the wound for infection, a definition of infection must be well understood. Burn wounds are never sterile, even in the presence of topical agents or systemic antibiotics. The presence of bacteria on the wound surface or in the nonviable tissue is called *colonization. Infection* of the wound (or *local wound sepsis*), in contrast, indicates invasion of the underlying viable tissue. As infection progresses, the viable tissue and its blood vessels are invaded, and sepsis develops.[14]

The clinical diagnosis of wound infection is difficult. Fever, leukocytosis, tachycardia, and intermittent temperature spikes are seen characteristically in the burn patient with or without infection. Wound purulence is a reliable indicator of infection only if the purulence is in the subeschar space.[11]

The organism most often involved in wound infection, particularly in the first week, is *Staphylococcus aureus*.[14,15] Infection with gram-negative organisms is more evident after the first week. *Pseudomonas aeruginosa* is present on the wounds of approximately 25% of burn patients. Enterococci and *Candida albicans* are now seen with increasing frequency, each being found in the wounds of about 50% of burn patients.

A reliable method of diagnosing a burn wound infection is bacterial analysis of a full-thickness wound biopsy.[14,16] It has been established that 10^5 organisms per gram of tissue is the bacterial load that is preinvasive and indicates infection and the need for systemic antibiotics.

EARLY WOUND EXCISION AND GRAFTING

Early excision and grafting should be considered for all burns that will not heal by primary intention within 3 weeks. Full-thickness burns require grafting unless they are smaller than 3 to 4 cm in diameter. The more rapidly the wound is closed, the better. At least in theory, burns covering less than 30% of the TBS can be closed rapidly because adequate donor sites are available. Larger burns are more difficult, if not impossible, to graft early. Deep partial-thickness burns are also difficult to assess clearly as regards time to healing. Considerable judgment and assessment skills, therefore, are essential (Fig. 99-5).

PAIN AND STRESS CONTROL

Management of pain and anxiety is of extreme importance and should begin soon after the burn injury to avoid accentuation of the stress response to injury, with further catabolism. Since pain and stress are present at all times and are amplified by wound management, a continuous background use of narcotics—often patient-regulated or continuously infused kind—is used. Low doses of benzodiazepines are also used. Burn patients are very prone to the extrapyramidal side effects of phenothiazines.[15,19,20] In many cases, the dosages of all drugs must be increased because of rapid drug clearance when the patient is in the hypermetabolic state.[23]

Chapter 100

BURNS: INFLAMMATION-INFECTION PHASE (DAY 7 TO WOUND CLOSURE)

ROBERT DEMLING
LESLIE DESANTI

KEY POINTS

- *This period is characterized by hypermetabolism and sepsis syndrome owing to wound inflammation.*
- *Adequate nutritional support is critical to attenuate the rate of catabolism.*
- *Enteral nutrition should begin by 3 days, and 80% of nutritional needs should be met by 7 days.*
- *Inappropriate use of systemic antibiotics is common during this period because infection is overdiagnosed.*
- *During this period, wound manipulation and operative procedures must be limited because of wound colonization and hypervascularity.*
- *Pulmonary complications are the most common cause of mortality during this period; general anesthesia and transport are high-risk periods.*
- *Anemia is characteristic of this period because of decreased red blood cell production and continued red blood cell losses.*
- *A close working relationship with the patient is the key to control stress.*
- *Pain and stress management are major problems often necessitating extensive use of narcotics, sedatives, and antipsychotic drugs.*

The interval from day 7 after a burn to wound closure is the most complicated phase of management of a large burn. The systemic effects of burn wound inflammation alter the function of all organ systems and magnify any preexisting organ dysfunction—especially cardiopulmonary dysfunction. There is marked catabolism with loss of body protein, especially from muscle but also from viscera, that can lead to organ dysfunction. The increase in metabolic rate resulting from hormonal response to the inflammatory process leads to a marked increase in O_2 consumption and CO_2 production. The burn wound is now colonized with bacteria, and wound sepsis is a prominent concern. The hyperdynamic hypermetabolic state makes it increasingly difficult to diagnose wound and lung infection.

Pulmonary Abnormalities

Pulmonary problems remain a major cause of morbidity and mortality during this phase.[1,2] Respiratory failure and pneumonia surpass burn wound sepsis as causes of mortality. The burn patient is especially prone to pulmonary infection after smoke inhalation. In addition, the hypermetabolic state produces a marked increase in O_2 consumption and CO_2 production at a time when respiratory function may be seriously impaired by pneumonia, pulmonary edema, or muscle weakness. Burn patients with the combination of inhalation injury and a major body burn have the greatest risk of pneumonia, with a rate approaching 50%. The high incidence is a result of the presence of virulent organisms in the ICU environment and the immunosuppressed state of burn patients. Ciliary action is injured directly by heat and by chemicals in inhaled smoke and often does not regenerate adequately, contributing further to the risk of retention of contaminated secretions and development of pneumonia. Since eradication of an established pneumonia in a burn patient is very difficult, prevention is of primary importance.[3]

When using antibiotics, it is important to remember that the dosages of most antimicrobials required to obtain adequate levels are much higher in hypermetabolic burn patients.[4] If continued intubation is expected for weeks, conversion to a tracheostomy in the first week will greatly assist the clearance of secretions. The tracheostomy should not be placed through burned tissue. If the neck is burned, early excision and grafting are indicated. The tracheostomy can be performed through the skin graft.

The increase in O_2 consumption and CO_2 production during this period imposes increased demand on the respiratory system relative to that seen in the previous periods.[5,6] A 50% to 100% increase in CO_2 production will be seen with burns in excess of 50% of total body surface (TBS). In addition, the severe catabolism initiated by the inflammatory response can lead to weakness of the respiratory muscles.

Protection of the lungs against processes that would impair their function is the best form of support. Controlling edema and infection, maintaining nutrition, and providing for adequate rest, as well as respiratory muscle exercise, are key components. CO_2 production should be limited by avoiding excess carbohydrate calories and controlling hyperthermia. Partial ventilatory support via a tracheostomy may be useful, especially if recovery is not anticipated for several weeks.

Hemodynamic and Metabolic Support

A good understanding of the metabolic and physiologic changes is necessary to determine fluid, electrolyte, and nutrient requirements.

FLUID, PROTEIN, AND RED BLOOD CELL LOSSES

Evaporative water losses remain increased until the wound is closed. Even after closure, evaporative losses through the grafted wound are much higher than through normal skin. Increased water intake is essential to compensate for this loss, which can be 2 to 4 L/d. Protein losses from wound exudation and from bleeding persist until wound closure.

THE HYPERMETABOLIC-CATABOLIC STATE

The host response to a severe burn is an amplification of the fright-flight reaction. The insult (afferent arc) leads to the release of inflammatory cytokines that activate a very

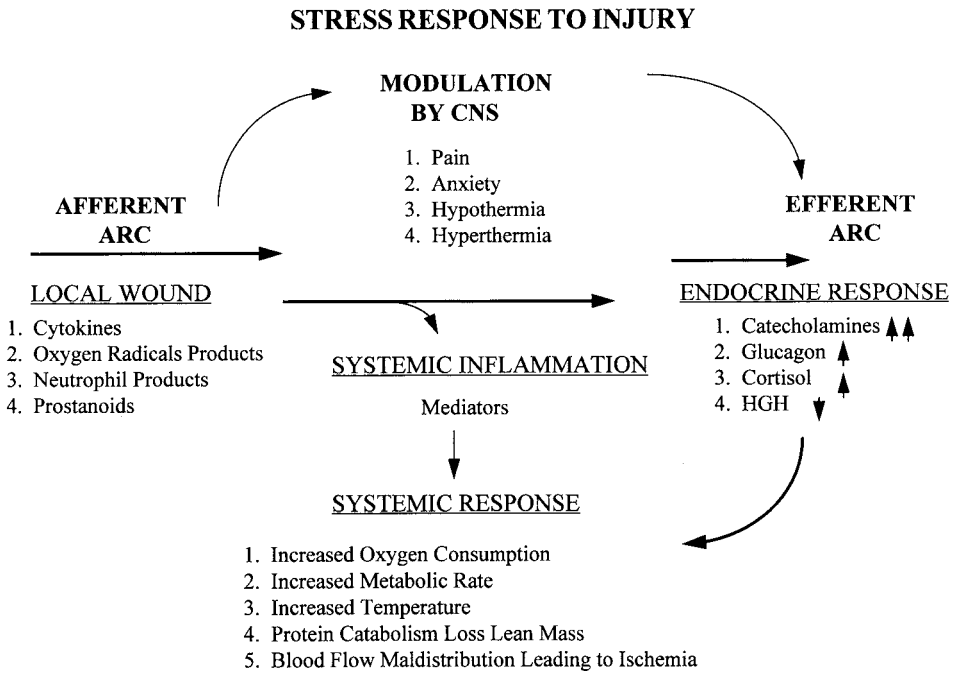

FIGURE 100-1 The host response to a severe burn.

abnormal hormonal response led by a marked increase in catecholamines and other hormones (efferent arc) that produce a hypermetabolic-catabolic state (Fig. 100-1 and Table 100-1). Oxygen consumption can double during this period because of the abnormal endocrine environment. Any added central nervous system (CNS) stress such as pain will further amplify the catechol-induced process.

Hepatic gluconeogenesis is intensely stimulated, and body protein is broken down rapidly to provide amino acids for carbohydrate substrate.[6–9] The amino acids are released mainly from muscle as alanine for liver glucose formation and glutamine. Glutamine from muscle is exported in large quantities for use as fuel for the gut, as well as a precursor for the endogenous antioxidant glutathione. As opposed to starvation, where 85% of calories come from fat, protein is not spared for use for fuel, and muscle is lost rapidly.

Optimal nutrition attenuates the process and decreases net protein losses by about 50%, but catabolism still outweighs anabolism because the catabolic hormones predominate and the anabolic hormones, especially growth hormones, are decreased. Morbidity from rapid protein depletion can occur in days to weeks after injury rather than after months, as seen with starvation alone (Fig. 100-2). Oxidants released by the generalized inflammation produce direct cell damage, especially because endogenous antioxidant levels are decreased. The direct cell injury and loss of cellular protein can result in progressive multiple-organ dysfunction.

The wound or focus of inflammation develops a high blood flow owing to demand for substrate caused by inflammatory mediators that produce local vasodilatation. This blood flow, which steals from the systemic circulation, can lead to a systemic O_2 debt. The wound consumes large quantities of energy during the healing process both by inflammatory cells and by fibroblast collagen formation. The wound uses glucose as its primary fuel for ATP but does so in an anaerobic fashion despite oxygen availability. Lactate is returned to the liver to re-form glucose. Gluconeogenesis also employs skeletal muscle amino acids, primarily alanine.

The size of the wound or focus of inflammation corresponds with the magnitude of the stress response. In addition, the wound becomes the preferred consumer of amino acids obtained from muscle until 20% of muscle is lost, at which time both muscle and wound compete equally. With a 30% loss of muscle, the wound now receives less protein substrate than muscle, and poor healing becomes evident as the body attempts to restore lean body mass before a lethal fall[10] (Fig. 100-3).

TREATMENT

CONTROLLING THE STRESS RESPONSE

It is not necessary that the "stress response" go unchecked. The underlying disease process and the degree and time course of the calorie and protein depletion can be modulated by (1) controlling the source of the stress response and

TABLE 100-1 The Hormonal and Metabolic Response to Burn

Insulin	↑	↓	↓	↓↓

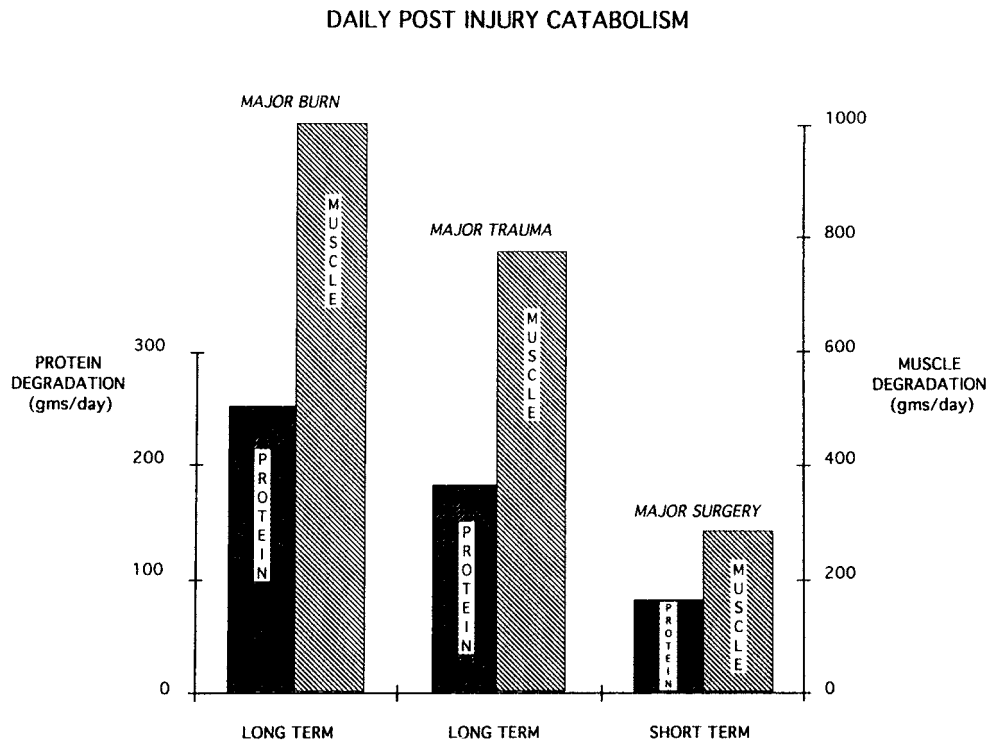

FIGURE 100-2 Daily catabolism following major injury.

(2) increasing the process of anabolism through nutrition, nutritional adjuvants, and increased muscle activity.

The hypermetabolic-catabolic state is driven by the presence of an injury, infection, or ischemia and resulting inflammation. Therefore, control of the source of the systemic response is critical[11] (Table 100-2). Aggressive surgical control of the focus, which is usually devitalized tissue such as burn eschar, is essential to minimize the degree and time course of the response. Both local ischemia and systemic oxygen debt are strong stimuli to continued inflammation and further catechol and cortisol release. The increase in cortisol requirements may not be able to be maintained. Liberal use of analgesics, anxiolytic drugs, and other methods to control psychological stress are required. A relative adrenal insufficiency has been reported with increasing frequency, especially in the elderly burn patient, requiring additional cortisol.[12] A controlled

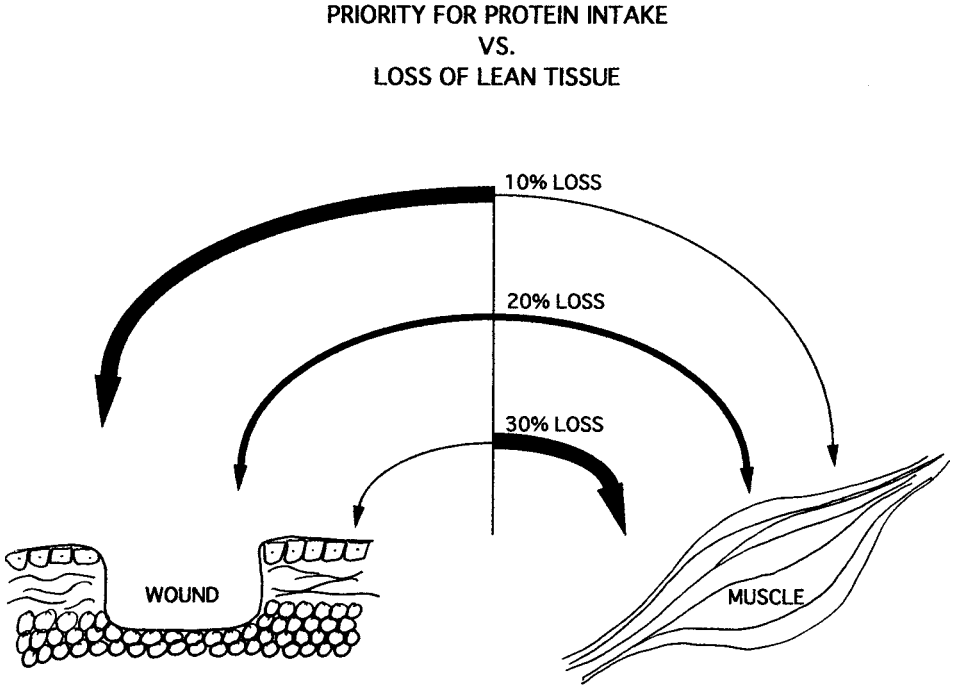

FIGURE 100-3 The wound healing rate progressively decreases as the muscle loss increases.

TABLE 100-2 Controlling the Source of the Stress Response

By removing dead tissue, draining infection, and decreasing inflammation and mediator changes in metabolism
By maintaining optimum blood volume thereby avoiding ischemia-induced catechol release
By controlling secondary stresses, e.g., pain, anxiety, which also increase catechol release

β blockade has been shown to decrease the degree of postburn catabolism significantly.[13] Optimizing tissue perfusion is essential.

NUTRITION

It is expected that nutritional support has been started in the early postresuscitation period; however, this support will require adjustment during this period of increasing metabolic activity. The first requirement is an estimation of energy requirements; this is followed by an organized approach to nutrient delivery, tailoring the proportions of carbohydrate, protein, and fat to the individual patient's needs. The use of indirect calorimetry and estimating nutrient needs based on burn size are the most common approaches used.[8,11]

The nutrition support should begin by the end of the resuscitation period. The enteral route is preferred because nutrient utilization clearly is improved over the parenteral route, and the gut integrity is maintained.[11] In general, the caloric requirements for burns of 30% of TBS or greater are 30 to 35 cal/kg per day based on formulas or direct measurements.

Nutrient Mix

Increased *carbohydrate* (CHO) calories (60% of total) are used to try to control the rate of gluconeogenesis, decreasing proteolysis. Excess CHO, however, is deleterious, leading to hyperglycemia, fat formation, and additional carbon dioxide. *Fat* calories (30% of total) are also given. Endogenous fat stores are also used. However, fat will not spare protein loss. Excess fat is also deleterious, being a substrate for immunosuppressive mediators.[11]

Protein Requirements

Protein requirements are two to three times the recommended daily allowance, 1.5 to 2.0 g/kg of body weight per day. The increased protein intake will decrease the net nitrogen (N) losses. Protein supplements usually are necessary to achieve this intake because tube feedings or regular food is not sufficiently protein-rich. Supplements must contain protein of high biologic value, a standard measure of the percentage of the protein amino acids that can be absorbed and used. Egg albumin has a 91% value compared with casein, which is 56% (Table 100-3).

Glutamine, the most common circulatory and intracellular amino acid, is depleted rapidly after a burn and needs to be replaced for glutathione synthesis.[12] Since glutamine represents over 30% of the amino acid used in catabolism and protein loss exceeds 100 g/d, replacement with 30 to 40 g will attenuate the deficiency state. Soluble glutamine is now available for oral use or via tube feedings (Cambridge Nutraceuticals, Boston, Mass.). Glutamine is also known to stimulate release of human growth hormone, adding to its anticatabolic effects.[13]

TABLE 100-3 Biologic Value of Common Proteins

Protein	Percent of N Retained for Protein Synthesis
Egg albumin	91
Beef muscle	67
Casein	56

Vitamin and Mineral Requirements

Vitamins and minerals are consumed at a rapid rate and should be given at a dose of 10 times the Recommended Daily Allowance (RDA).[11] Well-accepted daily doses include vitamin A, 10,000 to 15,000 units; vitamin C, 1 g; vitamin E, 500 to 1000 IU; selenium 100 μg; carotene 50 mg; and zinc sulfate, 220 mg bid.

Use of Anabolic Agents

Increasing the patient's anabolic activity has been shown to further attenuate net catabolism[15,16] during the stress phase and to increase muscle restoration in the recovery phase. Currently, only two agents are available—human growth hormone and the testosterone analog oxandrolone.

HUMAN GROWTH HORMONE This agent has been shown to increase healing rate, muscle mass, nitrogen retention, and survival in burn patients when given parenterally in doses of 5 to 10 times that normally produced (0.8 mg/d).[14] The major complication is hyperglycemia.

OXANDROLONE (OXANDRIN) Oxandrolone, a 17-hydroxyl-17-methyl ester of testosterone, is the anabolic steroid that is approved by the Food and Drug Administration (FDA) for restoration of muscle loss after severe trauma, burns or major surgical procedures, or infections.[17] The anabolic effect is primarily on muscle (or lean body mass).[15,16]

Clinical trials on a variety of burn patient populations from children to the elderly have demonstrated significant decrease in lean mass loss during the catabolic state and a marked increase in the rate of lean mass restoration. Oxandrolone (BTG Pharmaceuticals, Iselin, New Jersey) is the only steroid in which a carbon atom in the phenanthrene nucleus has been replaced by another element, namely, oxygen. This alteration appears to be responsible for its potent anabolic activity—5 to 10 times that of methyl testosterone. In addition, its androgenic effect is considerably less than testosterone, thereby minimizing the complication of excess androgen activity common to other testosterone derivatives. The drug is given orally with 99% bioavailability. It is protein-bound in plasma with a biologic half-life of 9 hours. The compound is excreted unchanged primarily by the kidney with minimal hepatic metabolism and therefore results in minimal to no hepatic toxicity. No significant complications have been reported.

INFECTION AND SEPSIS

Sepsis is the leading cause of morbidity and mortality during this period. The most common sites of infection in the burn patient are the lungs, the burn wound, and vascular catheters.[18] Intraabdominal processes, in particular, cholecystitis, are uncommon but are well recognized as sources of sepsis in critically ill patients.

Appropriate antibiotic dosing is a crucial aspect of management. Because of the hypermetabolic state, as well as the loss of antibiotics from the wound, the burn patient generally requires a larger total antibiotic dose and increased frequency

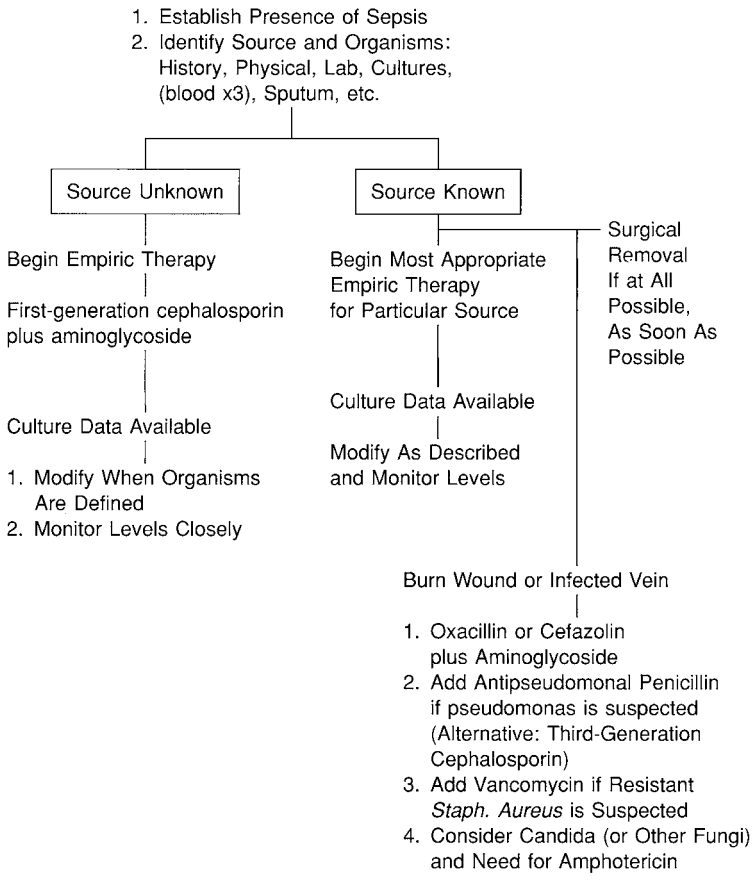

FIGURE 100-4 Approach to the burn patient with sepsis.

of doses to maintain adequate levels. This increased requirement is well documented for the aminoglycosides. Renal impairment may mandate lower doses. Monitoring antibiotic levels is the only valid approach to the use of systemic antibiotics in major burn patients.

Because of the immunocompromised nature of the burn patient, as well as the use of topical and systemic antibiotics, fungal sepsis—especially caused by *Candida albicans*—is relatively common. The prodrome is often more subtle than with other microorganisms, with patients appearing more chronically ill and just "not doing well."

As with any form of sepsis, the removal or control of the septic focus is of primary importance. Débridement should be performed gently to unroof pockets of infection and allow for better local wound and topical antibiotic care. Large excisions often are poorly tolerated during this period because of dissemination of infection and blood loss.[18] The approach to infection is summarized in Fig. 100-4.

Chapter 101

INTERVENTIONAL RADIOLOGY

JENNIFER E. GOULD
DANIEL PICUS

KEY POINTS

- *Availability of appropriately trained interventional radiologists is an important component of ICU patient care.*
- *Interventional radiologic techniques may be prophylactic (e.g., use of vena caval interruption to prevent pulmonary embolism), diagnostic (e.g., angiography in gastrointestinal hemorrhage), or therapeutic (e.g., drainage of abscess, control of gastrointestinal hemorrhage through embolotherapy or vasoconstrictor infusion, creation of transjugular intrahepatic portosystemic shunts [TIPS], or retrieval of a foreign body).*
- *Interventional radiologic techniques are as effective as many open surgical techniques but carry lower morbidity and mortality in the ICU patient.*
- *Interventional radiologic techniques should be considered in ICU patients when the risk of more invasive procedures is greater and the outcome is not predictably better.*
- *Appropriate ICU monitoring devices and support systems (oxygen, suction, ventilation, ICU-type personnel) must be available in the radiology suite for safe management of ICU patients.*

Interventional radiology encompasses a wide variety of percutaneous procedures that use one or more imaging modalities to guide the placement of needles, guidewires, and catheters. The choice of fluoroscopy, ultrasound (US), and/or computed tomography (CT) depends on the patient, the clinical circumstances, and the procedure. Many of these procedures are performed as an alternative or adjunct to surgery because they are less invasive and carry a lower overall morbidity and mortality as compared with the comparable surgical intervention. This fact is particularly important in ICU patients, who frequently are poor surgical candidates and for whom procedures carry a higher-than-average risk owing to associated comorbidities. Furthermore, while many surgical procedures require general anesthesia or deep conscious sedation, interventional radiology procedures typically can be performed with mild to moderate levels of conscious sedation and/or local anesthesia, further reducing the risk, the length of the procedure, and the need to consult the anesthesiology service for assistance.

When and Where to Perform the Procedure

Deciding when and where to perform an interventional radiologic procedure is often a difficult decision requiring close communication and cooperation between the critical care and interventional staffs. The interventional radiologist should be consulted early to allow adequate time for a meaningful exchange between the two services.

In general, working with "stable" patients is preferable, although not always possible. In certain situations, it is better to proceed with an examination despite patient instability. For instance, in a patient with gastrointestinal (GI) bleeding, instability may indicate active bleeding, and immediate angiography during ongoing bleeding is necessary to identify the source. If the patient is stabilized first, the opportunity to locate the bleeding site may be lost. Nevertheless, despite the need for prompt treatment, the appropriate venous lines, oxygen support, monitoring devices, and fluid resuscitation and blood product administration should be initiated prior to any interventional procedure.

The risks in complex interventional procedures are minimized and the success enhanced when the patient is transported to the special procedures suite. Although CT and US are useful for some nonvascular procedures, fluoroscopic guidance is required for all vascular interventions and many nonvascular procedures. Portable fluoroscopy units are available in most ICUs, but these units have several disadvantages. They are cumbersome to use, have no radiographic shielding, and restrict imaging to a small area of the body.

A few interventional procedures can be performed at the bedside with US guidance. US units are mobile, inexpensive, and allow cross-sectional imaging. This particular approach is useful for straightforward percutaneous procedures such as fluid aspiration, abscess drainage, biopsy, or cholecystostomy tube insertion. The limitations of US guidance include the need for direct contact between the US transducer and the skin and the need for a "window" without intervening bowel gas, bone, surgical dressings, or open wounds.

Despite the ability of US to provide portable guidance, many biopsies and drainage procedures preferably are performed with CT. CT provides a detailed display of the entire fluid collection and its relationship to surrounding structures, allowing precise planning of the safest percutaneous access route. Oral and intravenous contrast agents can be administered in circumstances that require differentiation among a fluid collection, bowel, and nearby vascular structures. Unlike US, CT is not limited by overlying dressings, wounds, or ostomy devices.

Preprocedure Evaluation and Preparation

It is necessary to obtain coagulation parameters prior to most interventions. The risk of procedure related hemorrhage is reduced when laboratory prothrombin time (PT) and platelet counts are within the normal reference ranges. In emergent situations, a PT of less than 20 seconds (International Normalization Ratio [INR] < 3.0) and a platelet count greater than $50{,}000/\mu L$ are acceptable for most vascular procedures. In nonvascular procedures, a PT of less than 16 seconds (INR <2.0) and a platelet count greater than $100{,}000/\mu L$ generally are required. If an emergent procedure is needed and the PT is elevated, fresh frozen plasma should be administered. When platelet counts are low, platelet transfusions can be administered just prior to the procedure to raise values to an acceptable level. Heparin infusions should be discontinued 2 to 4 hours before procedures. For emergent vascular studies, an arterial sheath can be left in place and subsequently removed when PT values decrease to acceptable levels.

An estimated 5% to 12% of patients receiving high-osmolality contrast agents and 0.5% to 3.0% of patients receiving newer low-osmolality contrast agents experience some type of acute adverse reaction. In patients at high risk for iodinated contrast anaphylaxis (asthma, severe allergies, or history of a previous reaction to a contrast agent), when possible, corticosteroid premedication should be administered to prevent or reduce the severity of any potential reaction. Prednisone 50 mg orally (or its equivalent intravenous dose) may be administered every 6 hours starting at least 12 hours (optimally 24 to 36 hours) before the procedure.[1]

Many patients in the ICU suffer from acute and/or chronic renal failure. Intravascular contrast agents are excreted renally, and therefore, adequate renal function is necessary to reduce the risk of contrast nephropathy. This risk cannot be overemphasized because radiocontrast nephropathy is associated with prolonged hospitalizations and higher rates of morbidity and in-hospital mortality.

There is no absolute creatinine value above which contrast agents should not be administered, but the risk of contrast nephropathy is increased in the setting of impaired renal function (serum creatinine > 1.5 mg/dL), diabetes mellitus, age over 60 years, dehydration, multiple myeloma, concomitant nephrotoxic medication administration, severe hypertension or cardiovascular disease, hyperuricemia, use of high-osmolar contrast agents, use of large volumes of contrast material in a short time period, or recent exposure to a large contrast load. Intravascular contrast administration typically is contraindicated in renal failure patients for whom renal function is expected to return unless evaluation of a life-threatening problem necessitates proceeding in spite of the risk of temporary or permanent renal dysfunction.

If a contrast study is necessary, hydration before and after the procedure and the use of low-osmolality contrast agents are the most important factors in reducing the rate of nephrotoxicity.[1a] Recently, investigative work has centered on use of two drugs to preserve renal function. Several studies have documented a reduction in the rise in creatinine levels and an increase in creatinine clearance with the use of oral or intravenous *N*-acetylcysteine in patients with stable moderate renal insufficiency.[2,3] Unfortunately, the results with this agent have been mixed, and some data suggest that it may be useful only for subsets of patients with lesser degrees of renal dysfunction who receive low to moderate doses of contrast material.[4]

Another agent undergoing active investigation is fenoldopam, a selective dopamine receptor agonist with renoprotective properties. Fenoldopam is administered by continuous IV infusion before, during, and after the procedure and is titrated to blood pressure. Although results have been mixed, some researchers have documented preservation of renal blood flow as well as lower rates of creatinine elevation and renal failure than hydration alone.[5–7]

In addition, several interventional radiology procedures can be performed with alternative contrast agents that reduce the amount of intravascular contrast material required or eliminate the need for it altogether. Carbon dioxide and gadolinium each have been used successfully in insertion of inferior vena caval filters.[6–8] Transjugular intrahepatic portosystemic shunts (TIPS), which typically use carbon dioxide for transhepatic retrograde portal venography, also have been created successfully with carbon dioxide alone.

Carbon dioxide gas is an effective negative contrast agent that displaces the blood volume during injection and then is excreted rapidly from the lungs through respiration.[8,9] This agent is particularly useful because it has no dose limitations and no allergic reactions and is of low cost. Unfortunately, it usually is injected by hand, and contamination by room air must be avoided. Carbon dioxide is contraindicated for arteriography of the thoracic aorta, cerebral arteries, or upper extremity arteries owing to the risk of neurologic symptoms from "vapor lock," which can obstruct flow within a vessel and cause distal ischemia.

Gadolinium, typically known for its use in magnetic resonance imaging (MRI), can be used in high doses for fluoroscopic vascular imaging and some genitourinary and biliary procedures. Its use is limited by the maximal approved dose (0.3 to 0.4 mmol/kg), its high expense, and its poor radiopacity. However, its safety profile is high for all vascular applications, and it has low rates of nephrotoxicity and anaphylaxis. It is used typically in conjunction with carbon dioxide, and in some cases it can be mixed with iodinated contrast agents to reduce the dose of iodinated agents administered.[10–12]

Monitoring the Patient in Interventional Radiology

Interventional suites should simulate the ICU environment to allow close patient monitoring during all procedures.

EQUIPMENT

All interventional radiology suites should be equipped with basic patient monitoring equipment, including electrocardiography (ECG), noninvasive blood pressure monitoring devices (preferably automated), and pulse oximetry devices. Pulse oximetry is useful for documenting a patient's baseline respiratory status and monitoring the effects of sedation with narcotic analgesics. It is also useful to have devices that record hemodynamic information. A standard emergency "crash" cart, defibrillator, and backboard always should be available for cardiopulmonary resuscitation, and all special procedure suites should be equipped with a reliable source of oxygen and suction.

PERSONNEL

ICU patients require constant nursing care while in the interventional suite. Most radiology departments employ nurses who are specially trained to care for patients during special procedures. However, the ICU patient generally has particular needs, and an ICU-trained nurse who can provide continuity of care should accompany the patient to the radiology department and be responsible for monitoring the patient, recording vital signs, and administering medications.

In general, an ICU physician need not accompany patients to the interventional radiology suite. However, this decision depends on the patient's condition and the complexity of the procedure and should be made on a case-by-case basis.

Nonvascular Interventional Radiology Procedures

PERCUTANEOUS ABSCESS DRAINAGE (PAD)

INDICATIONS AND PATIENT SELECTION

Fever in ICU patients is very common. Abscess formation, particularly in postoperative patients, is frequently the cause. Although small abscesses often respond to antibiotics alone, larger collections are best treated with drainage—especially when symptoms such as sepsis, pain, and/or visceral compression are present. In the past 10 to 15 years, percutaneous abscess drainage (PAD) has all but replaced surgical drainage as the treatment of choice for abscesses and other problematic fluid collections (e.g., biloma, urinoma).[13,14] PAD is less invasive and maintains the integrity of surrounding structures and overlying skin, thus reducing morbidity and saving time and expense. PAD also makes nursing care easier because drainage systems are closed, and there is no extensive surgical wound or need for frequent dressing changes. Drainage of sterile collections typically is not necessary unless there is a concern for infection or the collection is causing symptoms such as pain or visceral compression.

PAD is most successful when the fluid collection is well defined, unilocular, and free flowing (Fig. 101-1*A – C*). These characteristics are found in more than 90% of intraabdominal collections. PAD also may be helpful in less favorable situations (e.g., multilocular, necrotic debris), particularly when the patient is a high surgical risk. In such circumstances, PAD may improve the patient's condition so that a more definitive surgical drainage can be performed later. The only absolute contraindication to PAD is the lack of a safe access route. This rarely is a problem when CT guidance is used. Fluid collections deep within the pelvis may require transrectal or transvaginal drainage routes using special ultrasound probes for guidance.

TECHNIQUE

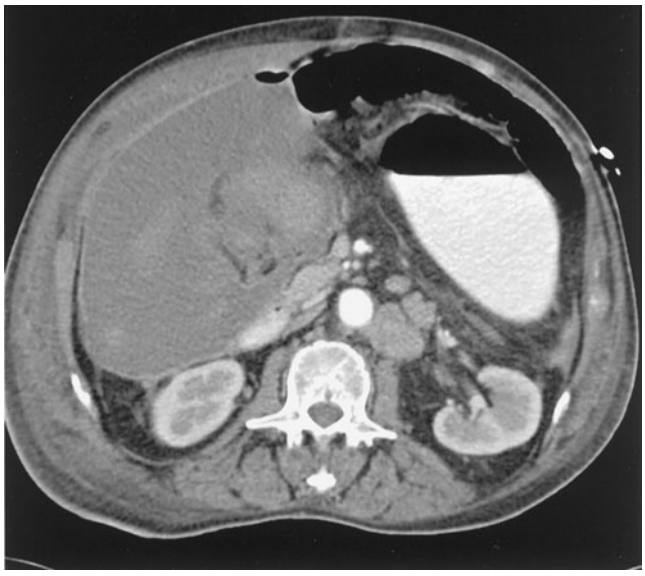
The most important step in PAD is planning the access route. This is done following review of all the pertinent imaging studies. In general, the shortest, straightest tract is the best approach, but care must be taken to avoid adjacent bowel, pleura, and major blood vessels.

Antibiotics selected to cover the likely microorganisms should be initiated as soon as an abscess is suspected by imaging and always prior to intervention because manipulation of the cavity and its contents may result in bacteremia or spillage into sterile cavities.

Diagnostic aspiration sometimes is performed first with a 20- to 22-gauge needle. The position of the needle is confirmed with US or CT, and the fluid is aspirated for culture and diagnosis. A small volume of contrast material can be injected to define the cavity. If the decision is made to drain the fluid, the collection can be accessed and drained using either an over-the-wire (Seldinger) or trocar (one-step) technique. The size of the drain ranges from 10F to 20F and depends on the type and viscosity of fluid obtained on aspiration. The catheter is then secured to the skin with a suture, allowing easy access for local skin care and reducing the risk of tube dislodgment.

When the catheter is in place, the collection may be aspirated completely, and the catheter is then connected to gravity drainage. When subsequent drainage has decreased, follow-up imaging should be obtained to ensure complete evacuation. If residual fluid or additional loculated collections are identified and drainage is incomplete, repositioning the catheter or placing a second drain may be necessary. For complex collections, dilute streptokinase or tissue-type plasminogen activator (t-PA) may be instilled into the cavity to chemically disrupt loculations and optimize drainage. Typically, percutaneously placed catheters are left to gravity drainage, but on occasion, they are connected to low intermittent suction. With empyema or infected intrathoracic collections, the drainage catheters are placed to Pleurovac or water-seal suction devices identical to standard thoracostomy tubes.

IMMEDIATE POSTPROCEDURE CARE

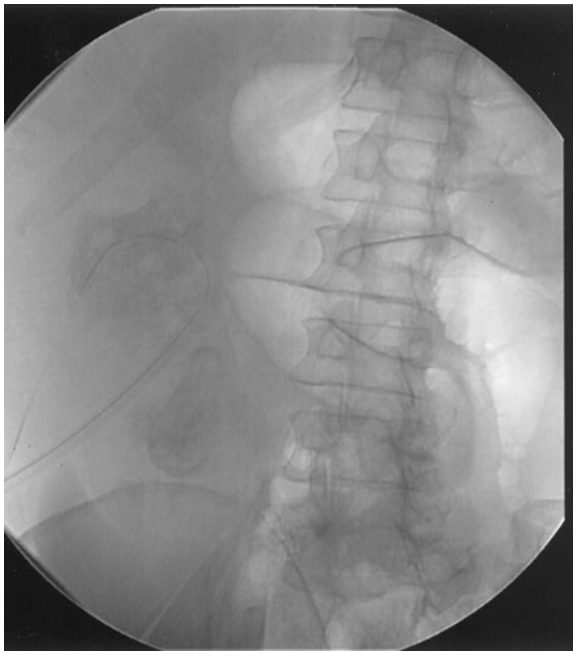


The output of the drainage catheter should be monitored and recorded carefully. The catheter is left in place as long as it continues to drain, which usually requires 3 to 10 days, although longer periods may be necessary for large or complicated collections or when a fistula is present. Antibiotic coverage should be modified after culture and sensitivity results are obtained from the initial aspirate.

Percutaneous catheters are irrigated only when material is too viscous to drain spontaneously. When necessary, it should be done with 5- to 10-mL aliquots of sterile saline. Fluid should be injected into the catheter and then allowed to drain on its own. Vigorous suction generally draws debris into the catheter that can obstruct the lumen. If the catheter occludes, fails to drain easily, or drains significantly around the tube, it may need to be exchanged for a larger one. This is a relatively quick and simple procedure but does require fluoroscopic guidance. When a culture-proved sterile collection is encountered, early tube removal is warranted to prevent secondary infection.

Once effective drainage has been established, the patient's condition should improve within 24 to 48 hours. Incomplete drainage should be suspected when the patient remains febrile or the white blood cell count remains elevated. In these cases, follow-up CT should be obtained promptly and additional drainage catheters placed as needed. If the drainage first tapers and then increases abruptly, a fistula may be present. Injection of contrast media through the catheter under fluoroscopic observation usually demonstrates the communication. When a fistula is present, PAD can still be successful but may require extended drainage with complete bowel rest. If present, obstruction distal to the fistula also should be corrected.

RESULTS AND COMPLICATIONS



PAD compares favorably with surgical treatment in overall success, duration of drainage, and recurrence rates.[13] Between 70% and 90% success rates have been reported and depend on abscess location and complexity, patient immunocompetency, and subsequent fistula formation. Failed or prolonged PAD is caused most often by an unrecognized fistula or an undrained collection. Premature withdrawal of the drainage catheter or attempts at draining a relatively solid collection (e.g., necrotic tumor, pancreatic phlegmon) are also causes of failed PAD.

FIGURE 101-1 This patient was status post total colectomy and ileostomy and developed fevers and an elevated white blood cell count. *A*, *B*. CT demonstrates a large, well-defined, rim-enhancing collection in the right abdomen with high-density contents suggesting a postoperative hematoma. Foci of gas within the collection (*black arrowhead*) and small amounts of peritoneal gas (*white arrow*) are of concern for anastomotic dehiscence or bowel perforation. Thickening and edema in the right abdominal wall soft tissues suggest cellulitis as well. *C*. Fluoroscopic image showing large-diameter drainage catheter insertion.

Overall complication rates for PAD range from 10% to 15%, with serious complications accounting for less than 5% of cases.[13,14] Minor complications include transient bacteremia, skin infection, and minor bleeding. Major complications include hemorrhage requiring transfusion, sepsis, and bowel perforation. The recurrence rate following PAD is approximately 5%. These statistics compare favorably with the surgical literature, which reports mortality rates of 10% to 20% and recurrence rates of 15 to 30%.

PERCUTANEOUS CHOLECYSTOSTOMY

INDICATIONS AND PATIENT SELECTION

Elective cholecystectomy in an otherwise healthy patient is a safe procedure with an operative mortality rate of less than 0.5%. Morbidity and mortality rates increase dramatically in ICU patients with multiorgan compromise, sepsis, diabetes, and/or immunosuppression and in the elderly. Historically, critically ill patients have been treated with operative cholecystostomy until they were stable enough to undergo elective cholecystectomy.

Percutaneous cholecystostomy has emerged as an alternative to standard surgical therapy.[15–19] A very important advantage to the newer approach is that it can be done at the patient's bedside without an incision using only local anesthesia.

Indications for percutaneous cholecystostomy include acute calculus or acalculous cholecystitis in a patient who is too ill to withstand surgical cholecystectomy. In calculous disease, the gallbladder can be removed electively when the patient's condition stabilizes. An alternative to operative

cholecystectomy is percutaneous stone removal or dissolution therapy via the existing cholecystostomy tract. This is especially useful in patients who remain poor surgical candidates after transfer from the ICU.[11]

Acute acalculous cholecystitis is increasingly recognized in ICU patients. Its diagnosis is difficult to establish despite the use of US. US is extremely accurate in identifying cholelithiasis but is less reliable in diagnosing acute acalculous cholecystitis, with reported accuracy rates of 50% to 60% (Fig. 101-2*A – C*). Nuclear medicine hepatobiliary scans are useful in evaluating cystic duct patency, but false-positive rates are in the range of 25% to 30%. Generalized hepatocellular dysfunction, prolonged total parenteral nutrition, sepsis, and fasting all predispose to false-positive hepatobiliary scans.

In patients with acalculous cholecystitis, percutaneous cholecystostomy can confirm the diagnosis and serve as definitive therapy. Prompt decompression can result in dramatic symptomatic relief. Typically, the cystic duct opens eventually, allowing tube removal without requiring a formal cholecystectomy.

TECHNIQUE

In unstable patients, percutaneous cholecystostomy can be done at the patient's bedside with portable US guidance. Transhepatic access to the gallbladder is preferred to decrease the risk of bile spillage into the peritoneal cavity. A 22-gauge needle is advanced into the gallbladder, and bile is aspirated (see Fig. 101-2*D*). Since Gram stain and culture results of the bile are helpful but not sensitive (30% to 50%), a cholecystostomy tube is inserted at the time of initial aspiration. Negative Gram stain and cultures do not exclude the diagnosis of acute cholecystitis. After aspiration, either a Seldinger or a trocar technique can be used to place a retention catheter for drainage (see Fig. 101-2*E*, *F*). If the procedure is guided by fluoroscopy, contrast agent injection is used to confirm catheter position. Care should be taken not to overdistend an acutely inflamed gallbladder.

IMMEDIATE POSTPROCEDURE CARE

Catheters are left to drain by gravity. When the cystic duct is obstructed, the gallbladder normally produces 50 to 70 mL of clear mucus daily. Larger volumes of bilious drainage indicate cystic duct patency. Very large volumes persisting may indicate common duct obstruction as well.

After the patient's condition stabilizes, the cholecystostomy tube is injected under fluoroscopy to evaluate for stones in the gallbladder, cystic duct, or common bile duct. If no stones are seen and contrast material flows freely into the duodenum, the tube can be capped and subsequently removed as early as 10 to 14 days following placement, when a mature tract has formed.

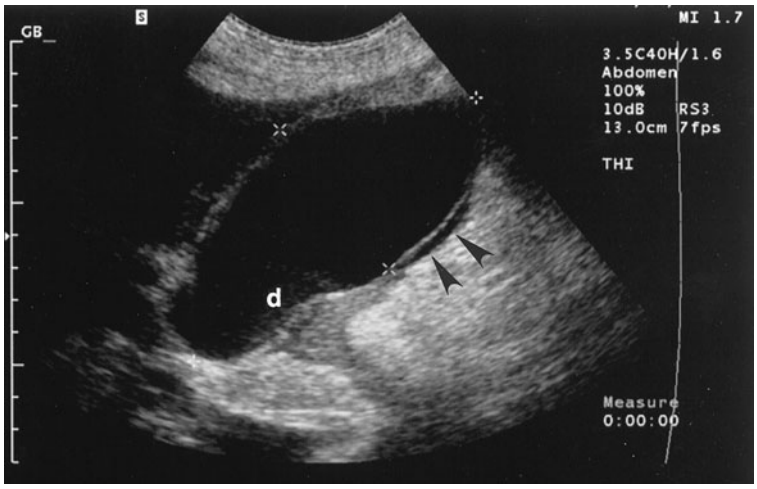
RESULTS AND COMPLICATIONS

Percutaneous cholecystostomy placement is technically successful in over 95% of patients.[18] In a study by Boland and colleagues,[19] approximately 60% of patients demonstrated clinical improvement following cholecystostomy in the setting of sepsis with suggestive US findings of a gallbladder source. Interestingly, up to 20% to 30% of patients will not have acute cholecystitis. This confirms the difficulty in diagnosing acute cholecystitis in critically ill patients. Percutaneous cholecystostomy still is helpful in these patients because it excludes the diagnosis of acute cholecystitis and avoids unnecessary surgery.

With proper technique, complications are few. Bile peritonitis is avoided by decompressing the gallbladder rapidly through the transhepatic route and by carefully performing cholangiography with fluoroscopic guidance. Sepsis, hemobilia, and vagal reactions all have been reported in less than 5% of patients.

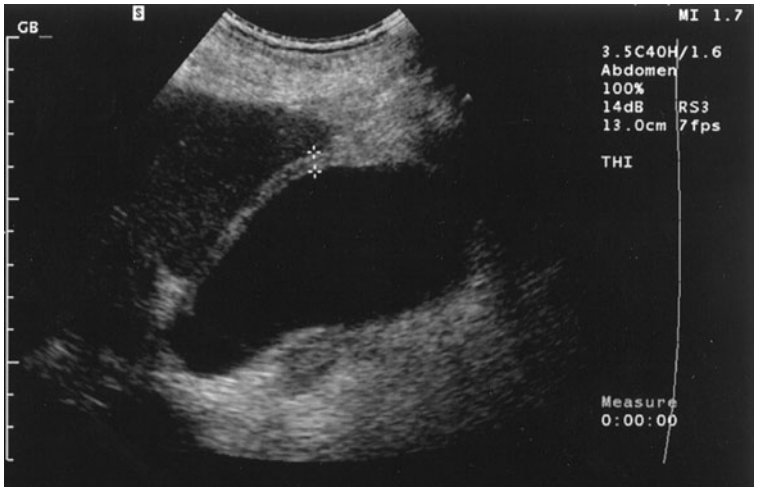
PERCUTANEOUS NEPHROSTOMY

INDICATIONS AND PATIENT SELECTION



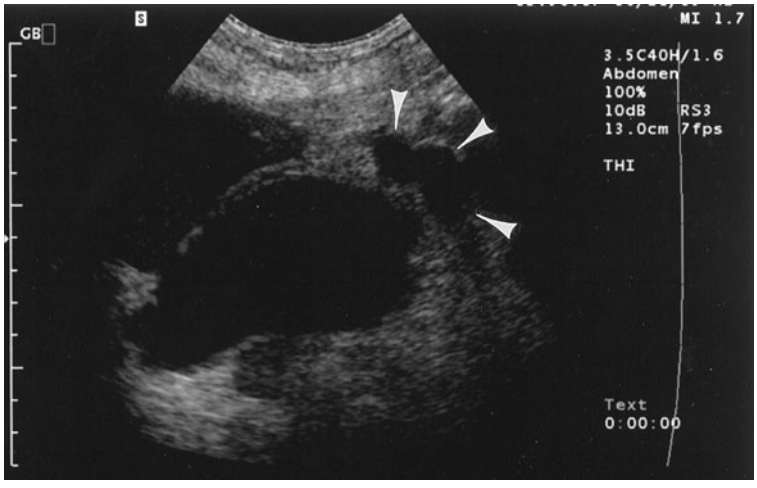
Percutaneous nephrostomy (PCN) is a standard interventional radiologic procedure.[20] Obstruction of the renal collecting system can be secondary to any number of causes ranging from stone disease to malignancy. ICU patients with fever and documented urinary tract obstruction are at high risk for pyonephrosis and urosepsis. In these situations, percutaneous nephrostomy can be a lifesaving procedure. Percutaneous drainage has become the treatment of choice for initial decompression of an infected collecting system, whatever the underlying etiology. Surgical alternatives are used only rarely in the treatment of renal infection. PCN is safe, but for critically ill patients on ventilators, placing them in the prone position can be difficult.

An obstructed collection system can be diagnosed by any number of imaging modalities. US is portable and readily identifies hydronephrosis (Fig. 101-3*A, B*). It is a good first-choice examination, especially when the patient's creatinine concentration is elevated and a genitourinary source is suspected. When the source of underlying sepsis is uncertain, CT evaluation may identify unsuspected hydronephrosis. Although contrast administration is preferable, it is not mandatory for diagnosing an obstructed system.



In patients with urosepsis/pyonephrosis, PCN can confirm the diagnosis and act as the initial therapy until the patient is stabilized (see Fig. 101-3*C*). Prompt decompression can result in rapid improvement in the patient's overall condition, and in some cases (e.g., fungal infection), medication can be infused into the collecting system as part of a therapeutic regimen. When renal calculi are present, the nephrostomy tract ultimately can be used for percutaneous nephrolithotomy after the initial infection has resolved. In this latter situation, care must be taken in placement of an appropriate access site for subsequent tract dilatation and stone removal.

TECHNIQUE



PCN insertion preferably is done in the interventional suite with the patient placed in the prone or semiprone position. Preprocedure antibiotics aimed at treating typical infectious organisms are necessary. As with other nonvascular interventional radiology procedures, the renal collecting system is accessed initially with a 22-gauge needle under US guidance, and fluid is aspirated for microbiologic evaluation. Contrast material and air are then instilled into the collecting system, and a posterior calyx is chosen and accessed with an 18-gauge needle. A guidewire is then advanced into the system, the tract is dilated, and a self-retaining drain is positioned into the renal pelvis. Aspirated samples are sent routinely for microbiologic studies. Contrast agent injection is

Sonographic imaging demonstrates an enlarged, distended gallbladder with a small amount of pericholecystic fluid (*black arrowheads*) and echogenic debris (*d*) but no calculi. *B*. Gallbladder wall thickening is present (normal < 3 mm). The wall measures 5.9 mm. *C*. A small inflammatory fluid collection is present adjacent to the gallbladder (*white arrowheads*). Under US, a needle was inserted into the gallbladder. *D*. Fluoroscopy of contrast injection reveals filling of the gallbladder with no filling of the cystic duct, indicating cystic duct obstruction. Using a Seldinger technique, (*E*) a guidewire was coiled within the gallbadder, and

F

FIGURE 101-2 (Continued) (*F*) a locking-loop catheter was inserted.

mandatory to confirm tube placement, and drainage is then left to gravity. In pyonephrosis or suspected infection, manipulations should be minimized to prevent bacteremia/sepsis.

IMMEDIATE POSTPROCEDURE CARE

Daily fluid input and urine and PCN output should be recorded. Tube output should reflect the output of the kidney drained. In patients with infection, broad-spectrum antibiotics should be continued and tailored to the offending organism when culture and sensitivity reports are available.

When the patient stabilizes, the fever resolves, and the white blood cell count returns to normal, a formal nephrostogram should be done to identify the cause of the obstruction. External decompression should be continued until the infection clears and obstruction is relieved. In cases of stone disease, either extracorporeal shock wave lithotrypsy or percutaneous nephrolithotomy can be performed as the definitive procedure. In patients with ureteral obstruction relating to neoplastic, inflammatory, or iatrogenic causes, an internal ureteral stent may be inserted to restore antegrade flow to the bladder. In situations when internal stenting is not feasible or practical, external drainage can be continued indefinitely.

RESULTS AND COMPLICATIONS

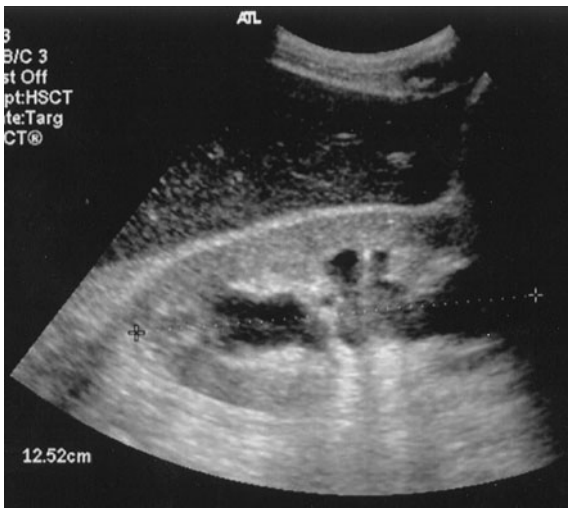
Technical success for emergent PCN placement is in excess of 95%.[20] This is particularly true when a dilated collecting system is encountered.

Major complications of percutaneous nephrostomy insertion are uncommon, with urosepsis, hydro/pneumothorax, and hemorrhage requiring transfusion occurring in less than 6% of patients.[16] Urosepsis is minimized by limiting catheter manipulation after the urinary system is accessed. A pneumothorax is a rare complication (<1%) that occurs most commonly when the route of entry is above the eleventh or twelfth rib.

Vascular Interventional Radiology Procedures

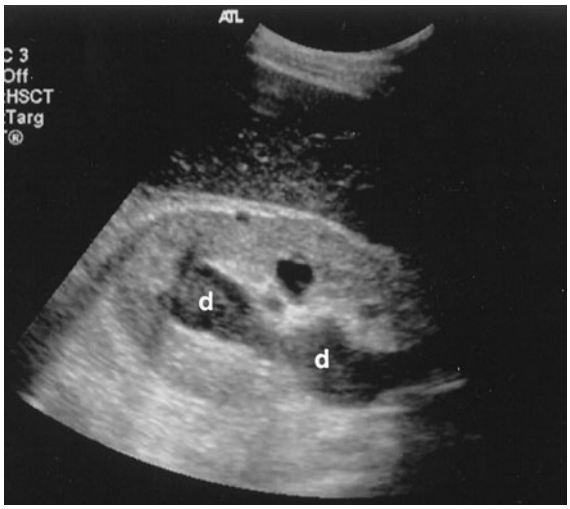
GI BLEEDING: DIAGNOSIS AND TREATMENT

Interventional radiology plays an important role in the diagnosis and treatment of GI bleeding.[21–36] The overall management of GI hemorrhage is discussed elsewhere (see Chap. 82). This section will focus on angiographic localization and treatment of upper and lower GI bleeding.



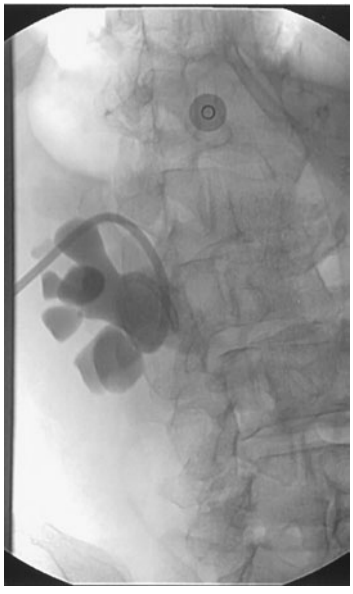
INDICATIONS AND PATIENT SELECTION

GI bleeding typically occurs intermittently, not continuously. Angiography should be performed during active bleeding because often the only angiographic abnormality to guide treatment is the presence of contrast agent extravasation. Unfortunately, the clinical determination of active bleeding can be difficult. A decline in the hematocrit reflects previous bleeding, and large quantities of blood can accumulate within the intestines and slowly be expelled over hours following a bleeding event. Therefore, hemodynamic parameters such as tachycardia and hypotension often are the most accurate indicators of *active* bleeding.



Fortunately, the widespread use of endoscopy and nuclear medicine bleeding scans has improved the ability to document active bleeding and localize the source. Endoscopy should be the initial diagnostic modality in the workup of GI hemorrhage, particularly in the upper tract where it also may be therapeutic. Even if the source is not visualized, secondary findings usually can confirm the presence of active bleeding.

Nuclear medicine bleeding scans with technetium-labeled red blood cells are most useful in the evaluation of bleeding distal to the ligament of Treitz. Radionuclide studies can confirm active bleeding and localize intermittent lower intestinal hemorrhage because the radiopharmaceutical can be monitored for up to 24 hours. These studies are noninvasive and can be performed portably in the ICU. Angiography, on the other hand, is an invasive test that requires transport to the special procedures suite. For diagnosis, there must be active bleeding during the 10-second angiographic injection at a rate sufficient for detection. It is estimated that a bleeding rate of at least 0.5 mL/min is needed for angiographic visualization, whereas a rate of only 0.1 mL/min is required for radionuclide localization.



Preprocedure assessment includes confirmation of probable active bleeding and an estimation of the rate and severity of the bleeding. It is important to document the presence of known cardiovascular disease that would preclude vasoconstrictor administration and establish if there is a history of intestinal or intraabdominal vascular surgeries that may have altered the vascular anatomy. Resuscitation with blood products should be ongoing. In particular, accurate assessment of the coagulation profile is necessary because all endovascular therapies rely on normal coagulation to form a stable clot. A treatment plan should be selected prior to angiography, and surgical consultation should be sought early because failure

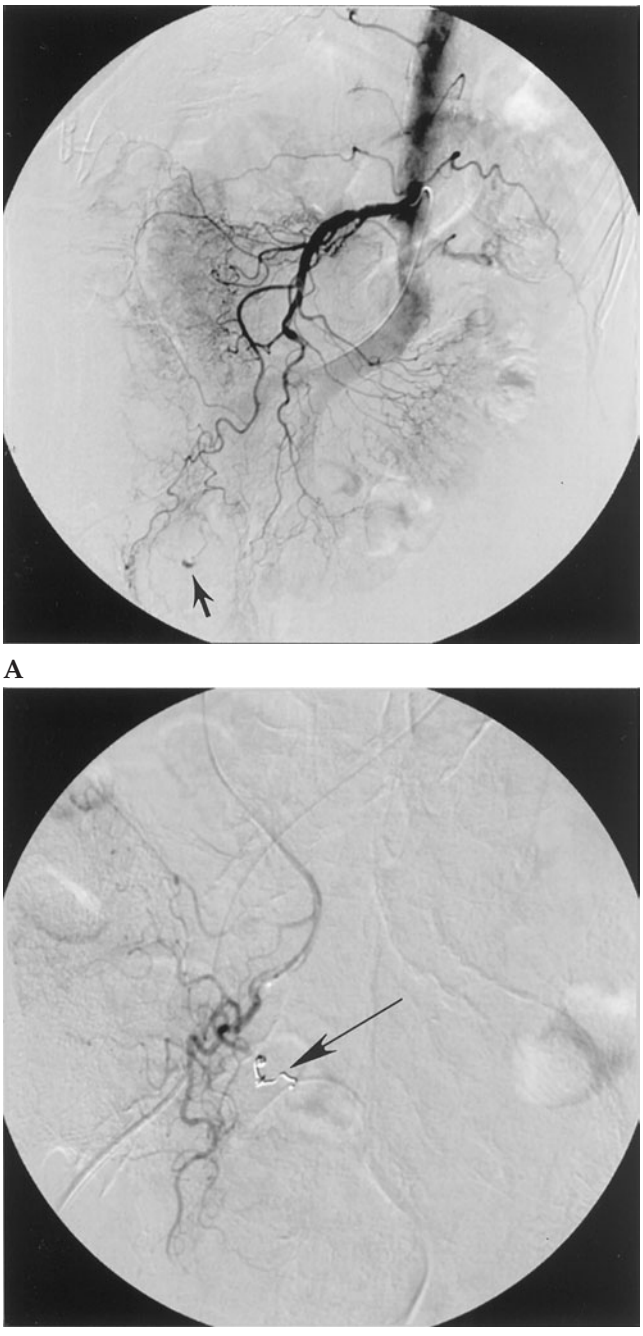
to control bleeding by endovascular methods may necessitate emergent surgery.

TECHNIQUE



Once active bleeding is confirmed and angiography is deemed beneficial, the patient should be transported promptly to the angiographic suite. Portable fluoroscopy units are inadequate for these complex examinations.

In upper GI bleeding, initial celiac axis and subsequent selective left gastric and gastroduodenal arteriography are performed. In lower GI bleeding, the superior and inferior mesenteric arteries, as well as the celiac artery, must be studied. The nuclear medicine bleeding scan is useful to guide selective injections.

The diagnosis of active bleeding is confirmed by identifying extravasated contrast material within the bowel lumen (Fig. 101-4*A*). In suspected lower intestinal bleeding, bladder catheterization is important so that extravasated contrast material is not obscured in the lower pelvis and rectum.

Transcatheter embolization or selective intraarterial vasoconstrictor infusion techniques are endovascular alternatives to surgery in these critically ill patients. Therapy is individualized to the patient's overall medical condition, the cause and location of the bleeding, and the experience of the interventional radiologist.

For lower GI bleeding, the nonoperative therapy of choice traditionally has been selective vasoconstrictor infusion. However, embolotherapy, which has long been valuable in

A

B

FIGURE 101-4 This elderly woman presented with severe lower GI bleeding. *A.* Digitial substraction angiography with selective injection of the superior mesenteric artery demonstrates a focus of contrast extravasation (*short arrow*) within the ileocolic region. *B.* After coil embolization (*long arrow*) of the bleeding vessel, repeat contrast injection demonstrates occlusion of the coiled vessel and no further extravasation.

upper GI bleeding, is being chosen more frequently in the treatment of lower GI bleeding as well. Embolotherapy typically has been considered safe in the upper GI tract owing to its rich collateral arterial network. Embolization of the lower GI tract, with its lesser degree of collateralization, raised concerns for precipitating bowel ischemia and infarction, suppositions that were proven true in the past.[21–23] However, with the development of microcatheters, there is renewed interest in embolization as the primary treatment for lower GI tract bleeding. Microcatheters allow selective catheterization of a peripheral bleeding vessel, thus limiting the region of intestine affected by embolization. Superselective embolization is proving to have high technical success rates with lower rebleeding rates than vasopressin infusion and low rates of ischemia and infarction[25,26] (see Fig. 101-4*B*). When superselective catheterization is not possible, vasoconstrictor infusion remains the best endovascular therapy.

Vasopressin is a potent vasoconstrictor that is the pressor component of the active hormone of the posterior pituitary gland. It produces constriction of the splanchnic vascular bed and contraction of the smooth muscle of the gut. Direct intraarterial injection of vasopressin results in fewer systemic side effects than intravenous administration because a lower dose is required.

Vasopressin therapy is started immediately after selective angiography with direct infusion into the major artery supplying the bleeding site. In an area with a dual blood supply (e.g., the duodenum), vasopressin must be infused through both vascular beds (celiac and superior mesenteric artery) and is less effective. Initial infusion rates generally range from 0.1 to 0.4 unit/min, with angiography repeated at 20-minute intervals to assess the vasoconstrictive effect. If the bleeding stops, the patient is returned to the ICU on a continuous infusion. If bleeding persists, the vasopressin infusion is increased. In general, an infusion of more than 0.4 unit/min results in significantly more systemic side effects. Therefore, if bleeding is not controlled at 0.4 unit/min, alternative therapies should be considered.

The vasopressin infusion is continued for 12 to 24 hours and then tapered gradually over 24 to 48 hours while the patient's condition is monitored carefully. An infusion of saline for the final 12 to 24 hours is helpful in the event of rebleeding. If rebleeding does occur, vasopressin infusion can be repeated.

Transcatheter embolotherapy carries a higher rate of success without rebleeding and eliminates the need for prolonged indwelling arterial catheters. In some cases, embolotherapy serves as definitive treatment of bleeding. Embolotherapy is most helpful in areas with rich collateral arterial networks (i.e., esophagus, stomach, duodenum, and rectum), where multiple blood supplies minimize the risk of ischemic injury. As discussed earlier, because of the high success rates without rebleeding, embolization is being selected more frequently as therapy for bleeding in the small intestine and colon, regions without the same degree of collateralization. Owing to the risk of ischemia and infarction, embolotherapy typically should be avoided in the postoperative gut, especially near anastomoses.

Multiple agents have been used for embolization in the GI tract, and the agent of choice varies by bleeding location and experience of the operator. Surgical gelatin (Gelfoam), polyvinyl alcohol (Ivalon), and microcoils all have been used with success. Gelfoam and coils are the most commonly used agents. Many authors favor Gelfoam because it is a resorbable agent that provides temporary occlusion (approximately 5 to 10 days), allowing the bowel lesion to heal. Injected as particles intermixed with contrast material, it carries a small risk of

nontarget embolization. Many authors prefer coil embolization because, when superselective catheterization is possible, the coils can be deployed precisely without affecting nearby vessels.

Certain locations are best treated using a particular agent. For example, the left gastric artery can be embolized with Gelfoam for treatment of a Mallory-Weiss tear, even when endoscopy has suggested a bleeding site near the gastroesophageal junction but angiography has failed to document active extravasation. Coil embolization of this vessel should be avoided because permanent occlusion would preclude treatment via this vessel should rebleeding occur. The morbidity of Gelfoam embolization of the left gastric artery is extremely low, and the method decreases rebleeding. In contrast, coils are much preferred in the small bowel and colon because they can be deployed precisely with permanent occlusion of the bleeding vessel.

IMMEDIATE POSTPROCEDURE CARE

Embolotherapy and vasoconstrictive infusions both work by decreasing the pulse pressure at the bleeding site. This allows hemostasis and healing of the bleeding lesion. This approach requires a functioning hemostatic mechanism. Frequently, patients with massive GI bleeding have multisystem organ failure or sepsis or have received many units of transfused blood. Any of these can result in an underlying coagulopathy, which should be corrected as rapidly as possible.

Patients on vasopressin infusion must be monitored carefully. During the initial infusion, many patients experience abdominal cramps secondary to the effects on intestinal smooth muscle. This may result in dramatic emptying of accumulated blood from the bowel. If cramps fail to subside within 30 to 60 minutes, or if they recur, significant gut ischemia may be present. The vasopressin dose should be decreased slowly until the pain is relieved. Patients also should be monitored carefully for signs of myocardial and peripheral ischemia, dysrhythmia, and hyponatremia secondary to the antidiuretic effect of vasopressin. Hyponatremia and decreased urine output usually are treated easily with diuretics.

RESULTS AND COMPLICATIONS

Results with transcatheter therapy for acute GI bleeding are highly variable depending on several factors, including the underlying medical condition, the cause of bleeding, and the bleeding site. In our experience, patients with extensive multisystem organ failure and GI bleeding rarely benefit from intervention. Unfortunately, it is difficult to determine beforehand which individuals may benefit.

In patients without multisystem organ failure, control of upper GI bleeding with embolotherapy usually is successful in 70% to 80% of cases.[28,30] In lower GI bleeding, vasopressin infusion is effective in 60% to 90% of patients, but the overall recurrence rate can be as high as 40%. Despite rebleeding, these patients can benefit from this temporary control, allowing elective surgical intervention under more favorable conditions. Embolization for lower GI tract bleeding has resulted in clinical success rates of 60% to 100%, with recent series limited to the colon reporting greater than 85% success. Rebleeding rates following embolization are approximately 10%.[24]

Complications of embolotherapy in the upper GI tract are rare[28] owing to the rich collateral network around the stomach and duodenum that protects against infarction. Care must be taken in postoperative patients, in whom collateral vessels have been ligated. Backflow of embolic material into the liver and spleen occurs occasionally and generally is well tolerated. Clinically significant hepatic or splenic infarctions are rare.

Complications of vasopressin treatment typically are related to diffuse vasoconstriction, which results in significant ischemia to the heart or extremities. Other complications include dysrhythmia and hyponatremia. Thrombosis of the femoral or visceral arteries may result from prolonged placement of the intraarterial catheter. Significant complications related to catheter-directed vasopressin therapy are infrequent, generally less than 10%.[31]

Despite multiple scintigrams, endoscopies, and/or arteriograms, some patients with lower GI tract hemorrhage will have no bleeding site identified. For this subset with obscure bleeding, elective arteriography is indicated to evaluate for the presence of a structural abnormality that may bleed intermittently and guide surgical resection of this offending lesion.[32] In addition, heparin, intraarterial vasodilators, and/or intravenous or intraarterial thrombolytics have been administered in an attempt to provoke bleeding. Several studies have evaluated one or a combination of these agents and have documented a contribution to detection and treatment of bleeding in between 20% and 50% of patients without any adverse events or complications.[33–36] Thus the diagnostic yield of provocative arteriography may be somewhat disappointing, but for a subset of patients with chronic, repetitive, nonlocalized bleeding, it may serve a role when all other measures have failed.

TRANSJUGULAR INTRAHEPATIC PORTOSYSTEMIC SHUNT

INDICATIONS AND PATIENT SELECTION

Patients with portal hypertension represent a diverse group in the ICU. Typically, patients fall into one of two broad categories with respect to their symptoms. The most urgently ill are those with uncontrollable bleeding from esophagogastric varices. The second group, consisting of those with fluid management problems, includes patients with intractable ascites, hydrothorax, or hepatorenal syndrome.

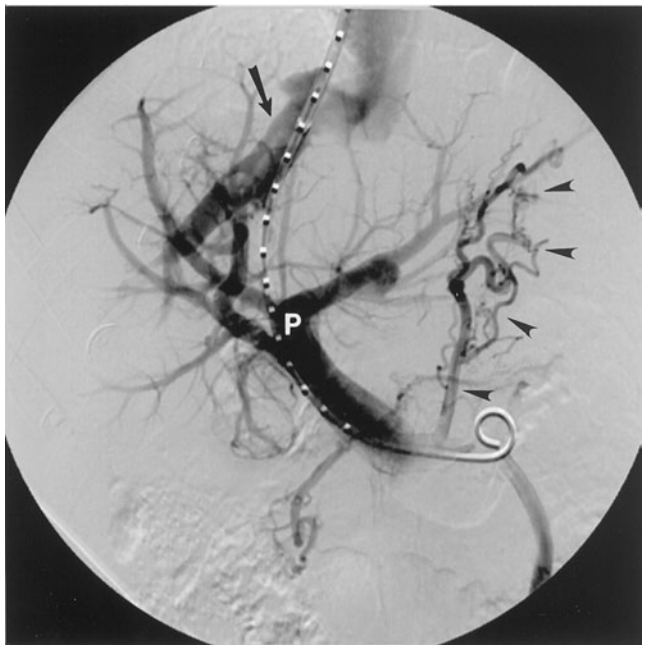
Portal hypertension with variceal bleeding is a special form of upper GI hemorrhage that requires a different approach than arterial bleeding. Endoscopy with sclerotherapy/banding remains the initial diagnostic and therapeutic procedure of choice. However, endoscopic treatment is not always successful, and recurrent bleeding occurs in about 30% to 50% of patients.

Portal hypertension with ascites or hydrothorax typically is managed with diuretics and paracentesis/thoracentesis. However, when the fluid reaccumulates in a short time period requiring frequent repeat percutaneous removal or therapy results in the development of renal failure, electrolyte imbalances, or encephalopathy, alternate therapy may need to be employed.

Historically, the definitive therapeutic intervention was the surgical creation of a shunt from the high-pressure portal system to the central circulation, allowing decompression of the portal system. Interventional radiologists now play a significant role in the treatment of these complex patients with percutaneous creation of transjugular intrahepatic portosystemic shunts (TIPS).[37–41] TIPS is a percutaneous portocaval

shunt through the liver parenchyma connecting a portal vein and a hepatic vein. Its function is identical to a surgically created portosystemic shunt, but morbidity and mortality are reduced markedly with this less invasive alternative.

Indications for TIPS include multiple episodes of esophagogastric variceal hemorrhage refractory to sclerotherapy, presence of gastric varices in the absence of splenic vein thrombosis, intractable ascites, hepatic hydrothorax, hepatorenal syndrome, Budd-Chiari syndrome, and preoperative portal decompression in patients awaiting liver transplantation.



Preprocedure evaluation includes a determination of the indication and urgency for TIPS, review of hepatic imaging, and assessment of patient candidacy. Patients with decompensated portal hypertension typically are very sick, and for some, TIPS will improve their symptomatology and may be lifesaving. However, for others, TIPS may result in fulminant liver failure, new or worsening encephalopathy, or premature death. Several parameters have been used in an attempt to stratify patient risk and predict survival after TIPS. The Child-Pugh classification considers the presence and degree of ascites and encephalopathy, as well as the serum bilirubin and albumin concentrations and the INR. A newer measurement, the MELD score, is a mathematical model based on the serum creatinine and bilirubin concentrations, the INR, and the etiology of the underlying liver disease. Although neither can predict survival with complete accuracy, recent data support that the MELD score is a better predictor of 3-month outcome than the Child-Pugh score[37] and that a MELD risk score less than 1.8 is associated with improved survival.[38]

Fluid resuscitation to treat ongoing bleeding and correction of an existing coagulopathy are critical prior to and during the procedure. For patients with ascites, paracentesis just prior to the procedure can facilitate safe creation of a TIPS. Finally, for some patients, general anesthesia may be necessary and helpful because many of these patients have low baseline blood pressures that preclude sedation at levels necessary to provide patient comfort.

TECHNIQUE

Prior to TIPS placement, it is useful to confirm portal vein patency. This is typically done by US evaluation or other noninvasive imaging but, if necessary, can be determined via superior mesenteric arteriography. In the emergent situation, this preprocedure imaging may not be feasible.

When the decision to perform a TIPS procedure has been made, the patient is transported to the interventional suite. The right internal jugular vein is accessed, and a venous sheath is inserted into the right atrium. The right hepatic vein is catheterized. Wedged hepatic venography typically is performed using carbon dioxide. This gas diffuses rapidly through the liver retrogradely, providing an image of the portal vein and its branches. Using this venogram for guidance, a needle is directed through the hepatic parenchyma into the portal vein. Pressure measurements between the portal vein and the right atrium are obtained, and the portosystemic gradient is calculated. Direct portal venography is then performed to document the anatomy and the presence of varices (Fig. 101-5*A*). The newly created tract is dilated and held open by one or more self-expanding metal stents. After stent placement, pressures are again obtained to confirm reduction of the portosystemic gradient, and venography is performed to document stent patency and assess the degree of variceal filling (see Fig. 101-5*B*). A gradient of less than 12 mm Hg is desired because pressure gradients above this level are associated with recurrent variceal hemorrhage. If initial shunt placement is unsuccessful at reducing the gradient

A

B

FIGURE 101-5 This 40-year-old woman with a history of cirrhosis due to ethanol abuse developed intractable ascites not responsive to medical management. Creation of a transjugular intrahepatic portosystemic shunt (TIPS) was requested. *A*. Initial venography after passage of a needle through the hepatic parenchyma from the right hepatic vein (*arrow*) into a portal vein (*P*) demonstrates filling of varices (*arrowheads*). *B*. Following TIPS creation, contrast agent injection demonstrates brisk flow through the shunt and no filling of the varices.

adequately and varices continue to opacify, variceal embolization with Gianturco coils or ethanol injection can be performed as an adjunct.

IMMEDIATE POSTPROCEDURE CARE

Following portal decompression and stabilization, patients should be monitored carefully for at least 24 hours and should continue to receive any needed blood products. A color duplex US of the shunt, as well as the hepatic and portal veins, should be obtained the following day to assess adequacy of flow through the shunt and to provide a baseline for subsequent follow-up.

RESULTS AND COMPLICATIONS

Technical success of TIPS placement is greater than 90% when the portal vein is patent. TIPS have been created in the presence of a thrombosed portal vein, but technical success rates are lower. Primary shunt patency at 6 months ranges from 75% to 90%,[39,40] with recurrent bleeding occurring in 4% to 17%. A 30-day mortality rate of approximately 15% and a 6-month mortality rate of 30% have been reported. The overall mortality rate varies by the Child-Pugh classification and patient stability at the time of the shunt procedure. A series by Encarnacion and coworkers[41] broke down the cumulative 30-day survival rates for Child-Pugh classes A and B (91%) and class C (71%). These figures compare favorably with surgically placed portosystemic shunts in terms of overall morbidity and mortality and the length of postprocedure survival. In terms of rebleeding, the recurrence rate is lower with TIPS when compared with sclerotherapy. It is, of course, understood that many of the patients undergoing percutaneous shunt creation have failed sclerotherapy.

TIPS creation has been very successful in acutely relieving portal hypertension and variceal bleeding, but shunt stenosis may occur in up to 70%.[40] Routine surveillance with Doppler US is necessary to identify shunt problems requiring further venographic examination and intervention. TIPS venography and revision can be performed on an outpatient basis in most cases.

Complications of TIPS include neck hematoma, liver capsule puncture with or without abdominal hemorrhage, encephalopathy, hemobilia, or worsening liver failure. Occasionally, patients develop multisystem organ failure with no evident source of sepsis. This may emphasize the importance of a functioning liver for the modulation of systemic inflammation.

BRONCHIAL ARTERY EMBOLIZATION

Life-threatening hemoptysis, although uncommon, is associated with an exceedingly high mortality rate (50% to 70%) in patients treated by conservative means (see Chap. 41). Since the early 1970s, interventions in the management of massive hemoptysis have gravitated toward transcatheter embolization. The mortality rate for surgery in the setting of acute hemorrhage remains high (33%). Embolization can act as palliative therapy or can temporize patients until surgery is feasible.[44–47]

INDICATIONS AND PATIENT SELECTION

Massive hemoptysis is defined as bleeding in excess of 300 mL during a 24-hour period. However, smaller amounts may be life threatening due to airway compromise, so intervention may be indicated with lesser amounts of hemorrhage. Bleeding arises from the systemic circulation (bronchial arteries and transpleural collaterals) in about 95% of patients. Chronic inflammatory diseases such as tuberculosis, bronchiectasis, aspergillosis, and cystic fibrosis and neoplastic diseases such as bronchogenic carcinoma all may predispose to bronchial bleeding. In about 5% of patients, hemoptysis relates to lesions of the pulmonary arterial circulation (Rasmussen/mycotic aneurysm or pulmonary arteriovenous fistula). A particular cause of massive hemoptysis in the ICU patient is an iatrogenic injury of the pulmonary artery following pulmonary artery catheter insertion. Both systemic and pulmonary arterial causes of hemoptysis are amenable to transcatheter embolization.

Attempts to localize or lateralize the bleeding to one or more lobes should be undertaken prior to angiography. Chest radiography, chest CT, and/or bronchoscopy can be used. Bronchoscopy has long been considered the primary method of diagnosis and localization, but CT has proven to be very helpful in preprocedure evaluation.[44] CT has higher rates of localization, may detect causative vascular lesions, may suggest a specific diagnosis, and may identify bronchial and nonbronchial systemic feeder arteries.[45,46] Protective measures prior to transport to angiography include insertion of a double-lumen endotracheal tube to allow selective ventilation and protection of the contralateral lung and/or insertion of a balloon occlusion catheter at the bleeding site to tamponade the source until embolization.

TECHNIQUE

As with other complicated vascular diagnostic and therapeutic interventional radiologic procedures, patients must be transported to the angiographic suite for optimal angiographic imaging and intervention.

There is marked variability in bronchial arterial anatomy, so evaluation begins with a nonselective descending thoracic aortogram. After anatomic mapping, selective arteriography is performed in the bronchial artery corresponding to the radiographic and/or bronchoscopic abnormality. In situations where the underlying process is related to chronic inflammation, transpleural collateral vessels from the subclavian, axillary, internal mammary, intercostal, and phrenic arteries may be recruited. Depending on the location of the bleeding site, evaluation of one or more of these potential pathways via selective arteriography may be necessary.

Unlike arteriographic evaluation of GI bleeding, extravasation of contrast material is not identified commonly. Angiography more often will reveal a hypertrophied and abnormal bronchial artery with neovascularity, hypervascularity, aneurysm formation, or shunting of blood into the pulmonary artery or vein. Prior to transcatheter embolization, the diagnostic arteriogram must be reviewed carefully for the presence of arterial branches supplying the spinal cord. This anatomic configuration occurs more commonly on the right, where 90% of patients have a common bronchial-intercostal artery trunk, 5% to 10% of which have branches supplying the spinal cord. Embolization should not be performed if a spinal branch could be embolized inadvertently as well. In some cases, the selective catheter or a coaxial microcatheter can be advanced beyond a spinal branch origin, allowing safe embolization. If no abnormal bronchial or other systemic transpleural collateral source is found, pulmonary arteriography should follow.

For bronchial and nonbronchial systemic sources of massive hemoptysis, polyvinyl alcohol foam (Ivalon) and gelatin sponge (Gelfoam) are the embolic agents used most commonly. In selected cases of hemoptysis secondary to an arteriovenous malformation (AVM) arising from the pulmonary artery, coils or detachable balloons can be used to occlude the large single feeding vessel with good results. This latter situation is seen more commonly in patients with hereditary hemorrhagic telangiectasia, where multiple AVMs may be present.

IMMEDIATE POSTPROCEDURE CARE

As with any embolization procedure performed to treat bleeding, patients should be monitored closely over at least 24 hours for signs of rebleeding. Considering the potential risk of nontarget embolization to the spinal cord, neuromuscular checks should be obtained at frequent intervals following embolization.

RESULTS AND COMPLICATIONS

Bronchial artery embolization for the immediate control of massive hemoptysis is successful in more than 75% of patients, with recurrence of bleeding in approximately 20%.[46,47] In one report, embolization was unsuccessful and hemoptysis continued to death in approximately 9% of patients.[47] Long-term success rates are lower, likely owing in part to progression or continuation of the underlying disease. Recurrent bleeding following embolization may be the result of partial embolization, recanalization, revascularization by collateral channels, inadequate treatment, development of systemic nonbronchial collaterals, or progression of the lung disease. Repeat embolization has been shown to improve outcomes in patients with recurrent hemoptysis, particularly when repeat embolization entails embolization of previously overlooked supplying vessels.[47] It is important to note that bronchial artery embolization should be considered a palliative, not a curative, procedure. It allows time to plan elective surgery or to treat the patient with antimicrobials.

Procedure-related complications of diagnostic arteriography are uncommon but include chest pain due to transient ischemia, temporary dysphagia due to embolization of esophageal branches, and arterial dissection. A rare additional risk is transverse myelitis following contrast agent injection into a spinal artery, particularly ionic agents. The major feared complication of bronchial artery embolization is spinal cord ischemia due to inadvertent embolization of one or more spinal arteries. Careful evaluation for bronchial or intercostal arteries that provide branches to the anterior spinal artery is critical because embolization should be avoided in such situations.

FOREIGN BODY RETRIEVAL AND CATHETER REPOSITIONING

INDICATIONS AND PATIENT SELECTION

ICU patients often require one or more intravascular infusion catheters and/or monitoring devices. On occasion, catheters are malpositioned or fractured and may lodge in the vascular system—usually the central veins, heart, or pulmonary arteries. This typically occurs during catheter introduction or repositioning and rarely is related to a defect in the material itself. Other types of intravascular foreign bodies may include broken pacemaker leads or migrated caval filters.

The presence of an intravascular foreign body usually is an indication for its removal. Complications have been reported in up to 70% of patients in whom catheter fragments were left in place.[48] Major complications of a retained catheter fragment include vascular or cardiac perforation, sepsis, dysrhythmia, and pulmonary embolism. The medicolegal implications also should be considered.

TECHNIQUE

Percutaneous retrieval of the intravascular foreign body is the treatment of choice. It generally can be accomplished without an incision or general anesthesia. The alternative is a major surgical procedure that can pose high risks. Standard monitoring is necessary, with special attention to ECG monitoring given the risk of inducing arrhythmias when manipulating catheters or fragments within the heart.

Access into the vascular system typically is chosen to facilitate easy, minimally traumatic removal. A venogram is performed to confirm the intravascular position of the fragment and to select a suitable site of engagement. A number of retrieval devices are available, but the snare device is selected most commonly. Once the fragment has been engaged and trapped, it is pulled taut and folded on itself so that it can be withdrawn at the venous access site. Rarely, a surgical cutdown is necessary if the fragment is large or not pliable. Alternative retrieval devices include baskets, graspers, and balloon catheters.

A number of maneuvers can redirect malpositioned central venous catheters. When standard replacement is unsuccessful at the patient's bedside, fluoroscopic guidance can facilitate repositioning. Prior to catheter manipulation, venography should be performed to define the anatomy and document any potential problems or occlusions. In many cases, redirection under direct visualization is all that is required. In other cases, the venous system can be entered from a separate site and the end of the catheter snared and pulled into the desired orientation.

RESULTS AND COMPLICATIONS

Percutaneous foreign body retrieval is very effective, with success rates ranging from 80% to 95%.[49] Unsuccessful retrieval often is due to the lack of a free end to grasp, incorporation of the fragment into the vessel wall, or location in an extravascular compartment.

Complications of percutaneous retrieval and catheter repositioning are rare. Transient dysrhythmias can occur during catheter manipulation within the heart. Most resolve by withdrawing all devices from the heart. If the foreign body is firmly adherent to the endothelium, endocardium, or a cardiac valve, traction must be applied gently to avoid vascular damage.

PERCUTANEOUS CAVAL FILTER PLACEMENT

INDICATIONS AND PATIENT SELECTION

Pulmonary embolism is a common cause of morbidity and mortality in the ICU patient. Anticoagulation with intravenous heparin, oral warfarin, or subcutaneous low-molecular-weight heparin remains the first-line therapy for treatment. However, in some patients, anticoagulation is

contraindicated or ineffective. This has led to the development of a number of mechanical devices to "filter" emboli from the pelvis and lower extremities.[50–58]

Until the mid-1980s, these devices required a surgical cutdown in the internal jugular vein owing to the large size of the deployment sheath. In recent years, the profile of caval filters has decreased from 24F (Greenfield filter) to between 6F and 12F, making percutaneous placement feasible. This approach is convenient and can be combined with pulmonary arteriography and/or central venous catheter insertion.

As insertion techniques evolved over the past 10 years, many new devices have been developed. Several excellent reviews of caval filters are available.[51–53] Currently, a number of permanent low-profile caval filters are available for patient use in the United States. These include the Titanium Greenfield, Bird's Nest, VenaTech, Simon Nitinol, TrapEase, Optease, and Gunther tulip vena caval filters.

Temporary or retrievable filters are the newest development in caval filtration devices. Temporary filters remain tethered to a transcutaneous catheter or wire at the insertion site so that early removal can be accomplished to prevent infection. Retrievable filters are designed with a hook at one end that can be engaged using a snare device, allowing removal through a long sheath. The Gunther tulip and TrapEase vena caval filters have been deployed and retrieved successfully, although each is approved by the Food and Drug Administration (FDA) for permanent deployment only, and this represents an off-label use of these products[52,53] (Fig. 101-6). Retrieval within 10 to 14 days of insertion is recommended owing to "endothelialization" of the filter legs and the potential for vein damage with later removal. Venography is required at the time of retrieval to ensure the absence of thrombus within or around the filter because removal of the filter would result in dislodgment of this clot and pulmonary embolism.

Indications for caval filter placement generally fall into three categories: (1) contraindication to or complication of anticoagulation in a patient with documented pulmonary emboli, (2) recurrent pulmonary embolism despite anticoagulation, and (3) prophylaxis. Although the first two are well-accepted indications, prophylaxis is controversial.[53] Indications for prophylactic vena caval interruption have become more liberal as the procedure has become simpler and safer and retrievable filters have been developed. Nevertheless, many physicians remain unfamiliar with filter placement or consider it too invasive for common use. Caval filtration is greatly underused in the management of critically ill patients.

Prophylactic filter placement (in addition to heparin therapy) is warranted in patients with proven venous thromboembolism and cardiovascular compromise or severe chronic obstructive pulmonary disease, as well as in all patients with free-floating pelvic thrombi. In addition, prophylactic caval filter placement should be considered in certain high-risk surgical (orthopedic, trauma, neurosurgical) and oncology patients. If retrievable filters become more accepted and gain FDA approval, prophylactic filter placement may become more common.

TECHNIQUE

Inferior vena caval filter placement generally requires transport to the interventional radiology suite. Rarely, in highly unstable patients, filter placement may be done at the bedside with portable fluoroscopy equipment. However, the lack of high-quality fluoroscopy equipment makes performance of an adequate inferior vena cavagram difficult (see below).

The femoral approach generally is preferred for percutaneous caval filter placement because it is easily accessible. The internal jugular approach may have advantages in patients with extensive pelvic and caval thrombosis, tortuous iliac veins, or multiple femoral lines.

An inferior vena cavagram should be performed before filter deployment to demonstrate the level of the renal veins, the presence of thrombus in the inferior vena cava, the diameter of the inferior vena cava, and the presence of congenital venous anomalies. After the inferior vena cavagram is performed, the puncture site is dilated to a suitable size, and a sheath is placed. The filter is introduced through the sheath and discharged below the renal veins. Infrarenal placement is preferred to maintain renal vein patency in the event of caval thrombosis. If thrombus extends to the level of the renal veins, suprarenal filter placement may be used.[53] A follow-up cavagram is done to document filter placement.

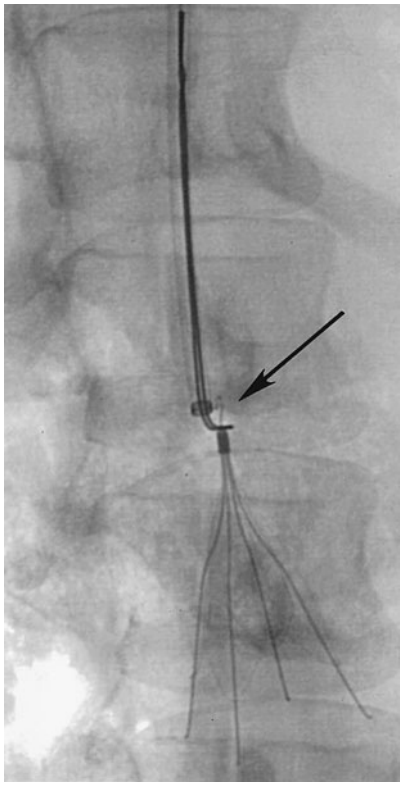
IMMEDIATE POSTPROCEDURE CARE

The patient should be kept at bed rest with close observation of the puncture site for 4 to 6 hours. If indicated, heparin can be restarted immediately after local hemostasis is obtained. Continued heparin therapy can be helpful to prevent extension of thrombus in the legs or pelvis.

RESULTS AND COMPLICATIONS

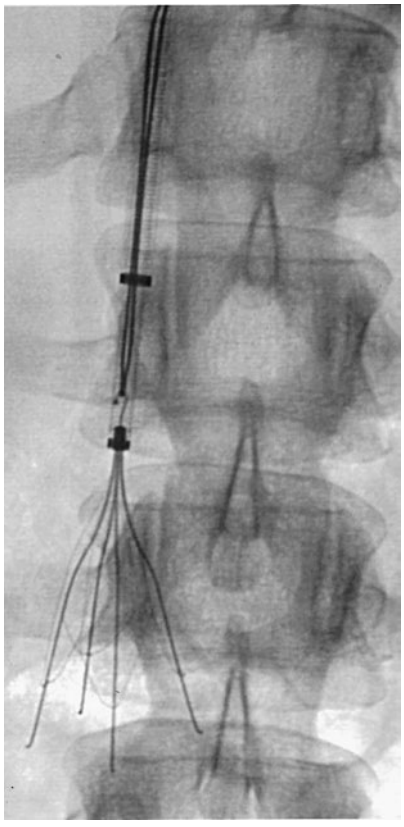
The reported rate of recurrent pulmonary emboli varies with each particular filter design but ranges from 0.5% to 3%. In most cases, however, documentation of recurrent pulmonary emboli is difficult to obtain.

Complications of inferior vena cava filter placement include caval thrombosis, filter migration, and trauma at the insertion site. Caval thrombosis varies with filter design and ranges from 2% to 9%. In recent years, the currently available filters have been modified such that filter migration is a rare event.



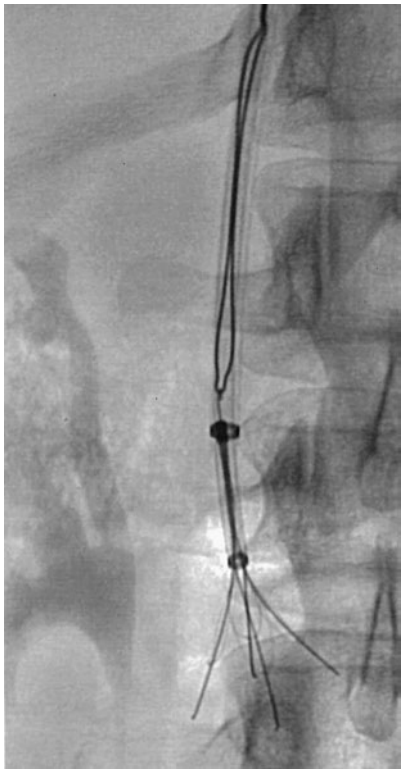
A potential complication with the percutaneous approach is puncture-site thrombosis. Significant access-site thrombosis with the newer low-profile filters ranges from 2% to 10%, with an overall (nonocclusive and occlusive) thrombosis frequency of up to 35%. Between 4% and 6% of patients display clinical symptoms.[58]

CATHETER-DIRECTED FIBRINOLYTIC THERAPY



Local catheter-directed fibrinolytic therapy is an important addition to the nonsurgical treatment of acute and subacute arterial occlusion. Catheter-directed fibrinolytic infusions infuse the thrombus directly and therefore concentrate the fibrinolytic agent's action at the site of the vascular occlusion. This is favored over systemic therapy because it permits lower doses and minimizes systemic side effects.[59–64]

INDICATIONS AND PATIENT SELECTION



Catheter-directed fibrinolytic therapy achieves the best results with acute thrombosis. Therefore, the best indication is thrombosis that occurs during angiography or angioplasty. The arterial catheter is already in place, and the clot is fresh.

D

FIGURE 101-6 Retrieval of a Gunther tulip inferior vena caval filter. ***A.*** **Fluoroscopy demonstrates a long vascular sheath through which a snare device is used to engage the hook of the filter (*arrow*).** ***B.*** **The hook is engaged and the sheath advanced over the snare and hook.** ***C.*** **As the sheath is further advanced over the filter, the legs collapse and pull away from the vessel wall.** ***D.*** **The filter is covered with fibrinous debris and blood clot.**

Fibrinolytic therapy also is beneficial in native-artery and bypass-graft occlusions. Thrombosis in these cases usually is a manifestation of underlying stenotic disease. Frequently, these stenoses can be treated with interventional radiologic techniques such as angioplasty, sparing the patient a surgical bypass. Although the exact age of the clot can be difficult to determine, best results are seen with occlusions that are less than 6 to 10 weeks old.

Another indication for fibrinolytic therapy is embolic occlusion. In large-vessel emboli (e.g., femoral or brachial artery), a surgical Fogarty embolectomy is extremely effective. Small-vessel emboli, however, are difficult to remove mechanically owing to vessel size, so catheter-directed fibrinolysis frequently is the best treatment available.

Despite the effectiveness of fibrinolytic therapy, not all patients are candidates. Patients with acute thrombosis and limb-threatening ischemia should be treated with surgery because catheter-directed thrombolysis is a slow process, requiring 12 or more hours of treatment for reperfusion. In addition, although the fibrinolytic agent is directed into the clot, a significant amount of it enters the systemic circulation as it diffuses through the clot. Therefore, patients at risk of significant bleeding are not candidates. Specifically, contraindications to thrombolysis include recent intracranial, thoracic, or abdominal surgery; recent GI bleeding; recent stroke or known intracranial neoplasm; recent major trauma; current pregnancy; severe hypertension; known bleeding diathesis; and infected thrombus.

TECHNIQUE

In catheter-directed fibrinolytic therapy, the goal is to deliver the drug directly into the thrombus in order to activate plasminogen bound to the fibrin clot directly without activating significant amounts of circulating plasminogen. Various coaxial catheters and multisidehole catheters are available that allow maximum permeation of the fibrinolytic agent into the thrombus. Typically, the infusion catheter is placed through an arterial sheath that facilitates the catheter exchanges necessary for repeat arteriograms.

After a complete diagnostic arteriogram, a multisidehole catheter is embedded into the thrombus and the infusion started. Traditionally, urokinase was the agent of choice. However, when sales of urokinase were suspended in 1998 owing to production problems, several other fibrinolytic agents, including tissue-type plasminogen activator (t-PA) and recombinant tissue-type plasminogen activator (rt-PA), became more widely used. Streptokinase, the first lytic agent used, is currently in disfavor because of its antigenicity and inferior results in clinical studies.[60] Although urokinase has now returned to the American market, its use remains limited in some areas because of cost.

No standard doses for these agents have been agreed on. Most involve a steady infusion over a period of hours with or without a loading dose. For urokinase, a typical protocol is to lace the clot with 250,000 units and then initiate infusion with 250,000 units/h for 2 hours. After the initial high-dose infusion, the dose is decreased to 80,000 to 100,000 units/h for the duration of the therapy, which may last up to 24 to 36 hours. A recent review of rt-PA indicates that protocols for rt-PA have been more variable, with both weight-based and non-weight-based dosing, dosing with or without an initial bolus, and/or the use of high-dose short-duration pulse-spray thrombolysis.[59] Typical doses range from 0.02 to 0.1 mg/kg per hour for weight-based and 0.25 to 10 mg/h for non-weight-based regimens to a maximum of 100 mg.

IMMEDIATE POSTPROCEDURE CARE

Patients undergoing catheter-directed fibrinolytic infusions are placed in the ICU. The puncture site, the affected extremity, and the patient's bleeding parameters are monitored frequently. Patients are kept at strict bed rest, with frequent Doppler examinations of the ischemic extremity.

Low-dose intravenous heparin (500 to 1000 units/h) is frequently instilled through a sheath to decrease the incidence of pericatheter thrombosis (see below). Anticoagulation with heparin also is helpful to prevent rebound thrombosis after the fibrinolytic infusion is completed.

Laboratory monitoring tests should include baseline fibrinogen, partial thromboplastin time, and hematocrit. Every 4 hours, the fibrinogen level should be checked to monitor for systemic effects of the fibrinolytic agent. If the fibrinogen level falls below 100 mg/dL, the infusion should be slowed or discontinued. Experience has shown that a fibrinogen level below 100 mg/dL is associated with a significantly increased incidence of remote bleeding.[60] However, fibrinogen levels rarely fall this low during catheter-directed urokinase infusions.

Periodic angiographic follow-up is essential and must be performed in the angiographic suite. High-quality fluoroscopic observation is necessary to evaluate progression of lysis. Frequently, the position of the catheter must be changed to keep it embedded in clot.

Successful lysis generally is achieved after 12 to 18 hours of infusion. At that point, underlying stenotic lesions are treated with angioplasty, and the catheter is removed. If no progress is noted over 6 to 12 hours, the infusion is stopped. It is critical that all decisions regarding institution of fibrinolytic therapy, continuation of the therapy, and termination of the infusion be made in conjunction with the vascular surgeon caring for the patient.

RESULTS AND COMPLICATIONS

A successful fibrinolytic infusion generally is one that yields either complete lysis or lysis with significant clinical improvement. Success rates reported in the literature vary from 40% to 90%, with an average of 60% to 70%[61,62] Comparison of various series and fibrinolytic agents is extremely difficult because of heterogeneous patient populations and protocols. Several studies, however, have evaluated the effectiveness of catheter-directed fibrinolysis versus surgery. The Rochester study found similar limb salvage rates for both groups (82%) but improved overall survival in the thrombolysis group at 1 year (84% versus 58% for surgery, $p = 0.01$).[63] The Surgery versus Thrombolysis for Ischemia of the Lower Extremity (STILE) trial comparing thrombolysis (urokinase or rt-PA) and surgery found no difference in morbidity or mortality between the two groups based on intent to treat but noted better amputation-free survival for the thrombolysis patients at 6 months (85% versus 62% for surgery, $p = 0.01$) and reduction in the extent of surgery needed for patients with acute limb ischemia, whereas patients with chronic limb ischemia had lower amputation rates with surgery (4% versus 14% for lysis).[47] Generally, success correlates best with age of the thrombus and status of the distal runoff vessels.

Complications are related primarily to bleeding. Most bleeding occurs at arterial puncture sites and is relatively minor. However, life-threatening bleeding at remote sites (intracranial, gastrointestinal, retroperitoneal) has been reported and can result in significant morbidity. When serious bleeding occurs, therapy should be discontinued unless the bleeding can be controlled by manual compression. Fresh frozen plasma can be given to replace coagulation factors. Significant bleeding generally is reported in 10% to 12% of patients. The risk of bleeding increases with the length of infusion, so the duration of the infusion should be kept under 24 hours if possible. In addition, bleeding risk increases when fibrinogen levels drop below 100 mg/dL, and the infusion should be reduced or stopped if levels fall. Finally, the use of systemic heparin adds to the risk of bleeding. Therefore, the partial thromboplastin time should be monitored carefully when concomitant heparin therapy is given.

Patients may experience dramatic worsening of their ischemic symptoms during the fibrinolytic infusion. This "trashing" of the extremity is usually due to fragmentation of the thrombus and distal embolization. Generally, the symptoms will resolve rapidly by continuing the fibrinolytic infusion and treating the patient with narcotic analgesia. Surgery usually is ineffective for such embolization. However, if significant clinical deterioration persists longer than an hour, angiography should be repeated, and emergent surgery should be considered.

Pericatheter thrombosis is an occasional problem that usually is caused by poor blood flow along the path of the catheter. To prevent this, the intravascular length of catheter must be kept to a minimum, and the smallest possible catheter system should be used. Pericatheter thrombosis can be minimized by using low-dose systemic heparin.

Chapter 102

TOXICOLOGY IN ADULTS

THOMAS CORBRIDGE
PATRICK MURRAY
BABAK MOKHLESI

KEY POINTS

General Measures

- *Supportive measures supercede other considerations in the management of the poisoned patient. After addressing the ABCDs of life support, the focus can switch to confirmation of intoxication and targeted therapy.*
- *Administer a "cocktail" of oxygen, dextrose, thiamine, and naloxone to patients with depressed mental status.*
- *An increase in anion gap, osmolal gap, or arterial saturation gap should raise the suspicion of intoxication.*
- *An osmolal gap of large magnitude (>25 mOsm) suggests methanol or ethylene glycol poisoning; however, serious intoxication with either agent can occur without increasing the osmolal gap. Serum levels of these alcohols should be measured when clinical features are suggestive.*
- *Carbon monoxide and methemoglobin elevate the arterial oxygen saturation gap. These toxins interfere with oxygen binding to hemoglobin and decrease oxygen content without lowering the Pa_{O_2}. Oxygen saturation measured by pulse oximetry is falsely high in this setting.*
- *Toxicology screening can provide direct evidence of intoxication, but it rarely impacts initial management.*
- *Poison control center consultation is advised to determine appropriate laboratory testing and patient disposition and treatment. The emergency phone number is 1-800-222-1222.*
- *Gastric lavage only improves outcome in obtunded patients if performed within 1 hour of ingestion (this time may be extended in poisonings that delay gastric emptying). Risks of lavage preclude its use in nontoxic ingestions, subtoxic amounts of a toxic ingestion, ingestion of caustic liquids, and when the toxin is no longer expected to be in the stomach. The airway must be protected prior to lavage.*
- *Activated charcoal should be administered for most oral ingestions after the airway has been protected.*
- *Whole-bowel irrigation with a polyethylene glycol electrolyte solution is indicated for iron overdose, ingestion of sustained-release tablets, and "body packing" with illicit drugs.*
- *Urinary alkalinization enhances excretion of nonpolar weak acids. Urinary acidification augments excretion of nonpolar weak bases, but is generally not recommended.*

Acetaminophen

- *All overdose cases should be screened for acetaminophen poisoning.*
- *The antidote, n-acetylcysteine (NAC), should be started within 8 hours of ingestion to decrease the risk of hepatotoxicity. The Rumack-Matthew nomogram allows for stratification of selected patients into categories of probable, possible, and no hepatic toxicity.*

Alcohols

- *Metabolic acidosis with an elevated anion gap and/or the presence of an osmolal gap are classic in methanol and ethylene glycol poisoning.*
- *Features of methanol poisoning include inebriation, optic papillitis, and pancreatitis. Treatment with fomepizole or ethanol inhibits metabolism by alcohol dehydrogenase to the toxic metabolite formic acid. Dialysis is indicated in severe cases.*
- *Features of ethylene glycol poisoning include inebriation, acute renal failure, crystalluria, and myocardial dysfunction.*
- *Treatment with fomepizole or ethanol inhibits metabolism by alcohol dehydrogenase to toxic metabolites (oxalic and glycolic acids). Dialytic removal of ethylene glycol and its metabolites is indicated in severe poisonings.*
- *Isopropanol causes hemorrhagic gastritis, ketonemia, and ketonuria, but not acidosis. Fomepizole and ethanol are not indicated because metabolites are nontoxic. Dialysis is effective in severe cases.*

Barbiturates

- *Hypothermia, hypotension, bradycardia, flaccidity, hyporeflexia, coma, and apnea are features of barbiturate overdose. Severe overdose can mimic death.*
- *Supportive measures include gastric emptying and activated charcoal. Alkalinization of the urine increases elimination of phenobarbital, but not other barbiturates, and may aggravate pulmonary edema. Of disputed importance, hemoperfusion may be considered in severe cases.*

Benzodiazepines

- *Supportive measures, gastric emptying, activated charcoal, and flumazenil treat benzodiazepine overdose.*
- *Flumazenil reverses sedation but may increase the toxicity of coingested drugs. Flumazenil should be avoided in patients taking benzodiazepines therapeutically and in benzodiazepine-addicted patients.*
- *There is no role for forced diuresis, dialysis, or hemoperfusion in benzodiazepine overdose.*

Beta-Blockers

- *Cardiovascular manifestations of overdose are treated with fluids, vasopressors, atropine, electrical pacing, and glucagon.*
- *Glucagon effectively reverses myocardial depression and bradycardia.*

Calcium Channel Blockers

- *Hypotension is treated first with fluids and calcium chloride. Glucagon may decrease vasopressor requirements.*

Carbon Monoxide

- *Exposure to smoke, poorly ventilated charcoal or gas heaters, and automobile exhaust are responsible for most poisonings.*
- *Carbon monoxide poisoning can present with myocardial ischemia, arrhythmias, mental status changes, headache, and generalized weakness.*
- *Prompt oxygen therapy is crucial.*

Copyright © 2005, 1998, 1992 by The McGraw-Hill Companies, Inc. Click here for terms of use.

- *Pulse oximetry is unreliable in detecting carboxyhemoglobin; pulse oximetry overestimates oxyhemoglobin by the amount of carboxyhemoglobin present; saturation by pulse oximetry may be normal despite elevated carboxyhemoglobin.*
- *The use of hyperbaric oxygen is controversial. Patients with potentially life-threatening exposures should receive hyperbaric therapy if it is readily available and other life-threatening conditions do not preclude its use.*
- *Delayed neurologic sequelae may occur in survivors.*

Cocaine

- *Cocaine is often mixed with other substances of abuse.*
- *Cocaine causes acute coronary syndromes, hypertensive crisis, seizures, rhabdomyolysis, intracranial hemorrhage, pneumomediastinum, and respiratory failure.*
- *Agitation and hyperthermia should be treated rapidly with benzodiazepines and cooling strategies. Paralysis is occasionally required.*
- *Benzodiazepines are first-line therapy for hypertensive crisis. Refractory patients should receive an α-adrenergic antagonist. Nonselective β-blockers (eg, propranolol) should not be used alone to treat hypertension because of the potential for unopposed α-adrenergic stimulation. Labetalol is controversial. Selective β-blockers do not aggravate hypertension but may cause hypotension.*
- *Acute coronary syndromes should be treated with nitrates and benzodiazepines. Refractory patients should receive α-adrenergic antagonists. Nonselective β-blockers are contraindicated; selective β-blockers do not aggravate hypertension, but may induce hypotension.*

Cyanide

- *Features of cyanide poisoning depend on the amount and rate of cyanide absorption. Patients who are asymptomatic after inhalation generally do not require treatment. Oral ingestion causes progressive symptoms over minutes to hours.*
- *Sodium nitroprusside infusions can cause cyanide and thiocyanate poisoning.*
- *Symptoms include anxiety, dyspnea, headache, confusion, tachycardia, and hypertension. High concentrations of cyanide cause stupor or coma, seizures, fixed and dilated pupils, hypoventilation, hypotension, arrhythmias, and cardiopulmonary collapse.*
- *In addition to supportive measures and oxygen, several antidotes are available: amyl and sodium nitrite, sodium thiosulfate, hydroxycobalamin, and dicobalt ethylenediamine tetraacetic acid (EDTA).*

Cyclic Antidepressants

- *Patients with anticholinergic, neurologic, or cardiac toxicity (including QRS prolongation ≥100 ms) require monitoring.*
- *Neurologic deterioration is often abrupt and unpredictable.*
- *Acidemia potentiates toxicity. Therapeutic alkalemia with sodium bicarbonate or hyperventilation is beneficial.*
- *Lidocaine should be used for ventricular arrhythmias resistant to sodium bicarbonate. Procainamide is contraindicated.*

Digoxin

- *Features of digitalis intoxication include fatigue, gastrointestinal symptoms, neurologic disturbances (blurred vision, visual color changes, headache, dizziness, and delirium), and cardiac arrhythmias (supraventricular tachycardia with AV block). Significant overdose may cause hyperkalemia.*
- *Supportive therapy includes rapid correction of arrhythmogenic metabolic disturbances, particularly hypokalemia if present. Hyperkalemia requires treatment unless Fab therapy is immediately available.*
- *Immunotherapy with digoxin-specific antibody Fab fragments is indicated for severe intoxications.*
- *Gastrointestinal decontamination measures include gastric lavage and activated charcoal. Hemodialysis removes only small amounts of total body digitalis, but may be indicated for correction of hyperkalemia or other acid-base derangements in renally impaired patients.*
- *Electrical cardioversion of a digitalis toxicity–induced arrhythmia should be reserved as a last resort, using the minimum effective energy level.*

Gamma Hydroxybutyrate

- *Depressed mental status, emesis, bradycardia, hypotension, and respiratory depression are features of GHB overdose.*
- *Treatment is mainly supportive.*
- *In cases of alleged sexual assault, GHB can be identified by analysis of hair, blood, and urine in selected laboratories.*

Lithium

- *Most cases of intoxication, associated with levels above 1.5 mEq/L, are caused by unintentional overdose during chronic therapy.*
- *High levels of lithium decrease the anion gap.*
- *Severe poisoning causes coma, seizures, and cardiovascular instability.*
- *Treatment includes seizure control and vasopressors for hypotension refractory to fluids. Gastric emptying should be performed initially. Oral charcoal is of little benefit. Whole-bowel irrigation is important with sustained-release preparations.*
- *Lithium is the prototypical dialyzable intoxicant.*

Methemoglobinemia

- *Hereditary methemoglobinemia (e.g., hemoglobin M or cytochrome* b5 *reductase deficiency) is generally insignificant and does not require treatment. Acquired and potentially life-threatening methemoglobinemia can occur after oxidant drug or toxin exposure.*
- *Methemoglobinemia decreases oxyhemoglobin saturation and blood oxygen carrying capacity by decreasing available hemoglobin and shifting the oxyhemoglobin dissociation curve to the left.*
- *Symptoms of moderate methemoglobinemia include dyspnea, headache, and weakness. Confusion, seizures, and death can occur with levels >60%.*
- *Co-oximetry measures methemoglobin saturation. Standard pulse oximetry registers falsely high in patients with methemoglobinemia. Arterial blood gases typically demonstrate a normal Pa_{O_2} and a normal calculated oxygen saturation.*
- *Treatment of methemoglobinemia consists of oxygen, methylene blue, and exchange transfusion.*

Opioids

- *The triad of miosis, respiratory depression, and coma suggests opioid intoxication.*
- *Naloxone reverses sedation, hypotension, and respiratory depression. The initial dose is 0.4 mg IV or 0.8 mg IM or SC. Lower doses should be given to opioid-dependent patients and when there is a concurrent stimulant overdose. Larger initial doses may be required when there is abuse of naloxone-resistant opioids. Lack of response to 6 to 10 mg of naloxone generally excludes opioid toxicity.*

Organophosphate and Carbamate Insecticides

- *Organophosphates are irreversible inhibitors of acetylcholinesterase (AChE); carbamates reversibly inhibit AChE.*
- *Signs of cholinergic poisoning include* s*alivation,* l*acrimation,* u*rination,* d*iarrhea,* g*astrointestinal cramping and* e*mesis (SLUDGE). Muscle fasciculations, coma, and seizures also occur.*
- *Respiratory failure results from muscle weakness, bronchorrhea, depressed respiratory drive, and bronchoconstriction.*
- *The level of red blood cell cholinesterase helps diagnose organophosphate poisoning.*
- *Treatment includes supportive measures, atropine, and oximes.*

Phencyclidine

- *PCP intoxication incites bizarre behavior, violence, agitation, euphoria, and lethargy, as well as stupor and coma that may last for days. Additional features include fever, tachycardia, hypertension, leukocytosis, renal failure, intracranial hemorrhage, and rhabdomyolysis.*
- *Pinpoint pupils in an agitated patient suggests PCP intoxication.*
- *Haloperidol is the drug of choice to treat PCP psychosis. Benzodiazepines expedite control of the difficult patient.*

Salicylates

- *The Done nomogram for predicting salicylate toxicity is of limited use in current practice.*
- *Salicylate poisoning causes respiratory alkalosis and metabolic acidosis; the latter is more prominent in children.*
- *Manifestations of chronic ingestion may be subtle and occur at relatively low serum salicylate levels.*
- *Acidemia favors tissue penetration of salicylates; urinary alkalinization enhances renal clearance; hypokalemia must be corrected to succeed in urinary alkalinization; carbonic anhydrase inhibitors should not be used to alkalinize urine.*
- *Seizures, coma, refractory acidosis, and high serum salicylate levels are indications for hemodialysis.*

Selective Serotonin Reuptake Inhibitors

- *In combination with a number of drugs, SSRIs may cause serotonin syndrome. Toxic combinations may not be evident for days to weeks.*
- *Features of serotonin syndrome include confusion, agitation, shivering, flushing, hyperthermia, tachycardia, disseminated intravascular coagulation, convulsions, coma, muscle rigidity, myoclonus, hyperreflexia, involuntary movements, autonomic instability, nausea, diarrhea, orthostatic hypotension, rhabdomyolysis, hyponatremia, and SIADH. Trazodone, which is also an α-adrenergic blocker, causes hypotension.*
- *Treatment is supportive. Gastric emptying and activated charcoal are effective. Serotonin antagonists have not been studied adequately in controlled trials.*

Theophylline

- *Clinical features of theophylline toxicity are cardiovascular, metabolic, and neurologic.*
- *Tachyarrhythmias are common at plasma levels >20 mg/L.*
- *Metabolic abnormalities include hypokalemia, hypomagnesemia, hyperglycemia, hypophosphatemia, hypercalcemia, and respiratory alkalosis.*
- *Uncontrolled seizures cause hyperthermia and rhabdomyolysis.*
- *For any plasma level, chronic intoxication causes more severe clinical sequelae.*
- *Extracorporeal removal by "in-series" hemodialysis and hemoperfusion is indicated for severe intoxications.*

Envenomations

- *The majority of poisonous snake bites in the United States involve the Crotalidae or pit viper family of snakes (e.g., rattlesnakes, copperheads, and water moccasins).*
- *Treatment of rattlesnake bite consists of immobilizing the bitten extremity and placing a loose-fitting tourniquet proximal to the bite to impede venom spread. Surgical consultation may be required for local wound management.*
- *Unstable patients should be treated with equine Crotalidae antivenin.*
- *In North America, only the widow spiders (*Latrodectus *species) and the recluse spiders (*Loxosceles *species) are medically important.*
- *Features of black widow spider bite include local pain and erythema followed by muscle cramps and fasciculations that may generalize to the abdomen, back, and chest. Hypertension, tachycardia, tremor, fever, agitation, diaphoresis, and nausea are common.*
- *Treatment of black widow spider bite consists of supportive measures, analgesia, calcium, methocarbamol, and in severe cases, equine-derived antivenin.*
- *Recluse spider bite (loxoscelism) is characterized by localized swelling, erythema, and formation of bullae, often forming a "bull's eye" lesion with central necrosis. Some patients develop fever, myalgias, headache, and nausea. Rare patients develop intravascular hemolysis, disseminated intravascular coagulopathy, acute renal failure, and the acute respiratory distress syndrome. Treatment is supportive; antivenin is not available.*

In their 2001 annual report, the American Association of Poison Control Centers reported 2,267,979 human toxic exposure cases. Three percent of these cases, or more than 69,000 patients, required critical care. There were 1074 fatalities, occurring most commonly after intentional overdose.[1]

Intentional overdose or accidental exposure may be the chief complaint at the time of emergency department evaluation, but not all patients provide this information, particularly when toxin or trauma clouds mental status. In these cases signs and symptoms may be attributed to another

disorder and poisoning remains obscure. In hospital, inappropriate drug dosing or unforeseen drug interactions may lead to toxic side effects.

Classic features of overdose, referred to as a toxidrome, help establish a diagnosis, but signs and symptoms may be nonspecific or lacking altogether, as in the early stages of acetaminophen overdose. The protean manifestations of intoxication mandate a high index of suspicion in critically ill patients.

Treatment of the poisoned patient often occurs before a diagnosis has been established. Most important in this regard are standard supportive measures. The ABCDs (airway, breathing, circulation, and differential diagnosis) come first while efforts ensue to confirm intoxication and initiate targeted therapy.

In this chapter we will review (1) initial supportive efforts, (2) diagnosis of poisoning and drug overdose, (3) techniques to limit drug absorption and enhance drug elimination, and (4) specific treatments of the most commonly encountered drugs, toxins, and envenomations seen in the intensive care unit.

Initial Supportive Measures

Primary physician responsibilities are to identify and treat life-threatening problems. The ABCDs of life support should be addressed as in any medically unstable patient, but for the first time, the 2000 version of the American Heart Association guidelines included a separate section on resuscitating the poisoned patient.[2] Recommendations provided in these guidelines are discussed in this chapter.

With cervical spine precautions in place (unless trauma has been reasonably excluded) airway patency must be established. In obtunded patients, obstruction by the tongue is treated initially with a jaw-thrust maneuver, followed by either placement of an oral airway, nasal trumpet, or endotracheal tube. The choice of airway depends on the level of obtundation, the vigor of protective reflexes, the degree of respiratory depression, and initial response to pharmacologic therapy (Table 102-1). In nonintubated patients, the left side down, head-down position allows the tongue to drop forward and decreases risk of aspiration of oral secretions and stomach contents.

Patients with an adequate airway and intact protective reflexes may not require intubation (even if they are lethargic), particularly if treatment improves mental status. Intubation is indicated when a patient is unable to protect the airway or maintain respirations. Intubation protects the airway and decreases but does not eliminate the risk of aspiration, which occurs in approximately 11% of comatose patients with drug overdose.[3–5] Intubation further allows for administration of high concentrations of oxygen and assisted ventilation.

Selected causes of hypoxemia in drug overdose and toxic ingestion are listed in Table 102-2. Hypoxemia must be corrected quickly to avoid anoxic brain injury, myocardial ischemia, and arrhythmias. In some poisonings (eg, carbon monoxide, cyanide, and methemoglobinemia), a fraction of inspired oxygen ($F_{I_{O_2}}$) of 1.0 is therapeutic, whereas in paraquat poisoning and bleomycin toxicity oxygen potentiates lung injury.

The clinician should choose a ventilator mode with which she or he is familiar and which achieves the greatest degree of synchrony between patient and machine. The initial ventilator mode should provide adequate back-up minute ventilation (which can be achieved with either assist control or synchronized intermittent mandatory ventilation). If intubation is performed solely to protect the airway or to provide supplemental oxygen, the endotracheal tube may be connected to a T-tube. Positive end-expiratory pressure (PEEP) recruits atelectatic and fluid-filled alveoli and may decrease ventilator-induced lung injury in selected patients. PEEP should be used cautiously in hypotensive patients to avoid decreasing cardiac preload. Low levels of pressure support ventilation (5 to 8 cm H_2O) help overcome endotracheal tube resistance and may decrease inspiratory work of breathing.

Circulatory manifestations of drug overdose are common and varied. Bradycardia and/or atrioventricular (AV) block can result from cholinergic excess (e.g., with organophosphate, carbamate, physostigmine, and digoxin toxicity), sympatholytic drugs (e.g., β-blockers, clonidine, and opioids), membrane-depressant agents (e.g., type 1a and 1c antiarrhythmic drugs, quinidine, and cyclic antidepressants), calcium channel blockers, and lithium overdose (Table 102-3). Bradycardia can also occur from a reflex response to

TABLE 102-1 Initial Pharmacologic Treatment of Patients with Altered Mental Status

Drug	Dose	Comment
Oxygen	Titrate to Sp_{O_2} >92%; $F_{I_{O_2}}$ 1.0 for carbon monoxide and cyanide toxicity	Oxygen may increase risk of pulmonary toxicity in paraquat intoxication
Dextrose	50 mg IV	Antidote for oral hypoglycemic or insulin overdose
Thiamine	100 mg IV	Used to prevent Wernicke encephalopathy; rare anaphylactoid reactions have been reported
Naloxone	0.2–0.4 mg IV initial dose; if no clinical response after 2–3 minutes, an additional 1–2 mg IV may be administered to a total dose of 10 mg; higher doses may be required in meperidine or propoxyphene overdose; in opioid-addicted patients, lower doses (0.1–0.2mg) may help without causing drug withdrawal	Short duration of action (approximately 20–60 minutes) requires repeat dosing or continuous infusion

TABLE 102-2 Selected Causes of Hypoxemia in Drug Overdose and Toxic Ingestion

Cause	Drugs/Toxins
Hypoventilation	Alcohols
	Barbiturates
	Benzodiazepines
	Botulinum toxin
	Cyclic antidepressants
	Neuromuscular blockade
	Opioids
	Sedative-hypnotics
	Snake bite
	Strychnine
	Tetanus
Aspiration	Drugs/toxins depressing mental status
Pneumonia	Drugs resulting in aspiration; IV drug abuse with pulmonary seeding of infectious agents; Inhalation injury interfering with lung protective mechanisms
Cardiogenic pulmonary edema	Antiarrhythmics
	β-Blockers
	Cyclic antidepressants
	Verapamil
Inert gases	Methane
	Nitrogen
	Propane
Noncardiogenic pulmonary edema	Cocaine
	Ethylene glycol
	Hydrocarbons
	Inhalation injury
	Opioids
	Phosgene
	Paraquat
	Salicylates
Bronchospasm	β-Blockers Cocaine Heroin
	Organophosphates
	Drugs resulting in aspiration
	Drugs associated with myocardial depression (cardiac asthma)
Alveolar hemorrhage	Cocaine
Pneumothorax	Cocaine
	IV drug abuse with aberrant venipuncture or bullous lung disease
Cellular hypoxia	Carbon monoxide
	Cyanide
	Hydrogen sulfide
	Methemoglobinemia
	Sulfhemoglobinemia

TABLE 102-3 Selected Drugs/Toxins Causing Tachycardia and Bradycardia

Tachycardia	Bradycardia
Amphetamines	Antiarrhythmics (types 1a and 1c)
Anticholinergics	β-Blockers
Antihistamines	Calcium channel blockers
Caffeine	Carbamates
Carbon monoxide	Clonidine
Clonidine	Cyclic antidepressants
Cocaine	Digoxin
Cyanide	Lithium
Cyclic antidepressants	Metoclopramide
Drug withdrawal	Opioids
Ephedrine	Organophosphates
Hydralazine	Phenylpropanolamine
Hydrogen sulfide	Physostigmine
Methemoglobinemia	Propoxyphene
Phencyclidine (PCP)	Quinidine
Phenothiazines	
Pseudoephedrine	
Theophylline	
Thyroid hormone overdose	

α-adrenergic-induced hypertension (e.g., phenylpropanola mine).

The differential diagnosis of bradycardia includes hypoxemia, myocardial infarction, hyperkalemia, hypothermia, hypothyroidism, and intracranial hypertension. If bradycardia persists despite correction of hypoxemia or hypothermia and is hemodynamically significant, atropine 0.5 to 1.0 mg IV should be given and repeated every 5 to 10 minutes until a therapeutic response has been achieved or adverse drug effects appear. Three milligrams of atropine is fully vagolytic, so further administration of atropine beyond this dose is unlikely to be beneficial. An exception to this tenet is cholinergic poisoning, in which extremely high doses of atropine may be required to increase heart rate and dry secretions. In selected overdoses, antidotes are available for treatment of bradycardia: calcium chloride for calcium channel blocker toxicity; glucagon in β-blocker overdose; sodium bicarbonate in cyclic antidepressant overdose; naloxone in opioid overdose; and digoxin-specific antibodies in digoxin toxicity. Refractory and symptomatic bradycardia or heart block is an indication for transcutaneous or transvenous pacing or infusion with dopamine or epinephrine. If transcutaneous pacing is used successfully, a prophylactic transvenous pacemaker is not recommended because the wire may trigger ventricular arrhythmias.[2]

Table 102-3 includes selected drugs and toxins causing tachycardia. Sinus tachycardia and supraventricular arrhythmias commonly result from sympathetic overstimulation (e.g., with cocaine, theophylline, amphetamines, or phencyclidine) or inhibition of parasympathetic tone (e.g., with cyclic antidepressants, phenothiazines, or antihistamines). Anxiety, hypovolemia, hypoxemia, myocardial infarction, hyperthermia, infection, and pregnancy are in the differential diagnosis. Treatment of sinus tachycardia should be aimed at correcting the underlying cause. In the setting of stimulant intoxication, sedation with benzodiazepines is usually sufficient. β-Blockade can be helpful in the setting of excessive sympathetic stimulation and myocardial ischemia; however, nonselective β-blockers should not be used alone to treat cocaine toxicity because of the potential for unopposed α-adrenergic stimulation. In anticholinergic intoxication, physostigmine decreases heart rate by increasing acetylcholine concentration at myoneural junctions; however, the potential for physostigmine to worsen cardiac conduction disturbances precludes its use in most cases of cyclic antidepressant overdose.

Drugs such as cocaine, caffeine, and amphetamines cause ventricular arrhythmias through sympathomimetic effects.

Membrane depressants such as cyclic antidepressants are arrhythmogenic by prolonging depolarization and negative inotropy. Drugs which prolong the QT interval (e.g., amiodarone, astemizole, terfenadine, cyclic antidepressants, quinidine, procainamide, and disopyramide) may induce polymorphic ventricular tachycardia or torsades de pointes. Drug-induced torsades de pointes is treated by correction of risk factors (hypokalemia, hypomagnesemia, and hypoxemia), magnesium supplementation (even when serum concentrations are normal), and overdrive pacing by electrical stimulation or isoproterenol.[2]

Treatment of ventricular tachycardia and ventricular fibrillation is similar to that recommended in advanced cardiac life support. However, important exceptions pertain to cyclic antidepressant overdose.[6] These patients should immediately receive hypertonic sodium bicarbonate (1 to 2 mEq/kg IV bolus) aiming for a serum pH of 7.5 to 7.55. In intubated patients, hyperventilation achieves alkalemia without the need to deliver a large sodium load, but hypertonic sodium usually provides greater benefit. Lidocaine is the drug of choice when ventricular arrhythmias are refractory to sodium bicarbonate.[6] Class 1a antiarrhythmics (e.g., procainamide) are contraindicated in cyclic antidepressant overdose because of added cardiac toxicity. Anecdotal reports have also suggested a primary role for phenytoin; however, convincing data are not available to support the use of phenytoin in the setting of cyclic antidepressant overdose as either a prophylactic or therapeutic drug.[7,8] Physostigmine should not be used in cyclic antidepressant overdose because of possible worsening of cardiac conduction disturbances.

Based on limited data in humans and animals and extensive unpublished experience, the expert panel on toxicologic-oriented advanced life support suggests a primary role for sodium bicarbonate and lidocaine in cocaine-associated ventricular tachycardia and ventricular fibrillation.[6,9–12] In making these recommendations the panel did take into account studies in animals showing that lidocaine worsened seizures and widened the QRS complex in the setting of cocaine toxicity.[6]

Cardioversion or defibrillation is appropriate for pulseless patients with drug-induced ventricular tachycardia (VT) or ventricular fibrillation (VF). Whether epinephrine should be used in this setting is unknown; if used, the working group of the AHA recommends increasing the interval between doses and avoidance of high-dose epinephrine.[2] This group also recommends more prolonged cardiopulmonary resuscitation (CPR) in poisoning cases because of anecdotal reports of good neurologic recovery after 3 to 5 hours of CPR.[2,13,14]

A variety of mechanisms are responsible for hypotension in drug overdose: hypovolemia, cardiac arrhythmias, systemic vasodilation and myocardial depression. An initial strategy of rapid fluid administration (e.g., 1 L normal saline over 30 minutes) is appropriate in most cases, although caution is warranted in the setting of pulmonary edema or poor cardiac contractility (e.g., in verapamil overdose). Cardiac arrhythmias and hypothermia should be corrected and antidotes administered if appropriate. Hypotension refractory to the above measures should be treated with vasopressors. Dopamine (5 to 20 μg/kg per minute IV) stimulates α, β, and dopaminergic receptors to increase heart rate, blood pressure, and cardiac output in most patients. In patients with tachyarrhythmias or ventricular fibrillation, agents with weak β_1-activity (norepinephrine) or no β-receptor activity (phenylephrine) are preferred. Norepinephrine and phenylephrine are preferred in cyclic antidepressant overdose because cyclic antidepressants deplete presynaptic catecholamine stores, limiting the effectiveness of dopamine.[15–17] In contrast, in the presence of cocaine, dopamine and other vasopressors may trigger an exaggerated response caused by inhibition of catecholamine reuptake; in the presence of monoamine oxidase inhibitors an exaggerated response occurs because of inhibition of catecholamine degradation. An enhanced hypertensive response to phenylephrine can occur in anticholinergic overdose because anticholinergics interfere with phenylephrine-induced reflex bradycardia. Vasopressor agents should not be used in the setting of ergot derivative toxicity because of the potential for severe and sustained vasoconstriction.

Hypertension with tachycardia occurs in the setting of (1) sympathomimetic drugs (amphetamines, cocaine, lysergic acid diethylamide [LSD], marijuana, monoamine oxidase inhibitors, and phencyclidine [PCP]); (2) anticholinergics (antihistamines, atropine, cyclic antidepressants, and phenothiazines); and (3) withdrawal from nicotine, alcohol, and sedative-hypnotics. Hypertension with reflex bradycardia occurs in ergot derivative, methoxamine, phenylephrine, and phenylpropanolamine toxicity.

Treatment of hypertension depends on the chronicity and severity of hypertension and on the response to initial supportive efforts (e.g., agitated patients often respond well to benzodiazepines alone). When hypertension is severe in the setting of chronic hypertension, lowering diastolic blood pressure by 20% or to approximately 100 to 110 mm Hg is recommended. In the absence of prior hypertension, diastolic blood pressure may be lowered safely into the normal range. Drug-induced hypertension refractory to benzodiazepines should be treated with a short-acting agent such as nitroprusside. Phentolamine is effective in the setting of α-adrenergic stimulation from phenylephrine, phenylpropanolamine, or cocaine. Labetalol in carefully titrated doses is a third-line agent. Nonselective β-blockers are contraindicated because they may worsen α-adrenergic-induced hypertension.[2,18]

"COMA COCKTAIL"

A "cocktail" of oxygen, dextrose, thiamine, and naloxone should be administered to patients with depressed mental status (see Table 102-1). These relatively innocuous drugs are helpful diagnostically and therapeutically. Although not well supported in the literature,[19] thiamine is administered to prevent Wernicke-Korsakoff syndrome. This disorder is characterized by ocular disturbances (nystagmus and weak external rectus muscles), ataxia, and deranged mental status (confusion, apathy, drowsiness, and confabulation). Tachycardia, hypotension, electrocardiographic abnormalities, and cardiovascular collapse also occur. Thiamine is particularly important in the nutritionally depleted alcoholic receiving intravenous glucose. Glucose further depletes thiamine and may precipitate or worsen Wernicke-Korsakoff syndrome. There are no compelling data to support the practice of withholding dextrose until thiamine has been administered.[19]

A blood dipstick test can be used to detect severe hypoglycemia. However, a normal value for glucose by dipstick does not exclude a low serum level, thereby warranting treatment in all patients with normal or low values. If the dipstick reading is high, it is reasonable to wait for serum confirmation

of hyperglycemia. There is concern that overadministration of dextrose may cause harm by increasing serum osmolality or extending ischemic stroke, but this has not been well supported in the literature.[19]

Naloxone is an opioid antagonist with no opioid agonist properties. It can rapidly reverse opioid-induced coma, hypotension, respiratory depression, and analgesia.[20] Naloxone is administered intravenously, intramuscularly, or subcutaneously. The initial dose is 0.4 mg IV or 0.8 mg IM or SC. Lower doses (0.1 to 0.2 mg) are preferred in opioid-dependent patients to avoid severe withdrawal.[6] A low dose is also appropriate when concurrent stimulant use is suspected.[6,19]

The goal is to restore airway reflexes and adequate ventilation, not complete arousal. Abrupt withdrawal may increase the risk of arrhythmias, agitation, and acute pulmonary edema.[2,21] If naloxone does not produce a clinical response after 2 to 3 minutes, an additional 1 to 2 mg IV may be administered to a total dose of 6 to 10 mg. In general, a lack of response to 6 to 10 mg of naloxone is required to exclude opioid toxicity.[6] Even higher doses may be required to antagonize the effects of meperidine, propoxyphene, diphenoxylate, methadone, and pentazocine.[22] Continuing naloxone beyond a total dose of 10 mg is reasonable if there is a suspicion of opioid overdose and a partial response has been achieved.

In general, opioid antagonism occurs within minutes of naloxone administration and lasts for 1 to 2 hours. The effects of naloxone do not last as long as those of heroin or methadone, so repeat boluses may be required every 20 to 60 minutes to maintain an adequate clinical response. Alternatively, a continuous naloxone infusion may be started (0.4 to 0.8 mg/h, or two thirds of the initial dose needed to achieve a response per hour IV).

Consider flumazenil if benzodiazepine overdose is highly suspected or confirmed and benzodiazepines have not been prescribed for a potentially life-threatening condition (such as status epilepticus or raised intracranial pressure). In the setting of long-term benzodiazepine use, flumazenil may result in severe withdrawal or seizures.[23,24] In a rat model of combined cocaine-diazepam poisoning, flumazenil precipitated seizures and increased mortality.[25]

Seizures may occur in the setting of cyclic antidepressant coingestion; however, prospective data demonstrate that cautious administration of flumazenil is safe in this setting.[26] Flumazenil is effective in improving mental status in patients with suspected drug overdose and depressed mental status; however, it does not decrease the cost or number of major diagnostic and therapeutic interventions.[27]

Flumazenil is generally not recommended as a routine diagnostic or therapeutic agent in patients with depressed mental status.[2] Still, flumazenil can be useful to distinguish benzodiazepine overdose from mixed-drug intoxication or non–drug-induced coma, and it may improve clinical status. The recommended initial dose of flumazenil is 0.2 mg (2 mL) IV over 30 seconds. A further 0.3-mg (3-mL) dose can be given over 30 seconds if the desired clinical effect is not seen within 30 seconds. Additional 0.5-mg doses can be administered over 30 seconds at 1-minute intervals as needed to a total dose of 3 mg. Flumazenil dosed beyond 3 mg generally does not provide additional benefit. Patients should be monitored for resedation, particularly in cases involving high-dose or long-acting preparations or when there has been long-term use of benzodiazepines.

When mental status changes persist, other conditions should be considered. These include subdural or epidural hematoma, intracerebral hemorrhage, embolic stroke, abnormalities of sodium and other electrolytes, hypoxemia, hypothyroidism, liver or renal failure, central nervous system infection, seizures, and significant alterations in temperature. A head CT scan should be performed early in the course of an obtunded patient, and there should be a low threshold to perform lumbar puncture.

THE AGITATED OR SEIZING PATIENT

Agitated, violent, or acutely psychotic patients unresponsive to verbal counseling and a calm environment require pharmacologic treatment and/or physical restraints to establish adequate control and enhance patient and staff safety. A common error in the management of the agitated patient is to delay treatment, allowing patients to harm themselves and others. Causes of agitation other than drug overdose should be considered: drug withdrawal, head trauma with subdural hematoma, intracerebral hemorrhage, meningitis, hypoglycemia, thyrotoxicosis, pheochromocytoma, malignant hypertension, hyperthermia, and acute psychiatric illnesses.

Haloperidol (1 to 5 mg IM or IV) may be repeated every 30 to 60 minutes to a total dose not exceeding 100 mg/d. Debilitated and elderly patients should receive lower doses, and care must be taken in patients with cardiovascular disease to avoid hypotension and arrhythmias. Haloperidol prolongs the QT interval and therefore must be used cautiously (and with continuous monitoring) in the presence of other QT-prolonging drugs. Haloperidol lowers the seizure threshold and can cause neuroleptic malignant syndrome, tardive dyskinesia, and extrapyramidal symptoms (which may be treated with benztropine 1 to 4 mg PO). Haloperidol also has anticholinergic effects that are undesirable in anticholinergic overdose. Adding a benzodiazepine (e.g., lorazepam 1 mg) to each dose of haloperidol may accelerate control of the difficult patient.

Seizures are a common cause of drug-related morbidity and mortality. Multiple drugs and toxins (Table 102-4) cause them, but other etiologies such as CNS infection, stroke, head trauma, and severe metabolic disturbance must be considered in the differential diagnosis. A brief seizure that is temporally

related to drug ingestion (e.g., cocaine) may be observed without further evaluation, provided the patient is alert and has a normal neurologic exam. Recurrent seizures should raise suspicion of body packing (which may be evaluated by abdominal imaging and digital and visual search of body cavities). Status epilepticus should be treated with a benzodiazepine IV followed by a barbiturate (amobarbital or phenobarbital) if necessary. Phenytoin is less likely to be of benefit in cocaine or caffeine/theophylline overdose. Patients who continue to seize despite adequate treatment with a benzodiazepine and barbiturate should be considered for paralysis to prevent hyperthermia and rhabdomyolysis. Paralysis requires continuous electroencephalographic (EEG) monitoring to follow seizure activity.

ALTERATIONS IN TEMPERATURE

Drugs and toxins have the potential to alter body temperature through a number of mechanisms (Table 102-5). Hypothermia is caused by peripheral vasodilation, inhibition of shivering, depression of metabolic activity, and exposure to a cold environment. Hyperthermia occurs when there is excessive heat generation from seizures, muscle rigidity, increased metabolic rate, or decreased sweating. Hyperthermia also occurs when drugs alter hypothalamic activity or a patient loses consciousness in a hot environment.

The differential diagnosis for hypothermia includes infection, hypoglycemia, CNS injury, and hypothyroidism. For hyperthermic patients consider infection, thyrotoxicosis, environmental heat stroke, and drug withdrawal.

Extreme temperatures must be treated aggressively to minimize life-threatening complications.[28] Specifics regarding complications and treatment of hypo- and hyperthermia are included in Chaps. 110 and 111. Two of the more notable life-threatening hyperthermic disorders are neuroleptic malignant syndrome and malignant hyperthermia. Neuroleptic malignant syndrome occurs in patients taking antipsychotic medications or withdrawing from levodopa. Clinical features include hyperthermia, muscle rigidity, mental status changes, rhabdomyolysis, and metabolic acidosis. Treatment consists of immediate administration of bromocriptine. Malignant hyperthermia is an inherited disorder characterized by hyperthermia, rigidity, and metabolic acidosis. It occurs in response to certain anesthetic agents and is treated with dantrolene.

Diagnosis of Toxic Ingestion

HISTORY AND PHYSICAL EXAMINATION

Clinical features mandating consideration of drug overdose or poisoning are listed in Table 102-6. Whenever possible, a careful history should be elicited from the patient to identify potential drugs or toxins, the timing and amount of drugs taken, and the clinical course. Information should be sought regarding prescription medications, over-the-counter drugs, and illicit substances. Friends, relatives, and other involved health care providers (including paramedics) should be questioned, and medications available to or in the vicinity of the patient should be identified. The pharmacy on the medication label should be called to determine the status of all prescription medications. Information gathered might prove unreliable or incomplete, particularly in cases of attempted suicide or illicit drug abuse, but it may also favorably impact care.[29]

Physical examination is directed toward evaluation and support of airway patency, respiration, and circulation (see above), followed by rapid assessment of mental status, temperature, pupil size, muscle tone, reflexes, skin, and peristaltic activity. In cases of a single or dominant exposure, the examination may reveal signs of a toxic syndrome (or toxidrome). A *toxidrome* is a pattern of signs and symptoms that suggests a specific class of poisoning. Common toxidromes are listed in Table 102-7.

When initial signs and symptoms are less specific, we find it is useful to categorize patients as physiologically depressed (Table 102-8) or agitated and hyperadrenergic (Table 102-9). This categorization narrows the list of possible ingestions and impacts initial treatment strategies (see below). When

TABLE 102-7 Common Toxidromes

confusion or delirium are primary, drugs listed in Table 102-10 deserve consideration.[30] Note that certain drugs, such as anticholinergics, present variably with stupor, coma, agitation, confusion, or delirium, depending on the timing, dose, and host factors.

Drugs affecting the autonomic nervous system (Table 102-11) alter pupil size. Combining the patient's physiologic state (i.e., agitated or depressed) with pupil size provides for rapid assessment of the dominant ingestion. For example, the constellation of agitation, tachycardia, and pinpoint pupils is suspicious for phencyclidine intoxication; lethargy and pinpoint pupils is characteristic of narcotic overdose.

Pupil reactivity and nystagmus are additional useful signs. In anticholinergic intoxication, pupils dilate and generally do not react to light, whereas in cocaine intoxication, dilated pupils usually respond to light. Alcohols, cholinergics, lithium, carbamazepine, phenytoin, and barbiturates cause horizontal gaze nystagmus. Phencyclidine, phenytoin, and barbiturates cause horizontal, vertical, or rotatory nystagmus.

Selected drugs and toxins affecting muscle tone and movement are listed in Table 102-12.[28,30] Dystonic reactions characterized by torticollis, tongue movements, and trismus are classic in haloperidol, phenothiazine, or metoclopramide overdose. Dyskinesias (e.g., myoclonus, hyperkinetic activity, and repetitive activity) are seen with anticholinergics, PCP, and cocaine. Muscle rigidity with hyperthermia is characteristic of neuroleptic malignant syndrome, malignant hyperthermia, PCP intoxication, and black widow spider bite.

LABORATORY EVALUATION

Clinical laboratory data include assessment of the "three gaps of toxicology": the anion gap, the osmolal gap, and the arterial oxygen saturation gap. Unexplained widening of

these gaps should raise the possibility of drug overdose or toxic ingestion.

ANION GAP

The *anion gap* (AG) refers to the difference between one measured cation (Na^+) and two measured anions (mainly Cl^- and HCO_3^-):

$$AG = [Na^+] - [Cl^-] - [HCO_3^-]$$

with a normal value of approximately 12 ± 4 mEq/L.[31–34]

The presence of an anion gap indicates that there are more unmeasured anions than cations, since total serum cations equals total serum anions. *Unmeasured cations* include potassium, magnesium, and calcium, totaling about 11 mEq/L under normal conditions. The concentration of *unmeasured anions*, including mainly albumin, sulfates, phosphates, and organic acids, is about 23 mEq/L (and thus the difference of approximately 12 mEq/L).[35] It follows that the presence of hypoalbuminemia requires a downward adjustment of the expected normal anion gap: the anion gap falls 2.5 mEq/L for every 1 g/L decrease in plasma albumin concentration.[36]

The anion gap increases through three possible mechanisms: a decrease in unmeasured cations, an increase in unmeasured anions, or a laboratory error in measurement of Na^+, Cl^- or HCO_3^-. An increase in anion gap resulting from decreased unmeasured cations is rare but may occur in severe potassium, calcium, or magnesium depletion. The most common cause of an elevated anion gap is an increase in unmeasured anions. This includes accumulation of organic acids, as in lactic acidosis or ketoacidosis, or accumulation of the anions of organic acids such as sulfate and phosphate in uremia. Common causes of an elevated anion gap are listed in Table 102-13.

Toxic ingestions may increase unmeasured anions and elevate the anion gap (e.g., ethylene glycol elevates the anions glycolate and lactate). An elevated anion gap mandates consideration of toxic ingestion, even in the presence of ketones or lactate, which can occur with toxic ingestion.[37,38] Drugs associated with an elevated anion gap are included in Table 102-14.

Rarely, toxic ingestion decreases the anion gap (<6 mEq/L). Causes of decreased anion gap are listed in Table 102-15. Note the presence of lithium on this list.

OSMOLAL GAP

Certain drugs and toxins of low molecular weight (Table 102-16) produce a discrepancy between measured and calculated plasma osmolality, commonly referred to as the *osmolal gap* (osmolal gap equals measured minus calculated osmolality). The plasma osmolal gap can thus be used to detect the presence of these toxins in the blood. Normal plasma osmolality, determined by the millimolar concentrations of major solutes in plasma, is approximately 285 to 295 mOsm and is calculated as:

$$\text{Calculated osmolality} = 2[Na^+] + [\text{BUN}]/2.8 + [\text{glucose}]/18 + [\text{ethanol}]/4.6$$

where Na^+ (in mmol/L) is multiplied by two to account for accompanying anions (chloride and bicarbonate), and the concentrations of BUN (blood urea nitrogen) and glucose

Sorbitol

are divided by 2.8 and 18, respectively, to convert mg/dL to mmol/L. Dividing ethanol concentration by 4.6 accounts for the effect of a measured plasma ethanol concentration (in mg/dL) on calculated plasma osmolality. Of note, spuriously low serum sodium values (pseudohyponatremia) due to hyperlipidemia or hyperproteinemia may indicate the presence of a factitious osmolal gap.

Methanol and ethylene glycol are unique in producing both severe metabolic acidosis with elevated anion gap and an elevated osmolal gap. Isopropanol intoxication can elevate the osmolal gap and cause ketonemia and ketonuria (owing to its metabolism to acetone) without elevation of the anion gap or acidosis. Through CNS and cardiac effects, isopropanol may cause respiratory acidosis and lactic acidosis, respectively.

Caution must be used when interpreting the osmolal gap. First, measurement of osmolality by vapor pressure osmometry does not detect volatile alcohols such as ethanol and methanol (but does detect ethylene glycol); freezing point depression osmometry does measure these solutes.[39,40] Although 10 mOsm is often used as the upper limit of normal, osmolal gaps may range from −9 mOsm to +5 mOsm in normal individuals (using the standard formula for calculations).[41] Thus, an osmolal gap of 10 mOsm in a patient whose baseline value is −2 mOsm could represent the presence of significant amounts of low-molecular-weight substances (e.g., ethylene glycol level over 70 mg/dL).[42,43] In one study the range of osmolal gaps measured in 300 consecutive patients presenting to Bellevue Hospital in New York (with indications for measurement of electrolytes and ethanol) was -2 ± 6 mOsm using the standard formula, including the contribution of measured ethanol concentrations.[44] Large variations existed in the range of osmolal gap that was very dependent on the equation used. Because of the large range of values, the authors noted that small osmolal gaps in no way exclude the possibility of toxic alcohol ingestion. Furthermore, as ethylene glycol/glycoaldehyde and methanol/formaldehyde are metabolized, the osmolal gap may decrease into the normal range in the continued presence of toxic metabolites. By contrast, concurrent ethanol ingestion may prevent early development of metabolic acidosis, so that the presence of an osmolal gap greater than expected from the measured ethanol level may be the only clue to the presence of a non-ethanol alcohol.[45] Lactic acidosis and ketoacidosis have also been reported to cause elevation of the osmolal gap.[46] Finally, chronic (but not acute) renal failure is a cause of increased osmolal gap, a phenomenon corrected by dialysis.[47]

In summary, the presence of an elevated anion gap metabolic acidosis, even in the presence of an apparent clinical explanation, warrants consideration of intoxication. The additional presence of an elevated osmolal gap, particularly of large magnitude (>25 mOsm), is indicative of methanol or ethylene glycol intoxication (see below). The converse is not true, in that serious intoxications with either agent can occur in the absence of a documented increased osmolal gap. Thus measuring serum levels of these alcohols is important in any patient in whom inebriation, acidosis, or other clinical features suggest intoxication with these agents.

OXYGEN SATURATION GAP

An elevated arterial oxygen saturation gap is defined by a >5% difference between saturation calculated from an arterial blood gas and saturation measured by co-oximetry. Elevated oxygen saturation gap is seen in carbon monoxide poisoning and with methemoglobinemia. These toxins interfere with oxygen binding to hemoglobin and thereby significantly decrease oxygen content without lowering arterial oxygen pressure (Pa_{O_2}). *It is important to note that oxygen saturation measured by pulse oximetry is falsely high in these settings*. Hydrogen sulfide and cyanide interfere with cellular utilization of oxygen, leading to an abnormally high venous oxygen saturation and "arteriolization" of venous blood.

ADDITIONAL LABORATORY TESTS

Additional useful laboratory data include: urine ferric chloride analysis, which provides rapid evidence of salicylate or phenothiazine intake; a pregnancy test in women of childbearing age; and abdominal radiography, which may detect retained pills (such as iron pills). Sustained-release preparations may be detected more easily through digital enhancement of the radiograph.[48]

TOXICOLOGY SCREENING

Toxicology screening provides direct evidence of ingestion, but it rarely impacts initial management; supportive measures should never await results of such analysis. In Brett's review of 209 cases of intentional drug overdose,[49] toxicology analysis supported the clinical suspicion in 47% of cases. Clinically unsuspected drugs were detected in 27% of cases, but unexpected findings altered management in only three cases. Kellerman and coworkers reviewed urine toxicology screens in 361 of 405 consecutive ED patients with suspected drug overdose.[50] Management changes followed drug screening in only 16 (4.4%) of cases.

Toxicology screening confirms the presence of a drug and provides grounds for treatment with a specific antidote or method for enhancing elimination. Toxicology screening also identifies drugs that should be quantitated to guide subsequent management.[51] If at all possible, samples should be collected before administration of medications that might confuse toxicologic analysis.

Understanding the limitations of toxicology screening is important, including which drugs are (and which drugs are not) included in routine screening panels. These panels are institutionally variable. Most institutions offer urine screening for commonly abused drugs only, preferring to send more extensive screening panels to outside laboratories. Other institutions routinely perform extensive urine and blood analysis

TABLE 102-17 Drugs Commonly Included in Urine Substances of Abuse Screens (Available in 30 Minutes)

Amphetamines
Barbiturates
Benzodiazepines
Cannabinoids
Cocaine
Opioids
Phencyclidine (PCP)

on all patients in selected categories (e.g., trauma patients). Urine screens used in the ED are aimed at detecting six or seven of the most commonly abused drugs (Table 102-17). Results are generally available in 30 minutes. Approximately 60 drugs are included in the expanded screening panel (Table 102-18), the results of which should be available in 2 to 3 hours. Table 102-19 lists some drugs not included in routine drug screening.

Toxicologic screening of blood is generally not additive to comprehensive urine testing,[52] although rarely blood analysis is useful in acute cases when the drug or toxin is not yet detectable in urine (particularly in anuric or oliguric patients). Quantitative blood analysis of suspected drugs can be useful for diagnostic and therapeutic reasons, particularly in overdoses involving alcohols, acetaminophen, salicylates, and cyclic antidepressants. A strong argument can be made for checking acetaminophen levels in all cases of suspected intoxication given the subtle manifestations of early poisoning and the importance of targeted therapy.

Poison Control Centers

Poison control centers provide 24-hour emergency and technical information by telephone to anyone concerned with drug overdose or toxic ingestion. These centers are staffed variably by nurses, pharmacists, pharmacologists, and physicians trained in clinical toxicology. The staff provides information regarding substance identification, drug interactions, adverse drug reactions, and management of poisoned patients. These centers maintain current references and information about toxins or drugs specific to certain areas, including information about street drug activity.

Poison control center consultation is strongly advised to help determine appropriate laboratory testing, patient disposition, and treatment, including the need for a specific antidote or method to enhance drug elimination. Information provided by regional poison control centers may be more accurate than advice provided by local EDs.[53] The national toll-free emergency phone number is 1-800-222-1222.

Detoxification

GASTRIC EMPTYING

Gastric emptying is achieved by gastric lavage (GL) or syrup of ipecac. Ipecac is useful for certain ingestions in pediatric patients, but it is contraindicated in poisoning with corrosives, petroleum products, antiemetics, and strychnine. There is little role for ipecac in hospital because delayed use is of

Theophylline

questionable efficacy and it is contraindicated in obtunded patients.[54,55]

GL is advocated in the initial management of many orally ingested agents. However, risk-benefit analysis casts doubt as to the appropriateness of GL in many situations. The risks associated with GL (including aspiration, arrhythmias, and stomach perforation) preclude its use in patients who have ingested a nontoxic substance or a nontoxic amount of a toxic substance. Additionally, GL should not be performed when the toxin is no longer expected to be present in the stomach. Examples include patients who have vomited extensively prior to admission, patients who present several hours after ingesting an agent that does not decrease gut motility, and patients who have taken agents that are readily absorbed from the gastrointestinal tract.

To minimize risk, experienced personnel should perform GL lavage in a facility where resources are available to manage complications. Nonintubated patients must be alert and have adequate pharyngeal and laryngeal protective reflexes. In semicomatose patients, GL should be performed after intubation. Intubation for the sole purpose of GL is reasonable only if there is a high likelihood that a highly lethal agent remains in the stomach.

The usual teaching is to empty the stomach of alert patients (who are expected to remain alert), with GL within 1 hour of ingestion of potentially dangerous amounts of a toxic substance.[56] In obtunded patients, GL results in a more satisfactory clinical outcome only if performed within 1 hour of ingestion.[57] Although controversial, this time limit may be extended to 12 hours in cases of poisoning with agents that delay gastric emptying such as cyclic antidepressants, opioids, or salicylates. In cases of ingestion of a caustic liquid like kerosene or its derivatives, GL should be avoided because of the risk of aspiration-induced lung injury.

Prior to inserting a large-bore gastric tube (Ewald tube), the mouth should be inspected for foreign material and equipment should be readied for suctioning. Large gastric tubes (37F to 40F) are less likely to enter the trachea than smaller nasogastric tubes, and are necessary to facilitate removal of gastric debris. Once the tube has been passed with the help of patient swallowing, proper position is confirmed by aspirating acidic stomach contents and auscultating the left upper abdominal quadrant during insufflation of air. Stomach contents should be retained for analysis. Lavage is performed by instilling 200-mL aliquots of warmed tap water until there is clearing of aspirated fluid. Tap water is preferred over normal saline because it avoids unnecessary salt loading, and neither irrigant significantly alters blood cell concentrations or electrolyte concentrations.[58] After clearing, the Ewald tube may be replaced by a nasogastric tube for intermittent suctioning and/or administration of activated charcoal.

ACTIVATED CHARCOAL

Charcoal is a by-product of the combustion of various organic compounds such as wood, coconut parts, bone, sucrose, rice, and starch. It is activated by removing materials previously absorbed by a process that involves steam heating and chemical treatment, thereby increasing the surface area available for absorption. The result is a powerful nonspecific adsorbent that irreversibly binds intraluminal drugs and interferes with their absorption. Activated charcoal (AC) also decreases serum drug levels in some cases by creating a favorable diffusion gradient between blood and gut, referred to as *gastrointestinal dialysis*.[59]

Activated charcoal should be administered in a timely fashion after gastric emptying (if performed) because efficacy decreases with time.[60] It should not be given to stuporous, comatose, or convulsing patients unless an endotracheal tube protects the airway and a gastric tube is in place to administer the charcoal. Gastric stapling is a risk factor for emesis and aspiration in patients treated with single or repeated doses of AC.[61] Aspiration of this particulate has been associated with pneumonia[62] (including fungal pneumonia),[63] bronchiolitis obliterans,[64] acute respiratory distress syndrome,[65] and death.[66]

Activated charcoal is generally given as a single dose. The dose is based on patient weight (1 g/kg added to 4 parts water to form an aqueous slurry). Mixing AC with juice may improve patient acceptance of this black and gritty adsorbent.

Multiple-dose AC can enhance the elimination of selected toxins that have been absorbed.[67] This may occur through interruption of the enterohepatic/enterogastric circulation of drugs or through the binding of drugs that diffuse from the circulation into the gut lumen (so called gastrointestinal dialysis). However, multiple-dose AC is of limited use because the toxin must have a low volume of distribution, low protein binding, prolonged elimination half-life, and low pK_a (negative logarithm of the acid ionization constant), which maximizes transport across mucosal membranes into the gastrointestinal tract.[68] Based on experimental and clinical studies, it should be considered only in life-threatening ingestions of selected drugs: carbamazepine, dapsone, phenobarbital, quinine, or theophylline.[69]

In a recent review, the American Academy of Clinical Toxicologists reported that multidose AC increases drug elimination, but has not been shown to reduce morbidity and mortality in controlled trials.[69] The optimal dose and frequency of administration of AC following the initial dose has not been established. Most experts recommend a dose not less than 12.5 g/h.[70] After the initial dose of 1 g/kg, AC may be administered at 0.5 g/kg every 2 to 4 hours for at least 3 doses. Multiple doses should be used with caution in patients with decreased bowel sounds, abdominal distension, and emesis.

Combining AC with a cathartic may facilitate evacuation of the toxin and avoids constipation. Preparations for coadministration with AC include 1 to 2 mL/kg of a 70% solution

of sorbitol titrated to several loose stools over the first day of treatment. An alternative is to use 2 to 3 mL/kg of a 10% solution of magnesium sulfate PO, but magnesium-based cathartics may lead to magnesium accumulation in the setting of renal failure, and sodium-based products carry the risk of exacerbating hypertension or congestive heart failure. If aspirated, oil-based cathartics may produce lipoid pneumonia.

The efficacy of adding a cathartic to AC is unclear. Keller and colleagues demonstrated that AC with sorbitol decreased absorption of salicylates compared to AC alone.[71] McNamara and colleagues found no benefit to adding sorbitol to a simulated acetaminophen overdose.[72] Catharsis has not been shown to decrease morbidity, mortality, or hospital length of stay, and it is not recommended for routine use in combination with AC by the American Academy of Clinical Toxicology.[73,74]

WHOLE-BOWEL IRRIGATION

Whole-bowel irrigation (WBI) with a polyethylene glycol electrolyte solution (e.g., GoLYTELY) 1 to 2 L/h by mouth or nasogastric tube may clear tablets or packages from the gastrointestinal tract. Irrigation is generally continued until the rectal effluent is clear or there is radiographic evidence of clearance. The efficacy of WBI has not been established in controlled trials, but it is reasonable to consider its use in iron and lithium overdose (situations in which AC is ineffective), ingestion of sustained-release tablets, and in cases of "body packing" with packages of illicit drugs. Contraindications to WBI include ileus, gastrointestinal hemorrhage, and bowel perforation.

FORCED DIURESIS AND URINARY PH MANIPULATIONS

We do not recommend forced diuresis by volume loading and diuretic administration, which is intended to augment elimination of renally excreted toxins through inhibition of tubular reabsorption. This regimen is of unproven benefit and has the potential to compromise fluid and electrolyte homeostasis.[75–78] The minimum criteria for augmented clearance of a drug by forced diuresis are that the substance normally undergoes extensive tubular reabsorption and that renal excretion becomes the major route of elimination under conditions of forced diuresis. It is notable that if tubular reabsorption is pH sensitive, then increased urine flow does not significantly increase urinary drug elimination when added to alkaline or acid diuresis (see below).[79]

Therapeutic manipulation of urinary pH can enhance elimination of some intoxicants. Most drugs are weak acids or bases and are present in both ionized and nonionized fractions in serum and glomerular filtrate. Normally, passive renal tubular reabsorption of the nonionized lipid-soluble fraction of such drugs occurs by nonionic diffusion; this process is accentuated by the progressive tubular reabsorption of water and solutes as the glomerular filtrate traverses the nephron, resulting in an increasing filtrate/serum concentration gradient which favors drug reabsorption. Back-diffusion of some acidic and basic drugs from renal tubular lumen to the peritubular fluid and capillaries can be decreased by manipulation of urinary pH to create more of the ionized (less lipid-soluble) salt of the drug. Urinary alkalinization is expected to augment excretion of nonpolar weak acids with pK_a values between 3 and 7.5 (Table 102-20), because these drugs become more dissociated as urinary pH rises, resulting in ion trapping of the drug in the tubular lumen.[79] (The *dissociation constant*, pK_a, of a drug refers to the pH at which the compound is equally ionized and unionized.) Because the limits of urinary pH are 4.5 to 7.5 under conditions of enhanced alkalinization and acidification, elimination of very strong (pK_a <3) or very weak (pK_a >8) acids is unaltered by urinary pH manipulation. Other acidic or basic drugs do not undergo renal tubular absorption regardless of urinary pH since they are polar in their nonionized form (e.g., gentamicin). Urinary alkalinization (pH >7) is usually achieved by administration of intravenous sodium bicarbonate (1 to 2 mEq/kg every 3 to 4 hours); this may be administered as two 50-mL ampules of 8.4% sodium bicarbonate (each containing 50 mEq of $NaHCO_3$) per liter of 5% dextrose in water infused at 250 mL/h.[80] Complications of this therapy include alkalemia (particularly in the presence of concurrent respiratory alkalosis), volume overload, hypernatremia, and hypokalemia. It is particularly important to avoid hypokalemia, which prevents excretion of alkaline urine by promoting distal tubular potassium reabsorption in exchange for hydrogen ion. Accordingly, bicarbonate administration in the presence of significant hypokalemia will not achieve an alkaline urine, yet increases the risk of alkalemia. Since urinary alkalinization can cause hypokalemia (caused by alkalemia-induced intracellular potassium shift and by increased urinary potassium losses with alkaline diuresis), addition of potassium chloride to the bicarbonate infusion is commonly required and may be considered prophylactically.[78] We do not recommend the use of acetazolamide to induce alkaline diuresis. This therapy causes metabolic acidosis, which can further complicate management, particularly in the case of salicylate intoxication (where acidemia increases CNS entry of the drug).

Urinary acidification (pH <5.5) likewise increases renal clearance of some nonpolar weak bases (see Table 102-20), with pK_a values between 6 and 12. These drugs include PCP (pK_a 8.5) and amphetamines (pK_a 9.9).[79] Again, elimination of very weak (pK_a <6) or very strong (pK_a >12) nonpolar bases is less affected by urinary pH changes. Arginine or lysine hydrochloride or ammonium chloride is most commonly used for urinary acidification. However, this therapy is generally not recommended because of the potential for urinary acidification to exacerbate myoglobinuric renal tubular injury. Also, systemic acidosis must be carefully controlled to avoid potential additive effects with toxin-induced metabolic or respiratory acidosis.

TABLE 102-20 Toxins Eliminated by Manipulation of Urinary pH

Alkaline Urine	Acid Urine
2,4 Dichlorophenoxyacetic acid	Amphetamines
Fluoride	Bismuth
Isoniazid	Ephedrine
Mephobarbital	Flecainide
Methotrexate	Nicotine
Phenobarbital	Phencyclidine
Primidone	Quinine
Quinolone antibiotics	
Salicylic acid	
Uranium	

EXTRACORPOREAL REMOVAL OF TOXINS

In some instances, treatment of an intoxicated patient with supportive measures, decontamination, and acceleration of renal drug elimination does not alter the course of events to optimize outcome. Application of extracorporeal drug removal (ECR) techniques may be life-saving for such patients, although clear proof that ECR favorably alters the course of any intoxication is generally lacking.[81] Application of ECR for any intoxication is based on critical appraisal of both the clinical status of the patient and of current available data on the prognosis and treatment of the intoxication. In general, ECR should be considered when (1) supportive care fails to stabilize the patient's clinical status; (2) the intoxication is projected to undergo delayed or insufficient clearance because of renal, hepatic, or cardiac dysfunction; (3) the intoxicating agent produces toxic metabolites; or (4) delayed toxicity is characteristic of the intoxication.[76–78,81–83] In addition to these general considerations, specific clinical features or serum drug levels may indicate the necessity for ECR. Finally, physicochemical properties of the intoxicant, and its pharmacokinetic behavior in overdose (which may differ from the agent's pharmacokinetic properties in the therapeutic range), also dictate the feasibility of ECR and the choice of method. Three methods for ECR are generally available: (1) dialysis (usually hemodialysis rather than peritoneal dialysis); (2) hemoperfusion; and (3) hemofiltration. Rarely, other techniques such as plasmapheresis and exchange transfusion are considered for specific intoxications; these will not be further discussed here.

HEMODIALYSIS

Hemodialysis (HD) is the treatment of choice for ECR of very few intoxicants, because hemoperfusion (HP) provides superior drug extraction in most cases in which ECR is considered. Hemodialysis is still preferred to HP for removal of substances that are particularly dialyzable (see below), especially in the presence of metabolic acidosis, renal failure, dialyzable toxic metabolites, or other HD indications. Hemodialysis removes water-soluble unbound (free) solutes that are small enough to pass through the pores of the semipermeable dialysis membrane, which separates the patient's blood from the countercurrent flow of the dialysis bath fluid (which is discarded as effluent dialysate following passage through the dialyzer). Solute transport, including transfer of drugs, toxins, or metabolites, occurs by diffusion down the blood-to-dialysis bath concentration gradient, which is maintained by countercurrent flow of dialysate. In addition to low molecular weight and water solubility, both low protein binding and a small volume of distribution are necessary characteristics of a substance that is readily cleared by HD.[84–88]

Criteria for potential dialyzability include:

1. *Water solubility:* Water-soluble substances cross dialysis membranes more readily than lipid-soluble agents (drugs or metabolites).
2. *Low molecular weight:* Traditionally, a substance is described as small enough to be significantly removed by hemodialysis when it has a molecular weight of <500 daltons (Da). More recently, high-flux dialysis membranes with increased porosity and surface area have been introduced. Such membranes are capable of removing drugs with weights in the middle-molecule range, up to 5000 Da. For example, vancomycin has a molecular weight of 1500 Da, but is significantly cleared by HD with a high-flux membrane.[87,89,90]
3. *Protein binding:* Low protein binding (<90%) facilitates drug removal by hemodialysis, since only unbound drug is free to cross the hemodialysis membrane; for example, for a drug which is 90% protein-bound, hemodialytic removal of 50% of free drug only reduces its concentration in blood passing through the dialyzer by 5%.
4. *Volume of distribution (Vd):* This is the theoretical volume into which the intoxicant is distributed. As a general rule, substances with a Vd of <250 L (approximately 3 to 4 L/kg) are potentially significantly cleared by hemodialysis. Conversely, hemodialytic removal of substances with a larger Vd is generally insignificant in comparison to the total body load of the substance, which often equilibrates too slowly with the vascular space to allow significant removal. In fact, most substances substantially removed by HD have a smaller Vd of 1 L/kg (Table 102-21).
5. *Intrinsic clearance of the substance:* Most drugs have a hemodialysis clearance of 5 to 100 mL/min; if a patient's clearance of a substance exceeds 500 to 700 mL/70 kg per minute, hemodialysis is unlikely to significantly augment the substance's clearance.[89] It is important to note that the clearance of a drug at toxic levels may be significantly less than that reported within the therapeutic range, because of saturable hepatic metabolism at high drug concentrations (concentration-dependent kinetics) or intoxication-induced renal, hepatic, or cardiac dysfunction. Furthermore, there is usually a paucity of information regarding the production and relative clearance (intrinsic versus extracorporeal) of toxic metabolites.

Complications of HD include:

1. Intravenous access complications: If possible, temporary vascular access should be placed in the femoral vein to minimize the potential for serious complications (pneumothorax, central vessel or nerve injury, or catheter-induced arrhythmia). Vascular access should also be removed as soon as possible (but not before the period for potential development of rebound intoxication has passed) to minimize the potential for access infection or thrombosis.
2. Hypophosphatemia: In patients without concomitant renal failure and hyperphosphatemia, the dialysis bath should be supplemented with phosphorus to prevent severe dialysis-induced hypophosphatemia. Addition of 1.3 mmol/L of phosphorus to the dialysis bath should prevent hypophosphatemia.
3. Alkalemia: Since the usual dialysis bath bicarbonate (buffer) concentration is 35 to 38 mEq/L, severe alkalemia can result from hemodialysis against a standard bath in the absence of associated acidosis (particularly in the presence of hyperventilation or emesis-induced metabolic alkalosis). If the predialysis plasma bicarbonate concentration is 28 mEq/L or higher, then the bath bicarbonate concentration must be lowered to 15 to 28 mEq/L.
4. Disequilibrium syndrome: Acute neurologic deterioration caused by large, rapid changes in cerebral tissue osmolality may occur in an acutely uremic patient who receives a prolonged initial session of intensive hemodialysis for

TABLE 102-21 Extracorporeal Removal (ECR) of Selected Intoxicants: Pharmacokinetic Considerations

Intoxicant	Molecular Weight (Da) Protein Binding (%) Vd (L/kg)	Endogenous Clearance (mL/min per kg)	Serum Level for ECR[a]	Removal Techniques
Acetaminophen	151 0–25 1.0	5.0		HP[b]

Valproic acid	144 90–95[e] 0.22	0.11		HD + HP[b]

ABBREVIATIONS: CrCl, creatinine clearance; HD, hemodialysis; HF, hemofiltration; HP, hemoperfusion; NAPA, *N*- acetyl-procainamide; Vd, volume of distribution.
[a] Approximate levels: use of ECR usually based upon clinical criteria.
[b] ECR use controversial.
[c] Saturable metabolism:Michaelis-Menten kinetics.
[d] Decreased in uremia and hypoalbuminemia.
[e] Decreases at levels above 90–100 (g/mL).

drug removal. High-sodium dialysis bath and intravenous mannitol may be useful prophylactically in blunting large acute transcellular water shifts caused by HD removal of uremic toxins.

5. System saturation: This is not possible using standard hemodialysis, because of maintenance of the concentration gradient for diffusion by countercurrent flow (blood versus dialysate), except when a sorbent dialysis system is used. This system is inappropriate for extracorporeal removal of an intoxicant, since the sorbent cartridge used to regenerate new dialysis solution from dialysate may become saturated and cease to function. If such a system is the only available option, frequent cartridge changes will be required.
6. Other: Hypotension is a potential adverse effect of HD (or HP), particularly if this therapy is instituted in an already unstable patient, though hemodynamic compromise is less likely if not actively removing plasma volume (by ultrafiltration). Finally, air embolism is an extremely rare consequence of HD.

PERITONEAL DIALYSIS

Intoxicant removal across the peritoneal membrane is generally only one-eighth to one-fourth as efficient as hemodialysis, even when maximizing solute exchange volume and frequency. This technique is therefore never the preferred method for extracorporeal drug removal, unless other considerations supervene (e.g., use as an adjunctive measure or in the absence of available HD or HP).

HEMOPERFUSION

Hemoperfusion (HP) is defined as direct contact of blood with a sorbent system.[82,91] Currently available systems perfuse a cartridge packed with coated AC (carbon). Blood perfusing such a cartridge is exposed (via a highly porous coating) to a large sorbent surface area, thus maximizing drug adsorption. Activated charcoal adsorbs both water-soluble and lipid-soluble substances and can remove essentially all of an adsorbing substance from blood perfusing the cartridge. Thus it is not unusual to achieve drug clearances of 200 to 400 mL/min, particularly early in the treatment period, before cartridge saturation begins. Polymer coating reduces adsorption of larger compounds (>3500 Da). The drug adsorption process competes with plasma proteins and tissue stores to greatly augment removal of bound drug beyond the level achievable by HD.

Complications of HP include:

1. *Cartridge saturation:* The extraction ratio (EX) of a substance by HP (or HD) is the amount of the solute removed as a fraction of the maximum it is theoretically possible to remove: $EX = (A - V)/A$, where A and V are the cartridge inlet and outlet blood concentrations, respectively. This ratio declines during an HP treatment session as the cartridge becomes saturated; as noted above, this occurs during HD only if a sorbent-based dialysis system is used.
2. *Hematologic:* Thrombocytopenia commonly occurs due to platelet adsorption, inducing up to a 30% decrement in platelet count, which usually recovers within 24 to 48 hours. Leukopenia and coagulation factor depletion also occur, to a lesser extent.
3. *Metabolic:* Cartridge adsorption can cause hypoglycemia and hypocalcemia.
4. *Technical:* Access complications can occur as for HD. Hypothermia is an additional risk, because HP pumps do not warm blood as the HD apparatus does. Particle embolization (prevented by a filter in the line returning effluent blood to the patient) and development of pyrogenic reactions are of largely historic interest at this point.

Most drugs are extractable by HP, which is particularly suitable for extracorporeal removal of toxins that are of high molecular weight, highly protein-bound, or lipid-soluble. Drugs poorly extracted by HP include heavy metals (lithium and bromide), some alcohols (ethanol and methanol), carbon monoxide, and some illicit drugs (cocaine, phencyclidine, and others). Efficacy of intoxicant removal is diminished for substances with a large Vd (i.e., highly lipid-soluble and/or extensively tissue-bound), which may be more effectively removed by hemofiltration.

TABLE 102-22 Antidotes

Drug/Poison	Antidotes
Acetaminophen	Acetylcysteine
Anticholinergics	Physostigmine
Anticholinesterases	Atropine
Benzodiazepines	Flumazenil
β-Blockers	Glucagon
Black widow spider bite	Equine-derived antivenin
Calcium channel blockers	Calcium chloride, glucagon
Carbon monoxide	Oxygen
Coral snake (Eastern and Texas) bite	Equine-derived antivenin
Cyanide	Amyl nitrite, sodium nitrite, sodium thiosulfate, hydroxycobalamin
Digoxin	Digoxin-specific antibodies
Ethylene glycol	Ethanol, 4-methylpyrazole
Heavy metals (arsenic, copper, gold, lead, mercury)	Dimercaprol, Ethylenediamine tetra-acetic acid (EDTA), penicillamine
Hypoglycemic agents	Dextrose, glucagon
Iron	Deferoxamine mesylate
Isoniazid	Pyridoxine
Methanol	Ethanol, folic acid, 4-methylpyrazole
Methemoglobinemia	Methylene blue
Opioids	Naloxone
Rattlesnake bite	Equine-derived antivenin

HEMOFILTRATION

Hemofiltration (HF) achieves drug removal by convection, transporting drugs and other solutes through a highly porous membrane by bulk flow with filtered plasma water. Such membranes are generally permeable to substances with weights of up to 6000 Da, including virtually all drugs, and in some cases HF membranes are permeable to substances weighing up to 20,000 Da.[92–94] There are increasing numbers of case reports of extracorporeal intoxicant removal using hemofiltration, by either the arteriovenous (continuous arteriovenous hemofiltration; CAVH) or venovenous (continuous venovenous hemofiltration; CVVH) method.[95,96] Hemofiltration is potentially useful for removal of substances with a large Vd, slow intercompartmental transfer, or avid tissue binding. Specific highly porous HF cartridges are also particularly useful for removal of large-molecular-weight solutes or complexes, such as combined digoxin-Fab fragment complexes or deferoxamine complexes with iron or with aluminum. CAVH also has the advantage that trained personnel can perform this technique without the assistance of a pump.

ANTIDOTES

An antidote is any substance that increases the mean lethal dose of a toxin, or that can favorably affect the toxic effects of a poison.[97] Table 102-22 lists antidotes for specific drugs/poisons.

Indications for ICU Admission

In the current healthcare environment, the practice of routinely admitting poisoned patients to the medical intensive

care unit or a cardiac monitored bed is being questioned. In one retrospective study, Brett and colleagues identified several factors that predicted the need for ICU admission: partial pressure of arterial carbon dioxide (Pa_{CO_2}) ≥45 mm Hg, the need for intubation, seizures, QRS duration ≥0.12 seconds, second- or third-degree atrioventricular block, cardiac arrhythmias, systolic blood pressure <80 mm Hg, and unresponsiveness to verbal stimuli.[98] If none of these factors was present, no ICU interventions (intubation, vasopressors, antiarrhythmics, dialysis, or hemoperfusion) were required. Other considerations include a Glasgow Coma Scale score <12, progressive metabolic acidosis, and a cyclic antidepressant or phenothiazine overdose with signs of anticholinergic cardiac toxicity.[99,100] Cyclic antidepressants in particular may cause delayed cardiac toxicity.[101] Severe hyperkalemia, extreme body temperatures, and need for continuous infusion of naloxone are also reasons to admit to an ICU. Often, staffing issues including the availability of a "sitter" in cases of attempted suicide, have an important impact on the disposition of the patient.

Specific Intoxications

ACETAMINOPHEN

In 2001, alone or in combination with other drugs, acetaminophen accounted for over 112,000 exposures, making it the most common pharmaceutical overdose reported to poison control centers. Approximately 60,000 of these cases were treated in health care facilities; 12,744 patients received n-acetylcysteine (NAC); 2257 had major complications; 238 died.[1]

The evolution of acetaminophen toxicity is often divided into four phases.[102,103] Phase I refers to the first 24 hours after ingestion. During this period, acetaminophen is absorbed and metabolized, glutathione stores are depleted, and hepatotoxicity begins. Patients are alert but may experience nausea, vomiting, anorexia, malaise, pallor, or diaphoresis. These nonspecific signs and symptoms create the potential for a missed diagnosis. Furthermore, when acetaminophen is combined with another drug such as codeine or oxycodone, the effects of the other drug may further mask the initial subtle manifestations of acetaminophen poisoning.

Phase II occurs 24 to 72 hours after untreated ingestion. During this period, patients may develop right upper quadrant pain and minor abnormalities of liver function consisting of elevation of hepatic enzymes, prothrombin time, and bilirubin. Phase III (72 to 96 hours after untreated ingestion) is characterized by continued hepatic necrosis, hepatic encephalopathy, disseminated intravascular coagulation, and jaundice. Liver function abnormalities typically peak during phase III. It is not unusual for serum aspartate aminotransferase levels to rise to 10,000 IU/L or higher. Extreme elevation of alanine aminotransferase may also be seen. Rare phase III sequelae include hemorrhagic pancreatitis, myocardial necrosis, and acute renal failure.[103] Phase IV takes place 4 days to 2 weeks after ingestion. During this period, the patient may die, fully recover without chronic liver disease, or undergo emergent liver transplantation. Some patients with untreated acetaminophen poisoning exhibit a pattern of rising prothrombin time, ammonia, and bilirubin, as levels of hepatic enzymes decline, indicating fulminant hepatic necrosis.

A product of normal acetaminophen metabolism is responsible for hepatotoxicity. As acetaminophen is metabolized by the cytochrome P-450 mixed oxidase system, a toxic product (possibly N-acetyl-p-benzoquinone imine or NAPQI)[104] is rapidly detoxified by hepatic intracellular glutathione. In overdose cases, glutathione is depleted, allowing the toxic metabolite to combine with hepatic cell proteins and cause centrilobular necrosis with periportal sparing. Local production of NAPQI makes the liver the primary target, but other organs can be affected as indicated above.

It follows that a relationship exists between plasma levels of acetaminophen and the potential for toxicity. The Rumack-Matthew nomogram (Fig. 102-1) for acetaminophen poisoning allows stratification of patients into categories of probable hepatic toxicity, possible hepatic toxicity, and no hepatic toxicity, based on the relationship between acetaminophen level and time after ingestion.[105] The lower line of this nomogram, which defines serum levels 25% below those expected to cause hepatotoxicity, is generally used to guide treatment.

There are several limitations to the use of the Rumack-Matthew nomogram. First, note that a serum level obtained prior to 4 hours postingestion is not interpretable because of ongoing absorption and distribution of the drug, and patients in phases II to IV may have trivial or undetectable serum concentrations despite a potentially lethal dose. Second, the nomogram is less predictive in chronic ingestion or use of an extended-release preparation. For extended-release preparations serial acetaminophen levels should be drawn every 4 to 6 hours after ingestion and plotted on the Rumack-Matthew nomogram. If any point is above the lower line, an entire course of the antidote NAC is indicated. Third, the nomogram does not take into account at-risk populations. Acute ingestion of 7.5 to 10 g is potentially hepatotoxic in normal adults; however, the risk of toxicity increases in alcoholics, individuals who are malnourished, patients with induced cytochrome P-450 enzymes, and patients with low glutathione stores at baseline (as may be seen with recent subtoxic acetaminophen use).[106] In such cases doses as low as 4 to 6 g may be toxic. In this situation, NAC should be considered even if the serum level falls below the lower line. Fourth, accurate risk assessment requires an accurate time of ingestion, which is not always attainable. A 1- to 2-hour difference easily moves the borderline patient above or below the treatment line. Based on these limitations, Bond and Lite reported that the Rumack-Matthew nomogram could not be used for risk assessment in 44% of hospitalized patients and 83% of patients who suffered severe hepatic injury.[107]

Treatment of acetaminophen overdose should be initiated during phase I. Gastric lavage is indicated in patients seen within 1 hour of ingestion. Children at home may be given ipecac. Activated charcoal may be administered even though it has the potential to partially adsorb orally administered NAC. Activated charcoal reduces the number of patients reaching toxic serum levels after ingesting more than 10 g of acetaminophen and presenting within 24 hours of ingestion, and may reduce the need for a full treatment course of NAC and hospital length of stay.[108] When AC and NAC are used simultaneously, they should be administered 2 hours apart to minimize interaction. Hemoperfusion effectively accelerates

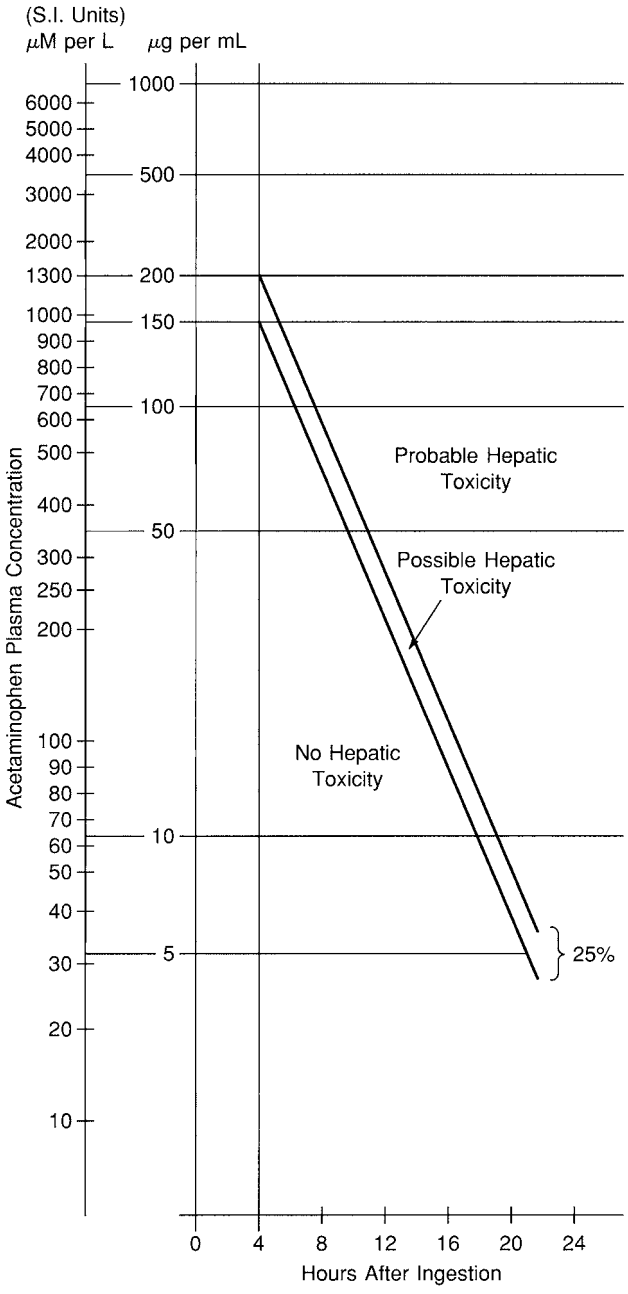

FIGURE 102-1 The Rumack-Matthew nomogram for predicting acetaminophen hepatoxicity. This nomogram allows for stratification of patients into categories of probable hepatic toxicity, possible hepatic toxicity, and no hepatic toxicity, based on the relationship between acetaminophen level and time after ingestion. When this relationship is known, n-acetylcysteine (NAC) therapy is indicated for acetaminophen levels above the lower nomogram line. NAC should also be given if there is >5 μg/mL acetaminophen and an unknown time of ingestion (but <24 hours), and if there is a history of overdose and a serum acetaminophen level is not immediately available. Serum levels obtained prior to 4 hours postingestion are uninterpretable because of ongoing absorption and distribution of the drug. (*Reproduced with permission from Rumack BH: Acetaminophen overdose in children and adolescents. Pediatr Clin North Am 33:691, 1986.*)

removal of acetaminophen from the blood; however, benefit has not been demonstrated in controlled trials. This technique may prove helpful in patients with high acetaminophen levels presenting late in the course of intoxication.[103]

All patients with probable or possible hepatic toxicity based on the Rumack-Matthew nomogram (i.e., all patients with serum acetaminophen levels above the lower line) should receive NAC to replete glutathione stores. NAC should also be given if there is >5 μg/mL acetaminophen and an unknown time of ingestion (but <24 hours), evidence of hepatotoxicity, or if a serum acetaminophen level is not immediately available. In this latter situation, the antidote may be discontinued if the acetaminophen level is found to be at a nontoxic level according to the nomogram. Importantly, NAC should be considered in at-risk patients even if levels are nontoxic.

The effectiveness of NAC depends on the time of administration. It is almost 100% effective when administered within the first 8 to 10 hours. Efficacy decreases over time, but there is still benefit for up to 24 hours.[109] NAC may even improve outcome when it is administered after the onset of fulminant hepatic failure.[110] In the setting of liver failure, NAC lowers the incidence of hepatic encephalopathy and improves oxygen transport and consumption.[111,112]

The oral loading dose of NAC is 140 mg/kg. This is followed by a dose of 70 mg/kg every 4 hours for 17 doses. There are limited data supporting shorter treatment courses in selected patients. Woo and colleagues conducted a retrospective, observational case study of short-course treatment in acute overdose with acetaminophen levels in the toxic range.[113] Patients received an oral loading dose of 140 mg/kg NAC followed by 70 mg/kg every 4 hours until the serum acetaminophen level was undetectable. Of the 75 patients, 25 (33.3%) were treated for less than 24 hours. The mean duration of therapy was 31 ± 16 hours. The incidence of hepatotoxicity was low and comparable to patients treated in the standard way. Protocols using a 20-hour IV course and a 48-hour IV course have also been shown to be safe and effective.[114,115] NAC is prepared using the standard 10% (100 mg/mL) or 20% (200 mg/mL) formulations diluted to a 5% solution in juice. If vomiting interferes with oral NAC use, the dose should be repeated along with an antiemetic such as metoclopramide or ondansetron. Occasionally, a nasogastric tube is necessary. Intravenous administration of NAC using the same dose and dosing schedule may be beneficial in patients unable to tolerate the oral preparation. When administered intravenously, a micropore filter should be used to decrease the risk of adverse reactions.

Fatal outcomes in acetaminophen overdose are associated with late presentation, high coma grade, prothrombin time >100 seconds, pH <7.30, creatinine >300 μmol/L, cerebral edema, and sepsis.[116,117] When poor prognostic features are present, liver transplantation is often considered, but whether to perform liver transplantation is a difficult decision. An accurate assessment of prognosis at the time of admission to the ICU would help to apply this therapy to the appropriate patient population. To this end, investigators from King's College Hospital Liver Unit demonstrated that an Acute Physiology and Chronic Health Evaluation (APACHE) II score >15 provided an accurate assessment of hospital mortality and identified patients in need of transplantation in the setting of acetaminophen-induced liver failure.[118]

TABLE 102-23 Toxic Alcohols: Clinical Features and Management

Sources	Distinguishing Features	Pharmacokinetic/ Pharmacodynamic Parameters	Specific Treatment
Methanol (Metabolites: Formaldehyde, Formic Acid, Lactic Acid)			
Antifreeze	Optic papillitis	Lethal serum level: 80–100 mg/dL Lethal dose: 150–240 mL of a 40% solution	Charcoal (<1–2 h after ingestion) Ethanol, 4-methylpyrazole
Solvent	Pancreatitis	Peak conc.: 30–90 min Vd: 0.6 L/kg	Consider bicarbonate infusion Folate 50–70 mg IV q4h × 24 h
Fuel		Excretion: 90–95% saturable hepatic metabolism; 5–10% unchanged renal Half-life is dose dependent: Mild intoxication: 14–20 h Severe intoxication: 24–30 h With ethanol: 30–35 h Ethanol + HD: 2.5 h	HD until serum level <20 mg/dL for: 1. Serum level >50 mg/dL 2. Eye involvement 3. Altered mental status 4. Ingestion of >30 mL 5. Elevated formic acid level 6. Refractory metabolic acidosis
Ethylene Glycol (Metabolites: Glycoaldehyde, Glycolic Acid, Oxalic Acid)			
Antifreeze	Acute renal failure	Lethal serum level: 19.2 mg/dL Lethal dose: 100 mL	GL (<1–2 h after ingestion) Ethanol, 4-methylpyrazole
Solvent	Crystalluria	Peak conc.: 1–4 h Vd: 0.6 L/kg	Thiamine 100 mg IM qid Pyridoxine 500 mg IM qid
	Wood light: urinary fluorescene	Excretion: hepatic metabolism	Consider bicarbonate infusion
	Myocardial dysfunction	Half-life: Untreated: 3–8.5 h With ethanol: 10–102 h Ethanol + HD: 2.5–3 h	Consider calcium administration Consider forced diuresis HD until serum level 20 mg/dL for: 1. Serum level >50 mg/dL 2. End-organ damage 3. Refractory metabolic acidosis
Isopropanol (Metabolite: Acetone)			
Rubbing alcohol	Hemorrhagic gastritis	Lethal serum level: 400 mg/dL Lethal dose: 150–240 mL of 40% solution (highly variable)	Supportive care GL (<1–2 h after ingestion)
Solvents			Ethanol not indicated (nontoxic metabolites)
	Ketonemia	Peak conc.: <2 h	
De-icers		Vd: 0.6 L/kg	HD for: 1. Serum level >400 mg/dL 2. Shock 3. Prolonged coma 4. Hepatic or renal insufficiency
	Ketonuria	Excretion: 50–80% hepatic metabolism; 20–50% unchanged renal	
	No acidosis or hyperglycemia	Half-life: Untreated: 2.5–3 h	

ABBREVIATIONS: GL, gastric lavage; HD, hemodialysis; Vd, volume of distribution.

ALCOHOLS

Clinical features of ethylene glycol, methanol, and isopropanol poisoning are listed in Table 102-23. Ethylene glycol is an odorless and sweet tasting fluid that is found in antifreeze, de-icers and industrial solvents. Blue or green fluorescent dye is added to some (e.g., antifreeze) but not all products to identify leaks, allowing for evidence of poisoning by urinary fluorescence under a Wood lamp. Methanol is colorless and odorless but has a bitter taste. It is present in many paint removers, gas-line antifreeze, windshield washing fluid, and solid canned fuel. Isopropanol is a colorless and bitter tasting alcohol. It has the smell of acetone or alcohol and is found in rubbing alcohol, skin lotions, hair tonics, aftershave, de-icers, and glass cleaners.

A history of ingestion or inebriation that is not explained by a blood ethanol level suggests toxic alcohol poisoning. Metabolic acidosis with an elevated anion gap and an elevated osmolal gap are cardinal features of methanol and ethylene glycol poisoning, but poisoning can occur without either.[119,120] Isopropanol elevates the osmolal gap but does not cause metabolic acidosis.[121]

Ethylene glycol is metabolized by alcohol dehydrogenase to glycoaldehyde and glycolic acid, and then to glyoxylic acid and oxalic acid. Accumulation and precipitation of oxalic acid and calcium oxalate in renal tubules produces calcium oxalate crystals that are present in the urine in 50% of cases.[122] Ingestion of as little as 100 mL can be lethal in an adult patient.

Ethylene glycol poisoning has a triphasic clinical course: stage 1 (30 minutes to 12 hours postingestion) consists of inebriation, ataxia, seizures, variable levels of elevated anion gap metabolic acidosis with Kussmaul breathing, elevated osmolal gap, crystalluria, and hypocalcemia. Cerebral edema causes coma or death. Symptoms may be delayed if there is concurrent ethanol consumption, which competes for alcohol

dehydrogenase and limits conversion of ethylene glycol to its toxic metabolites.

Stage 2 (12 to 24 hours) is dominated by myocardial dysfunction with high- or low-pressure pulmonary edema. Myocardial dysfunction or respiratory failure causes death in this stage. Stage 3 (2 to 3 days) is dominated by acute renal failure due to acute tubular necrosis with an element of tubular obstruction from calcium oxalate precipitation.[68,123,124] Late (6 to 18 days) neurologic sequelae have also been described in survivors.[125–128]

Methanol is metabolized by alcohol dehydrogenase to formaldehyde, which is metabolized to formic acid by aldehyde dehydrogenase. Formic acid is the primary toxin responsible for metabolic derangements and ocular disturbances. Intoxication can occur orally, by inhalation, or by absorption through skin. As little as 30 mL causes significant morbidity; 150 to 240 mL of 40% solution can be lethal. Methanol causes an initial period of headache, inebriation, dizziness, ataxia, and confusion. As formic acid accumulates (6 to 72 hours), the anion gap elevates and the optic nerve swells. Decreased visual acuity and blindness are classic features of this poisoning. Pancreatitis also occurs.[129,130] As in ethylene glycol poisoning, symptoms of methanol poisoning may be delayed by concurrent ethanol use.

Treatment of ethylene glycol and methanol poisoning is similar.[131] Inhibiting the formation of toxic metabolites by alcohol dehydrogenase and/or urgent dialytic removal of these alcohols and their metabolites are the cornerstones of therapy. Supportive measures include gastric lavage in the first hour postingestion. Bicarbonate infusion may be necessary to improve metabolic acidosis, but has not been shown to improve outcome. Hypocalcemia and hypoglycemia should be corrected. In methanol intoxication, folate is important in the metabolism of formic acid to CO_2 and water; in ethylene glycol poisoning, pyridoxine and thiamine are important in the metabolism of glycolic acid.

Fomepizole (4-methylpyrazole) inhibits alcohol dehydrogenase; ethanol prolongs the half-life of methanol and ethylene glycol by competing for alcohol dehydrogenase. Of the two, fomepizole is preferred because it does not exacerbate the inebriated state or require blood monitoring.[132,133] The protocol consists of a 15 mg/kg IV loading dose followed by a 10 mg/kg IV bolus every 12 hours. After 48 hours, the bolus dose should be increased to 15 mg/kg every 12 hours to account for enhanced fomepizole metabolism. For both ethylene glycol and methanol, patients are treated until serum levels fall below 20 mg/dL. Hemodialysis can be performed concurrently with fomepizole if clinically indicated. In ethylene glycol poisoning, hemodialysis is indicated when serum levels are greater than 50 mg/dL, when there is significant and refractory metabolic acidosis, or when there is evidence of end-organ damage. In methanol poisoning, hemodialysis is indicated if serum methanol levels are above 50 mg/dL, a lethal dose of methanol has been ingested, or there is significant and refractory metabolic acidosis or evidence of end-organ damage.

Ethanol can be administered orally or intravenously aiming for a level of 100 to 200 mg/dL. One protocol for therapeutic ethanol administration to such patients is as follows:[134]

Loading dose: 0.6 g/kg ethanol IV
Maintenance dose:
Nonalcoholic patient: 66 mg/kg per hour ethanol by continuous IV infusion
Alcoholic patient: 154 mg/kg per hour ethanol by continuous IV infusion
Patients receiving HD: double continuous infusion rate

Intravenous ethanol is supplied as a 10% solution in 5% dextrose, containing 10 g of ethanol per 100 mL of solution. Blood ethanol levels should be maintained in the target range during hemodialysis by either dialysis bath supplementation with 200 mg/dL ethanol, or doubling the dose of intravenous ethanol infusion.[134–140]

A high index of clinical suspicion is necessary to identify methanol- or ethylene glycol–intoxicated patients. Early institution of measures to inhibit metabolism by alcohol dehydrogenase of either substance to its toxic metabolites (formic acid from methanol, oxalic and glycolic acids from ethylene glycol) and urgent dialytic removal of the alcohol and its metabolites are of paramount importance in optimizing outcome. We also recommend alcohol dehydrogenase inhibition and prophylactic hemodialysis in any intoxicated patient with an unexplained elevation of the plasma osmolal gap, especially if serum levels are not immediately available. Further complicating matters, intoxication with diethylene glycol, which is undetected by assessment for serum ethylene glycol, but is associated with elevation of the osmolal gap and development of metabolic acidosis and acute renal failure, responds to inhibition of alcohol dehydrogenase and dialytic therapy. It is thus conceivable that an inebriated patient presenting with an elevated osmolal gap but negative serum levels for ethanol, methanol, and ethylene glycol, might benefit from empiric inhibition of alcohol dehydrogenase and hemodialysis.

Isopropanol is metabolized by alcohol dehydrogenase to acetone, which is excreted through the kidneys and breath, creating a sweet smell. Clinical features of poisoning include ketonemia, ketonuria, lack of an elevated anion gap or metabolic acidosis, an elevated osmolal gap, and hemorrhagic gastritis.[135] A serum isopropanol level confirms the diagnosis. Supportive measures are usually sufficient in the treatment of these patients. Gastric lavage can be helpful if performed in the first hour postingestion. Hemodialysis is indicated when lethal doses have been ingested (150 to 240 mL of 40% to 70% solution), or when lethal serum levels are detected (400 mg/dL). Refractory shock and prolonged coma are other indications for dialysis.[135] Fomepizole is not indicated.

AMPHETAMINES

Common amphetamine and amphetamine-like prescription drugs include methylphenidate, dextroamphetamine, and pemoline, used primarily for narcolepsy and attention-deficit disorder; and various anorectic medications used for weight loss, including diethylpropion and phentermine.

Illicit drugs include methamphetamine, an addictive stimulant that is made in small laboratories. Street methamphetamine is referred to by many names, such as "speed" and "meth." When it is inhaled in powder form or by smoking it is referred to as "crank," "crystal," or "ice." Over the past decade methamphetamine use has increased rapidly in the United States.[141] Ecstasy or "XTC" is the street name for 3,4-methylenedioxymethamphetamine or MDMA. Ecstasy use

has become common among teenagers and young adults, particularly at "rave" parties.

Amphetamines exert their toxicity via central nervous system stimulation, peripheral release of catecholamines, inhibition of reuptake of catecholamines, or inhibition of monoamine oxidase. They generally have a low therapeutic index. In overdose, they cause confusion, tremor, anxiety, agitation, and irritability. Additional features include mydriasis, tachyarrhythmias, myocardial ischemia, stroke, hypertension, hyperreflexia, hyperthermia, rhabdomyolysis, renal failure, coagulopathy, and seizures. Hepatotoxicity requiring liver transplantation has been reported with ecstasy abuse.[142] Death may result from arrhythmias, status epilepticus, intracranial hemorrhage, or aspiration pneumonitis.

Treatment is supportive, including maintenance of the airway and mechanical ventilation if necessary. Hypertension generally responds to systemic vasodilation with phentolamine or nitroprusside. Tachyarrhythmias may respond to esmolol or propranolol. Benzodiazepines, droperidol, or a phenothiazine are indicated for agitation.

Gastric lavage is helpful if performed within 1 hour of ingestion and AC should be administered promptly to adsorb remaining drug. Ipecac-induced emesis is not recommended because of the risk of abrupt onset of seizures and risk of aspiration. Elimination of amphetamines may be enhanced by forced-acid diuresis; however, acidification of the urine may increase risk of nephrotoxicity when there is myoglobinuria. Dialysis and hemoperfusion are not effective. In hyperthermic patients, the role of dantrolene is controversial, particularly due to its potential for hepatotoxicity.[143,144]

BARBITURATES

Clinical manifestations of mild to moderate barbiturate overdose include reduction in the level of consciousness, slurred speech, and ataxia. In higher doses, barbiturates cause hypothermia, hypotension, bradycardia, flaccidity, hyporeflexia, coma, and apnea. Patients with severe overdose may appear to be dead, including absence of EEG activity.

Cardiovascular depression is caused by a combination of decreased arterial tone and myocardial depression, leading to a high filling pressure, low cardiac output, and hypotension. Respiratory depression with hypercarbia and hypoxemia are common. In deep coma, the usual acid-base disturbance is a mixed respiratory and metabolic acidosis. Patients completely unresponsive to painful stimuli tend to be significantly more acidemic and hypoxemic than those who show some response, a finding that is not explained by differences in alveolar ventilation.[145] Hypoxemia may be aggravated by ventilation/perfusion mismatch and/or increased capillary permeability with development of the acute respiratory distress syndrome, possibly related to aspiration pneumonitis. Local tissue hypoxia resulting from vascular stasis and arterial hypoxemia may contribute to the development of barbiturate-related skin blisters, which commonly develop over areas of increased pressure.[146]

The diagnosis of sedative overdose is generally made on clinical grounds. Confirmation of barbiturate ingestion is readily available by routine urine toxicology screening. Blood levels are generally available and correlate with the severity of clinical findings; however, they rarely affect management.

As in all toxic ingestions, treatment of barbiturate overdose starts with supportive measures. There is no antidote. Gastric lavage is useful in acute massive overdose; ipecac-induced vomiting should be considered immediately after ingestion, particularly in children. Activated charcoal (AC) decreases further drug absorption and increases drug elimination,[147–149] but may not alter clinical course.[150] Multidose AC may be useful in life-threatening overdoses.[151]

Alkalinization of the urine (pH >7.5) increases the elimination of phenobarbital, but not other barbiturates, and may aggravate pulmonary edema.[152] Forced alkaline diuresis may be sustained by dopamine hydrochloride,[153] but this is generally not required or recommended. Charcoal hemoperfusion is indicated in severe poisoning characterized by prolonged coma or refractory hypotension, although its role is disputed.[154–156]

When mental status changes persist, other conditions should be considered and excluded: head trauma with subdural or epidural hematoma, intracerebral hemorrhage, embolic stroke, electrolyte abnormalities, hypoxemia, hypothyroidism, liver or renal failure, central nervous system infection, seizures, and significant alterations in temperature.

BENZODIAZEPINES

Benzodiazepines enhance the inhibitory effects of the neurotransmitter γ-aminobutyric acid (GABA), causing generalized depression of the central nervous system. Symptoms in overdose range from slurred speech and lethargy to respiratory arrest and coma, depending on the dose and compound ingested. In general, patients in coma from benzodiazepine poisoning are hyporeflexic with small to midposition pupils.

The diagnosis of benzodiazepine overdose depends on a history of ingestion or a high index of suspicion for drug overdose, combined with compatible clinical features. Confirmation of exposure is available by urine toxicology screening.

Treatment of benzodiazepine overdose consists of initial supportive measures, gastric emptying in acute ingestions, activated charcoal,[157] and flumazenil. There is no role for forced diuresis, dialysis, or hemoperfusion.

Flumazenil, a specific benzodiazepine antagonist, is useful in reversing sedation in patients undergoing procedures and in patients who have taken an intentional benzodiazepine overdose. Its effect on reversal of respiratory depression is less clear.[158,159] Judicious use of flumazenil provides diagnostic information, because flumazenil does not antagonize the CNS effects of alcohol, barbiturates, cyclic antidepressants, or narcotics.

Flumazenil should be considered if benzodiazepine overdose is highly suspected or confirmed and benzodiazepines have not been prescribed for a potentially life-threatening condition.[160] However, the risks and benefits of flumazenil compared to supportive measures alone are not clear. Flumazenil may cause severe withdrawal or seizures in dependent patients, and in an animal model of combined cocaine-diazepam poisoning, flumazenil precipitated seizures and increased mortality. Seizures may also occur in combined cyclic antidepressant-benzodiazepine overdose; however, cautious administration of flumazenil in this setting is likely to be safe.

Flumazenil is not a recommended component of the "coma cocktail."[2] Still, in selected cases it may help to distinguish benzodiazepine overdose from mixed-drug intoxication or

non–drug-induced coma, and it improves the clinical status of patients with benzodiazepine overdose. The recommended initial dose of flumazenil is 0.2 mg (2 mL) IV over 30 seconds. A further 0.3-mg (3 mL) dose can be given over 30 seconds if the desired clinical effect is not seen within 30 seconds. Additional 0.5-mg doses can be administered over 30 seconds at 1-minute intervals as needed to a total dose of 3 mg. Flumazenil dosed beyond 3 mg generally does not provide additional benefit.[161] Patients should be monitored for resedation. Resedation usually occurs within 0.5 to 3.0 hours after the first flumazenil dose.[162] In some cases repeat doses of flumazenil or a continuous infusion (0.1 to 0.5 mg/h) is necessary.[162] Hepatic dysfunction significantly changes the pharmacokinetic profile of flumazenil, requiring downward adjustment in dosage.[163]

Naloxone may partially reverse the antianxiety effects of benzodiazepines,[164] but it does not significantly alter motor or respiratory effects.[165,166]

When mental status changes persist, other conditions should be considered. These include subdural or epidural hematoma, intracerebral hemorrhage, embolic stroke, abnormalities of sodium and other electrolytes, hypoxemia, hypothyroidism, liver or renal failure, central nervous system infection, seizures, and significant alterations in temperature. A head CT scan should be performed early in the course of an obtunded patient, and there should be a low threshold to perform lumbar puncture.

BETA-BLOCKERS

Clinical features of β-blocker overdose depend on the drug type, amount and timing of overdose, coingestions, and comorbidities. The diagnosis is usually established on clinical grounds; blood levels are available but do not correlate well with severity.[167] Risk factors for cardiovascular morbidity include coingestion of another cardioactive drug and a β-blocker with myocardial membrane-stabilizing activity (acebutolol, betaxolol, pindolol, or propranolol).[168] Most patients develop β-blocker toxicity within 4 hours of ingestion.[169] Asymptomatic patients with a normal electrocardiogram after 6 hours generally do not require ICU monitoring.[169]

Cardiovascular complications of β-blockers include hypotension, bradycardia, atrioventricular block, and congestive heart failure and pulmonary edema. Hypotension is mainly due to decreased myocardial contractility rather than bradycardia. Other clinical manifestations of overdose are bronchospasm, hypoglycemia, hyperkalemia, lethargy, stupor, coma, and seizures. The risk of seizure is highest with propranolol, particularly when the QRS complex is >100 ms.[170] In a large retrospective review of 52,156 cases of β-blocker overdose, there were 164 deaths.[171] Propranolol was responsible for the greatest number of toxic exposures (44%) and implicated as the primary cause of death in a disproportionately higher percentage of fatalities (71%).

Treatment of β-blocker toxicity is largely supportive. Induced emesis is contraindicated because of the risk of sudden cardiovascular collapse.[170] Gastric lavage may help if the procedure is undertaken within 60 minutes of ingestion. Single-dose AC is recommended; there is no clear role for multidose AC.

Cardiovascular manifestations are treated with fluid resuscitation, vasopressors, atropine, electrical pacing, and glucagon. Glucagon effectively reverses myocardial depression and bradycardia. Its positive inotropic and chronotropic effect is mediated through adenyl cyclase, which increases cyclic adenosine monophosphate and intracellular calcium influx.[172] Improvements in bradycardia and hypotension occur within a few minutes and may preclude the need for high-dose catecholamine infusion.[173] Glucagon is given as bolus of 5 to 10 mg IV over 1 minute followed by an infusion of 1 to 10 mg/h. Dilution in saline or dextrose as opposed to the diluent provided by the manufacturer, which contains 2 mg of phenol per 1 mg of glucagon, is recommended to avoid phenol toxicity. The use of an insulin-glucose infusion for β-blocker toxicity may prove to be superior to glucagon alone; this strategy is under investigation.[174]

CALCIUM CHANNEL BLOCKERS

Calcium channel blockers (CCBs) selectively inhibit the movement of calcium ions through the membrane of cardiac and vascular smooth muscle during the slow inward phase of excitation-contraction. These agents have varying degrees of cardiovascular effects. Verapamil is more of a negative inotrope; nifedipine has more vasodilatory effects. Verapamil and diltiazem depress the sinus node and slow conduction through the atrioventricular node. The most common cardiovascular effect is hypotension, which generally occurs within 6 hours of CCB overdose (except with sustained-release preparations, in which toxicity may not be evident for 12 hours). Hypotension is mainly secondary to peripheral vasodilation as opposed to myocardial depression. Conduction abnormalities are worsened with concurrent β-blocker ingestion and existing cardiovascular disease.[175] Nausea, vomiting, hyperglycemia, confusion, lethargy, and coma have all been attributed to CCB overdose. Seizures are uncommon.

Gastric lavage may be useful for up to 8 hours after ingestion of a sustained-release preparation. Whole bowel irrigation has similarly been used for sustained-release preparations.[176] Multidose activated charcoal and hemodialysis are not indicated. However, charcoal hemoperfusion may have a role in verapamil overdose in the setting of hepatic dysfunction.[177]

Hypotension is treated first with fluids and vasopressors. For refractory hypotension, calcium chloride infusions (1 to 3 g by slow IV push) are recommended.[6] Additional calcium infusions (by bolus or constant infusion) are warranted in patients who demonstrate a transient response to the initial calcium infusion. Calcium gluconate (2 to 3 g total or 0.2 to 0.5 mL/kg of a 10% solution every 15 to 20 minutes to a total of 4 doses) has also been recommended.[178,179] Glucagon, given as a bolus of 5 to 10 mg IV over a minute followed by an infusion of 1 to 10 mg/h, may decrease vasopressor requirements.[173,180] Recently, several investigators have reported successful reversal of refractory shock in CCB toxicity with hyperinsulinemia-euglycemia therapy by continuous infusion of insulin and glucose.[181,182] Larger trials are needed to confirm its safety and efficacy.

CARBON MONOXIDE

Carbon monoxide (CO) is a nonirritating, colorless, tasteless, and odorless gas formed by incomplete combustion of carbon-containing materials (complete oxidation produces carbon dioxide). Poisoning occurs in the setting of smoke

inhalation, attempted suicide from automobile exhaust, and poorly ventilated charcoal and gas stoves. Rarely, CO is generated during hepatic metabolism of dichloromethane, a component of paint and varnish removers. Carbon monoxide is a common cause of death by poisoning in the United States.[183]

Carbon monoxide binds to hemoglobin with an affinity that is 240 times greater than oxygen. Fetal hemoglobin binds carbon monoxide to an even greater degree, placing the fetus at particularly high risk during CO exposure. Carboxyhemoglobin (HbCO) decreases oxyhemoglobin saturation and blood oxygen-carrying capacity, in a way that is analogous to anemia (a HbCO concentration of 50% effectively lowers hemoglobin concentration by half). However, CO poisoning causes significantly more toxicity than similar degrees of anemia because in CO poisoning (1) HbCO shifts the oxyhemoglobin dissociation curve to the left, interfering with off-loading of oxygen in peripheral tissues; (2) CO reacts with myoglobin to form carboxymyoglobin; (3) CO blocks myoglobin-facilitated diffusion of oxygen (particularly in tissues rich in myoglobin), as well as myoglobin-mediated oxidative phosphorylation, resulting in impaired cardiac contractility; (4) CO inhibits enzymes of the mitochondrial electron-transfer chain, further interfering with cellular function; and (5) CO binds and inhibits various intracellular enzymes including cytochrome P-450 and NADPH reductase.[184,185] Tissues with high oxygen consumption (namely, heart and brain) are particularly vulnerable to toxic effects.

The severity of CO poisoning depends on the concentration of CO, duration of exposure, and minute ventilation. Carboxyhemoglobin levels do not correlate well with clinical severity of CO poisoning. Generally, mild exposures (HbCO 5% to 10%) cause headache and mild dyspnea. These concentrations may be seen in heavy smokers and commuters on busy highways and are generally well tolerated, even in the presence of documented coronary artery disease and ventricular ectopy.[186] Carboxyhemoglobin concentrations between 10% and 30% cause headache, dizziness, weakness, dyspnea, and irritability. These concentrations may cause angina and myocardial infarction even in young and otherwise healthy patients.[187] Exposures to >50% HbCO result in coma, seizures, cardiovascular collapse, and death.

Ten to thirty percent of survivors of CO poisoning develop delayed neurologic sequelae (DNS) of hypoxic brain injury.[188,189] Clinical manifestations of DNS are variable, including persistent vegetative state, parkinsonism, memory deficits, behavioral changes, and hearing loss. Neurologic sequelae cannot be predicted by severity of carboxyhemoglobin exposure, age, method of exposure (accidental or intentional), or results of early neuroimaging (which may be normal or show low-density lesions in the globus pallidus or deep white matter changes).[190]

The diagnosis of CO poisoning is often made on clinical grounds in the setting of smoke inhalation or attempted suicide. However, the diagnosis can be missed if the history is incomplete and the clinical presentation is nondescript. There should be a high index of suspicion, particularly during cold weather months in patients with myocardial ischemia/infarction, cardiac arrhythmias, mental status changes, headache, and generalized weakness. Rarely, cherry-red skin discoloration reflecting high venous saturation (arteriolization of venous blood) provides an additional clue. Failure to diagnose CO may have disastrous consequences for the patient and other members of an affected household.

Laboratory confirmation of elevated HbCO is available by co-oximetry. Pulse oximetry is unreliable in detecting HbCO because it cannot distinguish carboxyhemoglobin from oxyhemoglobin. Pulse oximetry overestimates oxyhemoglobin by the amount of HbCO present, and may be in the normal range despite high concentrations of HbCO.[191] Arterial blood gases typically demonstrate a normal P_{O_2}, contrasting with low oxyhemoglobin saturation by co-oximeter, and metabolic acidosis. Of note, patients with suspected CO poisoning can be screened by analysis of venous blood because venous HbCO levels accurately predict arterial blood levels.[192]

Treatment of CO poisoning consists of immediate removal of the patient from the exposure and administration of 100% supplemental oxygen. Breathing 100% oxygen reduces the half-life of HbCO from 5 to 6 hours on room air to 40 to 90 minutes. Breathing oxygen that contains 4.5% to 4.8% carbon dioxide allows for a greater minute ventilation while maintaining normocapnia and further accelerates CO clearance. In one study of seven healthy volunteers, this method decreased the half-life of CO from 78 ± 24 minutes to 31 ± 6 minutes compared to 100% O_2 at resting minute ventilation.[193] Hyperbaric oxygen (HBO) (2.8 atmospheres) further decreases the half-life of HbCO to 15 to 30 minutes.

The role of HBO, which can result in arterial oxygen tensions greater than 2000 mm Hg and oxygen tensions in tissue approaching 400 mm Hg, is debated.[194] Several nonrandomized studies have demonstrated that HBO improves acute and delayed effects of CO poisoning.[195] One trial in 343 patients comparing HBO with 100% normobaric oxygen (NBO) delivered outside a hyperbaric chamber in patients without loss of consciousness showed no significant difference between groups in acute or delayed symptoms of CO poisoning.[196] Another unblinded study comparing HBO with 100% NBO in 65 patients without loss of consciousness demonstrated significantly fewer patients with DNS in the HBO group (0% versus 23%).[197] HBO has also been found to be beneficial in patients ($n = 26$) with loss of consciousness.[198] Another study comparing HBO with 100% NBO delivered in a hyperbaric chamber (i.e., blinded) in CO-poisoned patients with and without loss of consciousness showed no difference in the development of delayed neurologic sequelae, and that "normal neuropsychologic and functional outcomes are possible after severe CO poisoning without the use of HBO therapy."[199] In a recent double-blind, randomized trial, patients (76 in each group) with symptomatic CO poisoning were assigned to three HBO sessions within 24 hours or one NBO treatment plus two sessions of normobaric room air. Cognitive sequelae were less frequent in the HBO group at 6 weeks and 12 months.[200] In this study, the presence of cerebellar dysfunction before treatment was associated with the occurrence of cognitive sequelae.

Although the use of HBO remains controversial, we believe that patients with potentially life-threatening exposures should receive at least one HBO treatment (if hyperbaric capability is readily available). Particularly controversial is whether a patient with severe CO poisoning should be transferred solely for the purpose of HBO, a problem that may be solved by refinement of portable HBO chambers.[201] Also controversial is the relative efficacy of single versus multiple

HBO treatments.[202,203] Since CO poisoning may occur with other life-threatening injuries (e.g., burns or other trauma), the judgment to utilize HBO must take into consideration the patient's stability and the ability to monitor and treat during HBO therapy.

COCAINE

Cocaine may be snorted nasally, inhaled orally, or used intravenously. Body packers swallow multiple wrapped packages of cocaine in an attempt to smuggle the drug across national borders; body stuffers swallow or conceal wrapped packets of cocaine in various body cavities when law enforcement agents approach. Freebase cocaine is prepared for smoking by dissolving cocaine salt in an aqueous alkaline salt solution and then extracting the freebase form with a solvent such as ether. Heat is often used to speed this process, creating a fire hazard. The preferred freebase preparation for smoking is crack cocaine, which is a more potent, rapidly absorbed, water-soluble alkaloid form of the drug.

Cocaine is often mixed with other substances of abuse including heroin ("speedball"), phencyclidine, and various sympathomimetic drugs used to treat nasal congestion.[204] In the presence of ethanol, cocaine is transesterified in the liver to cocaethylene, which has similar properties to cocaine but a longer half-life. Cocaethylene is a myocardial depressant capable of reducing stroke volume and arterial pressure while increasing pulmonary artery wedge pressure. Cocaethylene also prolongs QRS and QTc intervals.[205] Individuals combine cocaine and ethanol to achieve a more pronounced and prolonged euphoria, but this combination is more toxic than either drug alone.

Toxic effects of cocaine stem from excessive central nervous system stimulation and inhibition of neuronal uptake of catecholamines. The result is generalized sympathetic overstimulation similar to that of amphetamine intoxication. Onset and duration of symptoms depend on route of administration, dose, and patient tolerance. Smoking and intravenous use produce symptoms within 1 to 2 minutes; oral use delays onset of symptoms by 20 to 30 minutes. The half-life of cocaine is approximately 60 minutes.

Common central nervous system manifestations include euphoria, anxiety, agitation, psychosis, and delirium. Rarely, cocaine-induced ischemic cerebral infarction is mistaken for a psychiatric condition.[206] Seizures are generally short-lived and self-limited unless there is ongoing drug absorption (as in body packers or body stuffers) or other central nervous system pathology. Several mechanisms are likely responsible for more serious central nervous system complications. A sudden rise in systemic arterial pressure may cause intracerebral hemorrhage and subarachnoid hemorrhage,[207] particularly in association with an underlying aneurysm or arteriovenous malformation. Vasospasm, vasculitis, myocardial infarction with cardiac arrhythmias, and increased platelet aggregation may further trigger ischemic events.[208] Benign angiopathy of the CNS has also been reported.[209] In most cases, the time interval between drug abuse and the cerebrovascular event is less than 3 hours.[210]

Cardiovascular manifestations of cocaine abuse include chest pain, myocardial ischemia and infarction, sudden death, arrhythmias, congestive heart failure, pulmonary hypertension, endocarditis, and aortic dissection.[211–214,144] Common findings include a significant increase in heart rate and mean arterial blood pressure consistent with sympathetic stimulation combined with a fall in ejection fraction as determined by two-dimensional echocardiography.[215] The pathogenesis of these cardiovascular complications has not been fully explained, but may be related to a combination of the sympathomimetic and membrane effects (sodium and potassium channel blockade) of cocaine.

The mechanism by which cocaine induces myocardial ischemia remains controversial. Most prior studies have postulated that cocaine-induced coronary vasoconstriction limits myocardial oxygen. Platelet aggregation and increased myocardial oxygen requirements may fuel the imbalance between supply and demand. Asymptomatic cocaine abusers have been reported to have left ventricular hypertrophy, segmental wall motion abnormalities, ST-T wave changes, pathologic Q waves, and increased QRS voltage on electrocardiogram.[216]

Baseline electrocardiographic changes complicate decisions regarding the need to hospitalize patients with cocaine-associated chest pain. Studies have yielded conflicting data regarding the incidence of myocardial infarction in cocaine abusers, and there are no clinical parameters that reliably identify patients at very low risk for myocardial infarction. These considerations mandate that all patients with cocaine-associated chest pain are evaluated for myocardial infarction.[217] Furthermore, cocaine-related mental status changes may interfere with patient reporting of cocaine-associated chest pain.[218]

Patients with cocaine-associated chest pain often continue to use cocaine after discharge. Cardiac stress tests or cardiac angiography may not be necessary for patients in whom myocardial infarction has been ruled out and who do not continue to have chest pain; such patients appear to have a low risk for subsequent myocardial infarction and death. Instead, efforts should emphasize cessation of cocaine abuse.[219]

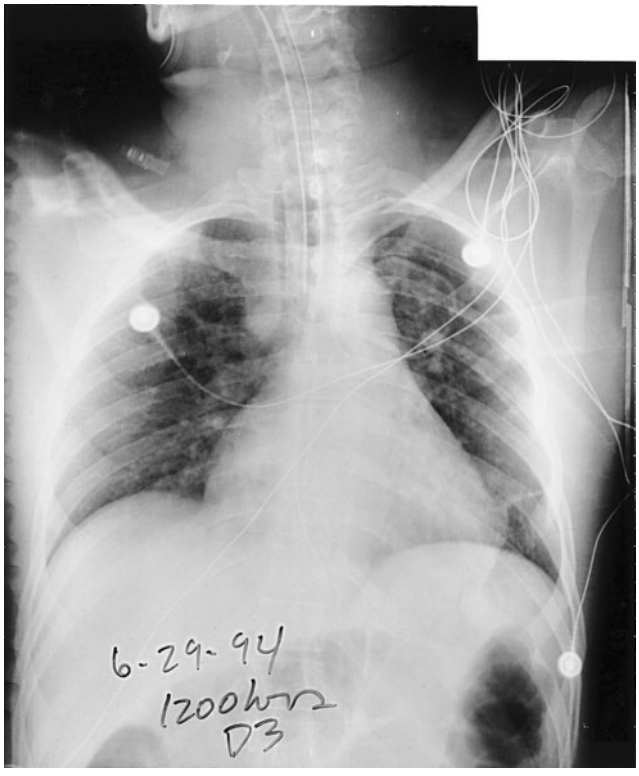
Respiratory complications of cocaine include status asthmaticus,[220] upper airway obstruction (stridor),[221] pulmonary hypertension,[222] barotrauma, pulmonary edema, and alveolar hemorrhage.[223] Not uncommonly, crack cocaine causes an acute pulmonary syndrome characterized by dyspnea, diffuse infiltrates, and hemoptysis.[224] The severity of respiratory complications ranges from mild dyspnea to severe respiratory failure requiring intubation and mechanical ventilation.

Another severe manifestation of cocaine abuse is rhabdomyolysis.[225] Creatine kinase levels are often over 10,000 U/L on presentation, with values reported as high as 85,000 U/L.[226] There is often concurrent hyperthermia, tachycardia, muscle rigidity, disseminated intravascular coagulation, hepatic dysfunction, and renal failure.[225,226] Cocaine also has a direct toxic effect on muscles.

Cocaine-induced hyperthermia resembles neuroleptic malignant syndrome;[227] both are characterized by a decrease in the number of dopamine receptors or depletion of dopamine. Contributors to hyperthermia include agitation and adrenergic stimulation causing vasoconstriction.

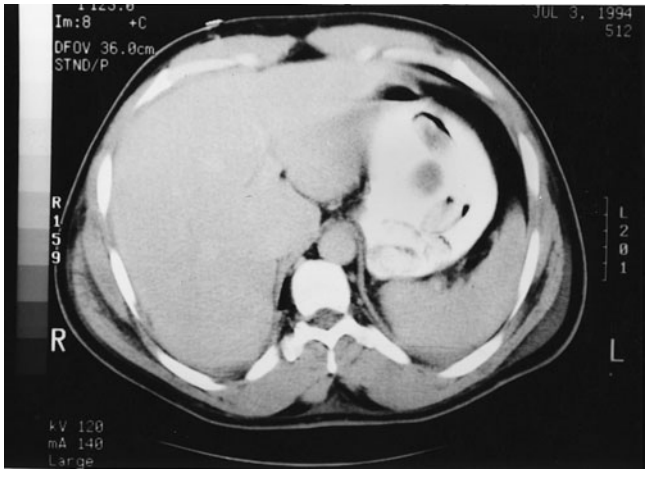
Rare cocaine-associated complications include ischemic colitis,[228] renal infarction,[229] nasal septal perforation, and localized areas of skin necrosis due to accidental subcutaneous injection. Intranasal use of cocaine has been associated

with sinusitis and botulism;[230] botulism also occurs with skin wounds.[231] In addition, the behavioral effects of cocaine increase the likelihood of violent fatal injuries.[232]



Treatment of cocaine intoxication starts with the ABCDs of resuscitation and treatment of seizures, hyperthermia, and agitation. For orally ingested drug, AC should be given to decrease drug absorption. Gastric lavage and ipecac-induced vomiting are not recommended because of the risk of seizures and subsequent aspiration. In body packers whole bowel irrigation with a polyethylene glycol electrolyte solution (e.g., GoLYTELY) 1 to 2 L/h is recommended until the rectal effluent clears and there is no radiographic evidence of retained drug condoms (Fig. 102-2).[233] For this purpose, abdominal ultrasound, a CT scan with contrast or a small bowel follow-through contrast study is more sensitive and specific than routine abdominal radiographs.[234] Contraindications to whole-bowel irrigation include ileus, gastrointestinal hemorrhage, and bowel perforation. Polyethylene glycol electrolyte solutions may also displace cocaine from AC.[235] Surgical removal of retained packages may be required, particularly if there is bowel obstruction or package perforation.[236] Endoscopic approaches risk packet rupture and are not recommended. Neither dialysis nor hemoperfusion effectively removes cocaine.

Perhaps the most important treatment strategy in cocaine intoxication is rapid treatment of agitation and hyperthermia. Along these lines, patient cooling, benzodiazepines, and occasionally muscle relaxation improve outcome,[237] although there are concerns that benzodiazepines may enhance cocaine-induced hyperactivity.[238] For purposes of patient sedation, haloperidol has not been shown to be of benefit,[237] and few data are available regarding a possible role for barbiturates.



First-line treatments of cocaine-associated chest pain are nitrates and benzodiazepines.[2,6,239,240] Use of an α-adrenergic receptor blocker such as phentolamine is recommended in patients refractory to nitrates and benzodiazepines.[6,241] Nonselective β-blockers should not be used alone to treat cocaine toxicity because of the potential for unopposed α-adrenergic stimulation and potentiation of coronary vasoconstriction.[242] Propranolol worsens outcome in an animal model;[243] esmolol produces an inconsistent antihypertensive response and may cause hypertension or hypotension.[244] The use of labetalol is controversial.[6] Labetalol blocks both α- and β-adrenergic receptors and may reverse cocaine-induced hypertension, but there are data that show that it is ineffective in cocaine-induced coronary vasoconstriction.[245]

The role of thrombolytic therapy remains unclear in patients with cocaine-associated acute myocardial infarction. Intracoronary administration of thrombolytics has been recommended over peripheral administration in refractory cases, but further studies addressing safety and efficacy are needed before firm recommendations can be made.[6,246] Thrombolytics are contraindicated in uncontrolled hypertension, aortic dissection, and intracerebral hemorrhage.

Treatment of respiratory complications is supportive. Oxygen is delivered to improve arterial oxygen saturation; continuous positive airway pressure or positive end-expiratory pressure may decrease intrapulmonary shunting in patients with diffuse lung disease. Inhaled bronchodilators and corticosteroids are indicated for cocaine-associated bronchospasm. Tube thoracostomy may be required for pneumothorax; pneumomediastinum is watched expectantly.

A

B

FIGURE 102-2 A chest radiograph (*A*) and an abdominal CT scan with oral contrast (*B*) in a patient "body packing" cocaine. Note the presence of multiple densities in the stomach visible on the abdominal CT scan consistent with partially filled bags of cocaine, and that these bags are barely visible (if at all) in the left upper quadrant on the plain film.

CYANIDE

Cyanide is found in a variety of synthetic and natural substances: plastics, glue removers, wool, silks, nylons, and various seeds and plants. Poisoning occurs through a number

of mechanisms including (1) ingestion (e.g., the cassava-based foodstuff "gari"[247] or tainted over-the-counter preparations[248]); (2) inhalation of hydrogen cyanide gas (HCN), a combustion by-product of cyanide-containing products; (3) sodium nitroprusside infusion; and very rarely (4) absorption of cyanide-containing solutions or gas through skin.

Cyanide is a rapidly-acting poison that binds to cellular cytochrome oxidase and interferes with aerobic oxygen utilization. Once ingested, it is detoxified by enzymatic conversion to the less toxic, renally excreted metabolite thiocyanate. The most important enzyme for cyanide conversion is rhodenase (a sulfur transferase), which forms thiocyanate in the presence of sulfane sulfur. This reaction occurs in liver, although the kidney also contains high concentrations of rhodenase. Serum albumin plays an important role in cyanide detoxification because it is a readily available source of sulfane sulfur and it has sulfurtransferase activity. A small amount of cyanide is also detoxified by the vitamin B_{12} precursor hydroxycobalamin. This agent binds cyanide to form nontoxic cyanocobalamin.

Clinical manifestations of cyanide poisoning depend upon the amount and rate of cyanide absorption. Patients who are asymptomatic after inhalation (which is associated with immediate absorption) do not require treatment and can be discharged after a short period of observation. Patients who ingest cyanide orally may present with progressive symptoms over minutes to hours. Oral ingestion on an empty stomach with low pH results in the rapid generation of HCN from potassium and sodium salts (KCN and NaCN). Oral ingestion into a full and alkaline stomach delays generation of HCN, resulting in progressive symptoms over 1 to 2 hours. Ingestion of plants containing cyanogenic glycosides also causes delayed and progressive toxicity.

At low concentrations, cyanide acts as a respiratory and central nervous system stimulant. Clinical manifestations include anxiety, dyspnea, headache, confusion, tachycardia, and hypertension. At higher concentrations, patients may develop stupor or coma, seizures, fixed and dilated pupils, hypoventilation, hypotension, bradycardia, heart block and ventricular arrhythmias. Patients with massive ingestion present in coma and cardiopulmonary collapse. Survival in these cases depends on the success of cardiopulmonary resuscitation, with survivors at great risk of permanent sequelae of anoxic brain injury.[249,250]

The diagnosis of cyanide poisoning is usually made on clinical grounds, often in the setting of smoke inhalation injury, where combined carbon monoxide and cyanide toxicity occurs. Highly suggestive is the rapid onset of coma, seizures, and cardiopulmonary dysfunction. Lactic acidosis and an elevated mixed venous oxyhemoglobin saturation provide evidence for the blocking of aerobic oxygen utilization.[251] Elevated venous oxyhemoglobin is further demonstrated by arteriolization of retinal veins on funduscopic examination or venous blood on venipuncture. The bitter almond scent of HCN may also be detected.

Short-term high-dose sodium nitroprusside therapy (>10 μg/kg per minute) may result in acute cyanide poisoning characterized by anxiety, agitation, tachycardia, myocardial ischemia, metabolic acidosis, hyperventilation, seizures, and paradoxical hypertension (or difficulty in lowering blood pressure). Cyanide poisoning is uncommon at nitroprusside infusion rates less than 10 μg/kg per minute; however, toxicity has been reported at an infusion rate of 4 μg/kg per minute after 3 hours of therapy.[252] Prolonged nitroprusside infusion increases the risk of thiocyanate toxicity. Thiocyanate levels should be followed in these cases, particularly when there is renal dysfunction. Thiocyanate levels greater than 50 to 100 mg/L cause confusion, somnolence, and seizures.[252]

When clinical features of cyanide poisoning are present, treatment should proceed before confirmation of the diagnosis by determination of whole blood cyanide levels. The laboratory should be notified prior to drawing the blood, since special instructions may be required to measure this unstable compound. Whole blood levels greater than 0.5 to 1.0 mg/L are considered toxic.[253] Smokers may have cyanide levels nearing 0.1 mg/mL.

Treatment begins by identifying and treating life-threatening problems. Survival depends on prompt and successful CPR.[254] Oxygen therapy at 100% fraction of inspired oxygen ($F_{I_{O_2}}$) is effective in cyanide poisoning and should be administered immediately.[255–258] Hyperbaric oxygen is of unproven benefit in cyanide poisoning (in part because of the time element involved).[259]

Several antidotes are available to treat cyanide poisoning. Amyl and sodium nitrite induce formation of methemoglobin. Cyanide has a high affinity for the ferric iron contained in methemoglobin, thereby rendering methemoglobin an effective scavenger of unbound cyanide. Amyl nitrite is administered by inhalation of crushable ampules. Ampules are inhaled for 15 to 30 seconds; effects last approximately 2 to 3 minutes. This therapy can be used in spontaneously breathing patients and in patients receiving ventilatory support by face mask or endotracheal tube until administration of sodium nitrite. Sodium nitrite is administered intravenously at a dose of 300 mg over 3 minutes to convert hemoglobin to methemoglobin. Half this dose may be repeated after 2 hours if there is persistent toxicity and a tolerable degree of methemoglobinemia. Conversion of 25% to 30% of hemoglobin to methemoglobin effectively treats cyanide poisoning,[260] although in usual practice, methemoglobin levels generally remain less than 20%.[261] Induction of methemoglobinemia of course has several disadvantages, including the reduction of circulating hemoglobin available for oxygen transport (which may be further aggravated by concurrent carboxyhemoglobinemia in the setting of smoke inhalation) and the risk of hemolysis in glucose-6-phosphate dehydrogenase (G6PD) deficient patients.[262] In one study evaluating serial cyanide, methemoglobin, and carbon monoxide levels in seven critically ill smoke inhalation patients receiving sodium nitrite, peak measured methemoglobin levels did not occur until a mean of 50 minutes following administration of sodium nitrite.[261] The total oxygen-carrying capacity reduced by the combination of carboxyhemoglobin and methemoglobin was never more than 21% (range = 10% to 21%). Of note, methylene blue should be avoided to treat methemoglobinemia because it will release free cyanide.

Sodium thiosulfate is safe and effective in cyanide poisoning. It acts as a sulfur donor to rhodenase and other sulfurtransferases thereby enhancing conversion of cyanide to thiocyanate.[263,264] The dose is 12.5 g IV (50 mL of a 25% solution) over 10 minutes. Half this dose may be repeated in 2 hours for persistent toxicity. Coadministration of thiosulfate with nitroprusside (in a ratio of 1:10 thiosulfate to nitroprusside) effectively eliminates the possibility of cyanide

intoxication without altering the efficacy of nitroprusside.[265] Treatment with sodium thiosulfate can cause thiocyanate toxicity, particularly in the setting of renal insufficiency. Fortunately, thiocyanate is readily dialyzable.

Hydroxycobalamin is a cyanide antidote capable of reducing red blood cell and plasma cyanide concentrations. Little is known, however, about the safety, efficacy, and pharmacokinetics of hydroxycobalamin in human cyanide poisoning. Acute allergic reactions have been reported,[266] and hydroxycobalamin may interfere with several chemistry methodologies affecting measurement of aspartate aminotransferase, total bilirubin, creatinine, magnesium, and iron.[267] In healthy adult smokers, hydroxycobalamin 5 g IV resulted in transient reddish discoloration of skin, mucous membranes, and urine, slight elevation in blood pressure, and a decrease in heart rate.[268] It did, however, decrease whole blood cyanide levels by 59% and increase urinary cyanide excretion. As with thiosulfate, coadministration of hydroxycobalamin (25 mg/h IV) with nitroprusside may protect against nitroprusside-induced cyanide toxicity.[269,270] The currently recommended dose of hydroxycobalamin in acute cyanide poisoning is 4 to 5 g IV administered as a one-time dose.[270–272]

Intravenous dicobalt ethylenediamine tetraacetic acid (EDTA) is a potent cyanide antidote. When cyanide binds to cobalt a stable and nontoxic compound is formed. The initial dose is 300 to 600 mg IV over 1 minute, followed by an additional 300 mg if the patient fails to improve. Side effects from EDTA include cardiac arrhythmias, hypotension, nausea, vomiting, and severe allergic reactions.[273]

Additional treatment strategies include removal and isolation of all contaminated clothing. Health care workers should avoid contact with cyanide-containing solutions and vapors. Gastric emptying is recommended for acute ingestions, followed by AC. Induced emesis is not recommended because of the risk of rapid cyanide-induced deterioration in clinical status (and subsequent risk of aspiration). There is no role for hemodialysis or hemoperfusion except to clear high levels of thiocyanate.

CYCLIC ANTIDEPRESSANTS

Cyclic antidepressant drugs (including the tricyclics, tetracyclics, bicyclics, and monocyclics) are among the most commonly encountered causes of self-poisoning.[2] Tricyclic antidepressants include amitriptyline, desipramine, doxepin, imipramine, nortriptyline, protriptyline, and amoxapine. In overdose, these drugs primarily affect the central nervous and cardiovascular systems. Lesser effects are seen in the gastrointestinal tract. Central nervous system toxicity results from anticholinergic effects and inhibition of neural reuptake of norepinephrine or serotonin. Cardiovascular manifestations stem from anticholinergic effects, inhibition of neural uptake of norepinephrine or serotonin, peripheral α-adrenergic blockade, and membrane depressant effects. Most patients develop symptoms within the first 6 hours after ingestion or not at all.

Clinical presentation is divided into anticholingeric effects, cardiovascular effects, and seizures. Mydriasis, blurred vision, fever, dry skin and mucous membranes, lethargy, delirium, coma, tachycardia, ileus, myoclonus, and urinary retention are manifestations of anticholinergic toxicity. These symptoms are described by the common mnemonic: "hot as a hare, dry as a bone, red as a beet, mad as a hatter."

Cardiovascular effects consist of sinus tachycardia with prolongation of the QRS, QTc, and PR intervals. Occasionally, sinus tachycardia with QRS prolongation is difficult to distinguish from ventricular tachycardia. Torsades de pointes is rare. Various forms of atrioventricular block may accompany cyclic antidepressant overdose. Right bundle-branch block is common.

A maximal limb-lead QRS interval longer than 0.10 second reliably predicts serious intoxication (except in cases of amoxapine overdose) requiring monitoring until resolution.[274] QRS duration <0.1 second is rarely associated with arrhythmias or seizures. Patients with QRS >0.10 second are at risk for seizures and arrhythmias. In one prospective trial seizures occurred at any QRS duration ≥ 0.10 second, but ventricular arrhythmias were seen only with a QRS duration ≥ 0.16 second.[274] Serum drug levels in this study did not predict complications.

Hypotension is relatively common (although hypertension also occurs). It results from venodilation and decreased myocardial contractility. In severe cyclic antidepressant overdose, hypotension may be refractory to fluid administration and vasopressors and associated with pulmonary edema.

Seizures are common in cyclic antidepressant overdose. They may be short-lived and self-limited or prolonged and refractory to treatment. Neurologic deterioration may be abrupt and unpredictable. A "downward spiral" occurs when seizures or arrhythmias cause metabolic acidosis. Metabolic acidosis increases the fraction of free drug and enhances drug toxicity.

The diagnosis of cyclic antidepressant overdose depends on a history of ingestion or a high index of suspicion and compatible clinical features. Cyclic antidepressant overdose should be considered in all patients with QRS prolongation. Confirmation of cyclic antidepressant exposure is rapidly available by urine toxicology screening.

Treatment of cyclic antidepressant overdose starts with identifying and treating life-threatening problems. Sodium bicarbonate (1 to 2 mEq/kg IV) is indicated if there is widening of the QRS interval to decrease the fraction of free drug. Sodium bicarbonate should be continued until there is narrowing of the QRS interval or serum pH exceeds 7.5 to 7.55. In intubated patients, hyperventilation can achieve the same target pH, but hypertonic sodium usually provides greater benefit.[6] The electrocardiogram (ECG) should be followed closely in all cases for 48 to 72 hours.[275] In general patients should remain in an ICU for 12 hours after discontinuation of all therapy and be asymptomatic with a normal ECG and pH before transfer.[276,276a]

Lidocaine is the drug of choice when ventricular arrhythmias are refractory to sodium bicarbonate.[6] Class 1a antiarrhythmics (e.g., procainamide) are contraindicated in cyclic antidepressant overdose because of added cardiac toxicity. Anecdotal reports have also suggested a primary role for phenytoin; however, convincing data are not available to support the use of phenytoin in the setting of cyclic antidepressants as either a prophylactic or therapeutic drug. Physostigmine should not be used in cyclic antidepressant overdose because of possible worsening of cardiac conduction disturbances.

Hypotension refractory to sodium bicarbonate should be treated with vasopressors. A pulmonary artery catheter rarely helps direct therapy and may be arrhythmogenic.

Norepinephrine and phenylephrine are the preferred vasopressors because cyclic antidepressants deplete presynaptic catecholamine stores, limiting the effectiveness of dopamine. Dopamine and other vasopressors may cause an exaggerated vasopressor response in the presence of cyclic antidepressants because of inhibition of catecholamine reuptake. An enhanced hypertensive response to phenylephrine can be also seen in anticholinergic overdose because anticholinergics interfere with phenylephrine-induced reflex bradycardia.

Seizures should be treated with intravenous diazepam or lorazepam. Phenytoin may be administered cautiously in refractory cases. Paralysis may be indicated when seizures are refractory (as may be seen in amoxapine overdose) to control temperature and muscle breakdown. After paralysis, an EEG monitor should be placed to guide subsequent therapy.

Because delayed gastric emptying is extremely common, gastric lavage may be considered during the first 12 hours after a large ingestion. Syrup of ipecac is contraindicated in cyclic antidepressant overdose because patients may suddenly seize or develop a lethal arrhythmia at any time after dosing. Single-dose AC is effective, although anticholinergic-induced ileus increases risk of charcoal-induced bowel obstruction. Because these drugs are lipid-soluble and protein-bound, dialysis and hemoperfusion are not effective.

GAMMA-HYDROXYBUTYRATE

Gamma-hydroxybutyrate (GHB), also known as "liquid ecstasy," "liquid G," "date-rape drug," or "fantasy," has become a popular drug of abuse among young individuals. In the 1980s, the drug was promoted to bodybuilders as a growth hormone stimulator and muscle-bulking agent. Recreationally, it was claimed to cause euphoria without a hangover and to increase sensuality and disinhibition. In 1990 GHB was banned outside of clinical trials approved by the FDA. However, products such as Revivarant, containing a precursor of GHB (gamma-butyrolactone), continued to be available until a recent ban by the federal government.[277,278]

GHB is derived from γ-aminobutyric acid (GABA) and is thought to function as an inhibitory transmitter through specific brain receptors for GHB and possibly through GABA receptors.[279] GHB increases stage IV of non–rapid eye movement sleep (slow-wave deep sleep).[280] In narcoleptics it decreases cataplexy, sleep paralysis, hallucinations, and daytime sleep attacks.[281] Clinical manifestations of GHB depend on the dose ingested. Regular use causes tolerance and dependence, and abrupt discontinuation can result in delirium and psychosis.[282] Low doses of GHB can induce a state of euphoria. Higher doses can cause coma and death.[283] Emesis, bradycardia, hypotension, and respiratory acidosis have all been described.[284]

Treatment of GHB poisoning is mainly supportive. It is important to keep in mind that coingestions are common, especially with ethanol and amphetamines.[284] Mechanical ventilation may be required for brief periods, as most patients regain consciousness spontaneously within 5 hours.[284]

Yates and Viera have described two patients with GHB overdose who awoke in less than 5 minutes after a single dose of physostigmine.[285] Whether physostigmine will prove to be useful in this setting is unclear since rapid recovery is the norm and there are risks in its use, particularly when there is coingestion of a cyclic antidepressant.

Normal toxicologic screens do not include GHB. However, when documentation is important in cases of sexual assault, GHB can be detected in urine and blood by special laboratories using gas chromatography-mass spectroscopy.[286,287] GHB can also be detected by hair analysis.[288]

DIGOXIN

Digitalis is a cardiac glycoside clinically used for treatment of systolic myocardial dysfunction and supraventricular arrhythmias. Two formulations are commercially available: digoxin and digitoxin. These compounds differ importantly in their routes of metabolism: digoxin depends upon renal excretion (60% to 70% unchanged, including filtration and some tubular secretion), whereas digitoxin is hepatically metabolized (to form renally excreted metabolites, including digoxin). They share the important property of prolonged half-life (42 hours for digoxin, 7 days for digitoxin). Digoxin is extensively tissue bound (mostly in muscle), resulting in a massive apparent volume of distribution (4 to 7 L/kg). Digoxin intoxication may occur accidentally during chronic therapy. Diminished clearance because of renal insufficiency, which often increases half-life to 80 to 180 hours, is the most common precipitant of such episodes. Drug interactions may also elevate digoxin levels by impairing renal excretion (e.g., verapamil, other calcium channel blockers, quinidine, or cyclosporine) or hepatic biotransformation (e.g., cyclosporine, verapamil, other calcium channel blockers, or amiodarone), or decreasing digoxin tissue binding and Vd (e.g., quinidine). Finally, increased oral bioavailability because of antibiotic-induced sterilization of digoxin-metabolizing gut flora may also precipitate digoxin toxicity.[289] Variability between digoxin preparations is no longer a major problem.[290] Digitalis may also be ingested in toxic amounts as an unsuspected component of herbal preparations[291] or as a deliberate self-overdose.

The clinical manifestations of digitalis intoxication include fatigue, gastrointestinal symptoms (anorexia, nausea, vomiting, diarrhea, and abdominal pain), neurologic disturbances (blurred vision, visual color changes, headache, dizziness, and delirium), and cardiac arrhythmias (including any category, classically supraventricular tachycardia with AV block). Massive digoxin overdose also causes hyperkalemia, because of inhibition of cellular Na-K-ATPase function. Plasma digoxin levels correlate generally with therapeutic and toxic effects, but interindividual variability in response to a particular digoxin level is common.[292–294] In addition, several factors aside from excess total body digoxin can precipitate digitalis toxicity, even in the therapeutic range, by increasing myocardial digitalis sensitivity. Such factors include hypokalemia, hypomagnesemia, myocardial disease, old age, hypothyroidism, and a variety of other metabolic disturbances (hypoxemia, acid-base abnormalities, hypercalcemia, and hypernatremia). More commonly, digitalis intoxication during chronic therapy results from renal insufficiency or drug interactions (see above).

To be most informative, a digoxin level should be taken when steady-state conditions are in effect. This occurs after approximately 1 week when renal function is normal. The timing of blood sampling is also crucial. To allow time for

distribution a sample should be obtained at least 6 hours after the last dose. Based on data demonstrating benefit of low serum digoxin concentrations in heart failure,[295] many laboratories have lowered the therapeutic range for digoxin to 0.5 to 1.0 ng/mL.

Supportive therapy of overdose includes rapid correction of arrhythmogenic metabolic disturbances, particularly hypokalemia. As noted above, hyperkalemia may also require treatment unless Fab therapy is immediately available. Severe bradyarrhythmias that are unresponsive to atropine may require electrical pacing. Ventricular tachycardia should be treated with lidocaine or phenytoin. Electrical cardioversion of any digitalis toxicity–induced arrhythmia should be reserved as a last resort, using the minimum effective energy level.

Gastrointestinal decontamination measures should include emesis or lavage and should be followed by activated charcoal. Charcoal doses may be repeated to minimize enterohepatic recirculation of active digitalis metabolites; orally administered cholestyramine has also been used for this purpose. Timely elimination of digoxin may be difficult to achieve in the face of significant renal insufficiency. Hemodialysis or hemoperfusion can remove only small amounts of total body digitalis (because of extensive tissue binding), but HD may still be indicated for correction of hyperkalemia or other acid-base derangements in renally impaired patients. Fortunately, immunotherapy with digoxin-specific antibody Fab fragments is widely available. These sheep-derived antibodies bind intravascular digoxin, also competitively removing digoxin bound to cellular Na-K-ATPase sites.[296–298] Indications and protocol for Fab therapy are contained in Table 102-24.

Following intravenous administration, plasma free digoxin levels and toxic effects (hyperkalemia and arrhythmia) decrease almost immediately, and the Fab fragments and bound digoxin are eliminated by glomerular filtration (Fab molecular weight is 50,000 Da). Standard digoxin levels can be misleading after treatment. Fab fragments have also been successfully used to treat digoxin toxicity in patients with renal insufficiency, including chronic hemodialysis patients; the potential late complication of rebound intoxication because of impaired Fab-digoxin complex excretion is not commonly seen even in such circumstances.[299] Nevertheless, monitoring of free (rather than total) plasma digoxin levels, and consideration of follow-up plasmapheresis to remove Fab-digoxin complexes has been advocated to prevent late rebound toxicity in renal failure patients.[300]

LITHIUM

Lithium (Li) is used for treatment of bipolar affective disorders. Chronic use is associated with development of nephrogenic diabetes insipidus, renal insufficiency, hypothyroidism, and leukocytosis. Lithium has a low therapeutic index (target range = 0.5 to 1.25 mEq/L). Most cases of intoxication, associated with levels above 1.5 mEq/L, are caused by unintentional overdose during chronic therapy. Volume depletion (aggravated by underlying diabetes insipidus) and renal insufficiency are the common precipitants of lithium overdose. Li is a low-molecular-weight monovalent cation (7 Da), has a small volume of distribution (0.66 L/kg), and is eliminated by glomerular filtration. Li has a prolonged elimination half-life that is increased by advancing age, renal insufficiency, and duration of therapy: 18 hours in adults with normal renal function; up to 36 hours in the elderly; and increased up to twofold in chronically treated subjects.[301] Lithium is predominantly (80%) reabsorbed in the proximal renal tubule, and the other 20% of filtered load is excreted. Any stimulus which augments proximal tubular sodium reabsorption tends to cause increased Li reabsorption in parallel and may precipitate Li intoxication; volume depletion, congestive heart failure, cirrhosis, and other salt-avid states all reduce Li clearance

TABLE 102-24 Indications and Protocol for Digoxin Immune Fab Therapy (Digibind)

Indications	Dose Estimate (# Vials) Based on Serum Steady State Digoxin Levels[a]		Approximate Digibind Dose for Treatment of a Single Large Ingestion[b]	
1. Severe ventricular arrhythmias	# Vials = (serum digoxin level in ng/mL) (weight in kg)/100		# Vials = (total digitalis body load in mg)/(0.5 mg digitalis bound/vial)[c]	
2. Progressive, atropine unresponsive bradyarrhythmias				
	Examples: for a 70-kg adult:		Examples:	
3. Ingestion of >10 mg of digoxin in adults	Serum concentration (ng/ml)	#Vials	Quantity of 0.25-mg tabs ingested (80% bioavailable)	#Vials
4. Steady-state concentration >10 mg/mL	1	1	25	10
	2	2	50	20
5. Progressive potassium elevation or potassium >5 mEq/L	4	3	75	30
	8	6	100	40
	12	9		
	16	11		
	20	14		

[a] Six vials is usually adequate to reverse most cases of chronic toxicity.
[b] Twenty vials is usually adequate to treat acute ingestions of unknown quantity.
[c] Each vial of Digibind contains 38 mg of purified digoxin-specific Fab fragments which will bind 0.5 mg of digoxin or digitoxin.

in this manner, independently of effects on glomerular filtration rate. Deliberate acute lithium overdose by ingestion with suicidal intent also commonly occurs.[302]

Serum levels following acute Li ingestion correlate poorly with intracellular Li levels and clinical symptoms. A closer correlation exists between serum levels and clinical symptoms in chronic and acute-on-chronic intoxications. Thus severe toxicity may occur at lower serum levels in the setting of chronic Li ingestion than following acute ingestion without previous use.

Clinical manifestations of overdose are primarily neurologic. Clinical features of mild (1.5 to 2.5 mEq/L) and moderate (2.5 to 3.5 mEq/L) intoxication include nausea, vomiting, diarrhea, weakness, and neurologic dysfunction (confusion, tremor, nystagmus, dysarthria, ataxia, and other signs of cerebellar dysfunction), and choreiform and Parkinsonian movements reflecting basal ganglia involvement. Severe toxicity (>3.5 mEq/L) is characterized by worsening neurologic dysfunction (seizures and coma) and cardiovascular instability (sinus bradycardia and hypotension). Decreased serum anion gap (<6 mEq/L, because of excess cation) is an interesting consequence of severely elevated (>3.5 mEq/L) Li levels. Both hypothermia and hyperthermia have been reported to occur in Li-intoxicated patients. Acute overdose has a 25% mortality, and 10% of survivors have permanent neurologic deficits.

Treatment of Li intoxication is guided by a combination of clinical features and serum levels. Supportive care includes seizure control and use of vasopressors for hypotension refractory to fluids. Gastrointestinal decontamination following excessive lithium ingestion is the subject of a number of in vitro and animal research projects and is particularly important because sustained-release preparations are usually involved. Induction of emesis or gastric lavage should be performed initially. Oral activated charcoal is ineffective in preventing Li absorption, because it adsorbs Li poorly.[303–305] However, it is not harmful in this setting, and should be administered to limit absorption of other potential ingested poisons. Animal and in vitro studies suggest that oral sodium polystyrene sulfonate (Kayexalate) impairs absorption of ingested Li,[304] and that a form of gastrointestinal dialysis using multiple doses also lowers serum Li levels, but this therapy is unproven in human subjects.[306] Polyethylene glycol whole bowel irrigation has also been used to limit absorption of an acute overdose of sustained-release lithium in normal volunteers.[307] Elimination of Li is enhanced by volume loading (with normal saline) of hypovolemic patients, but this therapy has limited efficacy after normovolemia has been restored and risks precipitating hypernatremia in the presence of excessive ongoing water losses because of underlying diabetes insipidus. Lithium is the prototypical dialyzable intoxicant, owing to its hydrophilicity, low molecular weight, complete absence of protein binding, small apparent volume of distribution (0.66 L/kg, reflecting distribution in the total body water space), and prolonged half-life.

HD indications include: (1) Serum level >4 mEq/L; (2) serum level >2.5 mEq/L with symptoms or renal insufficiency (the latter making timely endogenous clearance unlikely); (3) serum level <2.5 mEq/L but following a large ingestion, so that rising levels are anticipated; (4) serum level <2.5 mEq/L if levels not anticipated to be <0.6 mEq/L at 36 hours after ingestion (this assessment is made by plotting three or more 2-hourly Li levels on a log-linear scale to estimate half-life). HD (clearance 70 to 170 mL/min) is preferred to peritoneal dialysis (clearance 15 mL/min, compared to 10 to 40 mL/min by renal excretion in normal subjects).[301,302,308] Rebound increase of serum levels often occurs several hours after dialysis; this phenomenon is mostly attributable to slow extracellular transfer of intracellular lithium,[301,309] although delayed absorption from slow-release preparations may also be contributory.[310] Prolonged dialysis (8 to 12 hours) with a large surface area dialyzer is generally performed initially, with repetition as needed for levels in excess of 1.0 at 6 to 8 hours after treatment. Alternatively, there are advocates of the use of continuous arteriovenous or venovenous hemofiltration/hemodialysis (14 to 44 hours) to attain both dialytic clearance of extracellular Li and effective mobilization and removal of intracellular stores,[95,96] but the obtained clearances of 20.5 to 62 mL/min (highest with continuous venovenous hemodialysis) were inferior to reported results with standard HD. Rebound of serum Li levels was prevented by prolonged therapy in the latter report,[96] even in chronic intoxications, suggesting some utility in such cases. Acute hemodialysis followed by a period of continuous venovenous hemodialysis to prevent rebound is a potentially useful combination approach.

METHEMOGLOBINEMIA

Reduced (Fe^{2+}) hemoglobin (ferrihemoglobin) is capable of binding oxygen; oxidized (Fe^{3+}) hemoglobin (methemoglobin or ferrihemoglobin) is not. In health, a small amount of methemoglobin is formed by auto-oxidation of circulating red blood cells continuously exposed to high concentrations of oxygen. Reduced cytochrome *b*5 reacts with circulating methemoglobin to restore hemoglobin and oxidized cytochrome *b*5. The red cell enzyme NADH-cytochrome *b*5 reductase (methemoglobin reductase) is responsible for regenerating reduced cytochrome *b*5, thereby ensuring insignificant concentrations of methemoglobin in circulating blood.[311]

Hereditary methemoglobinemia develops when circulating methemoglobin cannot be reduced (e.g., hemoglobin M) or there is a deficiency in red cell cytochrome *b*5 reductase. These hereditary conditions are of little clinical significance and usually do not require treatment, although individuals with cytochrome *b*5 reductase deficiency and G6PD deficiency are at increased risk of developing acquired methemoglobinemia. Acquired methemoglobinemia, which can be life threatening, occurs in the setting of oxidant drugs or toxin exposure (Table 102-25). Many of these drugs, such as commonly used analgesics, sulfonamides, sulfones, and local anesthetics, are derivatives of aniline, originally called "blue oil" which may beget "blue people" (those with methemoglobinemia).[312] Aniline drugs, particularly if taken in combination, are the most common cause of methemoglobinemia today.[312]

Methemoglobinemia decreases oxyhemoglobin saturation and blood carrying capacity in a way that is analogous to carbon monoxide poisoning. Not only does 50% methemoglobinemia effectively decrease hemoglobin concentration by half, methemoglobinemia also shifts the oxyhemoglobin dissociation curve to the left, thereby interfering with off-loading of oxygen in peripheral tissues. In mild methemoglobinemia (<15% of the total hemoglobin) patients

Sodium nitrite
Sulfonamides

generally remain asymptomatic despite exam evidence of cyanosis. One possible exception is the patient with critical coronary artery disease, who may develop angina or myocardial infarction in the presence of mild functional anemia. Higher methemoglobin concentrations result in dyspnea, headache, and weakness. Severe methemoglobinemia (>60%) causes confusion, seizures, and death.

Laboratory confirmation of elevated methemoglobin is available by co-oximetry, which directly measures oxygen saturation and methemoglobin saturation. Of note, the antidote methylene blue (see below) causes falsely elevated methemoglobin levels by co-oximetry (a dose of 2 mg/kg methylene blue gives a falsely elevated methemoglobin level of 15%).[313] Pulse oximetry is unreliable in patients with methemoglobinemia. Pulse oximeter saturation may fall, but it is falsely high in patients with methemoglobinemia and falsely low after methylene blue.[314–316] Another clue is the finding of chocolate-colored venous blood.[317]

Treatment of methemoglobinemia starts with supportive measures and removal of the inciting drug or toxin. This may involve removal of contaminated clothing, washing of contaminated skin, gastric emptying, and AC, depending on the nature of the intoxication. Methylene blue, a dye capable of reversing drug- or toxin-induced methemoglobinemia by increasing conversion of methemoglobin to hemoglobin, should be considered in symptomatic patients. A dose of 1 to 2 mg/kg (0.1 to 0.2 mL/kg of a 1% solution) IV administered over 5 minutes generally results in a significant reduction in methemoglobin level within 30 to 60 minutes. A repeat dose of methylene blue may be given after 60 minutes if needed. Additional doses may be required in patients who have taken a long-acting oxidant drug such as dapsone; however, higher doses of methylene blue may paradoxically increase oxidant stress and methemoglobinemia. Contraindications to methylene blue include G6PD deficiency (in which methylene blue may trigger hemolytic anemia), renal failure (because the antidote is renally excreted), and reversal of nitrite-induced methemoglobinemia during treatment of cyanide poisoning.[318] Failure to respond to methylene blue suggests cytochrome *b*5 reductase deficiency, G6PD deficiency, or sulfhemoglobinemia. Additional therapies of possible value in severe conditions include exchange transfusion and hyperbaric oxygen.

OPIOIDS

Opioid stimulation of opiate receptors causes generalized depression of the central nervous system. Symptoms in cases of overdose range from lethargy to respiratory arrest and coma, depending on the dose, agent ingested, and patient tolerance. The majority of deaths occur in chronic abusers of IV heroin.[319,320] Ethanol appears to enhance the acute toxicity of heroin and may contribute to deaths in infrequent users of heroin with low tolerance to its acute toxic effects.[321]

Opioids cause respiratory failure through a number of mechanisms such as alveolar hypoventilation, aspiration, and acute noncardiogenic pulmonary edema (which occurs most notably with heroin).[322] Noncardiogenic pulmonary edema often occurs after successful resuscitation and administration of naloxone, which itself has been reported to induce pulmonary edema in certain individuals. By inhalation, heroin may trigger an acute exacerbation of asthma.[323,324]

Other features of opioid intoxication include hypotension, bradycardia, decreased gut motility, rhabdomyolysis, muscle flaccidity, hypothermia, and seizures. Seizures are most common with propoxyphene[325] and meperidine. The meperidine metabolite normeperidine may cause seizures in the therapeutic dosing range, particularly if there is renal insufficiency.[326]

Pupils are commonly small or pinpoint-sized and respond to naloxone; however, the lack of miosis does not rule out opioid poisoning, as coexisting toxins or other conditions such as anoxic brain injury may influence pupil size.

The diagnosis of opioid overdose depends on a history of ingestion or a high index of suspicion for drug overdose, combined with compatible clinical features. The combination of a Glasgow Coma Scale score ≤12 with one of the following: respiratory rate ≤12, miotic pupils, or circumstantial evidence of drug use, has a sensitivity of 92% and a specificity of 76% for opioid overdose.[327] Rapid response to naloxone corroborates the diagnosis, which can be confirmed by urine or blood toxicology screening. However, certain opioids such as fentanyl are not detected by routine urine toxicology screening.[328]

Treatment of opioid overdose involves initial supportive measures and naloxone (see below). Gastric emptying may be helpful acutely, but extreme care must be taken not to empty the stomach in lethargic or comatose patients unless

the airway has been adequately protected. Although gastric lavage is most useful when it is performed within 1 hour of ingestion, this time limit may be extended several hours because of decreased gut motility. Activated charcoal should be administered once the airway has been protected;[329] there is a small risk of small-bowel obstruction in the setting of decreased bowel motility.[330] There is no role for forced diuresis, dialysis, or hemoperfusion.

Naloxone, a specific opioid antagonist with no opioid agonist properties, reverses opioid-induced sedation, hypotension, and respiratory depression. The initial dose is 0.4 mg IV or 0.8 mg IM or SC. Endotracheal administration has been described.[331] Lower doses should be given to opioid-dependent patients and when there is a concurrent stimulant overdose. Larger initial doses may be required when there is abuse of naloxone-resistant opioids. If naloxone does not produce a clinical response after 2 to 3 minutes, an additional 1 to 2 mg IV may be administered to a total dose of 10 mg. In general, a lack of response to 6 to 10 mg naloxone is required to exclude opioid toxicity; rarely doses >10 mg are required to antagonize the effects of propoxyphene, diphenoxylate, methadone, and pentazocine. Continuing naloxone beyond a total dose of 10 mg is reasonable if there is a very high index of suspicion for opioid overdose or a partial response has been achieved. In general, opioid antagonism occurs within minutes of naloxone administration and lasts for 1 to 3 hours. Repeat boluses may be needed every 20 to 60 minutes to maintain an adequate clinical response. Alternatively, a continuous naloxone infusion may be used (0.4 to 0.8 mg/h, or two thirds of the initial dose needed to achieve a response, given each hour intravenously).

Noncardiogenic pulmonary edema may be initially difficult to distinguish from aspiration pneumonitis with the acute respiratory distress syndrome; however, improvement is generally more rapid in opioid-induced pulmonary edema. Supplemental oxygen, positive end-expiratory pressure, and mechanical ventilatory support may all be required to achieve adequate arterial oxygen saturation.[322] Since central venous pressure is low, diuresis may aggravate hypotension.

Seizures unresponsive to naloxone may be treated with intravenous diazepam or lorazepam. Refractory seizures suggest either body packing or a secondary process.

ORGANOPHOSPHATE AND CARBAMATE INSECTICIDES

Most insecticides in the United States are organophosphates or carbamates. Organophosphates act as irreversible acetylcholinesterase (AChE) inhibitors. Carbamates are reversible AChE inhibitors. Insecticides can be absorbed through the mouth, skin, conjunctiva, gastrointestinal tract, or respiratory tract. Toxicity occurs within 12 to 24 hours after exposure from excess acetylcholine at neural end-plates due to inhibition of AChE.[332]

The diagnosis of organophosphate poisoning is made on clinical grounds and by measurement of cholinesterase activity in the blood. The history may suggest attempted suicide, accidental ingestion, industrial/agricultural exposure, or rarely ingestion of contaminated food.[333,334] Emergency department personnel have also been inadvertently poisoned through contact with poisoned patients.[335] The signs and symptoms of poisoning by both classes of insecticides are virtually identical except that carbamates do not readily cross the blood-brain barrier to cause CNS toxicity. Clinical features include miosis (85%), vomiting (58%), excessive salivation (58%), respiratory distress (48%), abdominal pain (42%), depressed mental status (42%), and muscle fasciculations (40%).[336] In one large study, tachycardia occurred more often than bradycardia (21% versus 10% of cases). In early poisoning, there is a transient period of intense sympathetic tone causing tachycardia, followed by heightened parasympathetic tone and bradycardia, heart block, and ST- and T-wave abnormalities.[336] An odor of garlic may be noted from the breath or sweat.

TABLE 102-26 Classification of Signs and Symptoms of Acute Organophosphate Poisoning

Muscarinic	Nicotinic	Central
Salivation	Fasciculations	Anxiety
Lacrimation	Paresis/paralysis	Confusion
Urination	Hypertension	Seizures
Diarrhea	Tachycardia	Psychosis
GI cramps		Ataxia
Emesis		
Blurred vision		
Miosis		
Bradycardia		
Wheezing		

Clinical features of organophosphate poisoning result from overstimulation of muscarinic, nicotinic, and central receptors (Table 102-26). Muscarinic overstimulation results in sustained toxicity characterized by the mnemonic SLUDGE (*s*alivation, *l*acrimation, *u*rination, *d*iarrhea, *g*astrointestinal cramps, and *e*mesis). Blurred vision, miosis, bradycardia, and wheezing are also muscarinic effects. Nicotinic effects are less sustained and characterized by fasciculations, muscle weakness (that can progress to paralysis), hypertension, and tachycardia. Organophosphates penetrate the blood-brain barrier to cause anxiety, confusion, psychosis, seizures, and ataxia.

The two principal cholinesterases are RBC cholinesterase (also called acetylcholinesterase or AChE), which is present in red blood cells and nerve endings, and pseudocholinesterase (PChE), which is found primarily in liver and serum. Carbamates and organophosphates inhibit both. Clinical toxicity is due primarily to inhibition of AChE, but PChE is more readily quantified. Levels may not correlate with the severity of poisoning.[337] A falsely low PChE may be seen in liver disease, anemia and malnutrition, and as a normal genetic variant (familial succinylcholine sensitivity). Normal levels of enzyme activity do not exclude poisoning because of wide variations in normal levels. In the absence of a baseline AChE level, serial measurement helps confirm the diagnosis.[338]

During initial patient stabilization, attention should be paid to the respiratory status. Bronchoconstriction, excess secretions, muscle weakness and an altered mental status all increase the risk of respiratory failure requiring intubation and mechanical ventilation. In agricultural exposures it is extremely important to remove all contaminated clothing and cleanse hair and skin thoroughly to decrease skin absorption. Health care workers must protect themselves from accidental exposure by wearing appropriate gloves and gowns. Activated charcoal is indicated to limit further

absorption. Gastric lavage may be useful if done immediately after ingestion.

Symptomatic patients should receive atropine immediately. Treatment should not await results of AChE or PChE levels. Atropine competitively blocks acetylcholine at muscarinic receptors but has no effect on nicotinic receptors. Thus atropine should not worsen fasciculations, hypertension, or tachycardia. Atropine crosses the blood-brain barrier and can cause CNS toxicity that is difficult to distinguish from organophosphate toxicity. In this situation, glycopyrrolate (which does not penetrate the CNS) is a reasonable alternative to atropine.[339] The dose of atropine required to achieve atropinization (mydriasis, dry mouth, and tachycardia) varies depending on the severity of poisoning. Doses of up to 40 mg/d are not uncommon. If atropinization occurs after 1 to 2 mg of atropine, the diagnosis of acetylcholinesterase inhibitor poisoning should be questioned. The initial dose of atropine is 2 mg IV followed by 2 mg every 15 minutes until adequate atropinization has occurred.

Pralidoxime (2-PAM) reverses nicotinic and muscarinic effects of organophosphate poisoning by reactivating AChE and protecting the enzyme from further inhibition. In carbamate poisoning, pralidoxime is generally not needed because of the more rapid resolution of symptoms and reversible nature of enzyme inhibition. Moreover, pralidoxime may enhance carbaryl (or Sevin, a carbamate insecticide) toxicity.[340] To be effective pralidoxime should be given within the first 6 hours of poisoning (although treatment in the first 24 to 48 hours may still be effective), prior to irreversible phosphorylation of cholinesterase (a process referred to as "aging"). After this critical period, restoration of normal cholinesterase function requires regeneration of the enzyme, a process that may take weeks to complete. Antimuscarinic effects allow for atropinization more quickly, and with lower doses of atropine. The initial dose of pralidoxime is 1 to 2 g IV given over approximately 10 to 20 minutes. Clinical response should be evident within 30 minutes. If there is no improvement in fasciculations or weakness the dose may be repeated once. A continuous infusion is then administered at a rate of 200 to 500 mg/h, titrated to achieve the desired effect. Continuous infusion of pralidoxime may be necessary for over 24 hours, depending on the half-life and lipid solubility of the poison, after which the dose may be gradually reduced and stopped while the patient is observed for signs of recurrent muscle weakness.

PHENCYCLIDINE

Phencyclidine (PCP) or "angel dust" is a dissociative anesthetic agent that is similar in many ways to ketamine. It decreases the perception of pain and has variable anticholinergic, opioid, dopaminergic, CNS stimulant, and α-adrenergic effects. PCP is usually smoked; however, it can also be nasally snorted, orally ingested, or intravenously injected. PCP is often mixed with other substances including ethanol, marijuana, and LSD. The long-term outlook for chronic abusers is characterized by unemployment, financial dependence on others, and repeated need for hospitalization.[342]

Persons intoxicated with PCP may demonstrate fluctuating, bizarre, and violent behavior that occasionally lasts for days following exposure.[343,344] In one study of 1000 patients evaluated in the ED for PCP intoxication, violence was present in 35% of cases, bizarre behavior in 29%, and agitation in 34%.[345] Forty-six percent of patients were alert and oriented; others demonstrated alterations in mental status ranging from lethargy to coma. Nystagmus (vertical or horizontal) and hypertension occurred in 57% of cases. Diaphoresis, hypersalivation, bronchospasm, and urinary retention occurred in less than 5% of cases. Grand mal seizures, muscle rigidity, dystonic reactions, catalepsy and athetosis occurred but were rare. Twenty-eight cases (2.8%) were apneic, and three cases (0.3%) presented in cardiac arrest. Hypoglycemia and elevated serum CPK, uric acid, and SGOT/SPGT were common. Rhabdomyolysis results in renal failure in 50% of cases.[346] Other features of PCP intoxication include self-inflicted injuries, aspiration pneumonia, hypertensive crisis, and intracranial and subarachnoid hemorrhage.[347–349]

The diagnosis of PCP intoxication is usually made on clinical grounds (fluctuating behavior, signs of sympathomimetic overstimulation, and vertical nystagmus). Particularly suggestive is the finding of pinpoint pupils in an agitated patient. Confirmation of PCP exposure is available through qualitative urine screening. PCP levels do not correlate with the severity of the clinical findings.[345]

Treatment of PCP intoxication involves initial supportive measures aimed at identifying and treating life-threatening problems. Few data are available regarding safety and efficacy of gastric emptying in PCP toxicity; however, this strategy is unlikely to be of significant benefit in patients presenting more than 1 hour after oral ingestion, and gastric emptying carries significant risk. Ipecac-induced vomiting should be avoided because of the risk of wide fluctuations in mental status, and the placement of a nasogastric tube may result in extreme agitation. Activated charcoal is effective in reducing intoxication. Acidifying the urine with NH_4Cl and diuresis enhances drug elimination.[350–352] However, the benefits of urinary acidification are small,[353] and urinary acidification may exacerbate myoglobinuric renal failure. Therefore urinary acidification is not recommended for routine use in PCP overdose. Neither hemoperfusion nor dialysis effectively eliminates PCP because of its large volume of distribution.

Violent or acutely psychotic patients unresponsive to verbal feedback and reduction in environmental stimuli require immediate pharmacologic treatment or physical restraints to establish adequate patient and staff safety. A common error in the management of the agitated patient is to delay treatment, allowing patients to harm themselves or others; another error is premature discharge of PCP-intoxicated patients after they demonstrate a period of normal behavior. Haloperidol appears to be the drug of choice to treat PCP psychosis.[354] Haloperidol (2 to 5 mg IM) may be repeated every 30 to 60 minutes to a total dose not exceeding 100 mg. Haloperidol prolongs the QT interval and therefore should be used with continuous monitoring. In addition, haloperidol lowers the seizure threshold and is associated with neuroleptic malignant syndrome, tardive dyskinesia, and the development of extrapyramidal symptoms. Adding a benzodiazepine (e.g., lorazepam 1 mg) to each dose of haloperidol may expedite control of the difficult patient. Data are limited regarding the use of chlorpromazine and opioids in PCP psychosis.[355] Other causes of agitation including head trauma, intracerebral or subarachnoid hemorrhage, CNS infection, thyrotoxicosis,

pheochromocytoma, hyperthermia, and acute psychiatric illnesses should be considered.

Hypertension often responds to haloperidol or benzodiazepine therapy. In cases of severe hypertension, nitroprusside or labetalol may be required. β-Blockers should be avoided as sole drugs because of the risk of worsening hypertension as β_2 sites are blocked.

SALICYLATES

Acetylsalicylic acid or aspirin is converted rapidly to salicylic acid, its active moiety. Salicylic acid is readily absorbed from the stomach and small bowel. At therapeutic doses, it is metabolized by the liver and eliminated in 2 to 3 hours. Chronic ingestion can increase the half-life to more than 20 hours.[356] Overdose can be accidental or deliberate, acute or chronic. A number of over-the-counter combination formulations and herbal remedies contain salicylates. The use of alternate analgesics, child-resistant containers, and package size restrictions has decreased the incidence of poisoning.[357,358]

Therapeutic serum levels of salicylates are 10 to 30 mg/dL. Clinical features of intoxication occur in most individuals with serum levels above 40 to 50 mg/dL; in chronic intoxication, severe poisoning occurs at lower serum levels (particularly in elderly patients). In toxic amounts, salicylates are metabolic poisons that affect a number of organ systems by uncoupling oxidated phosphorylation and interfering with the Krebs cycle.[359]

Minor intoxication causes tinnitus, vertigo, nausea, vomiting, and diarrhea. More significant ingestions cause acid-base disturbances. Respiratory alkalosis is caused by direct central ventilatory stimulation. Organic acids (including lactate and ketoacids) accumulate with uncoupling of oxidative phosphorylation to cause an elevated anion gap metabolic acidosis. Salicylic acid itself contributes only minimally to the measured anion gap (only 3 mEq/L with a 50-mg/dL level). Adults commonly present with respiratory alkalosis or combined metabolic acidosis and respiratory alkalosis.[360,361] Children may develop pure metabolic acidosis. Severe poisoning also causes noncardiogenic pulmonary edema, mental status changes, seizures, coma, gastrointestinal bleeding, liver failure, renal failure, and death.[362] Low cerebrospinal fluid glucose is a characteristic finding.[362]

Thisted and colleagues reported the clinical findings in 177 consecutive admissions to an ICU with acute salicylate poisoning.[363] Neurologic abnormalities occurred in 61% of cases, acid-base disturbances in 50%, pulmonary complications in 43%, coagulation disorders in 38%, fever in 20%, and hypotension in 14%. In a separate 2-year review of salicylate deaths in Ontario, 31.4% of patients were dead on arrival.[364] ICU mortality has been reported to be 15%.[363] The clinical features of salicylate intoxication are reviewed in Tables 102-27 and 102-28.

The lethal adult dose is approximately 10 to 30 g (35 tablets or more). Lethality correlates poorly with serum levels. The Done nomogam may be of little value, particularly if the time of ingestion is incorrectly estimated, more than a single dose is taken, or an enteric-coated preparation is used.[356,365,366] These caveats hold particularly true for chronic salicylism, which commonly occurs unintentionally in elderly patients receiving long-term analgesic therapy.[367] These patients are more likely to present with CNS injury[368] or noncardiogenic pulmonary edema;[369] isolated mild elevation of the prothrombin time is another telltale sign. Salicylate ingestion is usually diagnosed by serum level measurements, which are less helpful in chronic intoxication. Urine tests with Phenistix or ferric chloride can also be used to detect salicylate poisoning.[370]

TABLE 102-27 Clinical Findings in 177 Patients Admitted to an ICU with Acute Salicylate Poisoning

Clinical Signs	Percent
Neurologic abnormalities (depressed consciousness)	61
Acid-base disturbances	50
Pulmonary complications	43
Coagulation disorders	38
Hyperpyrexia	20
Circulatory disorders (hypotension)	14
Electrocardiographic abnormalities (Wide QRS, first- and second-degree atrioventricular block, ventricular arrhythmias)	10
Renal abnormalities (oliguria)	7

SOURCE: Reproduced with permission from Thisted et al.[363]

Optimal management of a salicylate-intoxicated patient requires appreciation of the toxicokinetics of ingestion and the importance of serum pH in determining disposition of this drug. At therapeutic levels, salicylic acid is 90% protein-bound. Most (75%) is partially glycinated in the liver to form salicyluric acid, a less toxic and more water-soluble renally excreted metabolite. Proximal organic anion secretion, rather than glomerular filtration, is normally responsible for the bulk of salicylate excretion, since salicylate is a highly protein-bound drug; and pH-dependent nonionic back-diffusion from the tubular lumen occurs at alkaline urine pH. At toxic levels, however, only 50% of salicylic acid is protein-bound, so that (with increased tissue distribution) the customary metabolic pathway via salicyluric acid becomes saturated, and elimination half-life increases from 3 to 12 hours to 15 to 30 hours.

Supportive care includes empiric administration of dextrose to treat low CSF glucose level. Treatment of an acute ingestion starts with gastric lavage and AC. These strategies are not helpful in chronic salicylism, although there is debate regarding the efficacy of multidose AC.[371]

The extent of tissue distribution of absorbed salicylate is influenced by plasma pH. For instance, CNS toxicity may

Chronic ingestion

be ameliorated by administration of bicarbonate to raise plasma pH to 7.45 to 7.5 (of course, such therapy may be contraindicated in the presence of alkalemia caused by salicylate-induced hyperventilation). Systemic alkalinization has the additional salutary effect of augmenting renal salicylate excretion. Raising urinary pH from 6.1 to 8.1 results in an over 18-fold increase in renal clearance by preventing nonionic tubular back-diffusion.[372] This decreases the half-life of salicylates from 20 to 24 hours to <8 hours. To accomplish urinary alkalinization, it is vital to avoid hypokalemia that prevents excretion of alkaline urine by promoting distal tubular potassium reabsorption in exchange for hydrogen ion. Forced diuresis appears not to add additional clearance to such therapy and tends to precipitate volume overload. Treatment with acetazolamide has also been used to induce alkaline diuresis, but we do not recommend this approach because "overshoot" acidemia may increase drug entry into the CNS and salicylate toxicity.

Indications for hemodialysis are listed in Table 102-29.[356,365] They include a serum level >120 mg/dL acutely, >100 mg/dL 6 hours postingestion, refractory acidosis, coma, seizures, noncardiogenic pulmonary edema, and renal failure. In chronic overdose, hemodialysis may be necessary for symptomatic patients with serum levels over 60 mg/dL.[373]

SELECTIVE SEROTONIN REUPTAKE INHIBITORS

The SSRIs, which include sertraline, citalopram, nefazodone, venlafaxine, paroxetine, fluoxetine, escitalopram, trazodone, and fluvoxamine, are noncyclic antidepressant agents that selectively inhibit the presynaptic neural uptake of serotonin.[374] These drugs are indicated for treatment of patients with affective disorders. They are relatively nontoxic when taken alone, but when taken in combination with a number of other drugs (listed in Table 102-30), there is the potential for excessive stimulation of 5-HT1A and 5-HT2 receptors and development of the serotonin syndrome.[375–380] Because of the long half-life of some of these drugs, toxic combination therapy may not be apparent for days to weeks.

Features of the serotonin syndrome include various combinations of confusion, agitation, coma, shivering, flushing, hyperthermia, diaphoresis, mydriasis, tachycardia, disseminated intravascular coagulation, convulsions, muscle rigidity, myoclonus, hyperreflexia, involuntary movements, autonomic instability, nausea, diarrhea, orthostatic hypotension, and rhabdomyolysis, which may not develop until 6 to 12 hours after overdose.[28,375,378] Trazodone, which also acts as an α-adrenergic blocker, may cause a hypotensive response. Other findings include hyponatremia and SIADH.[381,382] Death is rare.

TABLE 102-30 Selected Drugs That Increase Risk of Serotonin Syndrome in Patients Taking Selective Serotonin Reuptake Inhibitors

Almotripan
Buspirone
Caffeine
Cocaine
Dextromethorphan
"Ecstasy" (3,4-methylenedioxymethamphetamine; MDMA)
Eletriptan
Ergotamine
Frovatriptan
L-tryptophan
Linezolid
Lithium
Monoamine oxidase inhibitors
Meperidine
Methylphenidate hydrochloride
Mirtazapine
Naratriptan
Nefazodone
Rizatriptan
Sumatriptan
Tramadol
Trazadone
Tricylic antidepressants
Venlafaxine
Zolmitriptan

The diagnosis of serotonin syndrome should be considered in any patient with compatible clinical features, particularly if there is a history of depression. Blood levels are not helpful because the syndrome is a result of increased concentrations at nerve endings.

Treatment of serotonin syndrome starts with identifying and treating life-threatening problems. Gastric emptying should be considered in patients with acute ingestion. Ipecac-induced vomiting may be useful in the early management of children outside the hospital setting. Activated charcoal with a cathartic should be administered. Dialysis and hemoperfusion are not effective. Prognosis is generally good in mild cases, with resolution within 24 to 36 hours with supportive therapy alone. In severe cases, anecdotal reports suggest that serotonin antagonists (methysergide and cyproheptadine) may be beneficial.[383] Chlorpromazine, diphenhydramine, and benzodiazepines have also been used to treat serotonin syndrome.[384,385]

THEOPHYLLINE

Theophylline has a low therapeutic index, with a recommended therapeutic range of plasma levels between 10 and 20 mg/L. Toxicity can occur in the therapeutic range, but is more frequently associated with plasma levels >20 mg/L. Intoxication may result from either acute massive ingestion or chronic overmedication. The latter scenario may result from diminishing theophylline clearance on a stable chronic regimen. Drug interactions, smoking cessation, congestive heart failure, and hepatic dysfunction all diminish theophylline clearance. Chronic intoxication is associated with more severe

clinical sequelae at any given plasma level due to larger body stores.[386,387]

Clinical features of theophylline toxicity are neurologic, cardiovascular, and metabolic.[388] Seizures occur at lower serum levels in chronic intoxication than in acute overdose.[389] For reasons unknown, seizures occur several hours after peak serum levels in acute intoxication. Uncontrolled seizures can lead to hyperthermia and rhabdomyolysis. Tachyarrhythmias, both supraventricular and ventricular, are common at theophylline levels of 20 to 30 mg/L;[390] cardiovascular collapse can occur at levels over 50 mg/L. Metabolic abnormalities include hypokalemia, hypomagnesemia, hyperglycemia, hypophosphatemia, hypercalcemia, and respiratory alkalosis.[391]

Initial treatment should include gastric lavage and activated charcoal. Emesis is contraindicated because of the risk of seizures. Since theophylline undergoes enterohepatic circulation, multidose AC can enhance elimination.[69]

Seizures should be treated with benzodiazepines. Refractory seizures are an indication for the addition of phenobarbital or other antiepileptics. Phenytoin can worsen theophylline-induced seizures and should be avoided.[392,393] Supraventricular tachyarrhythmias are best controlled by a cardioselective β-blocker (metoprolol or esmolol), but these must be used with care in patients with underlying obstructive airways disease and not at all in patients who are actively wheezing. Calcium channel blockers may be useful in supraventricular tachycardia.[394,395] However, hypotension due to β_2-adrenergic stimulation should be treated with fluids and phenylephrine. Interestingly, refractory hypotension has been treated with a nonselective β-blocker such as esmolol.[396–398] Lidocaine and other standard agents are suitable for therapy of ventricular arrhythmias. Electrolyte repletion may be required.

Patients presenting with seizures or arrhythmias are candidates for extracorporeal drug removal (ECR). Other indications are a plasma level >100 mg/L at 2 hours after initial charcoal therapy, a level >50 mg/L in chronic ingestion, a 2-hour level >35 mg/L associated with clinical instability (shock), and a high risk of adverse outcome and/or prolonged intoxication. High-risk characteristics include: (1) chronic intoxication; (2) intolerance of oral charcoal; (3) impaired theophylline metabolism (congestive heart failure, cirrhosis, or severe hypoxemia [P_{O_2} <40 mm Hg]); (4) susceptibility to cardiovascular toxicity (elderly or coronary artery disease), seizures (epilepsy or coingestion of other convulsant drugs), or respiratory failure (severe pulmonary disease).

Extracorporeal therapy is best achieved by use of "in-series" hemodialysis (HD) and hemoperfusion (HP).[389,399,400] The physical and disposition characteristics of theophylline allow fairly effective clearance by HD, which has an extraction ratio (ER) of 0.5, achieving a clearance of up to 150 mL/min at a 300 mL/min blood flow rate. HP is more effective, with ERs of 0.6 to 0.9, allowing clearance twice that of HD. Cartridge replacement is required every 2 hours during isolated HP, because of adsorption saturation and declining ER (0.99 at initiation of therapy, decreasing to 0.5 by 2 hours). Placement of a hemodialyzer in series proximal to the HP cartridge in the extracorporeal circuit delays development of system saturation, adds additional clearance by HD, and allows for more rapid correction of metabolic derangements. Peritoneal dialysis does not add to endogenous clearance, even though this is low in nonsmokers (0.7 to 1.0 mL/min). Continuous extracorporeal therapies are of some utility and are indicated only in the absence of available HD or HP. Other techniques such as plasmapheresis and exchange transfusion have been successfully used in pediatric patients.

ENVENOMATIONS

SNAKE BITE

The majority of poisonous snake bites in the United States involve the Crotalidae (pit viper) family of snakes (e.g., rattlesnakes, copperheads, and water moccasins) in the southwest, west, and southeast. Pit vipers are named for a small pit between their eyes and nostrils. Large venom glands located in the temporal region result in a triangular shaped head; a horny rattle on the tail is vibrated when the rattlesnake is agitated.

Most bites involve native, noncaptive snakes, and are considered accidental. Accidental bites are more common in the summer months, in the afternoon or evening, and during recreational activities.[401] Young men are the most frequent victims.

Rattlesnakes strike when they are disturbed. Telltale fang marks appear as paired puncture wounds or lacerations a few millimeters deep, although atypical wounds consisting of single or multiple puncture sites or scratches are also seen. Twenty-five percent of bites do not result in envenomation (i.e., "dry bites"); half of all bites result in minimal or no envenomation.[401,402] Dry bites are generally benign, although there is potential for infection due to bacteria in the snake's mouth or on the victim's skin. When envenomation occurs, a variety of toxic proteins and enzymes are introduced into the victim that are capable of producing serious local and systemic reactions. Local effects develop within minutes and consist of stinging, burning, swelling, erythema, ecchymosis, and hemorrhagic blebs. Extremities swell over the next several hours, occasionally resulting in compartment syndrome. Facial bites with severe local swelling may obstruct airways.[403] Systemic effects of rattlesnake venom include fever, nausea, vomiting, delirium, seizures, muscle cramps, jaundice, disseminated intravascular coagulation, acute renal failure, and shock. Death is rare but may occur hours to days after envenomation. Of note, the Mojave rattlesnake is unique in causing minimal local tissue damage and serious delayed systemic effects.

Treatment of rattlesnake bite consists of splinting and immobilizing the bitten extremity at heart level to slow the spread of venom.[404] A loose fitting tourniquet should be placed above the bite site to impede lymph flow and rate of venom spread. Surgical consultation should be obtained for management of serious wounds. Débridement of necrotic wounds may be necessary. If compartment syndrome is suspected, tissue pressure should be measured. Surgery should be reserved only for severe and refractory cases and may not improve outcome.[405] Tetanus prophylaxis should be provided.

Rapid volume infusion is indicated in the initial management of hypotensive patients. Several liters of isotonic fluid may be required. One animal study suggests that in severe cases colloid infusion is more effective than crystalloid.[406] Patients with significant envenomations with progressive local or systemic effects should be considered for specific

treatment with equine-derived Crotalidae antivenin. Antivenin is a lyophilized protein product derived from horses immunized with venom pooled from several members of the Crotalidae family of snakes. Prior to antivenin administration, patients should be skin tested with a 1:10 dilution of antivenin (or per instructions in the commercially available antivenin kit). Patients with a positive skin test should be reconsidered for supportive care only; however, in the setting of severe envenomation, diluted antivenin may still be administered slowly after pretreatment with diphenhydramine and corticosteroids. This situation mandates large-bore IV access and epinephrine at the bedside in anticipation of anaphylaxis. A negative skin test is reassuring but does not exclude the possibility of anaphylaxis or the need for close monitoring and bedside availability of antihistamines and epinephrine. Antivenin is dosed by vial. Minimal envenomations with progressive symptoms can be treated effectively with five vials. Severe envenomations with hypotension and coagulopathy should receive 15 to 20 vials as guided by the instructions in the antivenin kit.[407] Most patients respond to the initial antivenin infusion, but some patients require additional infusions every few hours. Patients should be monitored closely for immediate hypersensitivity reactions and delayed hypersensitivity reactions (i.e., serum sickness) which commonly occur 5 to 14 days later. Of note, commercially available equine antivenin is also available for eastern coral snake (*Micrurus fulvius*) and Texas coral snake (*Micrurus fulvius tenere*) envenomation.

SPIDER BITE

In North America, only the widow spiders (*Latrodectus* species) and the recluse spiders (*Loxosceles* species) are medically important. The female black widow spider (*Latrodectus mactans*) has a shiny black body approximately 1 cm in diameter with a red hourglass mark on the abdomen. This spider, which favors woodpiles, dimly lit sheds, greenhouses, basements, and outdoor toilets, is most often encountered during the summer months. It bites aggressively to introduce potent venom into its victim. Envenomation results in local pain and erythema followed by muscle cramps and muscle fasciculations near the bite site. Painful cramps may generalize to the abdomen, back, and chest, mimicking myocardial infarction or an acute surgical abdomen.[284] Cramps may last for several days. Hypertension, tachycardia, tremor, fever, agitation, diaphoresis, and nausea are also common. Rarely, black widow spider bite results in hypertensive crisis or cardiopulmonary arrest. Treatment of black widow spider bite consists of general supportive measures combined with adequate analgesia and sedation. Intravenous calcium and methocarbamol effectively treat muscle cramps. Rare patients with significant signs and symptoms not responding to conservative measures should be considered for specific treatment with equine antivenin. As with other equine-derived antivenins, skin testing should be performed prior to antivenin administration, and precautions should be taken for anaphylaxis.[284]

Recluse spider bite (loxoscelism) is characterized by pain and burning at the bite site followed by localized swelling, erythema, and formation of bullae. A bull's eye–shaped lesion ranging from 1 to 5 cm may develop, consisting of an erythematous or hemorrhagic center, surrounded by a blanched ring that is enclosed in an ecchymotic ring. Central necrosis may develop and last for weeks to months. Some patients develop systemic symptoms including fever, myalgias, headache, and nausea. Rare patients develop intravascular hemolysis, disseminated intravascular coagulation, acute renal failure, and the acute respiratory distress syndrome. Treatment of loxoscelism is largely supportive. Cool compresses have been recommended for the bite site. Systemic steroids and dapsone have been advocated in severe cases, but convincing evidence supporting the use of these agents is lacking, and they should be considered experimental. Antivenin is not currently available.

Chapter 103

CRITICAL CARE PHARMACOLOGY

VIDYA KRISHNAN
THOMAS CORBRIDGE
PATRICK MURRAY

KEY POINTS

- *Critical care therapeutics should be individualized to maximize therapeutic effect while minimizing the potential for adverse drug reactions.*
- *The appropriate loading dose is determined primarily by the volume of distribution of the drug in the patient.*
- *The maintenance dose is proportional to the clearance and the desired steady-state plasma concentration.*
- *Elimination half-life is inversely proportional to clearance and directly proportional to volume of distribution.*
- *Steady-state conditions are obtained after the passage of three to five half-lives.*
- *Prospective consideration of possible drug-patient, drug-disease, and drug-drug interactions minimizes the potential for undertreatment or adverse drug reactions.*
- *Therapeutic drug monitoring may follow purely pharmacodynamic parameters or additionally use plasma levels to calculate pharmacokinetic parameters.*
- *Therapeutic drug monitoring attempts to ensure adequate therapy and to prevent, detect, and appropriately report adverse drug reactions.*
- *Systemwide changes in management of critically ill patients, including physician order entry systems and dedicated intensivists and pharmacists, can potentially decrease the incidence of adverse drug reactions.*

Individualization of critical care therapeutics through the application of pharmacologic principles is intended to reconcile important features of ICU management including polypharmacy, altered drug disposition, and cost considerations, in the design of a rational drug regimen. Critically ill patients routinely receive multiple medications, and the potential for adverse drug reactions (ADRs), particularly drug-drug interactions, increases in proportion to the number of agents received. Furthermore, physiologic changes resulting from critical illness may alter several aspects of drug disposition in a manner that is often difficult to predict based on available information. Finally, rational critical care therapeutics is a major component of providing cost-effective critical care, because of the substantial fraction of the average hospital pharmacy budget consumed by critical care therapeutic agents.

Individualization of pharmacotherapy attempts to avoid ADRs caused by drug overdosage or undertreatment, including ADRs caused by drug-disease, drug-drug, and drug-patient interactions. Correct drug dosing is frequently complicated in critical illness by alterations in bioavailability, volume of distribution, and elimination.[1] Errors in choosing a therapeutic regimen are frequently poorly tolerated by these patients; rapid efficacy may be necessary for survival, but physiologic reserve may also be inadequate to withstand the effects of drug intoxication. Concentrating efforts on optimal dosing of drugs that have a low therapeutic index (low ratio of toxic to therapeutic plasma level) is therefore particularly important. Consideration of pharmacokinetic (PK) and pharmacodynamic (PD) principles, and their application to design an approximate patient model for individualized therapeutics, should precede addition of any new drug to an ICU patient's regimen. Furthermore, the dynamic physiology of these patients mandates frequent reassessment of the accuracy of this model, updating drug regimens as required. Therapeutic drug monitoring is used to titrate therapy with drugs that have both a low therapeutic index and readily measurable plasma concentrations that are proportional to drug effects (therapeutic and toxic). Finally, any change in the status of an ICU patient must be considered to be potentially the result of an adverse drug reaction, especially in the absence of a clear-cut explanation.

Pharmacokinetic and Pharmacodynamic Principles

Pharmacokinetics is the study of drug movement through the body,[2–7] encompassing all aspects of drug disposition ("what the body does to the drug"), including (1) entry, (2) distribution, and (3) elimination. The three most important quantifiable PK parameters considered in evaluating the disposition of a drug are therefore (1) bioavailability (fraction of administered dose reaching the systemic circulation), (2) volume of distribution, and (3) clearance (elimination by biotransformation and/or excretion). Pharmacokinetic models divide the body into one or more compartments (see below), so that drug disposition may be described by a series of mathematical equations. *Pharmacodynamics* refers to the relationship of drug movement to pharmacologic response ("what the drug does to the body"). The relationship between PK data and the PD phenomenon of drug effect is based on the drug-receptor complex theory, which states that there is a correlation between drug concentrations in the plasma and at the receptor site, and that drug effect is proportional to the extent of drug-receptor complex formation.

BIOAVAILABILITY

The fraction of administered drug reaching the systemic circulation is termed its *bioavailability*. Intravascular injection generally results in 100% bioavailability. Other parenteral routes (intramuscular, subcutaneous, transdermal, intraperitoneal, and inhalational) and enteral (oral, through enteral feeding tubes, and rectal) of administration often achieve bioavailability which is both less complete and less predictable, although selected agents administered by the sublingual, inhalational, and other routes may undergo extensive and rapid absorption. Formulation properties (e.g., elixir vs. tablet) and the physicochemical properties (e.g., lipid solubility and degree of ionization at gastric pH) of the administered drug can substantially affect systemic bioavailability, particularly following enteral administration. Enterally administered agents,

except drugs administered by sublingual or rectal routes, are uniquely subjected to the potential influence of first-pass (presystemic) metabolism of drug by gut flora and by intestinal and liver enzymes (see below), which tends to decrease the systemic bioavailability of the parent compound.[4,6,8] Presystemic metabolism may result in the production of metabolites that are inactive (e.g., most propranolol metabolites), or active (4-hydroxypropranolol from propranolol, morphine from codeine, or enalaprilat from enalapril) following enteral substrate administration. Agents requiring metabolism to an active metabolite to elicit pharmacologic response, such as enalapril and codeine, are commonly referred to as *prodrugs*. Locally administered drugs (e.g., intraperitoneal antibiotics for peritonitis or intraocular β-blocking agents for glaucoma) are intended for local effects, but it is important to remember the potential systemic absorption and systemic effects of these drugs. In addition to the factors that determine extent of absorption, drug formulation can be manipulated to alter the rate of drug absorption (e.g., standard-release vs. extended-release preparations), which will in turn potentially blunt the peak drug concentration obtained after drug administration. Important considerations in choosing the route of drug administration in the critically ill patient will be further discussed below.

DRUG DISTRIBUTION AND ELIMINATION

The simplest compartmental PK model describes the body as a single homogenous compartment. An amount or dose of drug (D) is administered intravenously, instantaneously distributed into a space of volume (Vd), and the immediate serum or plasma concentration (C) measured. Given these simplifications, the volume of this theoretical compartment Vd (the apparent volume of distribution) may be calculated: $Vd = D/C$, since $C = D/Vd$. By assuming instantaneous distribution and concentration sampling (before any elimination has occurred), this model describes the theoretical volume into which the administered drug must be distributed in order to produce the observed drug concentration (Fig. 103-1*A*). The volume of distribution of most drugs does not usually correspond to a physiologic volume (such as the extracellular fluid volume [0.2 L/kg] or total body water space [0.5 to 0.7 L/kg]), but is often many times larger than the total body volume; drugs with a large volume of distribution are usually characterized by low plasma protein binding, high lipid solubility, and extensive tissue binding.

Drugs whose disposition may be described by a one-compartment kinetic model exhibit log-linear plasma concentrations as a function of time, thus exhibiting "simple" or "linear" pharmacokinetics (see Fig. 103-1*B*). Since the absolute rate of drug elimination is a linear function of its plasma concentration, and the fraction of drug eliminated per unit time is constant, a "first-order" kinetic model applies. Following a single intravenous bolus (and assumed instantaneous complete distribution), plasma drug concentration declines owing to a first-order elimination process (biotransformation and/or excretion), so that a semilogarithmic plot of the logarithm of plasma drug concentration (log Cp) versus time yields a linear graph. Back-extrapolation of this graph to time zero permits estimation of the plasma drug concentration immediately following the bolus (Cp_0), and thus an estimate of Vd, since $Vd = D/C$. The slope of this plot is called the elimination rate constant k (or k_e).

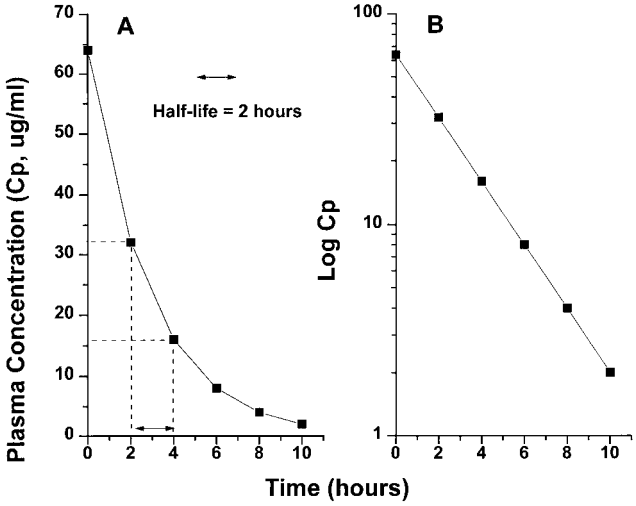

FIGURE 103-1 Linear pharmacokinetic profile with a single-compartment model. ***A*** **depicts the plasma concentration (Cp, μg/mL) versus time (hours) curve following intravenous administration of an 800-mg drug dose to a 100-kg adult. The first plasma sample, obtained 2 hours after bolus administration, contains a measured drug concentration of 32 mg/mL. Subsequent samples reveal that the plasma drug concentration declines by 50% every 2 hours, consistent with an elimination half-life of 2 hours.** ***B*** **shows the semilog plot of the same data plotted in panel** ***A*****. Log transformation of the plasma concentration values yields a linear plot, consistent with first-order elimination. Back-extrapolation to time 0 suggests that the plasma concentration at this time was 64 μg/mL (Cp_0); assuming instantaneous complete distribution, Vd is estimated (Vd = dose/Cp_0 = 800 mg divided by 64 μg/mL = 12.5 L, or 0.125 L/kg). The slope (k_e) of the log-linear plot is 0.3465 h^{-1}, consistent with the known half-life ($t_{1/2}$) of 2 hours ($k_e = 0.693/t_{1/2}$). Clearance (CL) may be estimated using the equation $CL = k_e \times Vd = 0.3465 \times 12.5 = 4.33$ L/h = 72 mL/min.**

The kinetics of drug elimination by this first-order process are described by the equation:

$$Cp_{(T2)} = Cp_{(T1)}e^{-k(T2-T1)}$$

where $Cp_{(T2)}$ and $Cp_{(T1)}$ are the plasma drug concentrations at later and earlier measurement points, respectively; T2 − T1 is the time elapsed between these two time points; and k is the elimination rate constant (in units of $time^{-1}$).

The elimination half-life ($t_{1/2}$) of the drug, which is the amount of time required for the plasma drug concentration to decrease by 50%, can be determined from the elimination rate constant by the equation:

$$t_{1/2} = 0.693/k_e$$

Using the above equation, it can be shown that the drug concentration declines by 50% during each half-life, so that little of the bolus dose remains after four to five half-lives (Table 103-1). Alternatively, if a drug is eliminated by a *saturable* process, elimination may become saturated at high concentration, so that kinetics become zero-order (a constant *amount* of drug, rather than a constant *fraction*, is eliminated per unit time). The half-life of elimination of such agents is concentration-dependent, because of *capacity-limited* (saturable) clearance, and PK assessment requires the use of

TABLE 103-1 Number of Half-Lives Required to Eliminate a Drug Bolus by a First-Order Process

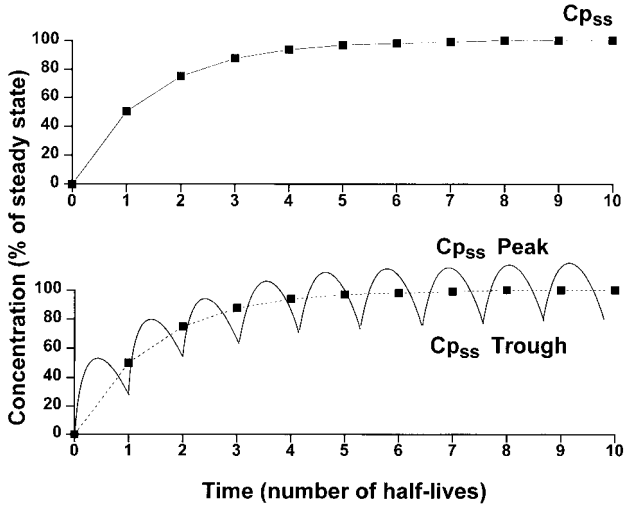
Michaelis-Menten kinetics. Small dose escalations may result in disproportionately large plasma concentration increments when the maximum metabolic capacity is exceeded. Ethanol, phenytoin, and salicylic acid are examples of drugs with capacity-limited clearance, and many other agents develop saturation of metabolic pathways in overdose (see Chap. 102).

If the same drug given above as a bolus to estimate simple (single-compartment) PK parameters is instead administered as a continuous intravenous infusion, and the rate of infusion exceeds the rate of simultaneous (first-order) elimination, then the plasma drug concentration will increase as accumulation occurs. Eventually, since the amount of drug excreted per unit time increases with increasing plasma drug concentration, the elimination rate becomes equal to the rate of administration; the plasma drug concentration at this time, which from then onward remains constant (unless the rates of administration or elimination change), is termed the *steady-state concentration* (Cp_{ss}) (Fig. 103-2, upper panel). Accumulation of an agent exhibiting linear pharmacokinetics proceeds in a fashion which is the mirror image of its elimination following a single intravenous bolus (Table 103-2). Accumulation of intermittently administered drugs differs from constant intravenous infusion only in the presence of peak and trough plasma drug concentration fluctuations; steady-state still develops over the same number of half-lives, with peak-to-trough fluctuations around a mean Cp_{ss} (see Fig. 103-2, lower panel). Therefore one can use the concept of half-life to estimate the time to attainment of a steady-state plasma drug level (and pharmacologic effect) following initiation of therapy, and to offset of drug effect following discontinuation of the agent, regardless of the dosing regimen in use.

The conceptually simple linear PK profile of a drug that fits a single-compartment model is actually inadequate to fully describe the disposition of most drugs. Multicompartmental models more accurately describe the rate and extent of drug shifts between these spaces, requiring multiple slope calculations to include the effects of intercompartmental distribution and elimination from the body (Fig. 103-3).[3] Such models divide the body into a *central* (the blood volume and highly perfused tissues, Vd_c) and one or more *peripheral* or *tissue* (fat, muscle, or skin) compartments. The final volume

FIGURE 103-2 Drug administration by continuous intravenous infusion (*upper panel*) or intermittent intravenous bolus (*lower panel*). Attainment of steady-state plasma concentration (Cp_{ss}) occurs after three to five half-lives, regardless of the dosing regimen. Peak and trough fluctuations around Cp_{ss} are aimed to each be within the therapeutic range (therapeutic but subtoxic plasma levels).



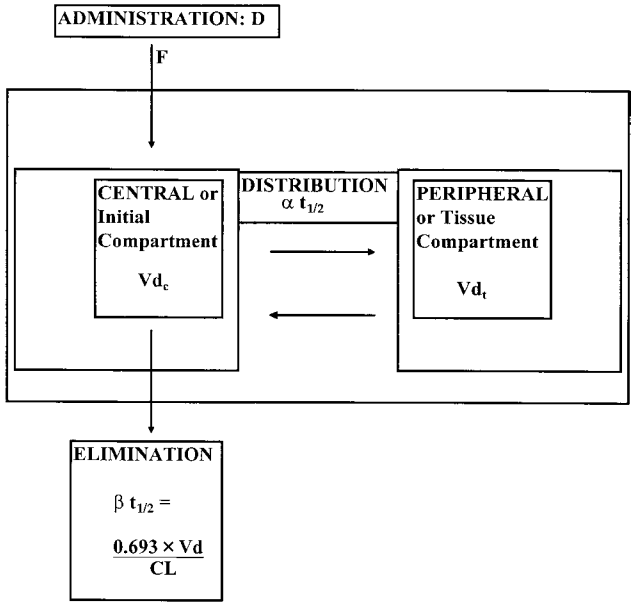


FIGURE 103-3 Schematic representation of a two-compartment pharmacokinetic model. A variable fraction (F, bioavailability) of administered dose (D) reaches the systemic circulation and is then distributed. Initial distribution occurs into the vascular space and rapidly perfused tissues, comprising the central or initial compartment (Vd_c). Subsequently, further distribution into the peripheral or tissue compartment (Vd_t) occurs, at a rate quantified by the *distribution* half-life ($\alpha t_{1/2}$). During and after the initial distribution period, drug is eliminated by metabolism and/or excretion. Following complete distribution to Vd_t, the rate of plasma drug concentration decline is quantified by the *terminal* or *elimination* half-life ($\beta t_{1/2}$), which is directly proportional to Vd_t and inversely proportional to clearance (CL).

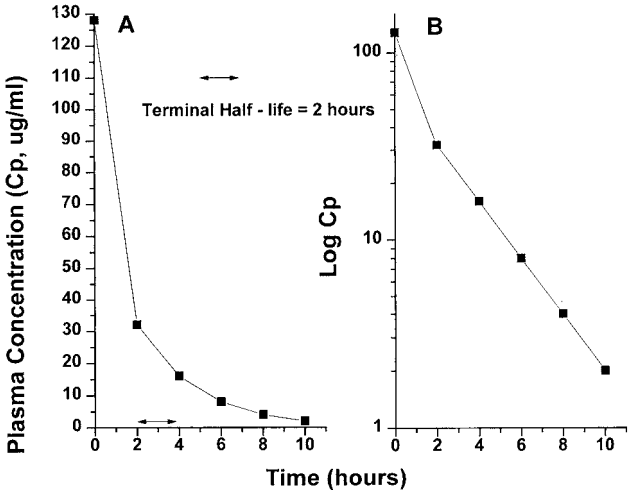

FIGURE 103-4 Linear pharmacokinetic profile with a two-compartment model. ***A.*** **When earlier plasma samples are obtained following repetition of the same drug administration procedure described in Fig. 103-1, it is apparent that in fact this drug is distributed into two compartments rather than a single space. The earliest plasma sample, obtained *immediately* after administration of the drug bolus, contains 128 μg/mL (Cp_0) of the drug; the initial volume of distribution is thus 6.25 L or 0.0625 L/kg. By 2 hours postinjection this has declined to 32 μg/mL, as found in the Fig. 103-1 protocol; subsequently the plasma concentration declines as in Fig. 103-1.** ***B.*** **Log transformation of the plasma concentration values now reveals multiexponential kinetics, with two distinct slopes, indicating a more rapid early decline owing to a combination of drug distribution and simultaneous elimination, followed by a second phase owing to elimination only (postdistribution).**

of distribution (Vd_{tot}) reflects the sum of central and tissue compartments. Vd_c is calculated by measuring the instantaneous plasma concentration (Cp_0) after an intravenous drug dose is administered (Fig. 103-4*A*), then Vd_{tot} is calculated by back-extrapolation from the *elimination* phase of the plasma concentration versus time curve to the y-axis (concentration) at zero time (see Fig. 103-4*B*). The two-compartment model also involves consideration of another aspect of drug distribution: the rate of distribution of drug from the central to the final volume of distribution is quantified by the *distribution half-life* ($\alpha t_{1/2}$), although some of the decline in plasma drug concentration during this period often is due to simultaneous drug elimination during the initial distribution phase. The *elimination half-life* ($\beta t_{1/2}$) corresponds to the half-life considered using a single-compartment approach.

Despite these refinements, the principles of linear pharmacokinetics hold for most agents in practice. Thus from a semilog plot [log concentration (y) versus time (x)], the slope is k_e (the elimination rate constant) following full distribution (Vd_{tot}), and the rate of drug clearance (CL) is based on the balance of distribution and excretion rates:

$$CL = -k_e \times Vd_{tot}(min^{-1} \cdot mL)$$

It is often incorrectly assumed that CL may be calculated from this equation. In fact, both CL and Vd_{tot} are quantified to determine k_e. In other words, CL and Vd_{tot} determine k_e: CL is a physiologic value, a measurement of the volume of plasma from which a substance is completely cleared per unit time (in units of volume per unit time, usually milliliters per minute); Vd_{tot} is a theoretical volume determined by a post-distribution plasma concentration measurement; thus k_e is a derived variable, and the rate of elimination may thus be considered to reflect the balance of drug distribution to tissues and drug elimination from the body,[9] so that it is useful to consider this relationship as follows:

$$k_e = CL/Vd_{tot}$$

and, since

$$t_{1/2} = 0.693/k_e$$

then

$$t_{1/2} = (0.693 \times Vd_{tot})/CL$$

In other words, the elimination half-life of drug is prolonged by a large volume of distribution or low clearance value, and shortened by limited distribution or a vigorous clearance process.[6] The measured clearance of a substance (CL_{TOT}) usually represents the algebraic sum of several clearance processes; in many cases, this may be represented as follows:

$$CL_{TOT} = CL_{renal} + CL_{hepatic} + CL_{other}$$

For most drugs, it is appropriate to consider the magnitude of each of these component processes and the effects of the altered physiology of critical illness on their relative importance in achieving clearance of parent drug and metabolites. Clearance of any agent by an eliminating organ is proportional to, but cannot exceed, blood flow to the eliminating organ: $CL = Q \times (C_A - C_V)$, where Q is organ blood flow, and C_A and C_V are the drug concentrations in the arterial and venous blood supplies to the eliminating organ, respectively. These and other PK parameters relevant to the individualization of critical care drug therapeutics will be discussed below.

PHARMACODYNAMIC MODELING

It is a basic tenet of the above approach that pharmacologic response is proportional to plasma drug concentration. Four additional determinants of pharmacologic response merit emphasis in this regard: (1) the "effect site" concept, (2) the importance of the free (unbound) plasma drug concentration, (3) interindividual variability in drug response, and (4) dose-dependent alterations in receptor activation and pharmacologic effect.

EFFECT SITE

The *effect site* concept was introduced to more completely describe the relationship of drug disposition to pharmacologic response. This term refers to the tissue compartment containing the receptors that must be bound in order to elicit drug effect.[10] If the effect site is located in a rapidly perfused compartment (Vd_c), then intravenous drug administration will elicit immediate pharmacologic response. The antiarrhythmic effect of lidocaine is an example of such behavior, and thus initial serum lidocaine levels correlate directly with drug effect. In fact, the well-established practice of empirically administering additional lidocaine boluses following an initial

load is based on the necessity of maintaining adequate serum levels, which tend to decline as the drug distributes into other tissues or is eliminated.[3,11] The distribution half-life ($\alpha t_{1/2}$) of lidocaine is only 8 minutes (see Fig. 103-3), so the plasma level following an initial bolus may decline to subtherapeutic levels before a simultaneously administered continuous infusion results in drug accumulation sufficient to attain the desired steady-state plasma level (Cp_{ss}). By contrast, plasma digoxin levels do not correlate with drug effect until the postdistribution phase (2 to 4 hours following an IV bolus), because distribution to tissues is required for binding to the target tissue receptors. The usual total digoxin loading dose of 1 mg is generally administered in smaller fractions (typically 0.5 mg first, with 0.25 mg following at 6 and 12 hours later), because the full effects of each loading dose fraction cannot be assessed until tissue distribution has occurred, at which time the loading procedure can continue, if it is necessary and safe to do so.

FREE OR UNBOUND PLASMA DRUG CONCENTRATION

Only free (unbound) drug is available for receptor binding, so that alterations in plasma protein binding may profoundly affect the interpretability of measured total (free plus bound) plasma drug concentrations. For example, plasma protein binding of phenytoin is diminished by either hypoalbuminemia or uremia, the former owing to lesser absolute availability of albumin binding sites, and the latter thought to be a result of competitive occupancy of these sites by "uremic substances." As a result of this phenomenon, total plasma phenytoin concentrations are often misleading in such patients. Phenytoin is normally 90% plasma protein-bound, so that the usual total plasma concentration range is 10 to 20 mg/L, and the free level is 1 to 2 mg/L. If plasma albumin is decreased from 4 g/dL to 2 g/dL, then an apparently therapeutic total plasma phenytoin level of 16 mg/L may be associated with a toxic free phenytoin level of over 7 mg/L; this is because the unbound or free fraction increases from the customary 10% toward 50%. It is therefore wise to monitor plasma free phenytoin levels in patients with hypoalbuminemia or renal insufficiency.

INTERINDIVIDUAL RESPONSE VARIABILITY (SENSITIVITY)

Another point to note is the variability between individual responses to a given plasma drug level; sensitivity to drug action may differ between individuals or groups. For example, elderly subjects are more sensitive to the sedative effects of benzodiazepines (and many other sedatives) than younger subjects;[12] American subjects of Chinese descent are twice as sensitive as American white men to the β-blocking effects of propranolol;[13] black subjects are less sensitive to the vasodilatory effect of isoproterenol than are white Americans.[14] Recent evidence implicates pharmacogenomics as the cause of variability of drug effect between races, and even individuals within races.[15]

DOSE-DEPENDENT EFFECTS

The predominant drug-receptor complex mediating a drug's effect may change according to drug concentration, resulting in variable pharmacologic responses at different plasma levels. For example, dopamine predominantly activates dopaminergic receptors (and causes mesenteric and renal vasodilation) only at infusion rates of up to 2 μg/kg per minute. β_1-Adrenergic (inotropic) and α-adrenergic (vasoconstrictor) activation occur at doses as low as 2 to 4 μg/kg per minute and 5 to 10 μg/kg per minute, respectively; as a result, the hemodynamic effect of dopamine infusion changes with increasing dose.[15] Despite such concerns, we expect the attainment of drug levels in the usual therapeutic range to elicit the desired effect in most patients.

Most drugs used in the ICU are dosed according to broadly applicable population-based PK and PD parameters and titrated to pharmacologic response only if this is readily quantifiable, rather than being subjected to rigorous PK modeling with therapeutic drug level monitoring. The latter approach is applied to drugs that have a low therapeutic index and plasma drug concentrations that correlate with drug effect. The intermediate-complexity approach of monitoring physiologic parameters (PD monitoring) of drug effect is more readily applied in the ICU (and operating room) than in other patient care settings because of the routine use of monitoring devices. Sedation, neuromuscular paralysis, seizure suppression, diuretic agent action, and the effects of cardiovascular drugs (antiarrhythmic, chronotropic, inotropic, vasodilator, and vasoconstrictor actions) and bronchodilators are commonly assessed in this fashion, in conjunction with formal PK monitoring using drug levels for appropriate agents.

What follows is a framework for drug administration based upon physiologic modeling of the patient and application of known drug characteristics to this patient model, in order to optimize ICU therapeutics and minimize the potential for iatrogenic adverse events. Furthermore, this approach includes routine surveillance to prevent adverse drug reactions, and to assess the potential for such a phenomenon to be the underlying cause of a change in patient status.

Individualization of Drug Therapy in the ICU: An Approach to Rational Drug Dosing in Critically Ill Patients

The PK and PD principles outlined above may be applied routinely to attempt optimal design of drug regimens for ICU patients. As shown in Fig. 103-5, focused consideration of PK and PD parameters to answer a series of questions can provide a framework for therapeutic individualization. Individualization of drug therapy requires consideration of the effects of multiple factors responsible for variability in drug response (aside from disease severity); these include: (1) drug-patient interactions (including body habitus, age, gender, and race); (2) drug-disease interactions; and (3) drug-drug interactions. This approach only yields an approximation of ideal therapeutics, because information addressing drug disposition in this population is often incomplete, and its interpretation is further complicated by the dynamic physiology of critical illness. This method simply attempts to maximize the potential for rational therapy based upon available information. As a result, any drug regimen in critically ill patients requires early and frequent reassessment. The customary prudent approach to drug dosing in settings in which altered disposition is anticipated but poorly quantifiable, embodied in the phrase "start low and go slow," is generally inappropriate in this setting, in which immediate therapeutic effect may be vital. Nevertheless, a rational approach to critical care therapeutics should

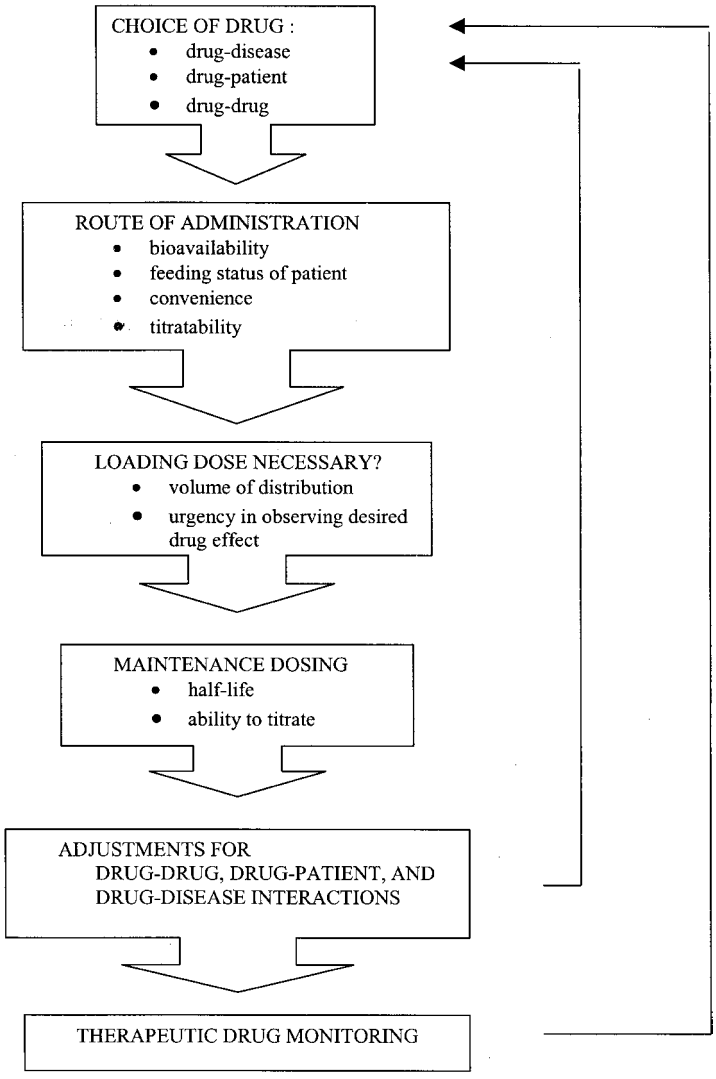

FIGURE 103-5 Flowchart for a suggested method of design for a rational drug dosing regimen. This illustration serves to depict the process of drug prescription and dosing as a perpetual cycle of actions. Individualization of drug therapy involves careful consideration of the patient's unique clinical status for each step along the path of drug prescription and dosing. The initial choice of drug, route of administration, loading dose, and maintenance dose calculations involve consideration of desired drug effects, titratability, and convenience. Modifications of the dosing regimen may be required to accommodate the individual characteristics of the patient, including allergies, age, sex, and race; potential drug-drug interactions; and potentially confounding disease states. Once a drug regimen is designed and implemented, therapeutic drug monitoring is indicated to ensure adequate drug effect and to minimize potential adverse events. The results of therapeutic drug monitoring may indicate the need for further modification of the drug regimen.

reduce the incidence of iatrogenic pharmacotherapeutic complications of critical illness.

The key principles underlying this approach, which relates PK parameters to choices of drug regimen, may be summarized as follows:

1. The appropriate loading dose is determined by estimation of the volume of distribution of the agent in the patient; the regimen for administering this dose is chosen based upon the desired effect site and the distribution half-life for the agent.
2. The maintenance dose is chosen to equal the elimination rate of the agent at steady state (the product of $CL \times Cp_{ss}$).
3. Steady-state plasma drug level and stable drug effect are not obtained until three to five half-lives (see Table 103-2 and Fig. 103-2) have passed.
4. Many adverse drug reactions are predictable and preventable by individualization of therapeutics and by consideration of known or potential drug interactions.

Patient characteristics are used to estimate physiologic and pathophysiologic variables affecting drug disposition. Several patient characteristics should be routinely considered, including age, gender, drug allergies, body habitus, volume status, plasma protein concentrations, and parameters of organ function (gastrointestinal tract, circulatory, renal, and liver function).

Age, gender, body habitus, and volume status are variables used to estimate expected parameters of drug disposition, based upon population PK/PD data. For most dosing calculations, the lesser of lean (or ideal) and actual body weight is used. Lean body weight (LBW) is calculated from the patient's height: For males, LBW (kg) = 50 + (2.3 × each inch above 5 feet). For females, LBW (kg) = 45.5 + (2.3 × each inch above feet). Some drugs are dosed according to actual weight or to patient body surface area, the latter obtainable from published nomograms using height and weight.

Using these data, we approach the design of individualized drug therapy for ICU patients as follows:

ROUTE OF DRUG ADMINISTRATION

Oral bioavailability of the agent may be inadequate to achieve systemic effect owing to luminal conditions (alkaline pH or tube feeds) or first-pass metabolism (by luminal bacteria, intestinal enzymes, or hepatic enzymes). Intravenous drug

administration is often preferred in the ICU, even for administration of highly bioavailable drugs, for several reasons. Rapid onset and offset of effect may be desirable to rapidly initiate therapy, while retaining the capacity for titration. Gastrointestinal dysfunction (ileus or bowel wall edema) may also result in unpredictable drug delivery by the enteral route, although there is no evidence (in subjects with decompensated congestive heart failure, renal failure, or cirrhosis) that this theoretical concern is actually relevant.[17] Formulation properties (e.g., extended-release preparations) do not affect the extent of absorption, but rather the rate of absorption and potentially the peak drug concentration after each dose.

LOADING DOSE

Many therapies initiated in the ICU are intended to have a rapid onset of effect. Whether administered by continuous intravenous infusion or by intermittent intravenous bolus or oral dosing, plasma drug concentration and therapeutic effect will not reach steady-state levels until three to five half-lives have passed; such a delay may be unacceptable, particularly for drugs which have a prolonged half-life (which may be a normal feature of a drug's disposition [e.g., digoxin], or caused by organ dysfunction and impaired elimination [e.g., aminoglycosides with renal failure]). Conversely, drugs that have a very short half-life (e.g., nitrovasodilators, esmolol, atracurium, and propofol) may achieve a rapid therapeutic effect when administered by infusion but without a loading bolus, since three to five half-lives pass in a matter of minutes. Administration of a loading dose, calculated as follows, rapidly achieves the desired target level (but does not alter the time required to attain steady-state conditions):

$$\text{Loading dose} = \text{Vd} \times \text{Cp}$$

where Cp is the desired plasma concentration.

The appropriate loading dose is primarily determined by the distribution characteristics of the drug (Vd) and the body habitus and volume status of the patient. Usual volume of distribution values are readily available for most drugs; however, the effects of alterations in body habitus, nutrition, and volume status are much more difficult to quantify. Estimates of drug distribution characteristics are further confounded in critically ill patients by dynamic hypercatabolic losses of fat and lean body mass, accompanied by massive third-space volume retention or intravascular volume depletion, often associated with development of hypoalbuminemia and relative hyperglobulinemia. Following a period of marked positive fluid balance in a hospitalized patient, the weight increment may be used to estimate the total body water increase. Otherwise, estimates of altered body water content are usually empiric, although therapeutics in some specific disease states have been studied in sufficient detail to provide useful information. For example, a decreased aminoglycoside loading dose is required in volume-depleted acute renal failure. Furthermore, "uremic substances" that accumulate in renal failure appear to displace some drugs from tissue-binding sites, thus reducing their Vd regardless of volume status. As a result, the appropriate digoxin loading dose is decreased by 50% in the presence of renal failure; Vd is also decreased for methotrexate and insulin in renal failure patients. Conversely, edematous states such as sepsis,[18,19] cirrhosis, nephrosis, and congestive heart failure often increase Vd. Determination of the ideal or lean body weight is difficult in the presence of obesity, cachexia, or combinations of the above factors, such as in a typical hypercatabolic patient with sepsis, acute renal failure, and postresuscitation volume overload. Loading dose regimens may also be altered based upon the relationship between the desired onset of effect to the distribution pattern at the effect site, as discussed above in contrasting the standard loading dose regimens for lidocaine and digoxin.

Volume of distribution for a given drug is reported in units of volume per weight in a normal patient. In the critically ill patient, the alterations in weight and body fluid compartments will alter the distribution of the drug. A reasonable approach to approximate these alterations in the calculation of the loading dose of hydrophilic drugs is to adjust the normal volume of distribution in proportion to the estimation of the patient's water compartment. It is reasonable to assume that water comprises approximately 10% of adipose tissue weight (estimated as actual body weight minus lean body weight). Additionally, the net weight gain secondary to fluid resuscitation will contribute to the volume of distribution for water-soluble drugs. Mathematically, we can express this by the following:

$$\begin{aligned}\text{Adjusted Vd} = {} & (\text{Vd based on ideal body weight}) \\ & + (10\% \text{ of adipose tissue weight}) \\ & + (\text{net weight gain from fluid resuscitation})\end{aligned}$$

MAINTENANCE DOSE

ADMINISTRATION REGIMEN

In the critical care setting, the administration regimen usually consists of a choice between intermittent intravenous bolus therapy and continuous intravenous infusion. Factors considered in this decision include: drug characteristics (half-life and therapeutic index), patient characteristics, the desired pharmacologic effect, and cost/staffing considerations. When drugs with a low therapeutic index are dosed intermittently, the fluctuations (peak-to-trough) of plasma concentration may require formal monitoring of plasma concentrations and PK parameter estimates to ensure adequate therapy without toxicity. Administration by infusion eliminates the peak-to-trough plasma concentration fluctuations associated with intermittent parenteral boluses, which may be accompanied not only by failure to achieve continuous therapeutic effect, but also by activation of rebound counterregulatory effects during trough periods (negating prior and subsequent drug action). Continuous intravenous infusion may thus improve therapeutic efficacy of some agents. Loop diuretic agent infusions have been reported to augment sodium excretion compared to equivalent intermittent dosing, probably because of a combination of effects: increased cumulative renal tubular diuretic agent exposure (the product of time and concentration) and avoidance of periods of physiologic rebound salt conservation.[20,21] Since diuretic effect onset is delayed when using only continuous intravenous infusion (until drug accumulates; see Fig. 103-2), the ideal regimen to maximize natriuresis may include an initial bolus dose to achieve the required luminal threshold drug concentration and induce immediate natriuresis. Likewise, gastric acidity is also far better controlled by continuous intravenous infusion of H_2 blockers than by equivalent intermittent dosing.[22]

Continuous infusion of short-acting agents may also be desirable to allow titration of effect; nitrovasodilators, esmolol, propofol, and atracurium may be used for optimal control of vasodilation, β-blockade, sedation, or neuromuscular paralysis, respectively. It is widely assumed that continuous infusion of agents that have a short elimination half-life guarantees rapid reversal of drug effect following cessation of the infusion, but various factors may retard offset of effect, as is the case for reversal of sedation using agents administered by continuous infusion.[23,24] Potential explanations for such alterations in drug disposition or response during continuous infusion compared to intermittent bolus therapy include compartmentalized tissue distribution, accumulation of active metabolites, or saturation of clearance mechanisms. Intermittent bolus administration titrated to specific sedation parameters is less likely than continuous infusion to result in undetected drug or metabolite accumulation if excretory mechanisms deteriorate or become saturated, unless a routine assessment of time to awakening is performed daily in patients receiving continuous infusion. Clinically, it has been shown that daily interruption of sedation of mechanically ventilated patients results in decreased duration of ventilation, likely due to the minimization of drug accumulation.[25] Conversely, tolerance to the effects of several drugs (a pharmacodynamic phenomenon) occurs if a drug-free interval cannot be included in the administration regimen, requiring escalating dosages of agents such as nitroglycerin, dobutamine, and opiate analgesics to maintain a therapeutic effect. Finally, the convenience for nursing staff of administering agents by continuous infusion rather than intermittent bolus translates into decreased staffing expenditures.

CLEARANCE

Clearance includes all processes that eliminate the drug from the body—both excretion and biotransformation. Because the total body clearance of a drug involves the actions of multiple organ systems, the estimation of the predominant rate of elimination and route of elimination is often complicated, and warrants further discussion.

What is the Predicted Elimination Rate of the Drug?

The predicted elimination of the drug usually corresponds to the drug administration regimen that elicits an optimal therapeutic response in most subjects. Agents with a low therapeutic index may be subjected to therapeutic drug monitoring, aiming for a maintenance dose equaling the product of $CL \times Cp_{ss}$. The desired Cp_{ss} is selected based on the therapeutic response required (e.g., target plasma lidocaine level for suppression of ventricular arrhythmias) and the clearance rate is estimated based on published data (usually obtained from healthy patients). At steady state, the rate of administration (Ra) equals the rate of excretion (Re). Ra is dose (mg) divided by interval (minutes), and Re is CL (mL/min) $\times$ Cp_{ss} (mg/mL).

What are the Predominant Routes of Elimination of the Parent Drug and Its Metabolites (Particularly Those that Are Pharmacologically Active or Toxic)?

Renal insufficiency (Table 103-3), hepatic disease (Table 103-4), or circulatory dysfunction (Table 103-5) may affect clearance of parent drug or metabolites. There are several well-known examples of drugs with metabolites that are pharmacologically active or even toxic. Accumulation of active or toxic metabolites in the presence of renal failure is probably the most common clinical scenario in which this feature of drug disposition is important (Table 103-6). Nonrenal (usually hepatic) elimination of parent drug or metabolites has been increasingly documented to be quantitatively important in subjects with renal impairment (as discussed below). Likewise, renal drug or metabolite elimination assumes an increased role in subjects with liver disease.

TABLE 103-3 Effects of Renal Failure on Drug Disposition and Effect

Bioavailability	Absorption of specific drugs may impaired by increased gastric pH (because of gastric urease-produced ammonia), chelation by orally-administrered phosphate-binding agents, or by bowel wall edema. Conversely, bioavailability may be increased by uremia-induced impairment of first-pass metabilism. Uremic effects on intestinal motility (ileus) affect the rate, rather than the extent, of drug absorption, unless emesis result in loss of ingested drug.
Protein binding	Binding of acidic drugs to albumin is decreased, because of competition with accumulated organic acids, and because of uremia-induced structural changes in albumin, which decrease drug-binding affinity (e.g., barbiturates, cephalosporins,. penicillins, phenytoin, salicylate, sulfonamides, valproate, warfarin).
Volume of distribution	Vd may be altered in the presence of renal failure. Drugs which are acidic, are highly protein-bound, and have a small volume of distribution are likely to be significantly affected. Other drugs may also be affected (e.g., aminoglycosides [volume status effects]), digoxin (displacement from tissue sites by ["uremic substances"]).
Biotransformation	Nonrenal (i.e., hepatic) clearance may be impaired. This phenomenon is best characterized in chronic renal insufficiency (rather than acute renal failure), affecting oxidative metabolism (phase I enzymes). Conversely, phenytoin clearance is augmented.
Excretion	Drugs which are more than 30% eliminated unchanged in the urine are likely to have significantly diminished CL in the presence of renal insufficiency. This results in a prolonged half-life for elimination of drugs such as digoxin, aminoglycosides, insulin, and others. The renal excretory route may assume increased importance in clearance of some drugs in the presence of hepatic impairment. Other drugs have toxic or active metabolites requiring renal elimination (Table 103-6). If dialysis or hemofiltration is required, drug removal may be significant.
Pharmacodynamic effects	Some drugs, such as sedative agents, may have enhanced effect in combination with the uremic milieu. Electrolyte abnormalities and acidosis may alter affects of drugs such as antiarrhythmic agents.

Is a Dose Reduction or Escalation Required, Owing to Impaired (Renal, Hepatic, or Circulatory Dysfunction) or Augmented (Induction of Metabolism or Extracorporeal Drug Removal) Clearance of the Drug or Its Metabolites?

As outlined below, glomerular filtration rate (GFR) may be estimated routinely to a reasonable approximation, and the

TABLE 103-4 Effects of Liver Dysfunction on Drug Disposition and Effect

Bioavailability	Drugs which undergo extensive first-pass metabolism may have a significantly higher oral bioavailability in cirrhotics than in normal subjects. Impaired drug absorption because of bowel wall edema has not been found in studies of cirrhotic subjects. GI hypomotility may delay peak response to enterally-administered drugs in these patients.
Protein binding	Hypoalbuminemia or altered glycoprotein levels may significantly affect the fractional protein binding of acidic or basic drugs, respectively. Monitoring of free drug levels may be indicated. In addition, drug-drug interactions by displacement from plasma protein binding sites may become important when biotransformation is concomitantly impaired.
Volume of distribution	Altered plasma protein concentrations may affect the extent of tissue distribution of drugs which are normally highly protin-bound. The presence of significant edema and ascites may alter she Vd of highly water-soluble agents (e.g., aminoglycosides).
Biotranformation	The presence of cirrhosis may result in some decrease in drug clearance, though not predictably so. Specific information regarding use of each agent prescribed in patients with a type and severity of liver disease similar to the patient in question should be sought, if possible.
Excretion	Renal elimination of drug or metabolites may be impired by concomitant renal insufficiency, which may be unsuspected based upon a "inappropriately" low serum creatinine in patients with severe liver disease.
Pharmacodynamic effects	Sedative effects (and side effects) of drugs may be augmented in patients with liver disease.

TABLE 103-5 Effects of Congestive Heart Failure (CHF) on Drug Disposition and Effect

Bioavailability	Impaired drug absorption because of bowel wall edema. Passive hepatic congestion may alter first-pass metabolism. Peripheral edema inhibits absorption of nonintravenous parenteral routes.
Protein binding	Protein amount and function is altered to the extent that renal and liver function is compromised with circulatory failure. In addition, competitive binding of plasma proteins may accur with common CHF therapy agents (e.g., furosemide).
Volume of distribution	The presence significant edema and pulmonery edema may alter the Vd of highly water-soluble agents (e.g., aminoglycosides).
Biotransformation	Hypoperfusion of liver may alter drug metabolizing enzyme function, especially with flow-dependent drugs (e.g., lidocaine).
Extretion	Renal elimination is decreased to extent that reanal and liver function are compromised by circulatory dysfunction; hepatic elimination is limited in flow-dependent drugs (e.g., lidocaine).
Pharmacodynamic effects	Increased sinsitivity to negative inotropes at therapeutic doses. Increased arrhythmic potential with antiarrhythmic drugs. Patients with CHF are more prone to contrast nephropathy.

TABLE 103-6 Selected Drugs Which Have Active Metabolites Requiring Renal Excretion

Drug	Metabolite
Acebutolol	N-Acetylacebutolol
Allopurinol	Oxypurinol
Atracurium	Laudanoside
Azathioprine	Mercaptopurine
Cimetidine	Cimetidine sulfoxide
Cyclophosphamide	4-Hydroxycyclophosphamide, others
Digitoxin	Digoxin
Disopyramide	Mono-N-desisopropyldisopyramide (MND)
Flecainide	Meta-O-Dealkylflecainide
Hydroxyzine	Cetirizine
Ifosfamide	4-Hydroxyifosfamide, others
Meperidine	Normeperidine
Metoprolol	α-Hydroxymetoprolol
Morphine	Morphine-6-glucuronide
Nitroprusside	Thiocyanate
Pancuronium	3-OH-pancuronium
Procainamide	N-Acetyl-procainamide (NAPA)
Propafenone	5-Hydroxypropafenone
Propoxyphene	Norpropoxyphene
Sulfonamides	Acetyl- metabolites
Tolbutamide	Hydroxy- and carboxy-tolbutamide
Vecuronium	3-Desacetylvecuronium

SOURCE: Modified with permission from Brater.[38]

effects of renal dysfunction on drug clearance may be estimated with some degree of precision (see Table 103-3). The effects of varying levels and etiologies of hepatic and circulatory dysfunction (see Tables 103-4 and 103-5) on drug disposition are far more difficult to predict. Estimation of renal and hepatic clearance functions and factors that alter drug metabolism and excretion will be further discussed below. Biliary, pulmonary, cutaneous, and extracorporeal elimination may be important for clearance of some specific agents and will not be discussed in detail here. For further information regarding drug clearance by extracorporeal devices, see Chap. 102; as a general rule, an increase in drug clearance by 30% or more is regarded as significant. Dialyzability by hemodialysis (HD) or peritoneal dialysis is suggested by water solubility, low molecular weight (<500 Da; up to 5000 Da with high-flux membranes), low protein binding (<90%), small volume of distribution (Vd <1 L/kg), and a low intrinsic clearance (<500 mL/70 kg per minute).[3] HD clearance is additionally affected by the porosity and surface area of the membrane used, and the blood pump and dialysate flow rates. Drug clearance by hemofiltration (slow continuous ultrafiltration, continuous arteriovenous hemofiltration, or continuous venovenous hemofiltration) may be achieved by either transmembrane sieving (convection) or membrane drug adsorption (e.g., it requires 20 mg of aminoglycosides such as gentamicin or tobramycin, which are polycationic, to saturate each new AN69 hemofilter, which is anionic); the addition of diffusive clearance by use of countercurrent dialysate flow (continuous arteriovenous hemodiafiltration or continuous venovenous hemodiafiltration) augments small-solute clearance (since the capacity of these substances to cross the membrane is limited by the concentration gradient, not particle size). Data regarding altered drug disposition (changes in Vd or clearance) induced by extracorporeal

membrane oxygenation (ECMO) or plasmapheresis are available only for agents which have been specifically studied (e.g., aminoglycosides, opiates, and phenytoin), and in the case of ECMO, studies have been performed almost exclusively in pediatric patient populations.

RENAL EXCRETION

Renal clearance of drugs or metabolites is usually achieved by glomerular filtration, and diminished clearance owing to renal insufficiency is therefore proportional, caused by a decline of GFR. Renal blood flow (RBF) averages approximately 1300 mL/min, which is about 20% to 25% of cardiac output. Renal plasma flow (RPF, 650 mL/min) is about 50% of RBF, and 20% of RPF undergoes glomerular filtration, so that GFR averages 130 mL/min. The remaining 80% of RPF circulates in peritubular capillaries, where constituents may be secreted into or reabsorbed from renal tubules. Only 1.8 L of urine is produced from the 190 L per 24 hours of daily glomerular filtrate (130 mL/min × 1440 minutes), because water and most solutes are predominantly reabsorbed (e.g., the fractional excretion of sodium in a stable subject is 1%, thus 99% of filtered sodium is reabsorbed).

Glomerular filtration of plasma constituents is primarily limited by size (≤50,000 Da), water solubility, plasma protein binding (only free drug is filtered), and volume of distribution (extensively tissue-bound substances are less likely to be renally excreted).[4,6] Some drugs also undergo significant renal tubular secretion or reabsorption (passive or active). Passive reabsorption of weak acids or bases from the renal tubular lumen may be influenced by urinary alkalization or acidification, respectively. Active tubular secretion by proximal tubular cationic or anionic pumps may be subject to competitive inhibition, resulting in decreased renal clearance and prolonged plasma half-life of the lower affinity substance. For example, probenecid inhibits tubular penicillin secretion, prolonging penicillin elimination half-life. Similarly, trimethoprim and cimetidine inhibit renal tubular creatinine secretion, reducing creatinine clearance and elevating serum creatinine, without affecting actual GFR (see below).

The plasma clearance of creatinine (creatinine clearance; CrCl) provides a close approximation of GFR, because creatinine is produced from muscle at a constant rate and freely filtered (it has a molecular weight of 113 Da, is water soluble, and is not protein bound). The amount of creatinine filtered (the product of the GFR and the plasma creatinine, PCr) is (theoretically) equal to the amount of creatinine excreted during the same period (the product of the urine creatinine concentration UCr, and the urine flow rate V); thus, GFR = (UCr × V)/PCr. Measurement of CrCl requires a timed urine collection to quantify the urinary excretion rate and a midpoint plasma creatinine sample (PCr). CrCl normally slightly overestimates GFR because some plasma creatinine is also secreted by renal tubules, augmenting the measured clearance value beyond that due to filtration. This effect is magnified with the development of progressive glomerular disease, as hypersecretion of creatinine by remnant tubules accounts for an increasing fraction of declining serial CrCl values.[26] In critically ill patients, collection of a urine sample during a period of stable renal function with a steady plasma creatinine value may not be possible; short (0.5- to 4-hour) collections have been used in an attempt to overcome this problem. Inulin clearance more closely approximates GFR, but is impractical for clinical use, since determination requires inulin infusion, and the assay is difficult to perform. Other clearance techniques are equally impractical for routine clinical use, and more complex devices measuring real-time changes in renal function are not widely available for clinical applications at this time.[27]

The steady-state serum creatinine concentration is commonly applied to the Cockcroft-Gault formula to estimate GFR, without urinary collection, because of the relationship between patient age and weight (muscle mass), serum creatinine value, and CrCl.[28] For males:

$$\text{CrCl (mL/min)} = \frac{(140 - \text{age})\ (\text{weight in kg})}{72 \times \text{SCr}_{ss}}$$

For females multiply the above value by 0.85.

Confounding factors include: requirement of a steady-state serum creatinine value (SCr_{ss}), estimation of ideal body weight, the empiricism of the age and gender estimates used in development of the formula,[29–31] and the effects of some medications on tubular creatinine secretion.[32] It is particularly difficult to account accurately for the effects on the estimated GFR calculation of diminished muscle mass (and thus creatinine generation) in the elderly, or in patients with cirrhosis, spinal cord injury, cachexia, or other causes of muscle wasting. Nevertheless, a rough estimate of the current GFR is obtained and should be used to guide dosing calculations.[33–35] In fact, one study found that this formula, using a "corrected" serum creatinine concentration of 1 mg/dL in cachectic patients, provided a more accurate GFR estimate in critically ill patients than either short (half-hour) or long (24-hour) creatinine clearance measurements.[35] The Modification of Diet in Renal Disease (MDRD) Equation offers another method to approximate GFR; the equation is found to be more accurate than the Cockcroft-Gault equation and takes into account more clinical factors, such as serum albumin and blood urea nitrogen, that likely reflect the patient's clinical status more accurately, but is much more complicated to use.[36] Websites are available (such as www.nephron.com) to facilitate the use of the MDRD Equation. Another interesting and accurate approach uses measured aminoglycoside clearance, which occurs entirely by glomerular filtration, as a surrogate measurement of GFR.[37]

Following GFR estimation, dosage is usually adjusted based upon published criteria for the agent in question. These maintenance dose adjustments for renal insufficiency are made as follows:[38–41]

$$\text{Patient's estimated GFR/normal GFR} \times 100 = \text{dose adjustment, \%}$$

(i.e., percentage increase in interval or percentage decrease in dose). The dosing interval may be increased (interval extension), the size of individual doses decreased (dose reduction), or a combination of both approaches may sometimes be necessary.

For the interval extension method, the usual size dose is given, but the intervals between individual doses are lengthened. This method is useful for drugs characterized by long plasma half-lives in the presence of renal impairment and a wide therapeutic range. This approach is convenient but results in large plasma concentration fluctuations between

peak and trough levels; in drugs with a low therapeutic index, toxic or subtherapeutic levels may result. For example, aminoglycosides are ideally suited to such a dosing strategy: The peak plasma concentration correlates with therapeutic efficacy, but trough levels must be monitored and kept low to minimize toxicity.

Alternatively, in drugs with a low therapeutic index, and those for which a constant level is preferred, the size of individual doses is reduced. This achieves a more constant plasma concentration, with less peak-trough fluctuation; however, increased toxicity because of higher average trough levels may result. For example, antiseizure drugs must be dose-adjusted in this fashion.

In the presence of renal insufficiency, hepatic metabolism accounts for the bulk of nonrenal elimination of drugs that are normally renally excreted. Hepatic biotransformation of some drugs is altered in patients with renal insufficiency; the cause of this phenomenon is unknown. Most available data come from studies of patients with chronic renal insufficiency, including those with end-stage renal disease.[39] Unfortunately, the effect of acute renal failure on hepatic drug biotransformation is little studied, and specific studies in this population have yielded some unexpected results. Normally, about 30% of vancomycin is cleared by nonrenal routes (approximately 40 mL/min). Nonrenal vancomycin clearance is decreased to 6 mL/min in patients with chronic renal failure on maintenance dialysis. The elimination pattern in acute renal failure (ARF) is more complex. Nonrenal elimination is approximately halved early in the course of ARF (16 to 17 mL/min), and decreases to values closer to those of subjects with chronic renal insufficiency (CRI) (10 mL/min) after 1 week of ARF.[43] This phenomenon requires an appropriate dosage adjustment, which is facilitated in this case by the routine availability of plasma level monitoring. Conversely, nonrenal clearance of imipenem in acute renal failure is nearly double that found in chronic renal insufficiency (95 mL/min vs. 51 mL/min), approaching that found in patients with normal renal function (130 mL/min; comprising over half of normal total clearance of approximately 230 mL/min). As a result, the total clearance of imipenem in anuric ARF patients is 108 mL/min, compared with 64 mL/min in CRI, and 230 mL/min in normal subjects. Therefore, the daily dose requirement is appropriately reduced from 2000 to 4000 mg/d hours in normal subjects to 1847 mg/d in ARF patients—a near doubling of the dose that would be administered based on CRI data (1111 mg/d).[44] In this case, the risk of seizure because of impaired clearance and imipenem accumulation is balanced against the risk of undertreatment, but accurate dosing would not be achieved based solely on clearance data from CRI patients, and plasma drug levels are not routinely available for clinical use in most institutions. Acute renal failure data should be used whenever possible; absent this information, CRI data must be used, but with an appropriate cautionary approach.

HEPATIC BIOTRANSFORMATION

Most drugs are lipophilic, so that they tend to be reabsorbed across renal tubular or intestinal membranes following glomerular filtration or biliary excretion, respectively. These drugs must therefore undergo biotransformation to more polar/hydrophilic compounds to allow urinary or biliary excretion. Drug biotransformation reactions are classified as phase I (functionalization reactions, exposing or introducing a functional group), or phase II (biosynthetic) reactions. Phase I reactions are predominantly oxidations, reductions, and hydrolysis reactions, and are usually catalyzed by enzymes of the cytochrome P450 (CYP450) system, located in the endoplasmic reticulum (Tables 103-7, 103-8, and 103-9). Phase II reactions are conjugations, catalyzed by a variety of (mainly cytosolic) enzymes, which covalently link the parent drug or metabolite to a variety of compounds. Biliary excretion of a conjugated compound may result in enterohepatic recirculation of the parent compound if intestinal flora cleave the conjugate bond. Both phase I and II reactions generally

TABLE 103-7 Selected Cytochrome P450 Inhibitors and Inducers

Inhibitors	Inducers
Amiodarone	Anticonvulsants
Celecoxib	Carbamazepine
Cimetidine	Phenobarbital
Erythromycin	Phenytoin
Ethanol (acute intoxication)	Cigarette smoking
Fluconazole	Corticosteroids
Fluoxetine	Prednisone
Isoniazid	Dexamethasone
Itraconazole	Ethanol (chronic use)
Ketoconazole	Grape fruit juice
Neuroleptics	Omeprazole
Oral contraceptives	Pioglitazone
Psoralen dermatologics	Rifampin
Quinidine	
Quinolone antibiotics	
Selective serotonin reuptake inhibitors	
Ticlopidine	
Tricyclic antidepressants

result in a loss of pharmacologic activity, although more active metabolites are less commonly produced. Hepatic drug metabolism is functionally characterized by two patterns of clearance, which may be flow-limited or capacity-limited. The hepatic extraction ratio (ER) is derived as follows: $ER = (C_A - Cv)/C_A$, where C_A and C_V are the drug concentration in hepatic arterial (or portal venous) and hepatic venous blood, respectively. The hepatic ER is low for capacity-limited drugs (which have saturable biotransformation pathways) and high for flow-limited drugs (the liver essentially metabolizes any drug delivered, a process limited only by drug-delivering blood flow).

The bulk of drug biotransformation is performed by hepatic enzymes, and the remainder by renal tubular, intestinal, cutaneous, and pulmonary enzymes. The CYP450 system, comprising at least 12 families (in humans) of heme-containing endoplasmic reticulum enzymes, is the major catalyst of hepatic drug biotransformation reactions (see Table 103-9).[5,45–48] Three families (CYP1, CYP2, and CYP3) are responsible for essentially all drug biotransformations, through phase I (primarily oxidative) reactions. Cytochrome P450 nomenclature is based on amino acid sequence homology. Families (designated by numbers, such as CYP3) contain at least 40% homology; subfamilies (designated by capital letters, such as CYP3A) are over 55% homologous; individual P450 enzymes are again designated by Arabic numerals (for example, CYP3A4). The CYP3A subfamily accounts for over 50% of phase I drug metabolism, predominantly by the

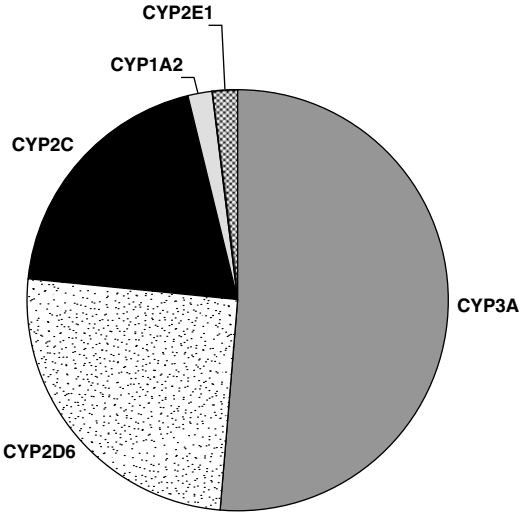

FIGURE 103-6 The proportion of drugs metabolized by the major cytochrome P450 enzymes. (*Reproduced with permission from Benet et al.*[5])

CYP3A4 subtype. Most other drug biotransformations are performed (in decreasing order of frequency) by CYP2D6, CYP2C, CYP2E1, and CYP1A2 (Fig. 103-6).[5] More than one enzyme may metabolize a particular drug, but metabolism of many drugs is dependent upon a single enzyme. Since the CYP450 nomenclature is based on structural criteria, rather than biotransformation function, isozymes of a particular class often lack any common substrates.

Phase II (conjugation) reactions form a covalent linkage between a drug's functional group and one of a number of compounds: glucuronic acid, sulfate, glutathione, acetate, or amino acids. These conjugates are highly polar, usually inactive, and undergo urinary or fecal excretion.[46,49]

Drug biotransformation may be enhanced or impaired by multiple factors, including age, gender, enzyme induction or inhibition (see Table 103-7), pharmacogenetics, and the effects of hepatic dysfunction or other disease states (including those which decrease hepatic perfusion). Conditions that impair drug biotransformation may result in type A adverse drug reactions, caused by accumulation of toxic concentrations of parent drug or metabolites (see section on adverse drug reactions, below).

EFFECTS OF AGE

CYP1A2 activity is increased in children compared to adults, causing the well-known increased theophylline dosage requirements in this population.[50,51] Similarly, CYP3A4 activity appears to decline in the elderly compared to younger adults,[52–54] although age-related declines in hepatic size, hepatic blood flow, or drug binding and distribution may underlie this phenomenon, because in vitro enzyme activity is unchanged with age.[55]

EFFECTS OF GENDER

Differences in pharmacokinetic and pharmacodynamic properties of drugs between men and women are more commonly being recognized. These differences can sometimes have major clinical impact, or be as subtle as gender-related differences in metabolism of specific stereoisomers of a particular drug formulation. Differences in rate of absorption and extent of first-pass metabolism have been reported for some drugs, including ondansetron[56] and zolmitriptan,[57] but these generally lack major clinical significance. Gender differences in volume of distribution, after adjustment for weight effects, have also been identified for a number of drugs. Theophylline exhibits a smaller volume of distribution in females compared to males,[58] as do the fluoroquinolones.[59] Possible explanations include differences in body composition between men and women, physiologic changes associated with menstrual cycles, and differences in plasma protein binding secondary to hormonal characteristics. Gender differences in drug elimination have been studied in hepatic and renal processes. Clinically significant differences were predominantly linked to gender-specific expression of metabolic enzymes (e.g., CYP3A4 and CYP1A2); gender differences in renal handling of drugs tend to be clinically silent. Pharmacodynamic variability in humans is more difficult to measure, because the measured parameters can often be subjective, such as pain or depression. Nonetheless, relevant gender differences have been identified. Women treated with thrombolytics after a myocardial infarction are more likely to experience intracranial hemorrhage. Other examples include drugs involved in glucose management and arrhythmia treatment.

PHARMACOGENETICS

Many adverse drug reactions which were formerly termed idiosyncratic are now recognized to be caused by genetic polymorphisms of expression (through autosomal recessive traits) of genes involved in drug disposition and effects, including the hepatic drug metabolizing enzymes (phase I or phase II) in particular individuals and racial groups, which have been most well-studied[16,61–64] (see Table 103-9; Tables 103-10 and 103-11). The identified polymorphisms of these metabolic enzymes differ in their rate of metabolism: "extensive metabolizers" are the common wild-type phenotype, "poor metabolizers" exhibit a decreased rate of substrate metabolism, and the rare "ultra-rapid metabolizers" display an increased rate of substrate metabolism. The incidence of expression of the different phenotypes varies by race and ethnic group. The effect of racial origin on drug metabolism is receiving increasing attention in the drug development process,[13,65–67] although it must be remembered that pharmacogenetic factors controlling drug disposition and response vary not only according to race and gender, but also between individuals of the same race and gender.

CYP2D6 Polymorphism

The most common P450 polymorphism in Caucasians is of CYP2D6 expression. CYP2D6 is responsible for metabolism of approximately 30 to 40 commonly used drugs, about half of which are psychoactive agents (antidepressants, including all tricyclic antidepressants [TCAs] and selective serotonin reuptake inhibitors [SSRIs], and antipsychotics, including haloperidol[68]); other substrates include β-blockers (all except atenolol and sotalol, which are renally excreted, not metabolized), other antiarrhythmic drugs, and codeine. Approximately 7% to 10% of the Caucasian population, 2% to 5% of Africans, but only rare Asian subjects lack expression of this enzyme and are poor metabolizers of CYP2D6 substrates.[66] Such patients are prone to develop profound bradycardia during standard β-blocker therapy or severe drowsiness when receiving psychoactive drug therapy; in each case the adverse

TABLE 103-10 Phase II Drug Metabolizing Enzymes: Substrates and Polymorphisms

Polymorphism	Examples
"Slow" acetylation	*N-acetylation polymorphism.* Slow acetylators have deficient N-acetylatransferase activity (NAT-2). Incidence of slow acetylators : 50%–60% (Caucasian and African Americans; southern Indians); 5%–20% (Chinese, Japanese, Eskimos) Incidence increased in HIV patients (thus sulfa reactions are more common) Slow acetylators have increased risk of (1) isoniazid-induced peripheral neuropathy, and possibly hepatotoxicity; (2) drug-induced lupus: hydralazine, procainamide; (3) sulfonamide hypersensitivity: deficient hydroxylamine metabolite detoxification; (4) sulfasalazine-induced hemolysis
Dihydropyrimidine dehydrogenase deficiency	*Dihydropyrimidine dehydrogenase polymorphism.* 3%–4% taking 5-fluorouracil (5-FU) have defidient metabolism, and develop severe toxicity (myelosuppression, etc).
Glucuronidation deficiency	*UDP-glucuronyltransferase polymorphism.* Deficiency of hepatic UDP-glucuronyltransferase activity manifests as two syndromes of impaired bilirubin conjugation: Gilbert's (2%–12% of population) and Crigler-najjar (<1%) syndromes. Potential but undocumented effects on metabolism of heavily glucuronidated drugs (acetaminophen; HIV drugs; oncologic agents).
Glucose-6-phosphate-dehydrogenase deficiency	*G-6-PD deficiency.* Occurs in approximately 20% of African-American males; less frequent in females. Since erythrocytes from these patients are susceptible to oxidative stress, they are prone to develop hemolytic anemia induced by antimalarials (chloroquine, mefloquine, primaquine), probenecid, nitrofurantoin, sulfa drugs (sulfamethoxazole, dapsone), sulfonylurea hypoglycemic agents (chlorpropamide, tolbutamide)
Glutathione transferase deficiency	*Glutathione-s-transferase polymorphism.* Absent activity of GSTM1 (50% Caucasians, 30% African-Americans) and/or GSTT1 (15% Caucasians, 24% African-Americans) impairs clearance of electrophilic toxins. Increased vulnrability to acetaminophen, metronidazole, and nitrofurantoin toxicity, because of depletion of mitochondrial glutathione stores.
Atypical pseudocholinesterase	*Pseudocholinesterase polymorphism.* Subjects have impaired hydrolysis of succinylcholine, resulting in prolonged paralysis following use of this agent; incidence is 1 in 2500 people.
Thiopurine methylation deficiency	*Thiopurine methyltransferase polymorphism.* Deficient (heterozygotes: 11%) or absent (homozygotes: 1 in 300) s-methylation of thiopurine drugs: azathioprine and 6-mercaptopurine, resulting in development of profound leukopenia with standard doses.
Atypical alcohol and aldehyde dehydrogenase activities	*Alcohol dehydrogenase activity.* Five-to six fold more rapid alcohol dehydrogenase activity is found in the majority of Japanese subjects (compared to Caucasians), resulting in acute symptoms following consumption of low doses of ethanol, because of rapid aldehyde production. *Aldehyde dehydrogenase deficiency.* Up to 50% of Asian and Native American subjects develop a disulfiram-like reaction (profound nausea and emesis) following ethanol consumption, because of deficient conversion of aldehyde to acetate. This enzyme also participtes in conversion of cyclophosphamide and ifosfamide to active metabolites (after cytochrome P450 oxidation).

event is caused by accumulation of the parent drug. Conversely, these individuals derive little analgesic effect from codeine, which must be metabolized by CYP2D6 to its more potent metabolite morphine to achieve therapeutic efficacy. Quinidine, fluoxetine, and amiodarone are potent inhibitors of CYP2D6 activity, and convert genetically extensive metabolizers to phenotypically poor metabolizers of CYP2D6 substrates.

CYP2C19 Polymorphism

The most prevalent P450 polymorphism in Asians is of CYP2C19 expression; 15% to 27% of Asians but only 3% to 5%

TABLE 103-11 Prevalence of Phase I and II Enzyme Polymorphisms by Race

	Polymorphism Phenotype	Overall U.S. Population	White	Black	Asian
CYP2D6	Poor	10%	5%–10%	0–20%	1%
	Ultrarapid	6%	1%–10%	2%	0–2%
CYP2C9	Poor	1%	0.2%–1%	Not determined	2%–3%
	Ultrarapid	Not identified	—	—	—
CYP2C19	Poor	4%–5%	3%–6%	4%	8%–23%
	Ultrarapid	Not identified	—	—	—
Dihydropyrimidine dehydrogenase	Poor	0–1%			
	Ultrarapid	Not identified	—	—	—
Plasma Pseudocholinesterase	Poor	<1%	0–1%	Not determined	Not determined
	Ultrarapid	Not identified	—	—	—
N-acetyltransferase	Poor		40%–70%	50%–60%	10%–20%
	Ultrarapid	Not identified	—	—	—
Thiopurine methyltransferase	Poor	0–3%	0.33%	Not determined	0.04%
	Ultrarapid	Not identified	—	—	—
UDP-glucuronosyltransferase	Poor	10%–15%	10.9%	Not determined	3%–5%
	Ultrarapid	Not identified	—	—	—

of Caucasians lack expression of this isozyme and are poor metabolizers of substrates such as S-mephenytoin, phenytoin itself, diazepam, and omeprazole.[67] Poor metabolizers of CYP2C19 have a better response to omeprazole in eradication of *Helicobacter pylori* than do extensive metabolizers. However, prolonged (>1 year) exposure to high serum omeprazole levels is more likely to cause cobalamin deficiency and result in neuropsychiatric and hematologic side effects.[69]

CYP2C9 Polymorphism

The incidence of CYP2C9 polymorphism is up to 20% in black patients, but only 1% in Caucasians; important substrates include S-warfarin, phenytoin, diclofenac (and other hepatically metabolized nonsteroidal anti-inflammatory drugs [NSAIDs]), glipizide, and losartan. Fluconazole at usual therapeutic doses is a powerful CYP2C9 inhibitor. Clinically useful laboratory studies are being developed to determine CYP2C9 phenotype and guide therapy of drugs with narrow therapeutic indices, such as warfarin and phenytoin.

CYP2E1 Polymorphism

CYP2E1 metabolizes acetaminophen and many volatile anesthetics and is induced by isoniazid and ethanol. Interestingly, 2.4% of Caucasians and 10% of subjects with alcoholic liver disease have a CYP2E1 rapid metabolizer phenotype and metabolize CYP2E1 substrates to a greater extent than most of the general population.

CYP3A Polymorphism

The CYP3A family of enzymes displays a wide range of expression of activity for each enzyme in normal populations, contributing to the difficulty in identifying clinically significant polymorphisms. Additionally, substrates of the CYP3A family enzymes often are metabolized in a multigenic pathway. Many common substrates are metabolized by both CYP3A4 and CYP3A5; the relatively common CYP3A5 poor-metabolizer phenotype may then be clinically obscured by this dual pathway. The role of the CYP3A4 enzyme in drug elimination is further complicated by the presence of polymorphisms that alter the rate of metabolism of some substrates but not others.[70] The clinical implications of these polymorphisms remain unclear.

Phase II Enzyme Polymorphisms

A genetic polymorphism for acetylation of procainamide, hydralazine, isoniazid, and sulfa drugs (see Table 103-10) underlies the "slow acetylator" phenotype seen in over 50% of American blacks and whites but only 10% of Asian individuals. Many other phase II reactions are subject to pharmacogenetic variation[56] (see Table 103-10), resulting in polymorphic expression of the metabolic capacity for specific agents. Examples include glucuronidation (Gilbert syndrome), and the activities of glutathione-S-transferase (acetaminophen metabolism), thiopurine methyltransferase (azathioprine metabolism), glucose-6-phosphate-dehydrogenase (quinine-induced hemolysis), pseudocholinesterase (prolonged paralysis following succinylcholine), and dihydropyrimidine dehydrogenase (5-fluorouracil toxicity).

ENZYME INDUCTION AND INHIBITION

Common substrates of the P450 enzyme responsible for metabolism of a particular drug may be inhibitors or inducers of its metabolism and therefore create the potential for drug interactions (see Tables 103-7 and 103-9). Substances that are not substrates of a P450 isozyme may also be inhibitors or inducers of its activity (e.g., fluconazole and CYP2C9, quinidine and CYP2D6). The potential for such an interaction is increasingly predictable, and consequent overdosage or underdosage preventable, owing to identification of the specific P450 isozyme responsible for drug metabolism in recent product package inserts and other standard sources (see section on general drug information reference texts, below). For example, since both cyclosporine and tacrolimus (formerly FK506) are metabolized by CYP3A4, biotransformation of both agents is predictably affected by known inhibitors and inducers of this enzyme (see Table 103-9). Ketoconazole is a particularly potent inhibitor of CYP3A4 and has been used to deliberately lower cyclosporine dosage requirements as a

cost-saving measure.[71,72] By contrast, phenobarbital induces cyclosporine metabolism to such an extent that concomitant use of these agents is not advisable; likewise, therapeutic cyclosporine levels are difficult to maintain during rifampin therapy. Inducers and inhibitors of phase II enzymes have been less extensively characterized, but some clinical applications of this information have emerged; for example, phenobarbital is used to induce glucuronyl transferase activity in icteric neonates, and both phenobarbital and valproate have been used to modulate chemotherapeutic agent glucuronidation and toxicity.[73]

EFFECTS OF DISEASE STATES

Critical illness routinely alters all the physiologic processes involved in drug disposition. It would be surprising if drug disposition and/or response were not significantly altered in such patients. Unfortunately, most data regarding drug disposition in critically ill patients must be extrapolated from other populations; clearly, such information must be interpreted with extreme caution.

EFFECTS OF CIRCULATORY DYSFUNCTION

The effects of congestive heart failure (CHF) on drug disposition are the best-studied examples of alterations of drug absorption, distribution, and elimination associated with circulatory insufficiency (see Table 103-5). Secondary decrements in hepatic and renal blood flow result in impaired clearance of some drugs excreted by these routes. Clearance of hepatically eliminated drugs is more likely to be impaired by CHF if their metabolism is flow-limited (i.e., characterized by a high extraction ratio, such as lidocaine). It is doubtful that most such information, even from populations with decompensated CHF, is applicable to the setting of cardiogenic shock. Even fewer data are available regarding disposition of most agents in patients with hypovolemic or septic shock, or even sepsis syndrome without frank hypoperfusion. Just as is the case in CHF, septic hypoperfusion may disproportionately involve the renal or splanchnic circulations, resulting in impairment of renal or hepatic perfusion to a degree that would not be expected based upon global hemodynamic data. Furthermore, experimental evidence suggests that endotoxemia impairs hepatic drug metabolizing-enzyme function[74] and that nitric oxide probably mediates much of this inhibition.[75]

Effects of Liver Disease

The effects of hepatic disease on PK and PD parameters of drug disposition are much more difficult to predict than the consequences of renal disease, based on data available for most agents.[76,77] Standard indices of hepatic function, such as the clinical features and biochemical values comprising the Child or Child-Turcotte scores, do not correlate even qualitatively with the capacity of the diseased liver to biotransform xenobiotics.[78] Activity of particular cytochrome P450 isozymes or conjugating enzymes may be decreased, preserved, or even increased in the presence of different liver diseases at various stages of severity.[17,77,79] Most data suggest that cirrhosis variably affects the hepatic content and activity of particular cytochrome 450 isozymes; contents of CYP3A are not demonstrably changed, CYP1A2 and CYP2E1 activities are decreased, and CYP2C activity may even be increased (as is tolbutamide clearance in cirrhosis).[77] In addition, the presence of gastrointestinal hypomotility, hypoalbuminemia, increased or decreased plasma glycoprotein levels, ascites/edema, and altered hepatic blood flow may all alter drug absorption, distribution, elimination, and effects unpredictably (see Table 103-4). Gastric hypomotility does not alter bioavailability; rather it delays absorption and reduces the peak plasma level. Altered levels of the major drug-binding plasma proteins in cirrhosis or other forms of liver dysfunction have complex secondary effects. The frequent presence of hypoalbuminemia decreases binding of acidic drugs, such as phenytoin. Production of α_1-acid glycoprotein, which binds many basic drugs (e.g., lidocaine and quinidine), is impaired by severe cirrhosis but increased by inflammatory states (it is an acute-phase reactant). The importance of decreased plasma protein binding (caused by decreased binding protein levels or by displacement by a competing substance) is determined by the hepatic extraction ratio of the drug, and the presence or absence of concomitant impairment of hepatic biotransformation capacity (caused by disease or by competition with an interacting agent). Changes in protein binding do not alter clearance of high-extraction (flow-limited) drugs, but if hepatic metabolism of a low-extraction (capacity-limited) drug is impaired and protein binding of the drug is also decreased, then the plasma free drug level will increase.[80] Renal elimination of drugs or metabolites (inactive, active, or toxic) is also commonly impaired in patients with cirrhosis by the associated decrement in glomerular filtration rate, which is often unappreciated because of the poor correlation between plasma creatinine values and GFR in cirrhotic subjects.[16] Finally, liver disease patients appear to have increased sensitivity to many drugs or their metabolites; some of this phenomenon is attributable to synergistic sedation (a PD phenomenon), although many such instances are probably caused by unrecognized accumulation of active or toxic metabolites or abnormally increased CNS distribution (e.g., increased blood-brain barrier permeability to cimetidine in cirrhosis).[81]

In practice, the presence of hepatic dysfunction should prompt a thorough drug regimen re-evaluation to examine all disposition parameters.[17,76,78,82] Useful data may be available regarding the effects of cirrhosis on clearance of the agent, permitting an appropriate dose reduction. More commonly, the only information available details the predominant route of drug elimination. In either case, careful dose titration upward from a dose lower than normal is obviously the prudent approach; however, such a cautious approach may not be consistent with the rapid therapeutic effect desired in critically ill patients. Dose reduction is most likely to be necessary when a drug which usually undergoes extensive first-pass metabolism is enterally administered in the presence of liver disease severe enough to impair hepatic clearance of the agent; in such a situation, both increased oral bioavailability and decreased clearance tend to increase plasma drug levels:

$$Cp_{ss} = (\text{bioavailability} \times \text{maintenance dose})/(\text{dosing interval} \times \text{clearance})$$

Careful therapeutic monitoring of agents that have a low therapeutic index (see Table 103-8), using plasma levels if these are clinically available, represents the optimal approach in cases in which impaired clearance is suspected. Otherwise, monitoring of physiologic parameters during graded upward

dose titration may be the best available option. It is important to remember that, because of impaired elimination and the resultant prolongation of half-life, achievement of steady-state plasma drug levels and corresponding maximal effect will be correspondingly delayed. Failure to wait for achievement of steady-state conditions prior to dose escalation may result in drug accumulation to toxic levels. Important drug interactions are also more likely to occur in the presence of impaired drug elimination "reserve," so that increased vigilance regarding potential protein-binding or hepatic biotransformation interactions is warranted in the presence of liver disease (see below).

HALF-LIFE

When clearance is diminished, elimination half-life increases proportionately, as does the time required to achieve steady-state plasma levels (three to five half-lives). The appropriate time for assessment of full pharmacologic effect and measurement of levels may thus be markedly delayed. For example, the elimination half-life of digoxin is normally 20 hours, but increases to 1 week with end-stage renal disease (ESRD); an ESRD patient discharged from the hospital with a plasma level within the therapeutic range 1 week after starting maintenance therapy with 0.25 mg per day of digoxin will probably subsequently develop digitalis toxicity.

CONSIDERATION OF POTENTIAL DRUG-DRUG INTERACTIONS

Drug-drug interactions may occur owing to alterations in drug disposition (PK interactions), or drug effect (PD interactions).[4,83,84] PK interactions occur through effects on four drug disposition mechanisms: (1) gastrointestinal absorption, (2) drug distribution, (3) hepatic metabolism, and (4) renal excretion. These categories will be further discussed below. PD interactions occur by three basic mechanisms: (1) pharmacologic interactions, usually based on binding of an antagonist to the target receptor mediating drug effect (e.g., use of a nonselective β-blocker such as propranolol in a patient requiring inhaled nebulized β-agonist therapy for bronchospasm); (2) physiologic interactions, such as the additive effects of multiple sedatives or vasodilators, or the opposing effects of warfarin and vitamin K on coagulation factor synthesis; and (3) drug-induced changes in the intracellular milieu resulting in altered effects of other agents (the best such example is the precipitation of digitalis toxicity by loop diuretic–induced hypokalemia and hypomagnesemia). It is worth emphasizing the fact that individual sensitivity to drug effect (e.g., sedative effects in the elderly) may predispose particular patients to suffer the consequences of PD drug interactions more readily than others. Prevention of PD drug interactions is best accomplished through a basic understanding of the mechanism of action, common side effects, and population-specific issues (if any) pertinent to any drug prescribed.

PK interactions are the subject of many exhaustive compendia, but a few general principles are required to interpret such information. In order for a reported PK drug interaction to be of clinical significance, three criteria should be fulfilled.[5,38] First, one of the drugs involved must have a low therapeutic index, so that an alteration in its disposition results in either toxic or subtherapeutic effect (there are important exceptions to this rule). Second, the drug disposition parameter alteration should be on the order of 30% or more, because changes of lesser magnitude are unlikely to be of clinical importance. Finally, only reports in humans should be considered definite, since animal studies of drug disposition do not always accurately reflect human processes. Conversely, the absence of reported data from animal studies does not preclude drug interactions in humans, particularly with respect to newer agents undergoing wide use for the first time.

ABSORPTION

Most such interactions affect the rate rather than the extent of absorption, so that the magnitude and timing of peak plasma drug level is altered, but the fraction absorbed (and thus bioavailability) is unchanged. Interaction mechanisms include physicochemical complexing (e.g., tetracycline and milk products); gastric pH changes (e.g., failure to absorb ketoconazole when gastric pH is made alkaline by coadministration of antisecretory agents); alterations in gastrointestinal motility; effects on gastrointestinal mucosa or flora (e.g., increased digoxin levels after antibiotic therapy; see Chap. 102); changes in mesenteric blood flow; and finally changes in first-pass metabolism (e.g., cyclosporine with ketoconazole[71,72,85]).

DISTRIBUTION

Altered drug binding because of displacement by another agent is of far lesser importance as a source of drug interaction than is generally appreciated. In fact, drug displacement from binding sites simply makes more free drug available for excretion or biotransformation.[84] The net effect on plasma levels of active drug is thus usually negligible, unless clearance of the displaced drug is also impaired because of organ dysfunction or the inhibition of drug metabolism or excretion by the displacing agent itself.

HEPATIC METABOLISM

Inducers and inhibitors of hepatic biotransformation are important causes of drug interactions. This is well illustrated by considering common interactions with the enzyme predominantly responsible for cyclosporine metabolism, underlining the importance of considering drug interactions when adding new agents to a patient's drug regimen. Cyclosporine, a potent immunosuppressive drug used in the prevention of allograft rejection, is metabolized by the CYP3A4 enzyme in both the liver and small intestine. Modulation of the pharmacokinetics of cyclosporine has been reported with a large number of drugs. For example, ketoconazole is known to be a potent inhibitor of CYP3A4, and therefore both increases oral bioavailability and reduces the rate of elimination of the drug, increasing blood cyclosporine levels. This predictable interaction can be used favorably to minimize the cost of therapy by decreasing the necessary dose of cyclosporine by co-administration with the cheaper drug, ketoconazole. More commonly, drug interactions result in unfavorable outcomes. Inadvertent coadministration of cyclosporine with a CYP3A4 inducer, such as troglitazone (now removed from the market) or rifampin, can result in rapid drug elimination (a state similar to the previously described "ultra-rapid metabolizer" phenotype) and subtherapeutic cyclosporine levels, with subsequent potential rejection of the transplanted organ.[87]

There are numerous clinically important examples of such interactions involving the other P450 isozymes also. Theophylline is metabolized by CYP1A2; theophylline toxicity

may be precipitated by addition of the quinolone antibiotic ciprofloxacin (an inhibitor of CYP1A2) or by smoking cessation (because of withdrawal of the CYP1A2-inducing effect of cigarette smoking), unless theophylline dosage is reduced appropriately. Only one dose of quinidine (a CYP3A4 substrate) is required to convert a normal, extensive metabolizer of CYP2D6 substrates (including numerous β-blockers, antidepressants, and antipsychotic agents) into a poor metabolizer of these agents. Inhibition of drug biotransformation activity by a drug which is not a substrate of the impaired enzyme is not uncommon: quinidine is a powerful CYP2D6 inhibitor and CYP3A4 substrate; fluconazole is also a CYP3A4 substrate but impairs phenytoin and warfarin metabolism by CYP2C enzymes, in addition to competitive inhibition of metabolism of other CYP3A substrates. Such instances reinforce the need to examine both the known and potential interactions of each additional agent with those in the patient's current regimen.

Finally, agents that diminish hepatic blood flow (vasopressors and cimetidine) may impair clearance of high-extraction drugs such as lidocaine and propranolol.

RENAL EXCRETION

Drug interactions can affect glomerular filtration, tubular secretion, or tubular reabsorption (active or passive). It is obvious that agents that impair or augment glomerular filtration tend to cause a corresponding change in excretion of drugs eliminated by this route, such as aminoglycosides. Active tubular drug secretion is performed primarily by two groups of proximal tubular pumps: an anion pump (which secretes organic acids) and a cation pump (which secretes organic bases). Competitive inhibition of the anion pump by probenecid impairs elimination of penicillin, thus prolonging the half-life of this organic acid. Methotrexate is another anion secreted by this pump, and subject to the same interaction. Cimetidine and trimethoprim inhibit cationic pump secretion of procainamide and some other cationic drugs. Digoxin undergoes distal tubular secretion by a third pump system, which is inhibited by multiple drugs, including quinidine, amiodarone, spironolactone, and several calcium channel blockers; this is the mechanism partly responsible for the elevation of serum digoxin levels routinely encountered following combination of these agents with digitalis therapy. Finally, as discussed in Chap. 102, alterations in urinary pH alter passive distal tubular reabsorption of weak acids and bases, including drugs such as salicylic acid and phenobarbital (a basic drug).

THERAPEUTIC DRUG MONITORING

Most drugs are dosed according to population-based PK/PD data. In most cases, critical care therapy is initiated in this fashion, but may be monitored and titrated using readily available pharmacodynamic parameters (sedation, analgesia, paralysis, hemodynamic data, cardiac rhythm, and electroencephalography). Selected agents, usually those with a low therapeutic index, are additionally monitored and dose-adjusted using plasma drug levels and calculations of individual drug disposition parameters. Whether monitored using pharmacodynamic indexes alone, or more precisely with the addition of PK data, ongoing attempts to optimize therapeutics should minimize the occurrence of inadequate therapy or adverse drug reactions (ADR).

Appropriate direct therapeutic drug monitoring involves consideration of many variables. The form of drug measured is important, especially in drugs with high plasma-protein binding. Because only the free fraction of the drug is clinically active, the useful plasma test is one that accurately reflects the free fraction. For example, phenytoin is highly albumin-bound. In the setting of critical illness, hypoalbuminemia, malnutrition, or cirrhosis, total phenytoin levels may be low, while free phenytoin levels are likely to be in the therapeutic range. The timing of plasma drug testing is also important. In drugs such as aminoglycosides, peak and trough levels need to be monitored, since peak levels reflect therapeutic efficacy and trough levels are monitored to ensure adequate drug clearance and to avoid drug accumulation.

Drug regimen adjustment may be precipitated by multiple intercurrent factors, including changes in volume status; alterations (worsening or improvement) in gastrointestinal tract or circulatory, renal, or liver function; the application of extracorporeal therapies which impact drug disposition; and potential drug interactions or other ADRs associated with addition of new agents. Finally, any change in patient status should be considered a potential ADR, and this possible diagnosis assessed using available resources. If an ADR is strongly suspected, this should be reported to the appropriate institutional and extramural authorities, and management altered accordingly.

ADVERSE DRUG REACTIONS

Drug prescribing intended to achieve beneficial therapeutic effects is necessarily accompanied by the possibility of eliciting an unintended adverse drug reaction (ADR). ADRs are common in the ICU, where multiple drugs are administered to unstable patients who commonly are unable to give a complete medical history and manifest altered drug disposition parameters (including metabolism and excretion). ADRs present diagnostic and therapeutic problems that complicate ICU admission, increasing morbidity, mortality, and length of stay.[89]

To minimize ADRs, all drugs prescribed by a critical care physician should be reviewed (prior to administration) by the critical care nurse and pharmacist for potential errors including patient identity, known patient allergies, correct dosing, and potential drug-drug interactions. Most preventable ADRs involve (1) prescribing a drug despite a documented allergy to the medication ordered or to a cross-reactive agent; (2) the use of anticoagulants or thrombolytic agents; (3) failure to appropriately monitor and adjust low-therapeutic-index drug administration using plasma drug concentration analysis; and (4) failure to adjust the regimen for administration of renally eliminated drugs in the presence of renal dysfunction.[81] Accordingly, we advocate a daily review of all medications given to each ICU patient, focusing on the following issues: (1) drug-patient interactions, including known drug allergies; (2) drug-disease interactions, including presence and severity of organ dysfunction, and appropriate dosing adjustments; (3) potential drug-drug interactions; (4) the possibility of an ADR causing any new corporeal dysfunction; and (5) discontinuation of all unnecessary drugs, in an ongoing attempt to simplify and

rationalize therapy. The importance of minimizing the number of drugs prescribed is demonstrated by the fact that there is a 40% probability of developing an ADR when more than 15 drugs are given to a hospitalized patient, compared to a 5% ADR probability when receiving fewer than 6 medications.[90]

Adverse drug reactions may be classified as type A (an exaggerated pharmacologic effect related to high drug concentration), or type B (an idiosyncratic reaction).[61] Increasingly, reactions formerly classified as idiosyncratic (type B) have been shown to be type A reactions based on polymorphic expression of metabolizing enzyme activity and impaired drug metabolism and target effect. Individuals deficient in activity of the necessary metabolizing enzyme develop ADRs caused by accumulation of previously undocumented toxic metabolites; for example, sulfonamide hypersensitivity has been linked to an increase in prevalence of the "slow acetylator" phenotype, and defective detoxification of hydroxylamine metabolites.[91,92] Other idiosyncratic phenomena, such as halothane hepatitis and carbamazepine reactions, may also be caused by defective metabolism.[92]

The diagnosis of an ADR requires a high index of suspicion that signs or symptoms may be drug-related. Distinguishing between an ADR and manifestations of other diseases can be challenging, particularly in critically ill patients with a myriad of problems.

Identification of a temporal relationship between drug initiation and onset of signs or symptoms is useful, but not always possible. For example, supraventricular tachycardia after initiation of theophylline, wheezing after β-blocker administration, or seizures during meperidine therapy may each be caused by, aggravated by, or unrelated to drug effects. Furthermore, patients may develop a type A adverse drug reaction in the ICU when elimination of an agent, which they have received chronically prior to hospitalization, is subject to a drug-disease interaction (e.g., theophylline toxicity precipitated by development of congestive heart failure), or drug-drug interaction (e.g., theophylline toxicity caused by concurrent ciprofloxacin administration). In the absence of another convincing etiology, discontinuation or dose reduction of the suspected drug is indicated. Subsequent improvement in signs or symptoms is presumptive evidence of an ADR; of note, ADRs precipitated by agents with long half-lives may require a longer period for resolution. The degree of certainty in ADR diagnosis increases if rechallenge with the suspected drug leads to reappearance of the presumed ADR; however, readministration of drug for this purpose is not recommended unless the information is crucial for subsequent patient management and alternative drugs are not available. If an idiosyncratic or allergic type reaction is suspected, drug readministration may be hazardous. Prior to considering rechallenge, appropriate consultation is suggested, to evaluate viable alternative therapies, the potential for challenge-induced anaphylaxis, possible desensitization procedures (if any), and formulation of a comprehensive treatment protocol to manage any adverse sequelae of re-exposure to the agent.

Identifying the culprit drug in patients receiving multiple medications can be challenging. The most likely offender should be either dose-reduced or discontinued (as appropriate based on the suspicion of a dose-dependent versus an idiosyncratic/allergic phenomenon), while less likely candidate drugs are continued. If the suspected reaction does not improve, remaining drugs may be discontinued sequentially, beginning with the most likely candidate. In a patient suffering a severe reaction, all medications should be stopped if possible. A common example in the ICU is the patient who develops thrombocytopenia while receiving prophylactic therapy with an H_2 blocker and subcutaneous heparin. In this situation, thrombocytopenia frequently represents a manifestation of disease, particularly if hemodynamic instability is present, and not an ADR. Nevertheless, in the presence of severe or progressive thrombocytopenia, an ADR should be considered and medication adjustments made. Heparin use correlates most firmly with drug-induced thrombocytopenia, and this agent should be discontinued first.[93] H_2 blockers (and indeed most other drugs used in the ICU) are not responsible for the majority of cases of thrombocytopenia and may be continued if clinically important.[93] In patients with critical thrombocytopenia, however, risk-benefit analysis supports discontinuation of both drugs pending further evaluation, which may include assay for antiplatelet antibodies (drug-specific tests are possible).

Numerous published tables list drugs associated with ADRs.[90,94] These lists are merely suggestive that a sign or symptom may be drug-related. They include both well-documented and poorly-documented drug reactions and are clearly not all inclusive. The absence of a drug from a particular category does not exclude the possibility of drug reaction, since there is always a first identified or reported reaction, especially during the initial period of postmarketing surveillance following approval and release of a new drug for widespread use. In the absence of a simple, dedicated, and exhaustive source of information about ADRs specific to critical care, most clinicians rely on their institution's hospital drug information service, and various library and Internet resources.[95] It is important to become familiar with these resources and to utilize government and pharmaceutical industry information services to aid in evaluating potential ADRs. Appropriate information resources include the following:

DRUG INTERACTION SOFTWARE SUBSCRIPTION SERVICES

Most institutions utilize one or more computer software programs available by subscription, such as ePocrates Rx Pro, to help identify drug interactions. These programs are continuously in development, and to date no system has been demonstrated to be superior to an experienced clinician in identifying drug interactions. Barriers to the development of drug-drug interaction (DDI) detection software for widespread use include difficulty of portability and integration

into existing hospital computer systems, development and maintenance of the knowledge base, and establishment of formal methodology of evaluation of these systems. Nonetheless, existing available software are a good initial step toward decreasing ADRs due to drug-drug interactions.

DEDICATED ICU INTENSIVISTS AND PHARMACISTS

Many studies have investigated the benefits of a dedicated team of professionals in the ICU, with the team led by a physician with specialized training in critical care medicine.[96,97] This advantage is theorized to be a result of specialized training in particular issues that arise in critically ill patients, a broader perspective of issues that pertain to critically ill patients, and improved continuity of care. In fact, the Leapfrog Initiative—a coalition of some of the nation's largest employers, such as General Electric and General Motors—has identified this as one of the three changes that they believe would most improve safety.[98] This same rationalization can be used to justify the role of a dedicated ICU pharmacist. The traditional role of a pharmacist to accept and clarify orders and dispense medications is antiquated. Having a pharmacist who participates in clinical rounds as a full member of the patient care team in the ICU can significantly decrease ADRs and decrease costs of hospitalization as compared to pharmacist review alone.[99] The benefits may be explained by improved communication between the health care professionals, optimization of therapy, and improved monitoring and management of adverse drug events. For example, for the treatment of an infection in a critically ill patient, the ICU pharmacist may contribute specialized knowledge in selecting the narrowest-spectrum antibiotic, in selecting an appropriate drug to minimize antibiotic resistance based on patterns of organism resistance in the hospital, in minimizing potential adverse drug reactions, and in selecting the most cost-effective agent. Barriers to implementing the dedicated ICU pharmacist model include the initial investment of money and time to create a new staff position, but these initial costs are likely to be easily overcome by savings in drug costs and prevention of adverse drug events.

COMPUTERIZED ORDER SCREENING SYSTEMS

Computerized screening of medication orders at the time of prescription data entry is performed in many acute care practice settings. Such programs allow for real-time checks for potential drug interactions with the patient, disease states, or other drugs. Physician order entry (POE) systems also obviate potential medical errors due to illegible handwriting or transcription errors. Common problems with these programs include a lack of primary literature referencing, routine detection of insignificant interactions, and a significant lag time between introduction of a new drug and interaction data updates. Physicians with minimal technological expertise may also be hesitant to use such technology. Nonetheless, POE systems are another change that the Leapfrog Initiative has identified that may contribute to significant reduction in ADRs.

REPORTING UNUSUAL OR NEW DRUG INTERACTIONS

Medwatch is a voluntary program sponsored by the Food and Drug Administration for reporting adverse events and problems with drugs and other products regulated by this agency. Although it is not a direct information source, contributed data collectively provide continuous new drug information. Medwatch is a major component of the FDA's postmarketing drug product surveillance and has identified ADRs that were not apparent during preapproval clinical trials (e.g., cardiotoxic effects of astemizole). Reports are encouraged even if the practitioner is not certain the product caused the event and whether or not all details are available. The program utilizes a consolidated reporting form (FDA form 3500), which may be submitted by mail or facsimile. Reports can also be sent by computer modem or by phone 24 hours a day 7 days a week. For more information or to report quality problems call 1-800-FDA-1088.

DRUG MANUFACTURER INFORMATION

The package insert which accompanies all products contains FDA-approved information regarding the known properties and appropriate use of the drug. Contact information (including toll-free telephone numbers) for pharmaceutical companies can also generally be found in this insert or other package labeling or through the hospital drug information center. Pharmaceutical manufacturing companies usually have drug information support services that can provide up-to-date information pertinent to their products. Manufacturers are required to perform postmarketing surveillance of their products and to collect information about drug interactions and other ADRs.

COMPUTERIZED RESOURCES IN THE ICU

Application of computer technology to medical care can improve efficacy and decrease errors at every step of drug administration. Computers can serve as a repository for references. Availability of textbooks, journals, review services and formularies may be valuable at the time of drug prescription. While availability of all references by print may be prohibitive, online references are easily accessible, such as Medline (National Library of Medicine, United States), MDConsult (LLC Ltd Liability Co., DE), Physician Drug References,[100] and UptoDate (UptoDate Inc., DE), to name a few.

Most institutions in the United States use computers to store patient medical records. A step further in the integration of computer technology into medical practice is patient information capture. Real-time capture of patient data, such as vital signs, pulse oximetry, and laboratory results, aids in the dissemination of information and more informed decisions for drug prescription and drug effect monitoring. Therapeutic drug monitoring can be more effectively regulated with integration of patient data and drug administration.

Recent advances in handheld devices make all of the aforementioned systems even more convenient and portable. Software for handheld devices, such as Epocrates Rx (Epocrates, Inc., CA) and Medcalc for example, allow for quick and convenient references for patient data interpretation. While computer technology continues to advance, the major barriers to incorporation of these systems into the medical practice include the initial costs of the computer devices and software, the time to install the appropriate software, the education and willingness of health care professionals to use the technology available, and the real possibility of technical malfunction. Future trends in computer technology in the ICU involve expert systems that can simulate human judgment to aid in diagnostic and therapeutic decision making, and data mining that can analyze large amounts of data to recognize relationships that have not been otherwise discovered.

Chapter 104

RHEUMATOLOGY IN THE ICU

WALTER G. BARR
JOHN A. ROBINSON

KEY POINTS

- *Most ICU admissions for rheumatology patients are prompted by infection.*
- *New-onset rheumatic diseases rarely prompt ICU admission in the absence of a revealing prodrome.*
- *In most patients without a previously established collagen vascular disease, suspected vasculitis will be explained by an alternative diagnosis.*
- *Immunoserologic assessment of critically ill patients is a double-edged sword providing both enlightenment and misleading shadows. All immunoserologic testing must be interpreted with a thorough understanding of the patient's clinical condition.*
- *Inability to assign specific diagnostic labels to patients with severe life-threatening immunoinflammatory disease should not delay therapeutic intervention.*
- *Not all ischemic skin lesions that appear to be vasculitis are. Pseudovasculitis of various causes should always be part of the differential diagnosis.*
- *Empiric trials with corticosteroids can be a rational approach to patient care when such trials are carried out appropriately.*
- *Acute organic brain syndrome without focal neurologic deficits or evidence of systemic vasculitis is unlikely to be secondary to vasculitis.*
- *Fever in patients with collagen vascular disease should be presumed infectious if accompanied by chills, leukocytosis with a left shift, or hypotension.*
- *Patients who have been treated with significant doses of corticosteroids within the past year may require empiric replacement therapy during critical illness or surgical procedures until adrenal insufficiency can be excluded.*

Rheumatologists seldom lend their expertise to the medical ICU. The tempo and level of intensity of most rheumatic disorders are more suited to outpatient management. Nonetheless, approximately 10% to 25% of all rheumatic disease patients visiting the emergency department require hospitalization and up to one-third of these patients will require intensive care.[1] Patients with rheumatic diseases admitted to the medical ICU most often have problems not directly related to their primary illness. Sepsis, massive gastrointestinal bleeding, and myocardial infarcts may arise secondary to treatment. The major direction of care in these circumstances often comes from the intensivist. Circumstances do arise that require the unique insight of the experienced clinical rheumatologist, who at times must direct the management of a disease-specific complication. Just as often the rheumatologist is asked to address a diagnostic dilemma spawned by puzzling clinical and laboratory data. This chapter addresses the more common issues that prompt the rheumatologist and the intensivist to collaborate.

Rheumatic Disease–Specific Intensive Care Scenarios

SYSTEMIC LUPUS ERYTHEMATOSUS

FEVER: IS IT THE LUPUS?

Fever in the patient with lupus presses the clinician for an urgent answer to the question: Is this caused by lupus activity or infection? Fever is a common finding in active systemic lupus erythematosus (SLE) and follows no specific curve or pattern.[2] It may respond to the usual antipyretics or require corticosteroids. Single-daily-morning dose prednisone may not control late afternoon or evening fevers. Leukocytosis and increased bands on peripheral smear are strong presumptive evidence for infection, as is the presence of shaking chills. Complement proteins or components, including C3 and C4, are acute-phase reactants and usually rise with infection. Low levels of complement occur in some but not all patients with active lupus. Using discriminant analysis, Inone and colleagues[3] showed that 95% of 74 febrile episodes could be correctly classified as to the cause of fever when a combination of white blood count (low in SLE, normal to high with infection) and α_2-globulin levels (high with SLE, normal with infection) are used as variables.

In the ICU setting, the febrile patient with SLE is probably best considered infected and treated with broad-spectrum antibiotics pending results of cultures.[4] Infection is most likely to be caused by nonopportunistic organisms, and coverage for gram-positive and gram-negative aerobes represents adequate empirical therapy when no obvious source has been recognized. Systemic infections with *Salmonella*, endocarditis involving lupus-related valvular lesions, and pneumococcal sepsis in the splenectomized (surgical or autosplenectomy) are among the infections that have special significance for lupus patients.

MYOCARDIAL INFARCT IN THE LUPUS PATIENT: IS IT VASCULITIS?

Myocardial infarction makes a major contribution to excessive mortality in SLE. Mortality data suggest a bimodal distribution with many late deaths in SLE secondary to ischemic heart disease. The primary cause of ischemic heart disease in lupus is atherosclerosis. Autopsy studies in young women with lupus with death from any cause show an excessive incidence of atherosclerosis in comparison to age-matched females.[5] The cause of accelerated atheroma is not totally clear, but inflammation of the vascular endothelium due to chronic immune complex disease compounded by the effects of corticosteroids probably is the major contributing factor.

Vasculitis in SLE may affect any organ including the heart. Most patients with coronary artery vasculitis have evidence of vasculitis in other organs. Serologic evidence of active lupus and markers of systemic inflammation including low hemoglobin and albumin are likely to be present. Acute therapy would include high-dose corticosteroids (see below). In the face of widespread vasculitis, additional intervention with parenteral immunosuppressives, B-cell–depleting biopharmaceuticals, and plasmapheresis may be indicated.

Copyright © 2005, 1998, 1992 by The McGraw-Hill Companies, Inc. Click here for terms of use.

Another potential cause of myocardial ischemia is coronary thrombosis secondary to antiphospholipid syndrome.[6] Treatment is anticoagulation with heparin. Thrombolytic therapy has been successfully used in some patients with antiphospholipid syndrome.[7]

Corticosteroids are potentially hazardous, and high doses may predispose to ventricular rupture. Therefore corticosteroids should not be used in the absence of reasonable clinical suspicion for coronary vasculitis. If the lupus patient is in apparent clinical remission without evidence of widespread vasculitis, treatment should be the same as that for the nonlupus patient. Early cardiac catheterization may help clarify the nature of the vascular disease.

RENAL FAILURE: IS IT TREATABLE LUPUS NEPHRITIS?

In patients with SLE in the ICU, renal insufficiency may be caused by a variety of factors, including drugs, especially nonsteroidal anti-inflammatory drugs (NSAIDs), hypovolemia, sepsis, or previous renal disease.[8] In some cases, active lupus nephritis is a contributing factor. A careful examination of the urinary sediment is the most critical diagnostic tool. Proteinuria, casts, and red blood cells indicate glomerulitis. Lupus patients with active nephritis are most often hypertensive. Significant renal lupus (other than membranous disease) is often associated with low complement levels and elevation of anti-DNA antibody.

In a patient with a creatinine level above 4.0 mg/dL who has been adequately hydrated, has been divorced from nephrotoxic drugs, and shows evidence of active glomerulitis, the question arises: Is more aggressive immunosuppression desirable? The answer to this question depends on the degree of potential disease reversibility. A renal biopsy can help clarify this issue. The presence of significant chronic disease should dampen enthusiasm for aggressive therapy. Review of old records can be enlightening if long-standing loss of renal function is documented.

Clinicians have become increasingly aware that immunosuppression in the lupus patient with advanced renal disease can be more hazardous than progression to complete renal failure. Patients with lupus tolerate dialysis in a fashion comparable to other patients, and results of renal transplantation are favorable.[9] Paradoxically, patients with lupus who develop chronic renal failure often enjoy an amelioration of extrarenal symptoms.[10] A few patients have recovered sufficient renal function to allow withdrawal from dialysis. For all these reasons, the overzealous administration of immunosuppression in patients with lupus and advanced renal disease is to be discouraged.

RESPIRATORY FAILURE AND LUNG INFILTRATES: IS IT LUPUS PNEUMONITIS?

Respiratory failure in the patient with SLE is an ominous development. A paradigm of a compromised host is a patient with lupus who is on high-dose corticosteroid therapy. The usual opportunistic pulmonary infections need to be urgently excluded by bronchoalveolar lavage, bronchoscopic transbronchial biopsy, or open lung biopsy. If no superimposed infections or embolic etiology can be found and treated, lupus-related respiratory failure remains a diagnosis of exclusion and can be caused by either lupus pneumonitis or diffuse pulmonary hemorrhage. Acute lupus pneumonitis may occur as an initial manifestation of SLE and is characterized by fever, tachypnea, and hypoxemia, which may be accompanied by cough, pleuritic chest pain, and hemoptysis.[11] Radiologic findings are highly variable but usually bilateral and at least bibasilar. This diagnosis is not only one of exclusion; it unfortunately still rests solely on clinical suspicion.

The other SLE-related cause of respiratory failure is diffuse alveolar pulmonary hemorrhage.[12] Although invasive *Aspergillus* or tuberculosis can erode a pulmonary vessel and cause hemorrhage, gross hemoptysis, when present, usually indicates alveolar hemorrhage. Hemoptysis is not usually seen in lupus pneumonitis; unfortunately, this finding is present in <50% of patients with alveolar hemorrhage. Blood or hemosiderin-laden macrophages found during bronchoscopy in a patient without heart failure can be helpful findings but are nonspecific. The presence of thrombocytopenia is not helpful, but bleeding sufficient to cause acute respiratory failure most invariably causes an acute drop in hematocrit. In fact, treatment should not be delayed in order to distinguish between lupus pneumonitis and lupus-associated hemorrhage, because mortality is extremely high in either syndrome and treatment strategies are similar.

Pulmonary hypertension, sometimes severe, is frequently present. Cardiac filling pressures, in contrast to B-type natriuretic peptide determinations, can occasionally be helpful discriminators to exclude acute cardiogenic pulmonary edema. Pulmonary artery thrombosis masquerading as massive pulmonary emboli can occur in patients with pulmonary hypertension or thrombotically active anticardiolipin (ACL) antibodies.

The mortality of lupus pneumonitis is high, and treatment should be aggressive. Individual preferences will dictate modes of therapy, since no consensus exists on either the etiology of the syndrome or effective treatment. Pulse methylprednisolone, usually 500 to 1000 mg intravenously given for 3 to 5 days, or bolus cyclophosphamide at 0.5 to 1.0 g/m^2 has been used. Uncontrolled studies of plasmapheresis for alveolar hemorrhage in SLE do not reveal striking therapeutic efficacy. In the absence of alternate therapy with proven effect, plasmapheresis may be useful as a temporizing measure during the induction period required for the optimal effects of immunosuppressive agents like cyclophosphamide.[13]

BRAIN DYSFUNCTION: IS IT LUPUS?

A patient with acute, severe neurologic deficits and a history of SLE or a clinical syndrome and laboratory evidence suggestive of systemic vasculitis presents a diagnostic and therapeutic dilemma for the critical care clinician. In the vast majority of instances, involvement of the central nervous system (CNS) in SLE occurs as an organic brain syndrome or seizures in young females with active multisystem disease. Patients with organic brain syndromes manifest psychosis usually early after the onset of SLE. A common dilemma is to differentiate between steroid-induced pseudo-organic brain syndromes and those owing to active SLE. Interleukin-6 (IL-6) levels are markedly increased in the CSF of patients with active CNS SLE. Minimal, if any, IL-6 should be present in the CSF of patients with steroid-induced psychosis, and IL-6 may prove very helpful in differentiating between drug-induced CNS changes and active SLE. Early-onset development of psychosis while on low doses of corticosteroids and fulminant progression usually characterize the CNS disease caused by SLE.[14] Depressive syndromes with or without

auditory, visual, or even olfactory hallucinations in a patient on a dose of corticosteroids usually higher than 0.5 mg/kg per day are usually drug-induced. Because there is little evidence that high-dose corticosteroids ameliorate the CNS manifestations of SLE, rapid reduction of corticosteroid dosage is usually the simplest and most direct clinical strategy when a quandary exists as to whether CNS dysfunction is drug-induced.

Lupus-induced seizures are usually grand mal but can be very pleomorphic and usually occur in patients with active SLE.[15] Rapidly progressive, multisystem SLE that is further complicated by early onset of a seizure syndrome usually portends a poor outcome. The development of a seizure disorder in a patient with a long history of inactive SLE or in a patient with SLE entering remission is usually caused by something else. There is also little clinical evidence that high-dose corticosteroids alone influence the course of seizure disorders in SLE, and these patients should be aggressively treated with conventional anticonvulsive therapy. A difficult but critical differentiation must be made in SLE patients with CNS findings, anemia, and thrombocytopenia. The latter findings, while very common in active SLE, coupled with peripheral blood smear evidence of microangiopathy, point instead to thrombotic thrombocytopenic purpura (TTP) (see Chap. 70). Case reports suggest that TTP and SLE can co-occur, and the differentiation between the two diseases is vital since the treatment of life-threatening TTP is plasma exchange and not concomitant pulse methlyprednisone, alkylating agents, and/or plasmapheresis that many rheumatologists, in spite of unproven benefit, will resort to in the setting of fulminant CNS SLE.

Three other CNS manifestations of SLE can be puzzling. A small subset of patients with SLE who have taken NSAIDs, especially ibuprofen, will develop a meningitis-like picture that is characterized by fever, severe headache, nuchal rigidity, and cerebrospinal fluid neutrophilia or pleocytosis.[16] In an immunosuppressed patient, these findings prompt consideration of both common and unusual bacterial and fungal etiologies. The entire syndrome will remit rapidly once the drug is discontinued.

Migraine headaches, some of spectacular intensity, are frequent in SLE.[17] They usually respond to increases in corticosteroid dosage.

Actual paralysis is uncommon in SLE. Rare instances of transverse myelitis occur in the context of active SLE, and myelopathy may rarely be the presenting symptom of lupus. Until recently this was thought to be secondary to necrotizing vasculitis in the spinal arteries. It is likely, however, that many instances have been secondary to thrombosis associated with high titers of IgG ACL antibodies.[18] This differentiation may be important because the primary treatment of this syndrome is not aggressive immunomodulation of SLE, but appropriate anticoagulation.

Some investigators have reported elevated serum levels of anti-ribosomal P antibodies in patients with lupus-induced depression or psychosis. Other studies have not confirmed the association of these antibodies with psychosis.

SCLERODERMA

PULMONARY HYPERTENSION

The emergence of effective therapeutic options has given the detection of pulmonary vascular disease a new sense of urgency. The exact prevalence of pulmonary hypertension in scleroderma is unknown. Hospital-based studies would suggest the number to be in the 10% to 15% range.[19] There are generally two settings in which it is identified. In patients with limited cutaneous systemic sclerosis (*c*alcinosis, *R*aynaud's phenomenon, *e*sophageal motility disorders, *s*clerodactyly, and *t*elangiectasia [CREST] variant of scleroderma) it occurs classically as an isolated phenomenon in the absence of pulmonary fibrosis. This generally occurs in the second decade of disease or later. Patients who fall into the second major category of scleroderma, diffuse disease, may develop pulmonary hypertension as the result of advanced pulmonary fibrosis. In both settings the vascular disease is characterized by bland endothelial proliferation and vascular occlusion. The vasculopathy of scleroderma is not characterized by an inflammatory infiltrate and is not treated with corticosteroids or immunosuppression in the manner that typifies the treatment of lupus vasculitis.

Early symptoms of pulmonary hypertension are exertional breathlessness, but later symptoms are likely to provoke admission to the medical ICU or critical care unit (CCU). These include near-syncope or syncope with exertion and right ventricular angina or heart failure. Scleroderma patients, especially those at greatest risk for pulmonary hypertension, are now screened yearly or every few years using Doppler echocardiography. Confirmation of diagnosis demands a right heart catheterization, which provides additional important information about pulmonary capillary wedge pressure and cardiac output.

The treatment of pulmonary hypertension in the context of scleroderma is similar to that in idiopathic and familial pulmonary hypertension.[20] Anticoagulation, diuretics, digoxin, and supplemental oxygen form the basic management program. A small subset of patients may benefit from calcium channel blockers. Two exciting breakthroughs have substantially changed the quality of life of these patients for the better. Parenteral epoprostenol was initially viewed as a bridge to transplant, but some patients have elected to continue the drug as a chronic maintenance therapy. The emergence of a broad-spectrum endothelin receptor antagonist in the form of bosentan now offers the option of oral therapy to patients with moderately severe disease.[20] End-stage pulmonary hypertension may require heart-lung transplantation. Traditionally scleroderma patients have been considered poor candidates for transplantation. However, a recent report of 12 patients with scleroderma-associated pulmonary artery hypertension who underwent transplantation suggests similar beneficial outcomes compared to those with other acquired lung diseases.[21]

Other less common causes of pulmonary hypertension should not be overlooked in scleroderma patients, including recurrent thromboembolic disease. This may be a particular problem in patients with antiphospholipid antibodies.

HYPERTENSIVE RENAL CRISIS

Until recently, hypertensive renal crisis in patients with scleroderma was the major cause of mortality. The advent of angiotensin-converting enzyme (ACE) inhibitors thrust pulmonary disease into the role of leading cause of death in scleroderma. Nonetheless even recent studies of patients with scleroderma renal crisis suggest a continued high mortality rate in this subset of patients.[22] Therefore strategies for prevention of scleroderma renal crisis are crucial. Scleroderma

renal crisis typically develops in patients with diffuse cutaneous disease and rarely in patients with limited cutaneous disease or CREST.[23] At its onset patients experience a marked increase in blood pressure that may be accompanied by abnormalities of urinary sediment (erythrocytes and protein) and the peripheral blood smear (fragmented cells) and thrombocytopenia. Headache, visual disturbance, congestive heart failure, and mental status dysfunction may accompany the hypertension.

The pathogenesis of hypertensive renal crisis is complex and involves a very high renin state. Although combinations of older antihypertensive agents were occasionally successful, the advent of ACE inhibitors has revolutionized the outlook for this problem. Rheumatologists have a low threshold for using these agents in scleroderma patients and typically initiate them at the first diagnosis of hypertension.

In the setting of acute hypertensive renal crisis, larger doses of ACE inhibitors should be used. Although captopril, enalapril, and newer ACE inhibitors have all been used, some prefer captopril because the dose can be adjusted more flexibly. Angiotensin receptor blockers, calcium channel blockers, prostacyclin, and endothelin receptor antagonists have all been suggested as adjunctive therapy for patients refractory to maximum doses of ACE inhibitors.[24]

Some patients may progress to complete renal failure despite blood pressure control. Continued use of ACE inhibitors and dialysis may be required for months prior to recovery of renal function. Such improvement can continue for up to 2 years.

Progressive renal failure can occur in the absence of significant hypertension in as many as 10% of patients with scleroderma renal crisis. Microangiopathic changes may be seen on peripheral smear. Treatment with ACE inhibitors is indicated for this normotensive subset of patients.

POLYMYOSITIS/DERMATOMYOSITIS

DIAGNOSIS IN THE ICU

Very ill patients in the ICU may be weak and have elevations of creatine phosphokinase (CPK). Such clinical data prompt speculation about the presence of immune-mediated myositis. The most common presentation of polymyositis is the insidious onset of proximal muscle weakness, at times associated with myalgia. The acute development of de novo polymyositis in the ICU is unlikely. Similarly, acute fulminant disease requiring ICU admission with subsequent diagnosis is uncommon. Nonetheless, patients with undiagnosed polymyositis may be discovered in the ICU following admission for another reason (e.g., aspiration pneumonia). More likely is the presence of weakness (usually generalized) in combination with a spurious or nonimmune cause of CPK elevation. Intramuscular injections and myonecrosis during severe episodes of hypotension are common causes of increased CPK levels in critically ill patients. ICU-acquired myopathy can usually be distinguished from polymyositis by clinical history. Critical illness myopathy is usually characterized by normal or modestly elevated serum CPK levels.[25]

The skin lesions of dermatomyositis are so highly characteristic as to be diagnostic of dermatomyositis when accompanied by weakness and an elevated CPK value. Nearly all patients with active polymyositis will display an elevated CPK or aldolase level, although occasional patients will have normal muscle enzymes.[26] A unilateral electromyogram (EMG) can provide supportive evidence for the presence of myopathy and identify a biopsy site. Fibrillation potentials suggest active inflammation. A bedside EMG can be done in the ICU, although technical artifact may complicate the interpretation. Magnetic resonance imaging (MRI) may also confirm the presence of inflammatory muscle disease, but is generally impractical for ICU patients.

The EMG should be done unilaterally because EMG needle artifact may be confused with muscle inflammation histologically. Because polymyositis/dermatomyositis is a symmetrical disease, the corresponding maximally affected muscle group can be biopsied on the opposite side. Open biopsy can be done at the bedside, preferably by an experienced surgeon to ensure proper handling of muscle tissue. Needle biopsy of muscle using a Polley-Bickel needle is advocated by some and appears suitable for providing confirmation of active muscle inflammation.

RESPIRATORY FAILURE

Patients with polymyositis/dermatomyositis may develop respiratory failure secondary to muscle weakness involving the diaphragm, intercostals, and accessory muscles. If pharyngeal muscles are involved, acute respiratory failure may be precipitated by aspiration pneumonia. Patients with respiratory failure have a poor prognosis.[27] Some patients with dermatomyositis and this type of profound weakness harbor an underlying malignancy. Such patients are notably refractory to treatment.

Steroids are the mainstay of acute management of inflammatory myositis. Prednisone, 1 to 2 mg/kg per day or its approximate intravenous equivalent of methylprednisolone (in single or divided doses) may be given. In the ventilator-dependent patient, a short trial of pulse steroids may be justified—500 to 1000 mg methylprednisolone intravenously every day for 3 days. Improvement in respiratory muscle strength can be judged by a rise in the maximal inspiratory pressure. Intravenous immunoglobulin (IVIg) is another option for the acute management of the severely ill patient refractory to therapy with corticosteroids.[28] Second-line agents in polymyositis/dermatomyositis include methotrexate, azathioprine, and cyclophosphamide. Azathioprine is not useful in the acute setting owing to slow onset of action. Methotrexate is most commonly used after corticosteroids. In the ICU setting the intravenous route of administration may be preferred; the dose is 25 to 75 mg intravenously weekly.

Uncontrolled trials with plasmapheresis and combination plasmapheresis and leukocytapheresis have reported benefits and may be considered in refractory patients.[29,30] However, a randomized double-blind trial comparing plasmapheresis, leukapheresis, and sham pheresis in 39 patients with polymyositis and dermatomyositis showed comparable improvements in the three treatment groups.[31] The role for therapeutic pheresis in patients refractory to conventional therapy seems limited.

RHEUMATOID ARTHRITIS

METHOTREXATE PNEUMONITIS

Oral low-dose methotrexate given intermittently emerged as the major therapeutic innovation in the treatment of rheumatoid arthritis (RA) during the 1980s. In the era of biological

therapies methotrexate continues to be the gold standard of RA therapy and a frequent adjunct to cytokine-directed therapy. Methotrexate therapy is both highly effective and generally well tolerated. A major, albeit uncommon, toxicity is an acute pneumonitis characterized by dyspnea and nonproductive cough.[32,33] Fever is a frequent accompaniment.[34] Diffuse alveolar and interstitial infiltrates are present at diagnosis or appear within days. Opportunistic infections mimicking this syndrome have only rarely been reported.[35] According to one study risk factors for the development of methotrexate-induced lung injury include elderly patients, diabetes, and underlying rheumatoid pleuropulmonary disease.[36] Patients suffer profound hypoxemia. They appear extremely ill, and deaths have been reported. The mechanism is unclear but is presumed to be a hypersensitivity reaction to the drug. Some patients have been rechallenged without developing the syndrome while others have relapsed.

Diagnosis depends on the above clinical scenario developing in a patient taking methotrexate at any dose. Duration of treatment prior to symptoms has been variable. Bronchoscopy with brushings and biopsy shows nonspecific inflammation, and bronchoscopy's main justification is to rule out an opportunistic infection. Because these are rare, it is not unreasonable to forego bronchoscopy initially. Open-lung biopsy is usually unnecessary.

Treatment includes O_2, withdrawal of drug, and corticosteroids. Some have argued that steroids are not critical to recovery. The usual dose is prednisone 1 mg/kg per day or its equivalent in single or divided doses. Most patients will show signs of recovery within a week. Eventually, recovery is typically near complete.

CERVICAL SPINE SUBLUXATION

Arthritis commonly affects the cervical spine in rheumatoid arthritis, with estimates as high as 80% of patients. Subluxation of vertebrae secondary to ligamentous laxity may occur at single or multiple levels. Anterior atlantoaxial subluxation of C1 on C2 is the most frequent cervical abnormality and is particularly dangerous because of the capacity of the odontoid process (or dens) of C2 to compress the anterior spinal cord with motion. Thus sudden hyperextension of the neck during intubation could result in quadriplegia. In reality such occurrences are rare. The explanation may in part include the fact that progressive resorption of the dens often accompanies the most severely unstable necks. Symptomatic patients can be diagnosed with MRI or a myelogram. However, some dramatic subluxations on MRI are not accompanied by neurologic signs or symptoms. Flexion and extension films of the cervical spine may show dynamic instability and subluxation of C1 on C2. There are few data about the specificity or sensitivity of such films to predict a cervical cord catastrophe. Clearly, caution should be exercised in the intubation of patients with rheumatoid arthritis and neck disease; if time allows, nasotracheal or fiberoptically guided endotracheal intubation is preferred. However, when the risk of delayed intubation is sufficiently great, the procedure should not be delayed for radiographic studies, because the risk of cord catastrophe is quite low. Cervical instability is a problem that attends advanced destructive rheumatoid arthritis. Early aggressive treatment of RA patients with disease-modifying therapy has dramatically reduced the prevalence of this problem.[37]

OUTCOMES OF PATIENTS WITH RHEUMATOLOGIC DISEASES IN THE INTENSIVE CARE UNIT

Mortality rates for patients with systemic rheumatic diseases admitted to the ICU is high.[38] This is perhaps not unexpected when consideration is given to a typical scenario of a chronically ill patient with multiple impaired organs, a disordered immune system, treatment with chronic immunosuppression, and admission to the ICU with infection. Reported ICU mortality rates for patients with rheumatic disease are higher than would be predicted using the Acute Physiology, Age, and Chronic Health Evaluation II or simplified acute physiology score II (SAPS).[39,40] Factors associated with poor outcome include higher SAPS II scores, poor health status prior to admission, duration of rheumatic disease, corticosteroids and immunosuppressive drugs, renal failure, coma, and acute respiratory distress syndrome. The overall ICU mortality rate for patients with rheumatic disease ranges from 30% to 60%.[38] Mortality rates are higher for patients admitted because of infection compared to those admitted for exacerbation of rheumatic disease.[39,40] Since infection may cause two-thirds of ICU admissions among patients with rheumatic disease, aggressive intense therapy of the febrile patient with broad-spectrum antibiotic coverage is appropriate.

Perplexing Cases: Is This a Rheumatic Disease?

FEVER OF UNDETERMINED ORIGIN: RHEUMATIC CAUSES

The traditional definition of a fever of undetermined origin (FUO) depicts a patient with a significant fever of 6 weeks' or greater duration and no definable cause. In actual practice, depending on the impatience of the attending physician, FUO usually becomes the working diagnosis within 3 to 14 days after a fruitless search for classic causes of pyrexia. The most common causes by far of FUO are occult infection, drugs, and occasionally malignancy. After those are excluded, one must consider a limited array of rheumatic diseases that could be present in a febrile patient with protracted fever. Rheumatic disorders may account for 10% of cases of FUO. Because rheumatoid arthritis, scleroderma and its variants, dermatomyositis, polymyositis, and polymyalgia rheumatica are not usual causes of significant fever, they need not be strongly considered.

SLE can present with high fevers, either spiking or relatively constant, and leukopenia, hypoalbuminemia, anemia, and an elevated erythrocyte sedimentation rate (ESR), but few other overt clinical signs of lupus such as rash or serositis, polyarthritis, or active urinary sediment. Since SLE is readily diagnosed serologically, it represents a small fraction of FUO patients. Most systemic necrotizing vasculitides will be evident after examination of the skin, chest radiograph, and urinary sediment. Myocardial dysfunction, age, and demographics of the patient with fever may point to either Kawasaki's disease or Lyme disease as the source, and acute valvular dysfunction is being increasingly recognized in SLE and may be the clue to acute rheumatic fever in an adult.[41] An extremely high ESR is a nonspecific laboratory clue in FUO, but antibodies to relevant specific antinuclear or streptococcal disorders provide supportive evidence.

A most vexing diagnosis to pin down is that of adult Still's disease. These patients will have relentless spiking fevers, at times a history of FUO in childhood, leukocytosis, mild to moderate hepatic enzyme changes, and an occasional truncal rash.[42] Polyarthritis or arthralgias are not a constant feature early in this syndrome. Hepatosplenomegaly and lymphadenopathy are common. Rarely, acute pericarditis with tamponade or myocarditis with respiratory failure may complicate the course of adult Still's disease.

In the final analysis, treatment may have to be based on the supposition that the patient has relentless, immunologically driven, noninfectious inflammation that evades specific diagnosis. Blanket suppression of cytokines and white blood cell responses by corticosteroids may be necessary. The steroid dose is tailored to control fever and normalize the acute-phase response. NSAIDs may provide a less potent but possibly better tolerated alternative strategy.

MULTIPLE AUTOANTIBODIES AND MULTISYSTEM INFLAMMATORY DISEASE: WHAT NAME DO I GIVE IT?

The collagen-vascular diseases are characterized by the presence of sterile inflammation in multiple organs and multiple autoantibodies.[43] The prototype disease is SLE, which is characterized by the widest clinical and serologic spectrum. Other diseases include scleroderma, Sjögren's syndrome, polymyositis dermatomyositis, rheumatoid arthritis, and syndromes with overlapping features (overlap syndrome or undifferentiated connective tissue disease). One subset of the latter group has been called *mixed connective tissue disease* (MCTD). The clustering of clinical features and the nature and diversity of autoantibodies may strongly suggest one disorder rather than another, but the overlap of clinical, serologic, and pathologic features among these diseases is great. This can lead to considerable consternation for clinicians. Debates about whether a given patient has SLE, primary Sjögren's syndrome, MCTD, or another overlap syndrome are tiring, usually unresolvable, and generally irrelevant. The therapy for the immunologically active phase of these disorders is not disease-specific. The absence of a consensus label should not delay therapeutic efforts.

THE ELDERLY PATIENT WITH AN ELEVATED SEDIMENTATION RATE: IS THIS TEMPORAL ARTERITIS?

Within the ICU, advanced age, elevation of the ESR, anemia, and various nonspecific clinical features—chiefly fever—may converge to raise the question of temporal arteritis. Temporal arteritis is a granulomatous vasculitis that affects those over age 60 (mean age 70) and has a proclivity to affect extracranial vessels and branches of the aorta. Myriad uncommon clinical features may develop, but headache, polymyalgia rheumatica, visual disturbance, scalp tenderness, and jaw claudication are the common fingerprints of this disease. Treatment is highly effective with prednisone in doses of 40 to 60 mg/d.[44]

The onset of this disease is typically insidious, and its complications rarely prompt admission to the ICU. Therefore, the question is more commonly framed in terms of whether the patient has developed new-onset temporal arteritis in the ICU (probably not) or have it as a comorbid state at admission? History and old records are critical in this regard.

Physical examination is unreliable. Temporal artery biopsy is the gold standard, although sensitivity varies with the institution. A classical clinical scenario that includes headache, visual symptoms, jaw claudication, scalp tenderness, and polymyalgia rheumatica may be sufficiently compelling to prompt treatment. Usually the situation is murkier. There is no substitute for the temporal artery biopsy, which can be done under local anesthesia with little morbidity. A sufficiently large piece (4 to 5 cm) should be obtained and adequate cuts done for pathology. Contralateral biopsy is done routinely by some if a first biopsy is negative. That decision will be influenced by the details of the clinical scenario and the risk of an empiric trial with steroids. A negative biopsy in a marginal clinical situation is reasonable grounds to withhold therapy.

ABDOMINAL PAIN AND ELEVATED ERYTHROCYTE SEDIMENTATION RATE: IS THIS VASCULITIS?

The clinical presentation of acute abdominal pain is constrained to a limited number of clinical findings, regardless of cause. Unfortunately, there is nothing unique about massive gastrointestinal bleeding or the development of an acute abdomen when a patient has a high ESR and vasculitis is the etiology.

If the patient is already known to have systemic vasculitis, and this is usually the case when the gut becomes involved, the differential diagnosis of the acute abdomen and elevated ESR is a bit more simple. Here, early gastroduodenoscopy and colonoscopy with biopsy and perhaps vascular contrast studies may be necessary. MRI can assess arterial wall thickening, and in large-vessel vasculitis magnetic resonance angiography correlates well with conventional angiography. In the rare situation when a patient with no or relatively limited vasculitic findings in skin and renal and pulmonary systems develops fulminant vasculitis of the bowel, diagnosis may remain elusive until arteriography or surgical exploration. Patients on high-dose corticosteroid therapy for pre-existing systemic vasculitis may develop small-bowel or colonic ischemia or perforation with relatively few physical findings, even in the face of profound intra-abdominal sepsis.

Unusual causes of acute abdominal pain in patients with systemic vasculitis include hepatic infarctions, especially in SLE and polyarteritis, which can mimic many other intraperitoneal acute events. In this situation, hepatic computed tomography (CT) or MRI imaging is helpful. Massive bleeding can occur in most forms of systemic vasculitis, especially Henoch-Schönlein purpura, polyarteritis, and mixed cryoglobulinemia. Diarrhea and profound protein-losing enteropathy and acute bowel obstruction secondary to adhesive serositis have occurred rarely in SLE. There is nothing unique about acute pancreatitis in the patient with SLE; appropriate biochemical and imaging assessment will confirm this diagnosis.

The proper perspective must be maintained when the clinician attempts to make the diagnosis of systemic vasculitis involving the gut by analysis of small bowel or colonic tissue, since <50% of endoscopically obtained biopsies will be helpful in the diagnosis.[45] Although careful circumspection should be exercised before embarking on exploratory laparotomy in patients with SLE or other vasculitis with abdominal pain and suspected perforation, one should err on the side

of surgical exploration. More than one-half the patients with SLE and an acute abdomen will die.[46] Surgical exploration will correctly identify the major pathophysiology of the syndrome and dictate appropriate management. Increasing availability of laparoscopes with enhanced optics may obviate the need for laparotomy. The vast majority of patients with polyarteritis nodosa who develop an acute abdomen usually die from extensive bowel ischemia, infarction, and perforation unless early surgical intervention is done. The contemporary use of alkylating agents, corticosteroids, and other aggressive therapies may reduce this highly fatal complication in this group of vasculitides.

In summary, any patient with vasculitis, especially one with SLE, who develops an acute abdomen is in dire jeopardy. Routine clinical, laboratory, and radiology assessments are not usually helpful. Early endoscopy, biopsy, arteriography in selected instances, and ultimately early surgical exploration are usually necessary.

LUNG INFILTRATES IN RENAL FAILURE: IS THIS AN IMMUNE-MEDIATED PULMONARY-RENAL SYNDROME?

When a patient, usually but not always a young male, has abnormalities of renal function and then develops increasing shortness of breath, hemoptysis, and bilateral diffuse infiltrates, an immune-mediated pulmonary-renal syndrome should be strongly considered and ruled out as soon as possible. The clinician must be wary because the symptoms can occur in reverse; that is, increasing compromise of pulmonary function may precede significant changes in renal function.

Hemoptysis has many causes in patients with renal failure. Some examples would include SLE, Wegener's granulomatosis, advanced cardiac failure, microscopic polyangiitis, infection, and rapidly progressive glomerulonephritis. The latter disease in actuality is probably one end of the spectrum of a group of diseases mediated by antibodies to epitopes common to both alveolar and glomerular basement membranes (GBM).[47] In its classical expression, anti-GBM disease is called *Goodpasture's syndrome.*

Most diseases with pulmonary and renal manifestations can be distinguished from the immune-mediated pulmonary renal syndromes by their unique extrarenal characteristics. Once they are excluded, one is then confronted with a patient with glomerulonephritis and pulmonary hemorrhage. The diagnosis of the pulmonary-renal syndrome rests on establishing the presence of anti–basement membrane antibodies in the peripheral blood or in situ deposition in a renal biopsy. Characteristic histologic findings in the renal biopsy are those of a diffuse proliferative necrotizing glomerulitis highlighted by a somewhat unique characteristic of rather exuberant crescent formation. Although not well documented by contemporary clinical studies, immunohistologic analysis of tissue obtained by the transbronchial route has not been helpful in most instances.[48] The diagnosis of an antibody-mediated pulmonary-renal syndrome is important because efficacious therapy exists, especially when initiated early in the disease course. Alveolar GBM antibodies can be rapidly removed by vigorous plasmapheresis, and then B-cell clones with basement membrane specificities can be suppressed or clonally eliminated with cytoreductive therapy.[49] The efficiency of GBM antibody removal can be monitored easily by sequential GBM antibody assays. The antibody-mediated pathogenesis of Goodpasture's disease is beyond doubt and makes this syndrome a logical candidate for B-cell attrition with the chimeric monoclonal anti-CD20 antibody rituximab.[50] The approach to a patient in the ICU with hemoptysis and renal failure should include close attention to maintenance of adequate pulmonary function, rapid acquisition of tissue (either renal or pulmonary or both), and appropriate immunopathologic analysis of any and all biopsy specimens in parallel with serologic assays for circulating GBM antibodies.

CNS DYSFUNCTION: IS THIS CEREBRAL VASCULITIS?

Patients with or without connective tissue disease and nonspecific markers of systemic inflammation who develop signs of brain dysfunction are routinely suspected of having CNS vasculitis. Often the likelihood is considered low but addressed in the interest of being thorough.

Rarely does CNS vasculitis cause psychosis or coma without focal neurologic signs. Primary angiitis of the CNS, particularly in early stages, is an exception, but would not be expected to show signs or symptoms of multisystem disease or coma that would prompt ICU admission. Finding focal deficits on examination is problematic in the comatose or disoriented patient. A skilled neurologist can contribute more than imaging techniques. MRI and CT scanning may reveal a lesion suggesting an ischemic event. While no pattern is specific for vasculitis, a completely normal MRI makes the diagnosis less likely. Angiography is the gold standard, although in small-vessel vasculitis angiography may be nondiagnostic. Access to angiography can be problematic for the critically ill ICU patient. Leptomeningeal biopsy is the gold standard for diagnosis of granulomatous angiitis of the CNS, an important subset of CNS vasculitis. An empiric trial with steroids may be appropriate.

HYPERSENSITIVITY VASCULITIS: WHAT IS THE CAUSE?

The most common form of cutaneous vasculitis in any setting is leukocytoclastic vasculitis (LCV), often referred to as *hypersensitivity vasculitis* and recognized clinically as palpable purpura. The palpability of these lesions is caused by inflammatory infiltrates. Other less common expressions include *bullous disease* and *cutaneous ulcers.* The lesions have a tendency to occur in dependent areas and in ambulatory patients are found in the legs and buttock area. Localization may be atypical in bedridden ICU patients. By far the most common cause of new-onset LCV in the ICU patient is drugs. Any drug may be implicated, but thiazides, sulfa drugs, and penicillins are common offenders. Clues to nondrug causes would include significant digital involvement including associated nailbed infarcts, ulcerative lesions, significant glomerular inflammation, and any other evidence of extracutaneous vasculitis such as mononeuritis multiplex.

The presence of cryoglobulins or low complement levels suggests a nondrug cause. Skin biopsy can be done early but usually adds no additional diagnostic information. Predominant lymphocytic infiltration may help to support a diagnosis of drug-induced disease.[51] Immunofluorescence on biopsied tissue is rarely helpful, but the presence of IgA is supportive of a diagnosis of Henoch-Schönlein purpura.[52] Progression to

major vasculitis does not predictably occur, but hypersensitivity vasculitis may be the presenting manifestation of a major systemic vasculitis such as Wegener's granulomatosis or Churg-Strauss vasculitis. Therapy may be restricted to withdrawal of the most likely offending drug. Refractory cases have been managed with prednisone (0.5 mg/kg per day), colchicine (0.6 mg twice daily), dapsone (150 mg/d), and rarely cytotoxic agents or azathioprine. Topical therapy adds little in the absence of skin breakdown. Complete resolution may take weeks.

HEPATITIS C VIRUS INFECTION

A significant number of patients with hepatitis C virus (HCV) infection can develop urticaria, livedo reticularis, leukocytoclastic vasculitis, and membranoproliferative glomerulonephritis. The syndrome is mediated by HCV-driven formation of cryoglobulins that act as immune complexes. Indeed, it is highly likely that almost all patients previously diagnosed as idiopathic mixed cryoglobulinemia with vasculitis were actually patients with HCV. High titers of rheumatoid factors and hypocomplementemia strongly support the diagnosis. Treatment is directed at control of viral replication in the liver and attenuation of immune complex activity by plasmapheresis and cyclophosphamide. Until the role of B cells in defense against HCV is better understood, the temptation to deplete antibody-producing cells with anti-CD20 monoclonals should be approached with caution.

ISCHEMIC DIGITS: IS THIS VASCULITIS?

Patients in the ICU may develop ischemic digits. Contributing factors include hypotension, use of radial arterial lines, and vasoconstrictors. Often the issue of vasculitis is raised.

Single extremity involvement speaks strongly against systemic vasculitis as the cause. Similarly, isolated toe involvement is more likely to be caused by a combination of noninflammatory vascular disease and diminished blood flow owing to hypotension, vasoconstrictors, or cholesterol emboli. The latter may shower from the aorta and create a pseudovasculitic picture, particularly after anticoagulation therapy is initiated or following instrumentation of the aorta.[53] Extreme symmetry of lesions with all digits involved is more suggestive of a generalized low-flow state than vasculitis.

Clues to vasculitis as the cause of digital ischemia include the coexistence of a disease associated with digital vasculitis such as SLE or scleroderma, random involvement of multiple limbs, the presence of nailbed infarcts, and other associated cutaneous markers specific to vasculitis such as palpable purpura. Likewise, extracutaneous markers of vasculitis including glomerulitis and patchy neurologic deficits would enhance suspicion for that diagnosis.

Male patients with a history of heavy smoking should be suspected of Buerger's disease (thromboangiitis obliterans). Patients with lupus and other connective tissue diseases who have ischemic digits may have thrombotic complications secondary to ACL antibody and not true vasculitis.[54]

Biopsy of ischemic digits is usually impractical and potentially hazardous. The necessity to amputate a gangrenous digit should prompt careful instruction to the surgeon to be sure to biopsy the digital artery immediately proximal to the gangrene. In this setting angiography often reveals nonspecific findings of small-vessel disease, but may suggest emboli, and at times reveal the source such as a subclavian plaque. An angiographic pattern suggestive of Buerger's disease has been described.[55]

LUNG INFILTRATES AND ELEVATED SEDIMENTATION RATE: IS THIS VASCULITIS?

Elevated ESRs frequently become laboratory aberrations looking for a disease state. The unwary clinician may let an elevated ESR be the driver for a costly and unrewarding workup. Once it is known that a patient has an elevated ESR and the usual causes for this nonspecific laboratory abnormality have been reasonably excluded, the impulse is to link any and all remaining clinical abnormalities to the abnormal ESR. Unexplained pulmonary infiltrates, a common finding in critically ill patients, are good examples that provoke the question: Is this a pulmonary vasculitis? Common sense should prevail and dictate that the diagnosis of pulmonary vasculitis as a principal entity should be one of exclusion. If a young female on corticosteroids with a fever, rash, alopecia, and pericarditis develops a pulmonary infiltrate, she should be considered to have an infectious disease or pulmonary embolism until otherwise proved. If a previously bedridden patient with advanced rheumatoid arthritis suddenly develops pulmonary infiltrates and hypoxemia, the etiology should be considered embolic until proved otherwise. If a patient with advanced scleroderma that includes the proximal gut develops pulmonary infiltrates, aspiration pneumonia should be strongly considered. Conversely, one can approach the patient with pulmonary infiltrates and an elevated ESR in reductionist fashion.

If a careful search for extrapulmonary evidence of vasculitis is not rewarding, it will be highly unlikely that primary pulmonary vasculitis is present, since vasculitis very rarely involves only the pulmonary tree. There are unusual instances when vasculitis can be isolated to the pulmonary tree in a systemic rheumatic disease. Rarely, patients with ACL antibodies may develop pulmonary infiltrates secondary to in situ pulmonary artery thrombosis and/or pulmonary embolism. These patients will simulate a primary vasculitic pulmonary picture, but the primary therapy is anticoagulation. The proclivity of lung infections (especially bacterial) to generate positive anti-neutrophil cytoplasmic antibodies (ANCA) can create a diagnostic quandary when the question of Wegener's granulomatosis is raised.

Interpretation of Rheumatology Laboratory Abnormalities in the ICU

ERYTHROCYTE SEDIMENTATION RATE

The ESR is an indirect determination of the acute phase response and may be elevated in the setting of infection or active rheumatic disease. Values are higher for women and the elderly. Although the exact appropriate adjustments for age and sex are not certain, a common rule used to calculate a "normal" ESR in patients over 40 is divide the age by 2 and add 10 if the patient is female.

The presence of monoclonal proteins, polyclonal hypergammaglobulinemia, hyperfibrinogenemia, and alterations in size, shape, and number of red blood cells will influence the ESR. ESR rises during normal pregnancy and should not

be used to monitor rheumatic diseases under these circumstances. The ESR increases in end-stage renal failure of whatever cause and is not indicative of an underlying rheumatic disorder.[56] Parallel confirmation of a normal C-reactive protein level often clarifies the noninflammatory origin of the elevated ESR. The level of the rise in ESR correlates imperfectly with disease activity and may at times be normal in patients with active rheumatoid arthritis or SLE. Patients with a markedly elevated ESR (MESR) are those with values >100 mm/h. These patients deserve special attention because such elevations are unlikely to be explained by age or normal physiologic state and are a more reliable sickness indicator. The illnesses associated with MESR include infection, malignancy, rheumatic disorders such as vasculitis, connective tissue disease, rheumatoid arthritis, and temporal arteritis, as well as end-stage renal failure, nephrotic syndrome, and other inflammatory diseases such as hepatitis and colitis. In most series looking at MESR, 3% to 10% of patients will have no diagnosis to explain the abnormal laboratory value.[57] Some of these patients will eventually reveal an underlying pathology, whereas others will demonstrate spontaneous improvement in the ESR.

In the ICU, the ESR is likely to be elevated for multiple reasons. An MESR should not prompt an unreasonable search for vasculitis or other concurrent rheumatic disease, particularly in the presence of renal failure and nephrotic syndrome.

C-REACTIVE PROTEIN

The availability of rapid, reproducible, high-sensitivity, low-cost assays for C-reactive protein (CRP) in many circumstances obviate a clinician's reliance on the vagaries of the ESR to detect inflammation. CRP is an acute phase serum protein that acts as a surrogate for the proinflammatory interleukin IL-6. Serum/plasma levels of CRP are tightly linked not only to the absolute level of IL-6, but also to the rise and fall of the cytokine. Sequential CRP determinations, in contrast to the slowly responsive ESR, can provide a more accurate assessment of inflammatory changes in response to therapy. CRP determination is most helpful in assigning a noninflammatory cause to a markedly abnormal ESR. An example would be a patient with a monoclonal protein without infection, who could have an ESR of 100 but a normal CRP. The latter alleviates concern that significant inflammation may be part of the clinical picture.

Several cautions apply to the interpretation of CRP levels. Although there are weak correlations between CRP levels and age and gender, they are less marked than the same variables and the ESR. CRP also varies directly with body mass index. The very new ultrasensitive CRP assays have not only changed the normal ranges, but are expressed in markedly different concentrations that can be very confusing to the unwary.

The bottom line for the critical care clinician might be that significant elevations of CRP usually signal the presence of clinically relevant inflammation, and the absence of a high CRP helps in excluding it.

ANTINUCLEAR ANTIBODIES

The presence of antinuclear antibodies (ANA) in high titer provides presumptive evidence for the presence of collagen vascular disease, and in particular, SLE (Table 104-1). Lower levels of ANA can be nonspecific, possibly normal, and at times explained by age, prior drug therapy, or a first-degree relative with lupus. Low levels of ANA in the elderly can be particularly misleading in the presence of an age-related elevation of the ESR. It has been estimated that 15% to 25% of normal, healthy individuals over the age of 60 will have circulating ANA.[58] These data are confounded by a small but definite incidence of new cases of SLE among the elderly.

Screening ANA is typically done by a standard, indirect immunofluorescence technique. The test is now performed most commonly on HEp-2 cells and is sensitive for detecting the presence of SLE and other collagen vascular diseases, but as noted above, the test is hindered by the lack of specificity. Interest in specific ANA has spawned a long and at times confusing list of tests of variable utility. A brief overview of the most useful specific ANA tests follows.

ANTICENTROMERE ANTIBODY

This antibody to the kinetechore of chromosomes is detected by recognition of a particular speckled pattern of immunofluorescence on HEp-2 cells. It is, in general, the only pattern detected on screening ANA useful for diagnostic purposes. The antibody is found most commonly in the limited cutaneous variant of scleroderma (CREST). In this subset of patients, the test has been positive in 44% to 98% of those tested.[59,60] Less commonly, it may be seen in diffuse scleroderma and primary biliary cirrhosis with or without evidence of scleroderma.

ANTIBODIES TO DNA

Antibodies to DNA fall into two major categories by virtue of reacting to antigenic determinants on the phosphate deoxyribose backbone of the DNA helix or determinants on the nucleotide bases. The former represent antibodies to native double-stranded DNA while the latter react with single-stranded DNA.

Antibodies to single-stranded DNA are more common and are found across a spectrum of rheumatic and nonrheumatic disorders. They are of no practical clinical utility. Antibodies to double-stranded DNA are useful since they have great specificity for SLE and are found in 60% to 70% of patients with that disease.[43,61] In many, but not all lupus patients, levels of anti-DNA antibody will correlate positively with disease activity. Low levels of this antibody have occasionally been found in other connective tissue diseases.

ANTIBODIES TO Sm

This antibody is named after a patient ("Smith") in whom it was first described. The antibody has high specificity for SLE and is rarely found in patients with other connective tissue diseases. Sensitivity is only about 30% for SLE. Sm is not to be confused with an antibody to smooth muscle (SM), which is not a marker for collagen vascular disease, but is found in patients with chronic liver disease. There is no specific clinical profile of Sm-positive patients with SLE. Titers are not useful for assessment of disease activity.

ANTIBODIES TO nRNP

Antigenic determinants for nuclear ribonucleoprotein (nRNP) may occur in a molecular complex with Sm, and antibodies to Sm and RNP are often found in the same patient. Antibodies to nRNP may be seen in SLE, scleroderma, or overlap syndromes. The presence of overlapping clinical features and high titers of antibody to RNP defines a clinical

TABLE 104-1 Serologic Tests in Rheumatic Diseases

Antibody	Disorder
Tests with high specificity[a] for collagen vascular disease:	
Anti-native DNA	SLE
	Rarely anything else
Anti-Sm (Smith)	SLE
Anti-Ro (SS-A)	Congenital heart block
	Antinuclear antibody-negative lupus
	Subacute cutaneous LE
	Primary Sjögren syndrome
	SLE
Anticentromere	Limited cutaneous variant of scleroderma (CREST)
Anti-Scl-70 (topoisomerase I)	Diffuse scleroderma, less commonly CREST
Antineutrophil cytoplasmic antibody	Wegener's granulomatosis
	Microscopic polyangiitis
	Idiopathic crescentic glomerulonephritis
Anti-ribonucleoprotein	SLE
	Mixed connective tissue disease
	Undifferentiated connective tissue disease
Anti-La (SS-B)	SLE
	Primary Sjögren syndrome
Tests with low specificity for collagen vascular disease:	
Antinuclear antibody	SLE
	Other autoimmune diseases
	Normals (usually low titer)
	Drug-induced
	Aging
Rheumatoid factor	Rheumatoid arthritis
	Mixed cryoglobulinemia
	Aging
	Subacute bacterial endocarditis
	Any cause of chronic antigenic stimulation
Anticardiolipin antibody	Anticardiolipin antibody syndrome
	Normals
	Viral illness
	SLE
	Other autoimmune diseases

[a] Unlikely to be found in normals, with aging, or as a nonspecific immune response to infection.
CREST (syndrome), *c*alcinosis, *R*aynaud's phenomenon, *e*sophageal motility disorders, *s*clerodactyly, and *t*elangiectasia; LE, lupus erythematosus; SLE, systemic lupus erythematosus.

subset of patients referred to as those with mixed connective tissue disease (MCTD).

ANTIBODIES TO SS-A/Ro AND SS-B/La

These antigens were originally described in patients with Sjögren's syndrome (SS) and SLE. They are RNA-protein conjugates. SS-A and Ro have antigenic identity, as do SS-B and La. The *Ro* and *La* refer to the antigen as localized to the cytoplasm, whereas *SS-A* and *SS-B* are nuclear antigens.

The presence of SS-B/La may be seen in SLE or Sjögren's syndrome, and in most assays is measured along with SS-A/Ro. The Ro antibody has been described in 60% of so-called ANA-negative SLE. Anti-Ro antibody is also highly prevalent in the setting of congenital heart block and neonatal SLE.[62] In those cases, the antibody is found in mother and child. Other clinical scenarios associated with anti-Ro antibody include subacute cutaneous lupus and C2 deficiency. Anti-Ro antibody occurs in 25% to 40% of unselected patients with SLE.

The major indications for ordering these tests are: in a setting in which SLE is strongly suspected but the screening ANA is negative, congenital heart block, neonatal lupus, and the initial evaluation of a patient with a positive ANA.

ANTIBODIES TO SCL-70 (TOPOISOMERASE I)

Antibodies to Scl-70 are directed toward DNA topoisomerase I and inhibit its function.[63] They are found in 20% to 40% of patients classified as diffuse systemic sclerosis, and less commonly in patients with limited cutaneous disease or CREST. Determination of this antibody is part of the evaluation of patients suspected of having scleroderma.

ANTINEUTROPHIL CYTOPLASMIC AUTOANTIBODIES

The detection of antibodies directed against neutrophil cytoplasmic components now offers a useful serologic tool for the diagnosis and management of a group of disorders characterized by systemic necrotizing vasculitis and glomerulonephritis.[64,65] These disorders include Wegener's granulomatosis, microscopic polyangiitis, Churg-Strauss syndrome, and idiopathic crescentic glomerulonephritis. The renal lesions in these disorders have in common necrotizing vascular injury and a paucity of immune deposits.

Antineutrophil cytoplasmic autoantibodies (ANCA) are found in 90% of patients with active, generalized Wegener's granulomatosis and 60% to 70% of those with limited disease. The titer often parallels disease activity and may be

helpful in distinguishing a disease flare from intercurrent infection or other morbidity in patients with Wegener's granulomatosis. ANCA can be found in 80% of patients with active pauci-immune necrotizing and crescentic glomerulonephritis, which is one of the major causes of rapidly progressing glomerulonephritis.

Two specific patterns of ANCA have been identified and are referred to as *cytoplasmic ANCA* (C-ANCA) and *perinuclear ANCA* (P-ANCA). In general, patients with Wegener's granulomatosis have demonstrated C-ANCA, whereas those with idiopathic crescentic glomerulonephritis have demonstrated P-ANCA.[66] P-ANCA has been reported with other forms of systemic vasculitis, including microscopic polyangiitis and Churg-Strauss vasculitis. P-ANCA has also been observed in patients with ulcerative colitis and Crohn's disease.

The clinical scenarios that warrant measurement of ANCA are patients with known or suspected Wegener's granulomatosis or other small-vessel vasculitis and patients with rapidly progressing glomerulonephritis. These antibodies have also been occasionally identified in Takayasu's disease, SLE, relapsing polychondritis, and Behçet's disease.

ANTIBODIES IN POLYMYOSITIS/DERMATOMYOSITIS

In general, serologic testing has been of little practical value in the diagnosis and management of patients with polymyositis or dermatomyositis. Recently, the emergence of a family of autoantibodies that are found nearly exclusively in patients with myositis, known as myositis-specific autoantibodies or MSA, has focused interest on the role of humoral immunity in this disease. MSA are usually directed against intracellular, intracytoplasmic antigens involved in protein synthesis. Specific ANA have been identified in patients with these diseases and are available commercially. The exact role of these antibodies in the management of patients is unclear, but identification of these antibodies may be useful in patients who represent a diagnostic dilemma.

Jo-1 antibody is the most common of the MSA and belongs to a family of autoantibodies known as antisynthetases. It can be found in 15% to 40% of patients with polymyositis, and less commonly in dermatomyositis. The presence of the antibody highly correlates with associated interstitial lung disease. Antibodies to the nuclear antigen Mi occur in about 5% of patients with dermatomyositis and rarely in polymyositis. MSA titers have not proved useful in monitoring the course of patients with polymyositis or dermatomyositis. Specific MSA may prove to define unique clinical and immunogenetic groups that represent separate but related diseases. Antibody to PM-1 or PM-Scl defines a small subset of polymyositis patients (10%), half of whom will have accompanying features of scleroderma. Occasionally, patients with scleroderma and no myositis will have this antibody.

RHEUMATOID FACTOR

Rheumatoid factors (RFs) are autoantibodies, predominantly IgM isotype, that are directed against multispecies antigenic determinants on the heavy chain of IgG. They are nonspecific, rarely diagnostic, and almost never useful in the critical care setting. These autoantibodies can be found in normals and many disease states and have a prevalence that varies directly with age and gender (female preponderance). RFs can arise as an epiphenomenon during acute illness or chronic antigenic stimulation of almost any cause. They are present, sometimes in significant titer, in bacterial endocarditis, granulomatous diseases, and most rheumatic diseases at some point in time. The presence of RFs, occurring in tandem with significant decreases of serum complement components C3 and C4, may provide a diagnostic clue in rarely encountered clinical syndromes such as rheumatoid vasculitis with cryoglobulins or hepatitis C–associated mixed cryoglobulinemia and vasculitis. These syndromes can present with gastrointestinal tract involvement and hemorrhage, compromised renal function or progressive peripheral neuropathy, and skin ulceration. The recognition of these vasculitic syndromes mandates aggressive intervention with cytoreductive therapy—usually cyclophosphamide and therapeutic plasmapheresis.[67,68]

COMPLEMENT LEVELS

In theory, the detection of direct (classic) complement pathway activation by the measurement of serum C3 and C4 levels should provide the clinician with laboratory support for using treatment protocols that suppress the sequelae of complement activation. A prototype disease where C3 and C4 changes should be helpful is SLE. Unfortunately, there is an imperfect correlation between clinical activity of any disease, especially SLE, and decreased C3 and C4 levels. In fact, reliance upon conventional measurements of serum C3 and C4 assays, which supposedly detect immune complex complement activation in the patient, can inappropriately drive therapy decisions toward the use of immunosuppressives or corticosteroids when they are not indicated.[69]

Moreover, C3 synthesis is increased by acute inflammation of any cause, serving as a classic acute-phase reactant. It is easy to visualize a scenario in which a patient with SLE being treated with corticosteroids who has increased consumption of C3 secondary to immune complex formation and deposition may develop secondary bacterial infection, which stimulates the production of C3 in its role as an acute-phase reactant. The end result will be a normal serum level of C3, which may engender a false sense of security with regard to SLE disease activity. Conversely, the significantly reduced synthesis of C3 in many hepatic diseases is reflected in low plasma levels that can be misinterpreted. Plasma C4 is a more sensitive indicator of direct pathway activation, but for many of the same reasons that relate to C3 determinations, a decreased C4 level should never be the sole determinant of intervention with potent immunosuppressive therapy. Patients with SLE or overlap variants may have heterozygous or homozygous defects in C4 production. These patients will always have low C4 levels, regardless of disease activity.

ICU patients admitted with either meningococcemia or gonoccocemia provide one of the rare reasons for the determination of total hemolytic complement level. This assay serves as a screening test that depends on the functional presence of all individual complement components. A significant decrease in hemolytic activity may identify patients with terminal complement component deficiency who are at high risk for recurrent bacteremia. Such patients may require fresh frozen plasma in conjunction with antibiotic therapy and should be immunized with meningococcal vaccine prior to discharge.

In summary, conventional measurements of serum complement levels are not helpful in predicting activation in this complex system. When sensitive assays for activation peptides or complement activation complexes become available,

assessment of the complement pathway may become more clinically relevant.

CRYOGLOBULINS

Cryoglobulins are monoclonal, oligoclonal, or polyclonal immunoglobulins with a thermal propensity for precipitation at decreased temperatures and subsequent resolubilization with warming. In the vast majority of instances, they occur as acute or chronic phase reactants during bacterial or viral infections and many rheumatic disease syndromes. Plasma cryoglobulins, especially when assessed as cryocrits, are very nonspecific and may simply reflect ongoing antibody formation and subsequent complexing with antigen; indeed, they have been termed "the poor man's immune complex assay." Abnormal elevations of the ESR can be masked by some cryoglobulins that form gels at ambient temperatures and impede the rate of erythrocyte descent. Pseudoleukocytosis can occur when automated cell-counting procedures count crystallized cryoproteins as white blood cells. Pseudohypogammaglobulinemia and pseudothrombocytosis have also been reported. Almost all patients with cryoglobulin-mediated immune complex syndromes have active HCV infection that should be aggressively treated. Cryoglobulin-mediated vasculitis should be followed in terms of its clinical activity; clinicians should not rely on cryocrit decreases during therapy. Falls in cryocrits may be misleading because cryoproteins, even at extremely low levels in plasma, can be highly efficient complement activators.

ANTICARDIOLIPIN ANTIBODIES

The anticardiolipin (ACL) antibodies belong to a family of antiphospholipid antibodies (APLA), including those responsible for the lupus anticoagulant (LA), the biologic false-positive test for syphilis, and anti-B_2-glycoprotein-I antibodies. These antibodies often, although not always, occur together. The clinical syndromes associated with these antibodies belong to a growing list that can be explained largely by the capacity of these antibodies to induce thrombosis in the venous and arterial circulation. Thrombocytopenia and recurrent fetal loss are the other major consequences of APLA. The combination of APLA and one or more of these clinical features has been termed the "antiphospholipid antibody syndrome." [70]

Chronic false-positive serologic tests for syphilis are associated with autoimmune disease, notably SLE, and are found with increased frequency in patients with ACL and LA activity. Lupus anticoagulants are IgG or IgM antibodies that prolong phospholipid-dependent tests in vitro by interference with the calcium-dependent binding of prothrombin (factor II) and factor Xa to phospholipids, thus inhibiting the generation of prothrombinase. This usually results in prolongation of the activated partial thromboplastin time (APTT) with or without slight prolongation of the prothrombin time (PT).[54] LA is a common cause of prolongation of the PTT, but not the only cause. Most patients with LA do not have SLE.

Usually ACL antibodies are detected in an enzyme-linked immunosorbent assay (ELISA) using bovine cardiolipin as substrate. These are the most commonly detected antiphospholipid antibodies. They are generated transiently in the course of acute infections including mycoplasma and gram-negative infections. These antibodies are usually of the IgM isotype and are not associated with thrombosis. IgM ACL as well as the LA may be induced by a variety of drugs including phenothiazines, procainamide, phenytoin, hydralazine, quinidine, and streptomycin. These antibodies are most often not associated with thrombotic events, but exceptions to this rule occur. Antibodies to B_2-glycoprotein-1 in the absence of phospholipids can be measured on oxidized polystyrene plates. These antibodies are more specific for the diagnosis of APLA syndrome than the anticardiolipin test.

ACL antibodies are noted in 2.5% of the general population.[54] For most of these patients, the antibodies have no clinical significance. The risk of thrombosis and fetal loss has been generally associated with higher levels of antibody and the IgG isotype. Unfortunately, exceptions occur. Thus the presence of ACL antibody should not in itself prompt therapeutic intervention.

A myriad of neurologic events including stroke, transient ischemic attacks, and amaurosis fugax have been associated with the presence of LA and ACL antibody. Their presence should be suspected in patients who have no risk factors for thrombosis or who have associated autoimmune disease or suggestive screening laboratory abnormalities, including prolonged PTT or false-positive serologic tests for syphilis. Skin lesions secondary to LA and ACL include gangrene, hemorrhage, and purpura. Necrosis may mimic vasculitis.

The vasculopathy of APLA syndrome is not vasculitis, but primarily thrombosis of large or small arteries or veins. Steroids may normalize the LA but have little impact on ACL antibody levels. Treatment for major thrombotic complications of this syndrome is heparin or enoxaparin and warfarin. Steroids are indicated for associated clinical features related to systemic inflammation.

Rarely patients may present with evidence of widespread vascular occlusion and multiorgan failure occurring concurrently or over a short period of time related to antiphospholipid antibodies. Kidneys, bowels, lungs, brain, and heart are frequently involved. This so-called catastrophic antiphospholipid syndrome (CAPS) is associated with significant morbidity and mortality in spite of empiric therapy with corticosteroids, anticoagulation, and apheresis.[72] CAPS needs to be distinguished from thrombotic thrombocytopenia purpura (TTP) and diffuse intravascular coagulation. Precipitating events, such as infection, trauma, surgical procedures, or reduction in anticoagulation therapy, may contribute to the development of CAPS.[73]

Use of Corticosteroids, Immunosuppressives, and Anti-inflammatory Drugs in the Critically Ill Patient

CORTICOSTEROIDS

Corticosteroids have potent immunosuppressive and anti-inflammatory properties that, in combination with rapid onset of action, make them the drugs of choice for the initial therapy of most acute, life-threatening rheumatic disorders. Even low doses of prednisone (<10 mg/d) have potent anti-inflammatory effects and are highly effective in patients with rheumatoid arthritis.

For purposes of controlling inflammation and immunomodulation, "short-acting" glucocorticoids with little

or no mineralocorticoid activity are preferred. The oral drug of choice is prednisone, which is converted to prednisolone in the liver. Whereas active liver disease impairs that conversion, it appears to be offset sufficiently by decreased rate of elimination of prednisolone to eliminate the need to preferentially use prednisolone in patients with cirrhosis or active liver disease. The intravenous drug of choice is methylprednisolone. The dose equivalency is 4 mg methylprednisolone to 5 mg prednisone.

The dose of prednisone or methylprednisolone is largely empiric. For serious, life-threatening problems, 1 mg/kg per day of prednisone is a good starting point. Dividing the dose into a twice-a-day or other dose-divided schedule may increase efficacy (as well as toxicity) and is recommended by some for initial therapy. Extremely large doses of intravenous methylprednisolone (500 to 1000 mg) daily have been used for brief periods (3 to 5 days) with variable success in a variety of clinical settings, mostly in the context of SLE. In vitro studies suggest that such large doses may produce a qualitatively different response in lymphocyte function.[74] Unique side effects to this form of therapy, including sudden overwhelming sepsis and sudden death, are rare. This form of therapy is generally reserved for patients who have failed conventional high-dose therapy with corticosteroids with or without another immunosuppressive agent.

Patient response to corticosteroids varies. Failure to respond is likely a result of the nature and severity of the disease. The effectiveness of glucocorticoids may be reduced by simultaneous use of other drugs that induce hepatic microsomal enzyme activity, such as phenytoin, barbiturates, and rifampin. Bioavailability of prednisone may be reduced by antacids sometimes prescribed for concurrent use. Cortisol and its synthetic derivatives are bound to corticosteroid-binding globulin and albumin. The bound steroid is not active. Increased frequency of prednisone side effects has been observed at low serum albumin levels, probably reflecting an increase in the unbound, active fraction of the drug.

Patients who have a positive purified protein derivative (PPD) test about to undergo corticosteroid therapy (particularly with doses of prednisone of 20 mg/d or greater) should be considered for isoniazid (INH) prophylaxis (300 mg/d orally). The reported risk of reactivation ranges from low in asthmatics to higher in the elderly and in patients immunosuppressed by virtue of other drugs or their primary disease. The patient with a positive PPD and either a normal chest x-ray or a single calcified nodule probably does not require prophylaxis.[76] If the patient has significant impairment of the immune system or the chest film shows fibronodular scarring, the risk is enhanced considerably, and prophylaxis with INH is advisable.[77]

Steroid therapy suppresses cutaneous delayed hypersensitivity responses by inhibiting recruitment of macrophages to the skin test site. This phenomenon is reversible on stopping the drug. In one study, treatment with 10 mg prednisone daily totally inhibited cutaneous tuberculin sensitivity in both active and inactive cases of tuberculosis, with a mean reversion time of 13.6 days and reconversion time of 6 days following discontinuation of the drug.

Acute adrenocortical insufficiency may occur in critically ill patients who have been treated with chronic glucocorticoid therapy. On the basis of available data, any patient who has received a glucocorticoid at a dose equivalent to 20 to 30 mg prednisone daily should be suspected of having hypothalamic-pituitary-adrenal (HPA) axis suppression.[78] At doses closer to but above the physiologic range, a month is probably the minimum duration required for HPA suppression. Patients receiving the equivalent replacement doses of steroid (5 mg prednisone) as single morning dose therapy are at low risk of iatrogenic adrenal insufficiency. In the absence of hemodynamic instability, these patients do not require full "stress dose" replacement therapy. An adrenocorticotropic hormone stimulation test can resolve the question of adrenal suppression, but the clinical reality usually dictates empirical coverage with "stress doses" of corticosteroids. This can be accomplished with 100 mg hydrocortisone intravenously every 8 hours. This is approximately the equivalent of 75 mg prednisone. Higher doses are not necessary and are potentially more hazardous.

Use of corticosteroids on alternate days is associated with some decrease in chronic drug morbidity. In the urgent setting of the critically ill patient, the greater effectiveness of daily or split daily doses of steroids recommends such a dosing schedule.

IMMUNOSUPPRESSIVES

CYCLOPHOSPHAMIDE

Cyclophosphamide is an alkylating agent with broad immunosuppressive properties. It is generally embraced as the drug of choice for suppression of progressive, life-threatening autoimmune disease unresponsive to corticosteroids alone. Effectiveness has been reported in a broad spectrum of collagen vascular diseases and primary vasculitides, including SLE, Wegener's granulomatosis, polyarteritis nodosa, and polymyositis/dermatomyositis.

Cyclophosphamide causes broad suppression of B- and T-cell function and acts as a potent inhibitor of antibody production. Anti-inflammatory effects have also been described.

The drug is rapidly absorbed orally. It is inert until metabolized in the liver. Extravasation of the drug is not caustic to soft tissues. Sixty percent of the drug is excreted in the urine in the form of active metabolites. Impaired excretion of these active metabolites because of renal insufficiency can potentiate the therapeutic and toxic effects of a given dose of drug.

The drug can be given orally, usually at a dose of 2 mg/kg per day, or intravenously. To circumvent toxic effects associated with chronic drug exposure, intravenous bolus cyclophosphamide therapy has become an increasingly popular alternative at doses of 0.5 to 1.0 g/m^2. The onset of immunosuppressive activity of cyclophosphamide is estimated at 10 to 14 days following initiation of therapy. Although unproved in rigorous clinical trials, there is an operational principle that immunosuppression can be achieved more rapidly with intravenous bolus therapy. Hence bolus cyclophosphamide is most often given in the setting of progressive life-threatening disease requiring immunosuppression. A major short-term side effect of bolus therapy is a predictable white blood cell count nadir 7 to 10 days after drug infusion. Leukocyte count levels typically recover in 2 to 3 days. However, if the patient has a concurrent bacterial infection during the nadir period, the consequences of even transient profound neutropenia can be disastrous. Gross hematuria may signal the development of hemorrhagic cystitis or bladder malignancy. Bladder problems are related to duration of therapy and total cumulative dose administered. Many of the other side effects of therapy with cyclophosphamide are related to chronic use, including

gonadal suppression, oncogenesis, pulmonary interstitial fibrosis, and hypogammaglobulinemia.

One report suggests that bolus cyclophosphamide is less effective than oral cyclophosphamide in patients with Wegener's granulomatosis.[71] This study raises questions about the predicted superiority of bolus cyclophosphamide in all clinical situations.

AZATHIOPRINE

Azathioprine is a commonly used immunomodulating drug with mild to moderate immunosuppressive properties that may in large part be explained by a preferential reduction of natural killer cells. Onset of action is slow, probably taking months. It is often used concurrently with corticosteroids in patients requiring unacceptably high doses of steroids, to reduce the steroid dose. Azathioprine is not the drug of choice when significant immunosuppressive effect is needed on an urgent basis. Risk for infection is modest in the absence of leukopenia.

Azathioprine is metabolized in the liver to the active metabolite, 6-mercaptopurine, a purine analogue. The drug interferes with purine biosynthesis and is ultimately metabolized by xanthine oxidase. Administration of allopurinol, which inhibits xanthine oxidase, to a patient on a stable dose of azathioprine may result in a fatal drug overdose. The azathioprine dose should be reduced by 50% to 75% in the presence of allopurinol.

Dose range for this drug is 1 to 3 mg/kg per day. The drug is primarily metabolized in the liver, but the need for dose adjustment in the presence of liver disease is variable and may be unnecessary. Drug half-life can increase in renal failure but may not prove clinically significant. Cautious observation for the development of cytopenia is indicated in the presence of hepatic or renal failure. The drug is well absorbed orally and may be given intravenously in doses equivalent to the oral form.

MYCOPHENOLATE MOFETIL

Mycophenolate mofetil (MMF) interferes with de novo purine synthesis by inhibiting inosine monophosphate dehydrogenase. Nonlymphocytic cells recycle purine precursors through salvage pathways and are not dependent on de novo purine synthesis, in contrast to proliferating T and B lymphocytes, which are completely dependent on the de novo pathway. This difference confers selectivity on MMF and makes it an attractive choice for preventing allograft rejection. MMF is rapidly supplanting azathioprine in multiagent immunosuppressive protocols used in heart, lung, and renal transplantation. The conventional daily dose of MMF is usually 2.0 g and greater therapeutic effects are not usually found with higher doses. Mild reversible leukopenia and mild gastrointestinal side effects have occurred with MMF, and dose adjustments should be made when a patient has a glomerular filtration rate less than 25% of predicted value. There is a low incidence of opportunistic infection that can be directly attributed to MMF when used at less than 3 g daily. In most clinical scenarios, plasma levels of its active metabolite, mycophenolic acid, do not need to be monitored to achieve therapeutic effects. Based on its selectivity, ease of administration, and low side-effect profile, there is increasing interest in using MMF for the treatment of patients with autoimmune diseases.

METHOTREXATE

Although methotrexate was introduced for the treatment of rheumatoid arthritis more than 30 years ago, several open trials in the early 1980s resulted in renewed interest in this drug. Low-dose oral methotrexate has now replaced gold as the remitting agent of first choice in rheumatoid arthritis for many rheumatologists. The drug is accepted as effective in psoriatic arthritis and Reiter's syndrome as well as polymyositis. Experience is being gained with its use in SLE and scleroderma. Use of methotrexate in the critically ill rheumatic disease patient is currently limited to patients with polymyositis/dermatomyositis that is refractory to corticosteroids.

Methotrexate is a folic acid analogue and the major folic acid antagonist in clinical use. The drug is absorbed after oral ingestion but with significant variability. More predictable serum levels can be achieved by intramuscular or intravenous administration. High-dose methotrexate can alter antibody production and cellular immunity. Low-dose oral methotrexate (25 mg/wk or less), as used in rheumatoid arthritis, may be mainly anti-inflammatory or directly inhibiting to synovial lining cells.

Low-dose methotrexate is given in rheumatoid arthritis in initial doses of 5.0 to 10 mg and may be gradually increased to levels of 25 mg/wk. Methotrexate for rheumatic disorders is delivered on a weekly basis. This regimen is associated with less toxicity than when the drug is given more frequently, particularly hepatotoxicity. Most patients will respond at doses between 10 and 20 mg weekly. Intravenous methotrexate for myositis is given in doses ranging from 25 to 75 mg weekly. A dose of 1 mg/kg per week has been used in childhood dermatomyositis/polymyositis.[79] Such a dose calculation may be a reasonable first approach in the treatment of adults.

Adverse reactions forcing discontinuation of the drug in short-term trials with rheumatoid arthritis occur in 5% to 31% of patients. Most toxicity is relatively minor and associated with advanced age, malnutrition, and impaired renal function. Nausea, vomiting, oral ulcers, rash, leukopenia, thrombocytopenia, and pancytopenia all may occur. Cirrhosis may occur in some patients treated for long periods and appears to be related to cumulative dose and probably the nature of the underlying disease being treated. The risk is asserted to be greater in psoriatic arthritis than rheumatoid arthritis. Ethanol potentiates the hepatotoxicity of methotrexate. Pretreatment screening for hepatitis B and C is usually done. Baseline liver biopsy is not indicated in the absence of risk factors for existing liver disease. The concurrent use of other antifolates (e.g., sulfonamides) increases toxicity. Pancytopenia has been reported in some patients receiving methotrexate and trimethoprim-sulfamethoxazole together. Patients with ascites and large effusions are at greater risk for methotrexate toxicity. Folic acid, 1 mg daily, has been recommended as a means of preventing adverse reactions and particularly hematologic side effects in patients treated for rheumatoid arthritis.[80] The use of folic acid does not appear to significantly reduce effectiveness of the drug. In serious episodes of pancytopenia, leucovorin may be used.

Toxicities of particular concern in ICU patients include leukocytoclastic vasculitis, which has been reported with high-dose therapy used to treat osteogenic sarcoma as well as low-dose therapy for rheumatoid arthritis. Opportunistic infections with herpes zoster and *Pneumocystis carinii* have been

reported even with low-dose methotrexate, although they are uncommon. Finally, an acute hypersensitivity pneumonitis as discussed earlier occurs infrequently but may result in profound hypoxemia.

CALCINEURIN INHIBITORS

The emergency use of cyclosporine and tacrolimus outside the setting of clinical transplantation will be rare. Their role in the urgent therapy for fulminant psoriasis and inflammatory bowel disease has been superseded by the availability of anti–tumor necrosis factor (TNF)-α biopharmaceuticals. The mechanism of action and dosing intricacies of both drugs are very similar. There is an accelerating trend favoring the use of tacrolimus in organ transplantation because the incidence of hypertension, hyperlipidemia, and nephrotoxicity appear to be less than with cyclosporine. If rapid achievement of therapeutic blood levels is needed, continuous intravenous administration of the calculated daily dose is required. The intravenous route is mandatory in children and patients with hypermotile or maladsorptive gastrointestinal disease. In a critically ill patient, maintenance of therapeutic plasma levels of a calcineurin inhibitor requires intensive monitoring of trough drug levels and frequent dose adjustments. A disparate group of commonly used drugs affect calcineurin inhibitor metabolism and eternal vigilance is required to prevent sudden decreases to subtherapeutic levels or increases that are nephrotoxic. The volume-depleted patient is especially susceptible to renal failure caused by either calcineurin inhibitor. Acute, severe gouty arthropathy is extremely common in patients being treated with cyclosporine.

HIGH-DOSE INTRAVENOUS GLOBULIN

Intravenous infusion of pooled IgG antibodies from large numbers of normal volunteers activates a diverse spectrum of immunomodulatory effects. The primary mechanism may be mediated by downregulation of Fc receptors on neutrophils and macrophages and inhibition of B-cell antigen receptors, but cytokine, idiotypic, and major histocompatibility antibodies may play a role also.[86] The spectrum of immunomodulation provides a rationale for the use of intravenous immunoglobulin (IVIg) in the treatment of life-threatening vasculitic syndromes of unknown etiology. IVIg can also be useful in patients who require immunosuppression or modulation, but cannot tolerate cyclophosphamide because their bone marrow is suppressed or hypoplastic.

High-dose intravenous antibody therapy may be indicated for therapy-resistant immune-mediated thrombocytopenia associated with significant bleeding, especially gastrointestinal bleeding, or when there is a need to either transiently elevate platelets or prolong the half-life of transfused platelets prior to splenectomy.[75] These modified, biologically active immunoglobulins are given at approximately a 0.4-g/kg dose and followed by platelet transfusions as indicated. Imaginative uses of these expensive biologics are frequent, usually in disease settings where all else has failed. Appropriate clinical trials are needed before their widespread use. There are few safety issues with the use of IVIg, but several instances of large vein thrombosis at the site of IVIg infusion have been reported.

The theoretical risk of generating anaphylatoxins or other complement-derived vasoactive mediators during rapid infusion of modified immunoglobulin preparations has been overstated.

ANTI-INFLAMMATORY AGENTS

NONSTEROIDAL ANTI-INFLAMMATORY DRUGS

The NSAIDs generally have little role to play in the management of patients in the ICU. Ulcerogenesis, hemostatic defects, and impairment of renal function converge as a group of notably unfriendly toxic effects for the critically ill patient. In general, corticosteroids are usually a safer alternative when an anti-inflammatory agent is necessary in the ICU. For instance, corticosteroids in low doses can be used to control symptomatic synovitis in the rheumatoid patient and are considerably less hazardous than NSAIDs. Moderate-dose oral, parenteral, or intra-articular steroids may be used for gout.

The emergence of drugs that selectively block the cyclooxygenase isoform COX-2, an inducible isoenzyme involved in inflammation, has created a safer class of NSAID. Selective COX-2 inhibitors including celecoxib, rofecoxib, and valdecoxib have been associated with a reduction in major gastrointestinal complications when compared to traditional NSAIDs. They are not renal sparing and do not appear to be safe in patients with aspirin-sensitive asthma. Nonetheless, because of the absence of platelet effect and lower GI toxicity they would be preferred agents if an NSAID was required. The concurrent use of a proton pump inhibitor to further reduce the risk of GI toxicity would seem prudent in the critically ill patient.

COX-2 drugs have recently been implicated in an increased risk of myocardial infarction and stroke. The story is unfolding as this book goes to press.

COLCHICINE

Colchicine is a plant-derived alkaloid that exerts a complex array of physiologic changes in the neutrophil. This appears to explain its therapeutic benefit in the acute phases of crystalline-induced arthritis, especially gout. Since it is not ulcerogenic and has no effect on platelet function it would seem to have advantages in the treatment of the medical ICU patient. However, because the therapeutic dose is close to the toxic dose there is substantial risk of inducing vomiting or diarrhea in a patient population not well suited to withstand additional stress. While the intravenous preparation of colchicine is associated with less gastrointestinal toxicity, it is associated with more systemic toxicity and occasionally death. Risk factors for toxicity with intravenous colchicine include renal and hepatic insufficiency, advanced age, volume depletion, and underlying cytopenia. The use of intravenous colchicine should be avoided in critically ill patients.

BIOLOGICAL AGENTS

Tumor Necrosis Factor-α Inhibition

The selective targeting of the proinflammatory cytokine TNF-α has produced a therapeutic revolution in rheumatology. While most widely used in the management of the synovitis of rheumatoid arthritis, these agents have been widely applied to a variety of immune-mediated disorders including psoriatic arthritis, ankylosing spondylitis, Behçet's disease, and sarcoidosis. Three commercial products are available, including two monoclonal antibodies (infliximab [chimeric] and adalimumab [humanized]) and one recombinant TNF receptor Fc fusion protein (etanercept). There is an emerging

consensus that the antibodies may be more effective in the non-RA patients, but perhaps not without additional toxicity. In general, these drugs are extremely well tolerated and are neither renal toxic or marrow suppressing. They can reactivate granulomatous infections, notably tuberculosis. They must be used cautiously in patients with chronic or recurrent infection. They should be discontinued in the setting of serious infection or sepsis. There is currently no established indication to begin TNF-directed therapy in critically ill patients. The observations that such therapy can benefit patients with refractory Wegener's granulomatosis and Behçet's disease with progressive visual loss suggest scenarios in which initiation of TNF-directed therapy might begin in the ICU.

Interleukin-1 Inhibition

The currently available therapy directed against the pivotal proinflammatory cytokine IL-1 is anakinra. It is a recombinant human IL-1 receptor antagonist. While moderately effective for rheumatoid arthritis, it has not been nearly as effective as the TNF-α drugs. Although it is associated with fewer serious infections than TNF-directed therapy, when they are used in combination the increased risk of serious infection outweighs any additional therapeutic benefit.

B-CELL DEPLETION

Rituximab is a chimeric (mouse/human) monoclonal antibody that targets the CD20 molecule on B cells. CD20 is unique to B cells and is a stable transmembrane marker expressed during all stages of their maturation. The monoclonal antibody depletes B cells by activating apoptosis signals and complement and Fc receptor cytotoxicity.[87] Rituximab has an extensive history of effective use in B-cell lymphomas, and this bioengineered smart bomb has a surprisingly low number of significant side effects that can be characterized as constitutional symptoms of fever, chills, and rare hypotension attributable to cytokine release. All of the latter are most frequently experienced on the first infusion and are probably much more common in lymphoma patients with a large lymphocyte burden. The ability to selectively target and destroy B cells has generated tremendous interest in the rheumatologic community because rituximab offers a novel way to treat autoantibody-mediated autoimmune diseases like SLE, myasthenia gravis, autoimmune hemolytic anemia, and Goodpasture's syndrome.[82] In critically ill patients who cannot tolerate or have failed alkylating agent therapy, rituximab offers the option of definitive suppression of autoantibody production. The creative use of rituximab in autoimmune disease will be limited only by the imagination of the rheumatologist, and the reality is that widespread off-label use is already in progress. However, it is doubtful that many of its diverse applications will be confirmed by appropriate clinical trials. In theory, the focused destruction of B cells should culminate eventually in hypogammaglobulinemia and put the patient at high risk for bacterial infection. However, this has not been the case in most patients with lymphoma who are treated with the standard protocol of two to six weekly infusions of 375 mg/m^2. The treatment of patients with an autoimmune disease like SLE and the nephrotic syndrome may be a different situation since significant hypogammaglobulinemia requiring monthly replacement with IVIg has been reported. Careful monitoring of serum immunoglobulin levels at least in these patients is warranted over the 6- to 9-month period of rituximab-induced depletion.

Therapeutic Pheresis in the Critically Ill Patient with Rheumatic Disease

PLASMAPHERESIS

Therapeutic plasmapheresis can effect rapid removal of circulating antigens, immune complexes, pathologic antibodies, and circulating cytokines, and improvement in the function of the fixed monocyte system. Plasmapheresis should be considered for patients with fulminant vasculitis of any cause, drug-resistant thyroid storm, selected poisonings, and a subset of life-threatening pulmonary-renal syndromes. Because cyclophosphamide has at least a 7- to 14-day window prior to a therapeutic effect, plasma exchange can be efficacious as a temporizing measure in many syndromes that will ultimately require cytoreductive therapy. Plasma exchange is also the treatment of choice for patients with thrombotic thrombocytopenic purpura (TTP), acutely deteriorating myasthenia gravis, and rapidly progressive or severe inflammatory peripheral neuropathies. Therapeutic apheresis may also provide an immediate clinical response in some patients with fulminant SLE with severe CNS dysfunction. Cryoglobulinemia with deteriorating renal or nervous system disease and hyperviscosity syndrome are other disorders for which plasmapheresis may play an important therapeutic role.

The procedure has a wide margin of safety when contemporary machines are used. At any point in time the amount of extracorporeal volume is much less than when the patient is exchanged with equipment that requires centrifuge bowl separation of blood components. Still, patients with decreased effective plasma volume or significant coronary artery disease remain at risk with all plasma-separation technologies available and must be closely monitored during the procedure. The frequency of exchange can be based on the isotype of the putative pathogenic antibody involved and the known kinetics of IgG clearance. Ultimately, however, the frequency and amount of exchange depends on the clinical status of the patient. Plasma volume varies with the height, size, sex, and hematocrit; nomograms are available that should be used for effective calculation if the apheresis machine itself does not calculate the values automatically. A 1.0 plasma volume exchange will remove approximately 65% of intravascular IgG from a patient and 1.5 plasma volume exchange 78% to 80% of IgG. Larger volume removals are associated with increased time on the machine, increased citrate toxicity, and most importantly, only very small incremental increases in IgG removal. A common rationale used to determine the frequency of plasmapheresis is based on "resting" the patient on alternate days to allow re-equilibration between extravascular and intravascular IgG. TTP and hyperviscosity syndromes, in which plasma volumes are expanded and the proteins generating hyperviscosity are predominantly within the intravascular space, can be effectively treated by aggressive and daily higher volume exchanges.

Patients with severe hepatic disease cannot metabolize citrate rapidly, and plasma exchanges should be done at the lowest possible citrate:plasma ratio. Serious side effects of citrate-induced hypocalcemia are extremely rare when volume is

replaced with calcium-spiked 5% albumin. Fresh frozen plasma should never be used for routine replacement unless the patient has TTP, concomitant severe clotting factor deficiencies, or will be undergoing major surgery within the next 24 to 48 hours. Temporary decreases in several clotting factors during plasma removal, reflected by changes in the PT and APTT, are usually transient and not of clinical concern unless the patient has significant associated hemostatic deficiencies or severe hepatic dysfunction.

Because many patients in ICUs will not have suitable antecubital venous access or will be unable to provide arm pumping to generate sufficient venous flow during an apheresis procedure, dual-lumen polyurethane dialysis apheresis catheters are usually placed in a central vein and will provide high-flow access. If subclavian or internal jugular catheters are used, the return port should be in the cava, since relatively undiluted citrated blood has on rare occasion been thought to precipitate arrhythmias. Most patients undergoing plasma exchange do not require intravenous antibody replacement after each apheresis procedure. Exceptions to this rule are patients with hypoproteinemic states, especially the nephrotic syndrome, those with active infection, and those undergoing intensive, daily, high-volume therapeutic aphereses.

A standard rule for apheresis treatment of patients with autoaggressive syndromes, especially those with autoimmune antibody production, is that plasma exchange alone, although an effective temporizing measure, will ultimately not be efficacious and theoretically could be deleterious to the patient unless the apheresis treatment is closely linked to the use of an alkylating agent. The theory behind coupled therapy is straightforward.[82] Reduction in levels of pathogenic antibody, regulatory antibody, and regulatory cytokines can induce proliferation of B cells and possibly also T cells. Proliferating cells then become susceptible to alkylation, and either clonal abortion or anergy occurs when cyclophosphamide is given. The dose of cyclophosphamide ranges from 500 mg to 1 g/m^2 in 5% dextrose and water over a period of 30 to 60 minutes. Premedication for nausea is given routinely but may be unnecessary in some patients. The alkylating treatment can be given immediately after the last plasmapheresis and up to 48 hours thereafter. Protocols for the frequency of apheresis, at least in the treatment of SLE, vary widely but usually encompass an induction period of five to seven exchanges of 1.0 to 1.5 plasma volume over 7 to 10 days until approximately 250 mL plasma per kilogram have been removed from the patient. This induction period is followed by some form of immunosuppressive therapy, usually cyclophosphamide.[83]

PROTEIN A COLUMNS

Protein A absorption columns provide on-line removal of IgG antibody and circulating immune complexes; they have the benefit of returning most other plasma components to the patient. Protein A pheresis has been sporadically effective in drug-resistant idiopathic thrombocytopenic purpura and cancer chemotherapy–associated TTP/hemolytic uremic syndrome.[84] Angiotensin-converting enzyme inhibitors should be discontinued prior to the procedure. The efflux of activated inflammatory and vasoactive mediators generated from plasma by the protein A silica absorption vehicle can cause transient shaking, chills, fever, and hypotension. This usually occurs at the end or after the termination of the procedure.

LEUKAPHERESIS

Leukapheresis can be performed efficiently on centrifuge belt machines and is highly effective in reducing peripheral blast counts to levels that are less threatening to maintenance of adequate microcirculation and more amenable to chemotherapy. Combination leukaplasmapheresis has been performed in patients with scleroderma and polymyositis/dermatomyositis that was refractory to conventional management.

Empirical Therapy for Suspected Rheumatic Disease

In puzzling cases the rheumatologist may discern from the nuances of the clinical examination, serologic testing, and invasive procedures that the patient has rheumatic disease. Sometimes the rheumatologist, like the intensivist, cannot make a definite diagnosis, yet confronts a critically ill patient who *may* have a rheumatic disease. The clinical status of such patients is usually at an unacceptable plateau or even more likely deteriorating. Should that patient be given empiric therapy? Recognition of our shortcomings in diagnosis and the inability of some patients to tolerate a critical invasive test recommends such a course in selected patients.

Prior to initiation of empirical therapy, it is helpful to ask a series of related questions:

1. Has infection been reasonably excluded? Infection and cancer most commonly mimic rheumatic disease. Since empiric therapy usually implies immunosuppressive drugs, most commonly corticosteroids, infection must be ruled out. Here the emphasis should be on *reasonably* making such an assessment. Endless sets of blood cultures should not delay a difficult decision.
2. What do I suspect the patient may have? It should be possible to formulate a plausible if unprovable diagnostic hypothesis. Such a hypothesis is critical to the rest of the experiment. If it is impossible to generate a "working diagnosis," it is doubtful that the therapeutic trial will work. Autopsy study of these patients is likely to reveal cancer or no diagnosis.
3. What is adequate therapy for this suspected diagnosis? Treatment for a suspected diagnosis ranges from adequate to aggressive. In the absence of a definite diagnosis, it is reasonable to choose a level of therapeutic intensity that is usually adequate for the suspected disorder. Aggressive treatment approaches to an unconfirmed illness create another set of confounding variables and may place the patient at a further disadvantage.
4. What will I use as my parameters to judge therapeutic success? Empiric therapy should proceed with a clear understanding of the yardsticks that will measure therapeutic responsiveness. These parameters can then be rigorously monitored. Furthermore, blind spots in the baseline data can be addressed before therapy is begun.
5. What is the duration of a reasonable trial for this disorder? Agreement on the duration of a therapeutic trial should precede its initiation. Failure to develop such an end point can result in excessively long and risky therapy on the one

hand, or a course that falls short of an adequate trial on the other. Furthermore, spontaneous improvement or improvement in response to other therapies may result in prolonged and unnecessary treatment.

The clinician needs to be vigilant about the risks associated with any trial of empiric therapy. However, after addressing the above questions, such a trial may represent both rational and compassionate care.

Chapter 105

CRITICAL ILLNESS IN PREGNANCY

MARY E. STREK
MICHAEL O'CONNOR
JESSE HALL

KEY POINTS

- *Understanding the normal physiology of pregnancy is essential to evaluate the adequacy of cardiopulmonary function in the critically ill gravid woman.*
- *Pregnancy results in an increased cardiac output, which in late pregnancy may be diminished in the supine position by vena caval compression from the enlarged uterus.*
- *The reduced functional residual capacity (FRC) and increased oxygen consumption noted in normal pregnancy increase the risk of hypoxemia during intubation or hypoventilation.*
- *Hyperventilation during pregnancy results in a primary respiratory alkalosis and a compensatory metabolic acidosis with the following typical arterial blood gas values: P_{O_2} >100 mm Hg, P_{CO_2} 27 to 32 mm Hg, and serum bicarbonate concentration 18 to 21 mEq/L.*
- *Fetal viability depends on adequate oxygen delivery. As a result of the dilutional anemia of pregnancy, cardiac output becomes the critical determinant of fetal oxygen delivery and must be maintained.*
- *Hemorrhage in pregnancy may be massive and require extraordinary fluid resuscitation.*
- *Vasoactive drugs should be used with caution in the pregnant patient, since they may reduce uterine blood flow.*
- *Control of increased afterload may require intravenous agents: Sodium nitroprusside should be used only for imminently life-threatening conditions, since cyanide toxicity may result in fetal injury or demise. Nicardipine is an intravenous calcium channel blocker that is preferable to nitroprusside, and experience with labetalol, a combined alpha-beta blocker, is growing and promising.*
- *Preeclampsia is a multisystem disorder characterized by hypertension, central nervous system dysfunction, coagulopathy, pulmonary edema, renal failure, and liver function abnormalities.*
- *Cardiopulmonary resuscitation must be modified in pregnancy and includes emergent cesarean section in selected patients.*
- *Pregnancy may represent a state of increased risk of pulmonary edema formation; acute hypoxemic respiratory failure is most often due to tocolytic therapy, and if due to tocolytics, usually resolves with supportive care.*
- *Successful management of critical illness in pregnancy requires continuous integration of the intensive care team with obstetric and neonatal consultants; mechanisms should exist for emergent involvement of the appropriate personnel.*

Pregnancy greatly complicates critical illness, since assessment, monitoring, and treatment must take into account both maternal and fetal well-being. Knowledge of the normal changes in maternal respiratory, cardiac, and acid-base physiology in pregnancy is essential to distinguish between adaptive and pathologic changes.

This chapter begins with an overview of the changes in cardiovascular, respiratory, renal, and gastrointestinal physiology in normal pregnancy. Next, the determinants of fetal oxygen delivery are reviewed. The remainder of the chapter focuses on the disorders that can result in critical illness in pregnancy and the appropriate management of each. Finally, the importance of acid-base homeostasis, prophylaxis to prevent gastrointestinal bleeding, and early nutrition are discussed.

In many ways our understanding of the complex interaction between disease state and maternal/fetal physiology is incomplete. Thus we rely on an approach that assumes that measures that optimize maternal well-being are usually best for the fetus as well. Nonetheless, throughout critical illness, monitoring and management decisions must take into account fetal as well as maternal parameters. That is best achieved by expanding the typical critical care team consisting of nurse, respiratory therapist, and intensivist to include obstetrician and neonatologist as well.

Physiology of Pregnancy

ADAPTATION OF THE CIRCULATION

In pregnancy, numerous circulatory adjustments occur that ensure adequate oxygen delivery to the fetus (Table 105-1). Early in pregnancy maternal blood volume increases, reaching a level 40% above baseline by the thirtieth week.[1–3] This increase is due both to a 20% to 40% increase in the number of erythrocytes and a larger 40% to 50% increase in plasma volume. A mild dilutional anemia results, with a decrease in hematocrit of about 12%.[1,2] The magnitude of the increase in blood volume is greater with multiple births. This extracellular volume expansion is associated with parallel decreases in colloid osmotic pressure and serum albumin concentration; both indices reach a plateau at 26 weeks, although there is a further decline in colloid osmotic pressure immediately postpartum.[2] The extracellular volume expansion is caused by activation of the renin-angiotensin system with increased aldosterone production and results in mild peripheral edema in 50% to 80% of normal pregnancies.[1,2]

Coincident with the change in maternal blood volume is a 30% to 50% increase in cardiac output, most of which occurs in the first trimester and continues throughout gestation.[4–6] The augmented cardiac output results from an increase in heart rate, and to a lesser degree stroke volume, with heart rate reaching a maximum of 15 to 20 beats per minute above resting nonpregnant levels by weeks 32 to 36.[5,7] The increase in stroke volume is due both to an increase in preload caused by augmented blood volume and to a decrease in afterload caused by a 20% to 30% fall in systemic vascular resistance (SVR). The fall in SVR is attributed both to arteriovenous shunting through the low-resistance uteroplacental bed and vasodilation that may result from decreased vascular responsiveness to endogenous pressors and/or increased synthesis of vasodilators. Some studies suggest that since left ventricular end-diastolic pressure remains normal despite a rise in left ventricular end-diastolic volume,[4,7] ventricular

TABLE 105-1 Circulatory Changes in Pregnancy

Parameter	Direction	Time Course
Heart rate	↑	First and second trimesters
Blood pressure	↓	Falls in first and second trimesters; returns to baseline in third trimester
Cardiac output	↑	Progressive increases throuhout pregnancy to as much as 50% above baseline value by the 24th week
Stroke volume	↑	Increase peaks at 16–24 weeks
Systemic vascular resistance	↓	Reaches nadir by mid-pregnancy: 20%–30% decline from baseline
Pulmonary vascular resistance	↓	20%–30% decrease

diastolic compliance may be increased. Others have postulated a decrease in ventricular compliance based on studies demonstrating increased left ventricular wall thickness and mass.[5,6] While some authors have suggested that left ventricular performance improves during pregnancy;[1] recent studies have noted no increase in ejection fraction as calculated from echocardiography.[4,6] The exact contributions of increased heart rate and stroke volume, loading conditions, and ventricular performance to the increase in flow have not been conclusively determined.

During the course of pregnancy, cardiac output becomes more dependent upon body position, since the gravid uterus can cause significant obstruction of the inferior vena cava with reduced venous return. This effect is most notable in the third trimester. Vena caval obstruction is maximal in the supine position and much less pronounced in the left lateral decubitus position.[1] During labor, uterine contraction can increase cardiac output 10% to 15% over resting pregnant levels by increasing blood return from the contracting uterus.[2,8] This effect on cardiac output, however, may be tempered by blood loss during delivery.

Blood pressure decreases early in pregnancy owing to peripheral vasodilation as noted above. The peak decreases in systolic and diastolic pressures average 5 to 9 and 6 to 17 mm Hg, respectively, and occur at 16 to 28 weeks.[9] Blood pressure then increases gradually, returning to prepregnancy levels shortly after delivery. A review of hypertension in pregnancy suggests that diastolic pressures of 75 mm Hg in the second trimester and 85 mm Hg in the third trimester should be considered the upper limits of normal.[9]

The normal adaptation of the circulatory system to pregnancy results in a physiologic third heart sound in the majority of pregnant patients. The chest radiograph reveals an enlarged cardiac silhouette. As will be discussed below, right ventricular, pulmonary artery, and pulmonary artery wedge pressures are unchanged from prepartum values in the healthy pregnant woman.[10]

ADAPTATION OF THE RESPIRATORY SYSTEM

Oxygen consumption increases 20% to 35% in normal pregnancy;[11,12] during labor there is a further rise in oxygen consumption.[13] The increase in oxygen consumption occurs because of fetal and placental needs, as well as maternal requirements resulting from increases in cardiac output and work of breathing.[12] Increased oxygen consumption is associated with a 34% to 50% increase in carbon dioxide production by the third trimester, necessitating an increase in minute ventilation that begins in the first trimester and peaks at 20% to 40% above baseline at term.[2,14] Alveolar ventilation is increased above the level needed to eliminate carbon dioxide, and partial pressure of carbon dioxide (P_{CO_2}) falls to a level of 27 to 32 mm Hg throughout pregnancy. The augmented alveolar ventilation is attributed to respiratory stimulation due to increased levels of progesterone, and results from a 30% to 35% increase in tidal volume (from 450 to 600 mL) while respiratory rate is unchanged.[2,11,15] Renal compensation results in a maternal pH that is only slightly alkalemic, in the range of 7.40 to 7.45, with serum bicarbonate decreasing to 18 to 21 mEq/L[11] (Table 105-2).

Maternal arterial partial oxygen pressure (P_{O_2}) is increased throughout pregnancy, to greater than 100 mm Hg, by virtue of augmented minute ventilation, but this increase does not significantly increase oxygen delivery. Mild hypoxemia and an increased alveolar-to-arterial oxygen gradient [$(A\text{-}a)_{O_2}$] may occur in the supine position.[16] This likely results from airway narrowing or closure with resultant ventilation-perfusion mismatch related to a further decrease in the already reduced difference between functional residual capacity (FRC) and closing capacity that occurs in gravid individuals (see below).[17] Whenever possible, arterial blood gas samples should be obtained in the seated position to avoid confounding effects from the mild positional hypoxemia of pregnancy (see Table 105-2).

FRC decreases progressively (10% to 25% at term) as a result of increased abdominal pressure from the enlarged uterus, which results in diaphragmatic elevation and decreased chest wall compliance.[2,15] Expiratory reserve volume (ERV) and residual volume are decreased during the second half of pregnancy.[15] Total lung capacity decreases minimally

TABLE 105-2 Typical Arterial Blood Gas Values

	P_{O_2}	P_{CO_2}	pH	$(A\text{-}a)_{O_2}$	S_{O_2},%
Nonpregnant	98	40	7.40	2	98
Term pregnancy, seated	101	28	7.45	14	98
Term pregnancy, supine	95	28	7.45	20	97

NOTE: $(A\text{-}a)_{O_2}$ is the difference between the predicted alveolar P_{O_2} and the measured arterial P_{O_2}, assuming a respiratory quotient of 0.8. Normally this value is <10 mm Hg. S_{O_2} is the saturation of hemoglobin with oxygen.
SOURCE: Reproduced with permission from Schmidt GA, Hall JB: Pulmonary diseases in pregnancy, in Barron W, Lindheimer M (eds): *Medical Disorders during Pregnancy,* 2nd ed. St. Louis, Mosby Year-Book, 1995, p 169.

because the function of the diaphragm and thoracic muscles is unimpaired, and widening of the thoracic cage results in an increased inspiratory capacity.[11,15] Vital capacity remains unchanged during pregnancy. Diffusing capacity is unchanged or slightly increased early in pregnancy and then decreases to normal or slightly below normal after the first trimester.[18] Airway closure may occur near or above FRC in some women late in pregnancy.[17,18] As discussed above, airway closure may be responsible, at least in part, for the positional hypoxemia noted late in pregnancy. The decreased FRC, when combined with the increased oxygen consumption found in pregnancy, makes the pregnant woman and fetus more vulnerable to hypoxia in the event of hypoventilation or apnea. This is an important consideration during endotracheal intubation.

Despite increases in levels of many hormones known to affect smooth muscle, the function of large airways does not appear to be altered in pregnancy. Forced expiratory volume in 1 second (FEV_1), the ratio of FEV_1 to forced vital capacity (FVC), and specific airways conductance are unchanged during pregnancy. The fact that flow-volume loops are also unaffected by pregnancy is further evidence of normal airway function.[19] Lung compliance is unchanged.

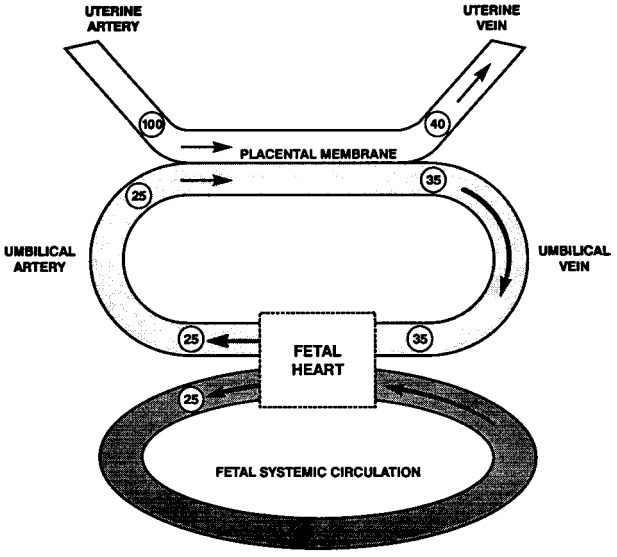

FIGURE 105-1 Maternal-fetal oxygen transfer. The circled numbers represent approximate values of the partial pressure of oxygen in mm Hg. (*Reproduced with permission from Lapinsky et al.*[2])

RENAL AND GASTROINTESTINAL ADAPTATION

Renal blood flow increases during the first and second trimesters to 60% to 80% above prepregnancy levels and then declines during the third trimester.[2] The glomerular filtration rate rises early in pregnancy to 50% above baseline at 12 to 16 weeks and remains increased during pregnancy.[20] This change means that serum creatinine during pregnancy (0.5 to 0.7 mg/dL) is somewhat lower than baseline. Therefore creatinine levels that would be normal in a nonpregnant patient can indicate renal dysfunction in pregnant patients.

Lower esophageal sphincter tone decreases during the first trimester of pregnancy and remains low until near term, perhaps as a result of increased plasma progesterone levels.[2] The gravid uterus displaces the stomach, further reducing the effectiveness of the gastroesophageal sphincter. Basal gastric acid secretion and pH remain unchanged during pregnancy.[21] Labor and narcotic analgesics given during labor delay gastric emptying time, significantly increasing the risk of aspiration.

FETAL OXYGEN DELIVERY

Oxygen delivery to the fetal tissues depends on the oxygen content of uterine artery blood, as determined by maternal P_{O_2}, hemoglobin concentration and saturation, and uterine artery blood flow.[2] As discussed above, the small increases in arterial P_{O_2} attributable to hyperventilation have little effect on oxygen content, since maternal hemoglobin saturation is only marginally increased. However, the anemia of pregnancy reduces the oxygen content significantly, and thus the critically ill gravid patient is more dependent than the nonpregnant individual on cardiac output for maintenance of oxygen delivery.

Numerous factors affect uterine artery blood flow. The uterine vasculature is maximally dilated under normal conditions and therefore is unable to adapt to stress by increasing flow through local vascular adjustment.[22] This assertion is supported by investigations in a gravid ewe model of progressive anemia in which the hematocrit was lowered from 31% to 8%.[23] There was no augmentation of flow to either the uterine or the placental beds, and consequently there was a progressive decline in oxygen delivery to the fetus. This finding suggests that the uterine bed is not readily able to increase fetal oxygen delivery by vascular autoregulation. Fetal oxygen delivery can be decreased by uterine artery vasoconstriction. Exogenous or endogenous sympathetic stimulation and maternal hypotension elicit uterine artery vasoconstriction. In addition, maternal alkalosis causes uterine artery vasoconstriction.[2] The latter effect may be compounded by the resulting leftward shift of the maternal oxyhemoglobin saturation curve, which increases oxygen affinity, thereby reducing the P_{O_2} in the uterine artery and decreasing the gradient that drives oxygen across the placenta.

In the placenta, a concurrent exchange mechanism driven by the difference in oxygen tension between maternal and fetal blood results in the transfer of oxygen from the maternal to the fetal circulation (Fig. 105-1).[2] Complete equilibration does not occur, so the umbilical venous blood going to the fetus has a lower oxygen tension than the blood in the uterine vein. The oxygenated umbilical venous blood, which has a P_{O_2} of 30 to 40 mm Hg, combines with deoxygenated fetal inferior vena caval blood, resulting in a fetal arterial P_{O_2} of 20 to 25 mm Hg.[2] In spite of the low umbilical vein and fetal arterial P_{O_2} values, compensatory mechanisms maintain fetal oxygen delivery, and fetal oxygen content is relatively high. At all levels of P_{O_2}, fetal hemoglobin has a higher affinity for oxygen than maternal hemoglobin, being 80% to 90% saturated at a P_{O_2} of 30 to 35 mm Hg.[2] In addition, the fetus has a higher hemoglobin concentration (150 g/L) than does the adult and has a high systemic cardiac output, with both left and right ventricles delivering blood to the systemic circulation. Studies indicate that fetal tissue hypoxia does not occur until levels of hypoxemia are reached that would be catastrophic by adult criteria. Brief reductions by up to 50% in uterine blood flow are well tolerated in animal models.[2] In a primate model of asphyxia, brain injury did not occur until fetal P_{O_2} fell to 9 to 14 mm Hg.[24] Protective responses to hypoxic stress also exist

at the level of the fetal circulation. A reduction in oxygen supply by >50% in a sheep preparation caused some fetal tissues to shift to anaerobic metabolism, and the fetal cardiac output was redirected to the brain, heart, and adrenal glands.[25] When fetal oxygen content is reduced by more than 75%, the oxygen supply is inadequate to most of the organism, including the central nervous system. Irreversible brain damage begins after 10 minutes without oxygen.[2] This fact suggests that compensatory mechanisms, such as redistribution of fetal blood flow to vital organs, decreased oxygen consumption in response to hypoxic stress, and the successful prolonged dependence of certain tissue beds on anaerobic metabolism may occur.

In summary, during pregnancy oxygen delivery to maternal and fetoplacental tissue beds is highly dependent on adequate blood flow and maternal oxygen content. Maternal oxygen consumption increases progressively during gestation and rises further in labor. In late pregnancy or near term, the fetoplacental unit is unable to increase oxygen delivery by local vascular adjustment. The fetus, however, is protected from hypoxic insult by the avidity of fetal hemoglobin for oxygen relative to maternal hemoglobin, the high fetal hemoglobin content, the high fetal cardiac output, and the autoregulatory responses of the fetal circulation in response to hypoxic insult. These general physiologic characteristics of pregnancy have the following implications for management of critical illness:

1. Assessment of the adequacy of maternal blood flow must be made with an understanding that baseline flow is substantially increased, with further increases during active labor or with fever, infection, or pain.
2. Diminished placental blood flow represents a threat to fetal well-being and viability, especially if superimposed on maternal anemia, hypoxemia, or both. Maternal hypoxemia can be particularly damaging if it elicits vasodilation of nonplacental beds, as this results in redistribution of blood flow from the fetoplacental unit.
3. The delivery of oxygen to the fetoplacental unit can be optimized by maintaining or restoring adequate circulating volume and cardiac function, giving blood transfusions to increase oxygen carrying capacity, by putting the mother in the left lateral decubitus position to improve maternal cardiac output, and by giving supplemental oxygen to increase maternal oxygenation.
4. Delivery of the fetus may be the best option if gestational age permits. However, since labor represents a tremendous aerobic load for the mother, the team must judge whether labor should be avoided or postponed during periods of critical illness in which oxygen delivery is marginal.
5. One effective way to reduce aerobic requirements in the critically ill gravid patient is to assume the work of breathing in evolving respiratory failure. Thus early elective intubation and mechanical ventilation may be beneficial in selected patients.
6. Fetal monitoring is at present an inexact and evolving science and should be performed in conjunction with the obstetric team. Measurement of fetal heart rate is a useful but nonspecific indicator of well-being and a late sign of inadequate oxygen delivery. It is most accurate after 32 weeks of gestation and is best used as a screening tool. Although continuous transcutaneous P_{O_2} measurement is feasible in the fetus, the results are difficult to interpret, and the low baseline value does not provide a wide margin for identifying evolving hypoxia. Fetal acid-base status can be measured by means of scalp blood sampling if membrane rupture and cervical dilation have occurred. A pH less than 7.2 suggests physiologic depression of the fetus.[2] In general, the routinely obtained parameters of oxygen delivery and acid-base status in the mother are the best measures of the adequacy of oxygen delivery for both the fetus and the mother.

[b] The majority of the other maedical conditions were cardiovascular, pulmonary, and neurologic problems.
SOURCE: From *MMWR*.[26]

Circulatory Disorders of Pregnancy

In pregnancy, circulatory impairment may be life-threatening, given the dependence of the mother and fetus on cardiac output for oxygen delivery. In the next section, common causes of hypoperfusion, such as hemorrhage, cardiac dysfunction, aortic dissection, trauma, and sepsis, are discussed. The pathophysiology and treatment of preeclampsia, which may occur as a result of uteroplacental hypoperfusion, is also explored. Venous thromboembolic disease in the setting of pregnancy is addressed in Chap. 27. Together these disorders account for a significant percentage of maternal deaths related to pregnancy (Table 105-3).[26] Finally, modifications of cardiopulmonary resuscitation algorithms that are necessary in pregnancy are considered.

HYPOPERFUSED STATES

The initial approach to the critically ill hypoperfused gravida is to distinguish between low-flow states caused by inadequate circulating volume, cardiac dysfunction, or trauma, and high-flow states such as septic shock, while taking into account the physiologic alterations associated with pregnancy. Most often the state of perfusion of the critically ill gravid patient can be determined by bedside assessment. Occasionally, the adequacy of intravascular volume remains unclear despite a careful history, physical examination, and review of routine laboratory data. Other patients are encountered who have obvious ventricular failure requiring the use of vasoactive drugs or respiratory failure requiring careful fluid management. In these instances right heart catheterization should be considered (Table 105-4), although a survival benefit from this invasive procedure has not been confirmed in obstetric patients.[27] When this procedure is necessary in a pregnant patient, a subclavian or internal jugular approach should be used. Femoral vein catheterization is relatively

TABLE 105-4 Relative Indications for Right Heart Catheterization

Routine operative or labor/delivery monitoring for:
Severe pulmonary hypertension
Significant valvular heart disease
New York Heart Association class III or IV congestive heart failure
Hypertension or preeclampsia comlicated by:
Pulmonary edema
Heart failure
Oliguric renal failure
Shock, if :
Etiology is obscure
Volume resuscitation fails
Central venous pressure is elevated
Vasoactive drugs are required
Acute respiratory failure that is:
Accompanied by shock
Requires mechanical ventilation and positive end-expiratory pressure
Accompanied by pulmonary edema of unknown etiology

contraindicated because of the obstruction of the vena cava by the uterus and the possible need for emergent delivery. In the healthy pregnant woman, right ventricular, pulmonary artery, and pulmonary capillary wedge pressures are unchanged from prepartum values.[2,10] As discussed above, cardiac output is increased, and SVR and pulmonary vascular resistance are decreased during pregnancy (see Table 105-1). Assessment of left and right ventricular hemodynamics by echocardiography was shown to correlate with pulmonary artery catheter results in a heterogeneous group of critically ill obstetric patients.[28] Thus in centers with sophisticated echocardiography techniques this may provide an alternative to invasive monitoring.

HEMORRHAGIC SHOCK

The common causes of hemorrhagic shock in pregnancy are listed in Table 105-5. When hemorrhage occurs in pregnancy, it can be massive and swift, necessitating immediate intervention. It is the second leading cause of both maternal death and admission to the ICU.[26,29] Antepartum hemorrhage is most often caused by premature separation of the normal placental attachment site (abruptio placentae), disruption of an abnormal placental attachment (placenta previa), and spontaneous uterine rupture.

Abruptio placentae occurs in 1 of every 77 to 250 pregnancies, with an increased incidence in patients with hypertension (half from chronic hypertension, half from preeclampsia), high parity, cigarette smoking, cocaine use, and previous abruption.[30–33] Maternal mortality, usually from postpartum hemorrhage, ranges from 0% to 5.2%, while fetal mortality is higher (between 5% and 36%).[30] The cause of the premature placental separation is not well understood, but the initiating event may be a rupture of the spiral arterioles with formation of a hematoma, which then separates the placenta from its site of attachment.[31] The severity of maternal blood loss is correlated with the extent and duration of abruption and fetal demise. Blood loss averages 2 to 3 L when abruption results in fetal death, and much of this blood can remain concealed within the uterus.[30] Maternal complications include acute renal failure and disseminated intravascular coagulation (DIC), which occurs in up to 30% of patients with fetal death.[2,30] Patients may initially present with painful vaginal bleeding and be misdiagnosed as having premature labor. The diagnosis is made using a combination of clinical information and ultrasound.

Placenta previa occurs in approximately 1 of 200 pregnancies and only infrequently causes massive hemorrhage because near-universal ultrasound examination during pregnancy leads to identification prior to delivery. Nonetheless, if vaginal examination results in disruption of the placenta over the cervical os, or if trophoblastic tissue invades the myometrium (placenta previa et accreta), the patient is at risk for massive hemorrhage at delivery.[31] Placenta previa is more common in multiparas with prior cesarean delivery and in cigarette smokers.[3,32,34] Fetal mortality is low, but it can be much higher if maternal shock occurs.

Uterine rupture occurs in approximately 1 of 2000 pregnancies.[31] The most common setting in which rupture occurs spontaneously is the multipara with protracted labor. Other risk factors include prior cesarean section, operative (assisted) vaginal delivery, and use of uterotonic agents.[34] In overt rupture, peritoneal signs may be observed. Nonetheless, substantial blood loss can occur in the absence of significant physical findings.

Common causes of postpartum hemorrhage include uterine atony, surgical obstetric trauma, uterine inversion, retained placental tissue, and coagulopathies due to DIC from amniotic fluid embolism, fetal death, and saline solution abortion.[2,3] Uterine atony occurs after prolonged labor, overdistention of the uterus from multiple gestation or hydramnios, abruptio placentae, oxytocin administration, or cesarean section, or as a result of retained intrauterine contents or chorioamnionitis. Hemorrhage from surgical obstetric trauma may be due to cervical or vaginal lacerations or uterine incision for cesarean section.

Management

Patients at increased risk of bleeding should be identified early, so that intravenous access and blood typing can be achieved ahead of time. When massive hemorrhage occurs, the initial management of the patient is similar to that of the nonpregnant patient, and two or three large-bore (16-gauge

TABLE 105-5 Etiology of Hemorrhagic Shock in Pregnancy

Abortion	Uterine rupture	Uterine inversion
DIC	DIC	DIC
Hydatidiform mole	Marginal sinus rupture	Retained placenta

ABBREVIATION: DIC, disseminated intravascular coagulation.

or larger) venous catheters should be inserted. Immediate volume replacement with crystalloid should be instituted until blood is available, and supplemental oxygen should be administered. It is beneficial to position the patient in the left lateral decubitus position to prevent vena caval obstruction from worsening the reduction in venous return that results from massive hemorrhage. Fetal monitoring is important, as fetal distress in the setting of obstetric hemorrhage indicates hemodynamic compromise.[2]

If shock is not immediately reversed by volume resuscitation or is accompanied by respiratory dysfunction, elective intubation and mechanical ventilation is indicated, since hypoxemia superimposed on a low-flow state is particularly injurious to fetus and mother. Blood replacement with packed red blood cells should begin immediately. Massive obstetric hemorrhage is one setting in which initial resuscitation may require the use of unmatched type-specific blood until more complete cross-matching can be accomplished (see Chap. 68). Because critical illness in pregnancy is frequently associated with DIC, massive bleeding should prompt an evaluation for coagulopathy. If the peripheral blood smear, platelet count, prothrombin time (PT), partial thromboplastin time (PTT), or fibrinogen level suggests excessive factor consumption (DIC), measurement of plasma levels of fibrin degradation products and specific factors should be performed (see Chap. 69). Measurement of factor VIII levels is inexpensive and can be accomplished more quickly than a full DIC screen. Massive blood loss can result in a dilutional coagulopathy with secondary thrombocytopenia which needs to be corrected with appropriate blood product replacement.

Uterine atony is routinely treated with uterine massage, draining the bladder, and intravenous oxytocin.[2,34] Oxytocin can cause hyponatremia by virtue of its antidiuretic effect. Alternatively, prostaglandin analogues such as carboprost tromethamine can be used to improve uterine contraction and decrease bleeding.[2,34] Side effects include hypertension, bronchoconstriction, and intrapulmonary shunt with arterial oxygen desaturation. Ergot preparations such as methyl- ergonovine have been associated with cerebral hemorrhage and are contraindicated if the patient is hypertensive. Ultrasonography is used to diagnose retained intrauterine products of conception that require curettage. Embolization of the hypogastric, internal pudendal, or uterine artery with slowly absorbable gelatin sponge can sometimes control hemorrhage and allow subsequent recanalization of the embolized vessel.[35] Surgical exploration to repair lacerations, ligate arteries, or remove the uterus is necessary in some cases.

CARDIAC DYSFUNCTION

Hypoperfusion from cardiac dysfunction is most often caused by congestive heart failure due to either preexisting myocardial or valvular heart disease, or to a cardiomyopathy arising de novo. However, the prevalence of heart disease during pregnancy is low, but its presence increases the likelihood of maternal and fetal morbidity and mortality. Patients with Eisenmenger syndrome, cyanotic congenital heart disease, or pulmonary hypertension have a high mortality rate (33% to 40%) during pregnancy.[36] A recent study of 599 pregnancies in Canadian women with either congenital or acquired heart disease (40% had valvular heart disease) identified risk factors for adverse outcomes.[37] Pulmonary edema, arrhythmia, stroke, or cardiac death complicated 13% of pregnancies. Predictors of maternal cardiac complications included prior cardiac events, poor functional class (New York Heart Association class III or IV) or cyanosis, left heart obstruction (aortic or mitral stenosis), and left ventricular systolic dysfunction. Adverse outcomes (<1% mortality) occurred in 27% of those with one risk factor and 62% of those with two or more risk factors. Neonatal complications (2% mortality) occurred in 20% of pregnancies and were associated with poor functional class or cyanosis, left heart obstruction, anticoagulation, smoking, and multiple gestation.

Prior subclinical heart disease may manifest itself for the first time during pregnancy owing to the physiologic changes of pregnancy described earlier. Peripartum cardiomyopathy (1 of every 1300 to 4000 deliveries) first presents in the last month of pregnancy or the first 6 months after parturition.[38] Postulated risk factors include black race, older age, twin gestations, multiparity, anemia, preeclampsia, and postpartum hypertension. Bacterial endocarditis rarely complicates pregnancy, most often occurring in patients with preexisting cardiac abnormalities, although infection of previously normal valves has been reported in pregnancy, particularly in patients with a history of intravenous drug use.[39] Myocardial infarction is extremely uncommon during pregnancy but should be considered in the hypoperfused patient with chest pain. Maternal mortality is high in patients delivering within 2 weeks of infarction.[40] There is an increased incidence of aortic dissection during pregnancy, perhaps related to the increase in shear stress on the aorta from the increased heart rate and stroke volume associated with pregnancy and hormonal factors.[40] Risk factors include hypertension, older age, multiparity, trauma, Marfan syndrome, Ehlers-Danlos syndrome, coarctation of the aorta, and bicuspid aortic valve. Aortic dissection presents most commonly during the third trimester, often as a tearing interscapular pain. Pulse asymmetry or aortic insufficiency may be noted on examination.

Management

It is essential to determine the cause of the underlying cardiac dysfunction and hypoperfusion. The chest radiograph may suggest the diagnosis; mediastinal widening is often noted in patients with aortic dissection. Echocardiography can help determine the volume status and detect valvular abnormalities, myocardial dysfunction, or ischemia. Transesophageal echocardiography and magnetic resonance imaging are the most sensitive and specific tests for detecting aortic dissection, although computed tomography of the chest is often done first given its ready availability.[40] Once the cause of cardiac dysfunction is determined, the initial management of the hypoperfused cardiac patient should focus on volume status, and hypovolemia should be excluded as a cause of the low-flow state. As discussed above (see Table 105-4), right heart catheterization may be helpful in this regard, as well as in the further management of cardiogenic shock. Metabolic disturbances can worsen ventricular function in patients with a cardiomyopathy; therefore hypocalcemia, hypophosphatemia, acidosis, and hypoxemia should be avoided. Vasoactive drugs are reserved for situations in which hypovolemia has been corrected and maternal perfusion remains inadequate. If cardiogenic shock persists despite an adequate preload, dobutamine is the drug of choice. However, it should be reserved for life-threatening conditions because at least in animal models, it reduces placental blood flow.[41] Infusion of dopamine in

low doses [2 to 3 $\mu g/(kg \cdot min)$] has been advocated to preserve splanchnic and renal perfusion. Its use in pregnancy has been limited, and recent studies demonstrated that it does not benefit critically ill patients with sepsis syndrome.[42] Accordingly, we do not advocate its routine use in the critically ill pregnant patient, but it may be useful in treating oliguria associated with preeclampsia (see below). When cardiogenic shock is complicated by pulmonary edema, parenteral furosemide should be given; right heart catheterization may help to titrate therapy.

When cardiogenic shock persists despite inotropic drug support, afterload reduction with nicardipine should be considered.[43] Intravenous sodium nitroprusside or nitroglycerin are second-line agents and when used the dose and duration of therapy should be minimized, and oral agents such as hydralazine or labetalol should be substituted as soon as possible to avoid nitroprusside toxicity. Angiotensin-converting enzyme inhibitors are absolutely contraindicated during pregnancy, because they have been found to cause fetal growth retardation, oligohydramnios, congenital malformations, and anuric renal failure in human neonates exposed in utero, as well as neonatal death.[44]

The hemodynamic alterations of labor and delivery, superimposed on those of pregnancy, make this an especially dangerous time for women with cardiac disease. The optimal method of delivery is an assisted vaginal delivery in the left lateral decubitus position.[38] Epidural anesthesia will ameliorate tachycardia in response to pain, and its vasodilatory actions may be of benefit in patients with congestive heart failure.[1] Since decreased SVR may lead to further decompensation in patients with aortic stenosis, hypertrophic cardiomyopathy, or pulmonary hypertension, general anesthesia may be preferred in these patients.[1] The current consensus is that cesarean section should be reserved for cases with obstetric complications or fetal distress, although with improved surgical techniques and close hemodynamic monitoring, cesarean sections may be safer than in the past.[1] Invasive monitoring may be required to follow shifts in volume status that occur from the tremendous "autotransfusions" produced by each uterine contraction and the blood loss that occurs with delivery.

TRAUMA

Death from trauma is a leading cause of nonobstetric maternal mortality. During pregnancy, hypoperfusion and shock may occur as a result of injury from motor vehicle accidents, falls, and assaults.[45] The gravid woman is at greater risk of hemorrhage after trauma, as blood flow to the entire pelvis is increased. Some injuries are unique to pregnancy, including amniotic membrane rupture, abruptio placentae, uterine rupture, premature labor, and fetal trauma.[45] In a series of patients with blunt abdominal trauma in late pregnancy, the most serious complications were placental abruption and uterine rupture and preterm labor was the most common.[46] Rapid deceleration injury can cause abruptio placentae (20% to 40% of major injuries) as a result of deformation of the elastic uterus around the less elastic placenta. In most cases, vaginal bleeding will be present when abruption has occurred, although there are reports of occult abruption without vaginal bleeding following traumatic injury.[46] Abruption can be complicated rapidly by DIC; therefore coagulation profiles should be monitored in all severely injured gravid patients. The cephalad displacement of abdominal contents in pregnancy increases the risk of visceral injury from penetrating trauma of the upper abdomen including splenic rupture. The urinary bladder is a target for injury because it is displaced into the abdominal cavity beyond 12 weeks of gestation.

The physiologic changes of pregnancy may make evaluation and treatment of the gravid trauma patient more difficult. Borderline tachycardia and supine hypotension (from obstruction of the vena cava by the uterus in late pregnancy) may be caused by pregnancy itself and thus may not indicate significant blood loss. Clinical signs of hypovolemia are not observed in trauma victims until intravascular volume is reduced by 15% to 20%. When hypovolemia is clinically evident in gravid patients, it signifies enormous blood loss because of the expanded blood volume associated with pregnancy. Pregnancy may mask findings of peritoneal irritation. In one series of 12 gravid patients undergoing peritoneal lavage for evaluation of blunt abdominal trauma, only 2 of the patients exhibited abnormal abdominal signs or symptoms.[47] Nonetheless, 8 had positive lavage with confirmation of intra-abdominal bleeding or injury at laparotomy.

Blunt trauma rarely causes fetal injuries. Fetal skull fracture occurs most often in the third trimester, when the engaged fetal head is at risk of injury from maternal pelvic fractures.[45] The risk of fetal death depends on the severity of maternal injury and hemodynamic compromise and on the extent of injury to the fetus.[2] Maternal shock, pelvic fractures, severe head injury, and hypoxemia all increase the risk of fetal demise.

Management

Initially, maternal cardiopulmonary function and the extent of injury should be assessed. If required, emergent intubation should be performed by a skilled individual because of the increased risk of aspiration during pregnancy. Since maternal shock is a major cause of fetal demise, ensuring the adequacy of the maternal circulation is paramount. If significant hemorrhage is obvious, aggressive fluid replacement, as discussed above for hemorrhagic shock, is appropriate. Once the cervical spine is cleared, the patient should be placed in the left lateral position. Pelvic examination should be performed, provided there is no overt vaginal bleeding, to look for blood, urine, and amniotic fluid. Nitrazine paper can identify amniotic fluid and confirm rupture of the amniotic membranes. The diagnosis of pelvic or abdominal injury can usually be made by ultrasonography, computed tomography, or lavage.[47–49] Because needle paracentesis is difficult to perform in the second and third trimesters, open peritoneal lavage is advised for assessing severe blunt abdominal trauma and confirming that intraperitoneal fluid noted on imaging studies is hemorrhagic. Once the mother is stabilized, cardiotocographic monitoring, including Doppler measurement of fetal cardiac activity and measurement of uterine activity, should be performed for 4 hours after the injury. When used in trauma patients who are beyond the twentieth week of pregnancy, cardiotocographic monitoring can identify placental abruption, fetal distress, and uterine contractions.[45] Fetomaternal hemorrhage—that is, blood loss from the fetal to the maternal circulation—may be identified by the Kleihauer-Betke test, which identifies fetal hemoglobin in red blood cells. Rh sensitization of Rh-negative patients, neonatal anemia, fetal cardiac arrhythmias, and fetal exsanguination are

potential complications of fetomaternal hemorrhage.[45] Maternal Rh sensitization can be prevented by administration of Rh_O(D) immune globulin.

If maternal death occurs despite aggressive resuscitation and the fetus is alive and undelivered, a postmortem cesarean section should be considered. A review of over 150 cases revealed that the outcome was significantly related to the length of time between maternal death and delivery and to the gestational age of the fetus.[50]

SEPTIC SHOCK

Sepsis is another important cause of hypoperfusion in pregnancy, accounting for 13% of maternal deaths in the United States in the 1990s.[26] The diagnosis of sepsis in the febrile gravid patient can be obscured by the normal hemodynamic changes of pregnancy (i.e., increased cardiac output and decreased SVR). An awareness of the usual settings and patients at risk for sepsis will increase the chance of recognizing this life-threatening state. Animal data suggest pregnancy may cause increased vulnerability to the systemic effects of bacteremia and endotoxemia.[51] In addition, pregnant patients have an increased susceptibility to infection with *Listeria monocytogenes* and disseminated herpesvirus, varicella, and coccidioidomycosis infections, perhaps owing to a decreased cell-mediated immune response during pregnancy.[2]

The common causes of sepsis in pregnancy include septic abortions, antepartum pyelonephritis, chorioamnionitis, and postpartum infections (puerperal sepsis) (Table 105-6).[52] Septic abortion is more often seen in countries where access to abortion is limited. Chorioamnionitis or intra-amniotic infection complicates up to 1% of all pregnancies. It occurs most commonly after prolonged rupture of membranes or prolonged labor, or after invasive procedures such as amniocentesis or cervical cerclage, but occasionally it reflects hematogenous spread from maternal bacteremia.[53] Patients present with fever, tachycardia (both maternal and fetal), uterine tenderness, and foul-smelling amniotic fluid.

Sepsis in obstetric patients usually occurs postpartum. Clinical settings that increase the risk of postpartum sepsis include cesarean section, prolonged rupture of membranes, and prior instrumentation of the genitourinary tract.[52,54] Infection usually occurs at the placental site, resulting in endometritis. Patients with endometritis may present with fever, abdominal pain and tenderness, and purulent lochia. Episiotomy sites and cesarean section incisions are less common sources of postpartum infection. Rarely, life-threatening wound infection with group A streptococci results in necrotizing fasciitis, while *Clostridium* species may cause gas gangrene of the uterus.[2,52] The bacteria that must be considered include *Staphylococcus aureus* and *S. epidermidis;* groups A, B, and D streptococci; *Escherichia coli; Proteus mirabilis; Enterobacter* spp.; *Klebsiella* spp.; *Pseudomonas* spp.; anaerobic streptococci and *Bacteroides* spp.; and *Clostridium perfringens* (Table 105-7).[52] Rarely, toxic streptococcal syndrome may occur as a result of infection with pyrogenic exotoxin A–producing group A streptococci in patients with necrotizing fasciitis or may unexpectedly follow an uncomplicated pregnancy and delivery.[2] Patients present with an influenza-like prodrome and gastrointestinal symptoms followed by shock and multiple organ system dysfunction. If a patient deteriorates while receiving appropriate antibiotic therapy, surgical exploration with possible hysterectomy are indicated.[2]

The hemodynamic profile in septic shock is similar to that of the nonpregnant septic patient.[54] In a study by Lee and colleagues of 10 obstetric patients with septic shock, right heart catheterization of the 8 surviving patients revealed a high cardiac index and heart rate with a low blood pressure and a decreased systemic vascular resistance index (SVRI). Analysis of left ventricular function curves revealed that 50% of the patients had evidence of myocardial depression despite an increased cardiac index. The greatest improvement in SVRI occurred in the eight surviving women; their initial SVRI was 885 ± 253 dyne $\cdot$ s/($cm^5 \cdot m^2$), and it rose to 1672 ± 413 dyne $\cdot$ s/($cm^5 \cdot m^2$) following resolution of their hyperdynamic state. It is important to remember that pregnancy itself results in a 25% decrease in vascular resistance from the prepregnancy level of 900 to 1500 dyne $\cdot$ s/cm^5, a decrease in blood pressure, and a 20% increase in heart rate. Thus three useful signs of sepsis—tachycardia, hypotension, and low systemic vascular resistance—must be interpreted with caution in the gravid patient, particularly in the third trimester. However, a rapid

change in hemodynamic parameters suggests infection. Complications of sepsis in pregnancy include pulmonary capillary leakage with subsequent acute respiratory distress syndrome (ARDS) and DIC.[54]

Management

The septic gravid patient requires thorough culturing and evaluation of pelvic sites. Empiric antibiotic therapy, designed to cover what is typically a polymicrobial infection involving gram-positive, gram-negative, and anaerobic organisms, as discussed above, should be given until specific bacteriologic cultures are available. Reasonable regimens to cover the above organisms should include at least two antibiotics such as clindamycin and a third-generation cephalosporin; in certain patients it is necessary to expand the initial regimen to include a semisynthetic penicillin, an aminoglycoside, or another broad-spectrum agent.[52] If possible, however, it is best to avoid aminoglycosides in patients with sepsis antepartum, because these agents can be ototoxic and nephrotoxic to the fetus. Chorioamnionitis associated with sepsis is unlikely to respond to antibiotic therapy alone, and delivery of the fetus is required.[2] Postpartum deterioration in septic patients receiving adequate antibiotic coverage suggests a localized abscess, a resistant organism, or septic pelvic thrombophlebitis.[2] Surgical drainage of appropriate pelvic and abdominal sources, with possible hysterectomy, may be required, particularly in patients with myometrial microabscesses or gas gangrene from clostridial species. Computed tomography or magnetic resonance imaging of the pelvis may help in the diagnosis of septic pelvic thrombophlebitis, which is treated with antibiotics and anticoagulation.[2] Venous ligation or surgical excision is sometimes required.

Patients who have evidence of adequate tissue perfusion and oxygen delivery may not require fluid or vasoactive drugs for the treatment of tachycardia and moderate hypotension. Lactic acidosis or end-organ dysfunction is an indication for volume resuscitation, but given the risk of precipitating low-pressure pulmonary edema, right heart catheterization may be helpful to allow titration of volume therapy. Mechanical ventilatory support should be instituted if needed. If hypoperfusion persists despite volume replacement, the use of vasoactive agents such as dobutamine to increase forward flow may be of value in patients who have markedly abnormal ventricular performance. Since there are no clear benefits from inotropic agents in patients with high-flow states whose cardiac function is near normal, these drugs should be withdrawn if adverse effects are noted. Elevated temperature should be controlled with acetaminophen and a cooling blanket, because fever is detrimental to the fetus. The role that vasopressin might play in the pregnant patient with septic shock remains undefined, but institution of an infusion at 40 mU/h is reasonable in the patient with refractory shock.

Naloxone has not proven useful in septic shock, and recent trials of immunotherapeutic agents directed against bacterial antigens or exotoxins have to date not added to the armamentarium available to treat these patients.[55] As in the nonpregnant septic patient, corticosteroids should be given if adrenal insufficiency is documented.[56] The corticotropin stimulation test may be difficult to interpret in the pregnant woman because baseline cortisol may be elevated in pregnancy and stimulation tests have not been studied in this population. Recombinant protein C has not been systematically evaluated in pregnant patients and it is impossible to make informed commentary on its risk/benefit profile in this setting. At present, the essentials of treatment are early appropriate antibiotics, surgical treatment if necessary, and meticulous supportive care.

PREECLAMPSIA

Preeclampsia is a unique disorder of pregnancy that complicates 5% to 10% of all pregnancies, accounting for a substantial proportion of obstetric ICU admissions (38% in a recent series in the United States) and 10% to 15% of maternal deaths.[3,26,57] It occurs most often in nulliparous women after the twentieth week of gestation, typically near term, and may even occur postpartum. It is characterized by hypertension, proteinuria, and generalized edema; however, these features may be mild and may not occur simultaneously, making the diagnosis of early disease difficult in some cases. Hyperuricemia is also present in almost all cases of preeclampsia and may be useful in differentiating preeclampsia from both preexisting chronic hypertension and gestational hypertension.[44] Multiple other organ systems may be involved, as discussed below. Risk factors for the development of preeclampsia, besides the primigravid state, include both preexisting and gestational hypertension, maternal or paternal family history of preeclampsia, preexisting renal disease, diabetes mellitus, multiple gestation, hydatidiform mole, and antiphospholipid antibody syndrome.[2,58] Preeclampsia may progress to a convulsive and potentially lethal phase, termed *eclampsia*, without warning. Eclampsia occurs in more than 0.2% of all deliveries, with an incidence of 1.5% in twin deliveries.[59] An especially fulminant complication of preeclampsia is the HELLP syndrome (*h*emolysis, *e*levated *l*iver enzymes, and *l*ow *p*latelets), which occurred in 0.3% of deliveries in one large clinical series.[60] Maternal and fetal morbidity and mortality are significant if eclampsia or the HELLP syndrome develops or if preeclampsia develops prior to 34 weeks of gestation.[44] In one large study of women with eclampsia, perinatal mortality was 8.6%, with placental abruption accounting for four of the six perinatal deaths; there were no maternal deaths.[59] In a recent review of women with HELLP syndrome, perinatal mortality was 12.6%.[60] While there were no maternal deaths, life-threatening complications such as placental abruption often with associated DIC, pulmonary edema, and ARDS, cerebral hemorrhage, and hepatic hematoma occurred in 10.3% of patients.

Although the exact etiology of preeclampsia is unknown, nearly all maternal organ systems are affected. The common pathologic feature is vascular endothelial damage that may be due to mediator release as a result of placental ischemia.[61] Maternal vascular endothelial dysfunction results in increased loss of fluid from the intravascular compartment, increased sensitivity to pressor agents and activation of the coagulation cascade.[62] Increased endothelin production and decreased release of nitric oxide may also be important in the development of this disorder.[63] The reduction in placental perfusion and increased circulating concentrations of markers of endothelial activation and intravascular coagulation occurs before the onset of clinical disease.[9,62] Cardiac output and plasma volume are reduced in preeclampsia, while SVR is increased.[44] In one study, right heart catheterization of 44 untreated preeclamptic

patients revealed low normal right atrial and pulmonary capillary wedge pressures (Ppw), a reduced cardiac output, and a markedly elevated systemic vascular resistance.[9] A study of 41 preeclamptic patients found that the majority of the patients had a normal Ppw, normal to high cardiac index, and upper normal to moderately elevated SVR compared to historical controls.[64] The eight patients with pulmonary edema had a high wedge pressure.

Preeclampsia may be mild or severe. Markers of disease severity that should alert the physician to an increased risk of complications include systolic or diastolic blood pressures of ≥160 and ≥110 mm Hg, respectively (especially after 24 hours of hospitalization), proteinuria ≥2 g in 24 hours or ≥100 mg/dL in a random specimen, oliguria, or pulmonary edema.[2,9] Especially worrisome symptoms and signs in any patient with preeclampsia include headache, blurred vision, scotomata, altered consciousness, clonus, epigastric or right upper quadrant pain, increasing serum creatinine level, consumptive coagulopathy with thrombocytopenia and/or microangiopathic hemolytic anemia, and even mildly elevated values on liver function tests.[2,9]

Maternal complications of severe preeclampsia include seizures (eclampsia); cerebral hemorrhage or edema; renal dysfunction; pulmonary edema; placental abruption with DIC; the HELLP syndrome; and hepatic infarction, failure, subcapsular hemorrhage, or rupture.[44,65] The etiology of eclamptic seizures is presumed to be related to cerebral vasospasm, ischemia, or edema and hypertensive encephalopathy.[2] Although the risks of eclampsia are higher when the above markers of disease severity are present, in one large clinical series 20% of eclamptic patients had a blood pressure below 90 mm Hg or no proteinuria prior to experiencing convulsions.[44] Though it is rare, cerebral edema is a cause of death in patients with preeclampsia. It may result from severe hypertension and large volumes of fluid administered to treat the oliguria and decreased plasma oncotic pressure frequently noted in preeclampsia.[66] Renal dysfunction may result from intravascular volume depletion, renal ischemia, and glomerular disease characterized by swollen glomerular endothelial cells known as glomeruloendotheliosis.[20,67] Acute renal failure is rare and most often is seen in patients with the HELLP syndrome, placental abruption, massive hemorrhage, or coagulopathy.[2] Pulmonary edema is uncommon, having an incidence of 2.9% in patients with severe preeclampsia.[68] Contributing factors include increased left ventricular afterload, myocardial dysfunction, decreased colloid osmotic pressure, vigorous fluid therapy, and in some cases increased capillary permeability.[2] It most commonly occurs after parturition. In a subgroup of patients, antepartum pulmonary edema develops.[69] These patients are typically obese and chronically hypertensive with secondary left ventricular hypertrophy. The increased intravascular volume of pregnancy and the hemodynamic derangements of preeclampsia cause diastolic dysfunction with an elevated Ppw and pulmonary edema.

The HELLP syndrome is characterized by multiorgan dysfunction arising from an endothelial abnormality with secondary fibrin deposition and organ hypoperfusion.[2] A microangiopathic hemolytic anemia and consumptive coagulopathy develop. When DIC occurs, it is often in the setting of placental abruption, sepsis, or fetal demise.[2] The liver involvement is characterized by periportal or focal parenchymal necrosis with elevated liver function tests. Intrahepatic hemorrhage or subcapsular hematoma occurs in 2% of patients and may progress to hepatic rupture.[60,65]

The HELLP syndrome occurs in 4% to 20% of patients with preeclampsia.[61] There is an increased incidence in white women and in one series 45% of the patients were multiparous.[2,60] Patients are more often preterm than those with uncomplicated eclampsia. In up to 30% of patients, the HELLP syndrome develops after parturition; typically it appears within 48 hours, but it has been reported up to 7 days postpartum. Presenting symptoms are usually nonspecific, the most common being malaise, epigastric or right upper quadrant pain, nausea, vomiting, and edema. Patients less frequently present with jaundice, gastrointestinal bleeding, or hematuria. Signs and symptoms of preeclampsia may be mild or absent upon initial presentation. Complications include acute renal failure, ARDS, hemorrhage, hypoglycemia, hyponatremia, and nephrogenic diabetes insipidus. Fetal growth restriction and prematurity are the major causes of perinatal morbidity and mortality. Maternal mortality ranges from 0% to 24%, with higher perinatal mortality (8% to 60%).

Laboratory values that suggest the diagnosis include:[61] (1) hemolysis demonstrated by an abnormal peripheral smear; (2) increased levels of bilirubin (≥1.2 mg/dL) or lactate dehydrogenase (≥600 U/L); (3) increased liver enzyme levels with an elevated serum level of glutamic oxaloacetic transaminase (≥70 U/L); and (4) thrombocytopenia with a platelet count of <100,000/μL. Isolated thrombocytopenia that progresses may be one of the first clues to the diagnosis.

Management

The principles of management of preeclampsia include early diagnosis, close medical observation, and timely delivery. Delivery is curative in most cases. The differential diagnosis of preeclampsia includes thrombotic thrombocytopenic purpura (TTP), hemolytic uremic syndrome (HUS), acute fatty liver of pregnancy, and idiopathic postpartum renal failure (Table 105-8) (see Chap. 70). Once the diagnosis is made, further management is based on an evaluation of the mother and fetus. Mild preeclampsia may be managed on an outpatient basis if hypertension is mild, the fetus is doing well, and compliance is good.[44] The patient will require close monitoring, since this condition can worsen suddenly. The presence of symptoms and proteinuria increases the risk of placental abruption and eclampsia. These patients and those with disease progression should be hospitalized and observed closely. In patients who have mild preeclampsia at term and have a favorable cervix, labor should be induced. There is no consensus regarding the utility of bed rest, antihypertensive therapy, or anticonvulsant prophylaxis in this group of patients. Based on a number of clinical trials, there is no clear benefit to antihypertensive drug treatment in women with mild gestational hypertension or preeclampsia.[44]

Because severe eclampsia can progress rapidly, delivery is recommended in these patients. Immediate delivery is appropriate when there are signs of impending eclampsia, multiorgan involvement, or fetal distress, and in patients who are more than 34 weeks pregnant.[44] Early in gestation, conservative management with close monitoring to improve neonatal survival and morbidity may be appropriate in selected cases at tertiary perinatal centers. The objective of antihypertensive

TABLE 105-8 Differential Diagnosis of Characteristic Features of Preeclampsia and Its Complications

Feature	Pregnancy-Specific	Nonspecific
Hypertension	Preeclampsia	Essential hypertension
	Preeclampsia superimposed on chronic hypertension	Secondary hypertension (renal, pheochromocytoma)
	Transient hypertension	
Thrombocytopenia	Preeclampsia	TTP
	HELLP syndrome	ITP
	Acute fatty liver of pregnancy	Sepsis
Elevated liver enzymes	Preeclampsia	Viral hepatitis
	HELLP syndrome	Drug-induced hepatitis
	Acute fatty liver of pregnancy	
	Cholestasis of pregnancy	
Renal dysfunction	Preeclampsia	Sepsis
	Acute fatty liver of pregnancy	Hypovolemia/hemorrhage
	Idiopathic postpartum renal failure	TTP/HUS
Pulmonary edema	Preeclampsia	Valvular heart disease
	Peripartum cardiomyopathy	Ischemic heart disease
	Tocolytic pulmonary edema	ARDS
	Amniotic fluid embolism

therapy is to prevent cerebral complications such as encephalopathy and hemorrhage. A sustained diastolic blood pressure of 110 mm Hg or greater should be treated to keep the mean arterial pressure between 105 and 126 mm Hg and the diastolic pressure between 90 and 105 mm Hg. While hydralazine 5 mg IV every 20 minutes to a total dose of 20 mg has been the traditional treatment, blood pressure control in the ICU setting is best obtained with either intravenous labetalol or nicardipine.[43] A loading dose of labetalol 20 mg is recommended, followed by either repeated incremental doses of 20 to 80 mg at 10- to 15-minute intervals or an infusion starting at 1 to 2 mg/min and titrated up until the target blood pressure is achieved.[43] Since calcium channel blockers may be potentiated by magnesium infusion, care should be taken to avoid hypotension when the two medications are used together.[3] Acute nicardipine infusion can induce severe maternal tachycardia.[70] (Table 105-9). *Nitroprusside is relatively contraindicated, and angiotensin-converting enzyme inhibitors are absolutely contraindicated, in pregnancy.* Diuretics should be used with caution, as they may aggravate the reduction in intravascular volume that is often seen in preeclampsia. Volume expansion may decrease SVR and improve oliguria; however, the increased risk of pulmonary or cerebral edema makes fluid administration difficult without a right heart catheter in place.[3,71] Antihypertensive therapy has no effect on the progression of disease and does not prevent complications such as HELLP.

Magnesium sulfate prophylaxis has been shown to be better than placebo, phenytoin, or nimodipine in the prevention of eclampsia.[72–74] In a recent large study, magnesium sulfate was superior to both phenytoin and diazepam for the treatment and prevention of recurrent convulsions in women with eclampsia.[75] Magnesium sulfate should be given to all women with either preeclampsia or eclampsia and for a minimum of 24 hours postpartum. Aspirin has no role in the treatment of preeclampsia.

The preeclamptic patient with oliguria may benefit from judicious volume loading and low-dose dopamine therapy.[76] Invasive monitoring is recommended to prevent pulmonary and cerebral edema. Pulmonary edema is managed conventionally. Patients with delayed postpartum resolution of the HELLP syndrome with persistent thrombocytopenia, hemolysis, or organ dysfunction may benefit from plasmapheresis with fresh frozen plasma.[2,77] Many of these patients may actually have TTP or HUS, which can be difficult to distinguish from the HELLP syndrome. In two studies, administration of corticosteroids resulted in improved maternal platelet counts and liver function test results and in a trend toward better

TABLE 105-9 Drugs Used in the Management of Acute Hypertensive Crises in Pregnancy

Drug	Regimen
Nicardipine	5 mg/h increasing the infusion rate by 2.5 mg/h every 5 min (to a maximum of 15 mg/h)
Hydralazine	Initial dose: 5 mg IV bolus; then 5–10 mg every 20–30 min; side effects include tachycardia and headache
Labetalol	Small IV boluses, initially 20-mg, followed by 20 mg to 80 mg, given every 10–20 min until blood pressure is controlled or total dose is 300 mg; can use continuous infusion of 1–2 mg/min titrated up until blood pressure is controlled.
Diazoxide	For use in refractory patients; given in 30-mg miniboluses every 5 min
Sodium nitroprusside	May be used in standard doses [initially 0.25 μg/(kg. min)] for a short period (30 min) in acute crises; potential for fetal cyanide toxicity.

SOURCE: Reproduced with permission from Lapinsky et al[2] and Varon et al.[43]

fetal outcome.[78] No significant effect in delaying delivery was noted. Management of intrahepatic hemorrhage with subcapsular hematoma includes administration of blood products, delivery, and control of liver hemorrhage.[65] Embolization of the hepatic artery is often successful, but evacuation of the hematoma and packing of the liver may be required.

CARDIOPULMONARY RESUSCITATION

Pregnancy can interfere with the performance of adequate cardiopulmonary resuscitation (CPR). If cardiopulmonary arrest occurs, the physiologic changes of pregnancy must be taken into account when performing CPR, including the increased metabolic rate and cardiac output and decreased oxygen reserve typical of the pregnant patient. The gravid uterus may impede venous return and distal arterial perfusion by compressing the inferior vena cava and aorta. In late pregnancy, the gravid uterus acts like an abdominal binder; the resulting elevation of intrathoracic pressure may limit the ability to create forward flow during CPR.

These considerations have prompted some pregnancy-specific modifications of the usual approach to CPR.[79,80] The key modification is that the pregnant patient should receive standard CPR while in the left lateral decubitus position to decrease aortocaval compression by the uterus. That can be accomplished by using a table that provides a lateral tilt, by placing a wedge under the patient's right hip, or by manually displacing the uterus to the left.[2] Otherwise, standard resuscitative measures using currently approved protocols should be followed. Defibrillation (after removal of fetal monitoring devices to prevent arcing) and pharmacologic therapy should be employed as clinically indicated.

If standard closed-chest CPR cannot generate a pulse, especially in late pregnancy, open-chest massage and emergency cesarean section should be considered. In one case report, the mother could not be resuscitated until the fetus was delivered; both subsequently survived.[81] To facilitate this plan, obstetric, internal medicine, and anesthesiology staff need to be apprised early of any acute deterioration in the circulation of a critically ill gravida. Delivery within 4 to 5 minutes of the arrest will improve the chance of a good outcome for both mother and fetus.[79]

Respiratory Disorders of Pregnancy

During pregnancy, ventilatory failure may occur as a result of a chronic lung disease such as cystic fibrosis or asthma and may require mechanical ventilation. A more common cause of respiratory compromise in pregnant women is acute hypoxemic respiratory failure related to amniotic or venous air embolism, tocolytic-induced pulmonary edema, aspiration, or pneumonia. This section focuses on the management of both ventilatory and hypoxemic respiratory failure in the gravid patient.[82]

VENTILATORY FAILURE

With improved medical care, patients with chronic lung diseases such as cystic fibrosis are surviving to childbearing age, presenting new management problems for the intensivist. Asthma, however, remains the most common pulmonary problem encountered in pregnancy, affecting 1% to 4% of all gravidas. When these conditions require mechanical support, ventilator management necessitates careful attention to the special needs of mother and fetus.

MECHANICAL VENTILATION

If ventilatory failure is imminent, intubation and mechanical ventilation should be performed electively. The indications for intubation and mechanical ventilation are not significantly changed by pregnancy, although the normal P_{CO_2} of 27 to 32 mm Hg during pregnancy should be considered when deciding on mechanical ventilation.[3] Several difficulties in airway management should be anticipated in the critically ill pregnant patient (Table 105-10). Pharyngeal, laryngeal, and vocal cord edema are common, and the highly vascular upper airway may bleed from even minor intubation-related trauma.[83] Relatively small endotracheal tubes (6- to 7-mm diameter) may be necessary, and nasotracheal intubation is best avoided because of this upper airway narrowing.[2] There may be an increased risk of aspiration during pregnancy because of delayed gastric emptying, increased intra-abdominal pressure from compression by the gravid uterus, and diminished competence of the gastroesophageal sphincter.[84] Use of cricoid pressure to minimize the risk of pulmonary aspiration is recommended. Approximately 40% of maternal deaths associated with general anesthesia in England and Wales from 1976 to 1978 were related to difficulties with endotracheal intubation.[85] Control of the airway should be achieved in an early and elective fashion by a skilled individual. Noninvasive mask ventilation for acute respiratory failure has not been studied in pregnancy. In the awake patient needing temporary ventilatory assistance, noninvasive positive pressure ventilation is a reasonable first step. Theoretical limitations to this therapy include pregnancy-related upper airway edema and increased risk of aspiration.

The initial ventilator settings should be aimed at achieving eucapnia, which in this patient population is a P_{CO_2} of 28 to 35 mm Hg. Respiratory alkalosis should be avoided, since studies in animal models suggest that hyperventilation can reduce fetal oxygenation and decrease uteroplacental flow.[2,86] Alkalosis can usually be avoided with tidal volumes in the range of 10 mL/kg and respiratory rates of 15 to 18 breaths per minute (bpm). In the asthmatic patient (see below), the use of a lower tidal volume and respiratory rate minimizes the adverse effects of intrinsic positive end-expiratory pressure (PEEP) (see Chap. 38).

The patient with acute pulmonary edema (see below) should be ventilated with a small tidal volume (4 to 6 mL/kg) and a high respiratory rate (24 to 30 bpm).[87] While recent studies of nonpregnant adults managed with mechanical ventilation for ARDS have shown improved survival when low (~6 mL/kg) tidal volumes were used—even if this was associated with hypercapnia—the safety of this permissive hypercapnia in pregnancy remains to be determined. In one animal model, acute hypercapnia during mechanical ventilation was associated with fetal distress. During any mechanical ventilatory period, continuous fetal monitoring should be conducted, usually accomplished by heart tone determination,

TABLE 105-10 Problems with Airway Management in Pregnancy

Upper airway edema
Diminished airway caliber
Propensity for hemorrhage
Increased risk of aspiration

and if acute ventilatory changes are associated with any evidence of challenge to the fetus, they should be avoided. It is important to note that pregnancy, particularly in the third trimester, can result in significant chest wall stiffness resulting from the gravid uterus, and high airway pressures may not signal lung stiffness or overdistension per se. Taken together, these observations would suggest an approach to acute hypoxemic respiratory failure in pregnancy that would begin with careful fetal monitoring, instituting low tidal volumes, avoiding acute rises in partial arterial pressure of carbon dioxide (Pa_{CO_2}) and increasing tidal volume if they occur in association with fetal distress, and allowing plateau airway pressures to be somewhat higher than the 30 cm H_2O often recommended for individuals without such abdominal distension.

When a diffuse lung lesion is present and toxic levels of oxygen would be needed, sufficient PEEP should be imposed to correct arterial hypoxemia at a nontoxic fraction of inspired oxygen ($F_{I_{O_2}}$ <0.6). In the pregnant patient, we aim to keep the Pa_{O_2} >90 mm Hg, a value higher than that used in the nonpregnant patient, to prevent fetal distress. To minimize the decrease in venous return that occurs with positive pressure ventilation, it is important that the pregnant patient be managed in a lateral position whenever possible. Measures to avoid atelectasis in the ventilated gravid patient include PEEP, sighs, and alternating the position between left lateral and right lateral.

In patients with severe lung lesions requiring toxic concentrations of oxygen and high levels of PEEP, and in patients with hemodynamic instability, muscle relaxation and sedation will decrease oxygen consumption and assist in stabilization. Nondepolarizing neuromuscular blocking agents including cisatracurium, pancuronium, vecuronium, and atracurium, produce no adverse fetal effects with short-term use.[2] Of these, cisatracurium is preferred because it does not depend on renal or hepatic function for elimination. Benzodiazepines may increase the risk of cleft palate and other major birth defects when used early in pregnancy, although this has not been conclusively demonstrated. If enzodiazepines are necessary for sedation, the lowest dose and shortest duration of use are recommended. Propofol, pregnancy category B hypnotic agent (see Chap. 14), may be considered, however no data exist on its use in the first or second trimesters in humans. Narcotic analgesics such as morphine sulfate and fentanyl may be used safely during pregnancy. These agents all cross the placenta; therefore if given near the time of delivery, immediate intubation of the neonate may be required.

Fetal viability can be maintained throughout pregnancy with mechanical ventilation, even when maternal death occurs. Mechanical ventilation is most appropriate when instituted early in the course of progressive ventilatory failure, to stabilize mother and fetus and then permit identification of reversible factors to allow either safe withdrawal of mechanical support or controlled delivery. These complex decisions are best made in collaboration with the critical care physician, obstetrician, and neonatologist.

CHRONIC LUNG DISEASE

Most chronic pulmonary diseases that can result in ventilatory failure, such as cystic fibrosis, kyphoscoliosis, neuromuscular diseases, pulmonary fibrosis, and chronic obstructive pulmonary disease (COPD), are uncommon in pregnant women. Despite the increased ventilatory demands that occur in pregnancy, ventilatory failure is rare. In one study, several women with a preconception vital capacity of 40% to 70% predicted due to lung resection or collapse for tuberculosis, carried their pregnancy to term and had few respiratory symptoms.[88] Although several authorities suggest that a vital capacity of at least 1 L is essential for a safe and successful pregnancy,[89] one patient has been reported to have completed pregnancy with a vital capacity of only 0.8 L (25% of predicted) and a P_{CO_2} of 45 mm Hg.[90] Thus severe reduction in lung volume to a level that would represent impairment of ventilatory function in a nonpregnant individual does not in itself preclude a successful conception and pregnancy.

Patients with severe restrictive lung disease and progressive ventilatory insufficiency during pregnancy may benefit from nocturnal positive pressure ventilation and oxygen administration. One patient with severe kyphoscoliosis and a forced vital capacity of 580 mL, a P_{O_2} of 59 mm Hg, and a P_{CO_2} of 52 mm Hg at 25 to 28 weeks of gestation avoided mechanical ventilation by using nocturnal positive pressure ventilation with a tight-fitting mask during weeks 28 to 30 of pregnancy, until delivery could be accomplished by cesarean section.[91] This approach may be applicable to other pregnant patients with chronic ventilatory impairment. Pulse oximetry should be used to screen patients with marginal ventilatory function for nocturnal hypoxemia.

ASTHMA

The course of asthma during pregnancy is variable: In approximately 35% of pregnant asthmatic women the asthma does not change; in 36% it improves; and in 28% it worsens.[92] Patients with more severe asthma are more likely to experience worsening of their asthma during pregnancy. Asthma typically worsens during the second and third trimester with improvement during the last month of pregnancy. Adverse maternal outcomes in pregnant women with asthma have been noted including preterm labor, pregnancy-induced hypertension and preeclampsia, chorioamnionitis, and cesarean delivery. Adverse fetal outcomes include preterm birth and infants small for gestational age.[93] Treatment of the gravid patient with asthma by a specialist reduces the likelihood of preterm birth, low birth weight infants, and perinatal mortality, suggesting that control of asthma and prevention of acute exacerbations are crucial to a good outcome.[94,95]

Management

The management of the pregnant patient with status asthmaticus is similar to that of the nonpregnant patient, with a few exceptions.[2] Even the usually mild hypoxemia seen in asthma should be treated aggressively in the gravid patient because it is detrimental to the fetus. Oxygenation therefore should be assessed even in mild attacks. Since the baseline P_{CO_2} is decreased in pregnancy and probably falls further with an acute asthma attack, an arterial blood gas determination that shows a P_{CO_2} of >35 mm Hg during status asthmaticus should alert the clinician to impending ventilatory failure. However, experience with nonpregnant patients with status asthmaticus and mild hypercapnia has suggested that many can be managed without mechanical ventilatory support.

Most drugs used to treat asthma are considered safe for use during pregnancy.[94,95] Inhaled bronchodilators are standard therapy. A study of inhaled β-agonists in 259 pregnancies (most subjects used metaproterenol) noted no difference in the incidence of congenital malformations,

premature births, low birth weight, poor Apgar scores, or perinatal mortality when compared with asthmatic subjects not using inhaled bronchodilators.[96] Use of parenteral β-agonists is generally limited to situations in which inhaled agents have been ineffective, since epinephrine causes vasoconstriction of the uteroplacental circulation in animal studies, and there is one report of an increased incidence of congenital malformations in humans who used this drug in the first trimester, and terbutaline may inhibit labor and cause pulmonary edema if given near term.[3] Inhaled corticosteroids have been shown to decrease the incidence of asthma attacks and hospital readmissions in studies of pregnant women with asthma.[87] Budesonide is the inhaled corticosteroid of choice with triamcinolone being absolutely contraindicated due to cleft palate formation in rabbits. Oral corticosteroids have been associated with a twofold increase in the incidence of preeclampsia, and in one study an increased risk of cleft palate (0.4% absolute incidence). Systemic corticosteroids remain recommended therapy for the treatment of acute asthma exacerbations and patients with severe asthma.[97] Although there is a risk of causing fetal adrenal insufficiency, this is a rare occurrence. Heliox, a low-density mixture of helium and oxygen, may decrease the work of breathing and preclude intubation and mechanical ventilation when given to subjects in status asthmaticus (see Chap. 40). Despite isolated reports of congenital cardiovascular anomalies in infants born to asthmatic women taking theophylline, it has an extensive safety record in pregnancy, with the only fetal risk being neonatal theophylline toxicity when the drug is given at the time of delivery.[3] Pregnancy decreases theophylline clearance in the third trimester, so dose adjustment may be necessary.[83]

ACUTE HYPOXEMIC RESPIRATORY FAILURE

Pregnancy creates an increased susceptibility to acute hypoxemic respiratory failure caused by a variety of disorders, including those that result in pulmonary edema, such as amniotic fluid embolism, β-adrenergic tocolytic therapy, and aspiration (Table 105-11). Other causes of hypoxemic respiratory failure include venous air embolism and respiratory infections.

AMNIOTIC FLUID EMBOLISM

Amniotic fluid embolism occurs in 1 of every 8000 to 80,000 pregnancies, and is estimated to account for over 10% of peripartum maternal deaths.[98] The mortality rate is very high (80% to 90%) with many of the deaths occurring within 1 hour of the onset of symptoms.[98,99]

The two most important risk factors are advanced maternal age (mean = 32 years) and multiparity. Other, less well established risk factors include amniotomy, cesarean section, insertion of intrauterine fetal or pressure monitoring devices, and term pregnancy in the presence of an intrauterine device. The use of uterine stimulants, tumultuous labor, excessive fetal size, and intrauterine fetal death have not been substantiated as important risk factors.[83] It is important to note that while most cases occur during labor and delivery, amniotic fluid embolism may be associated with uterine manipulation during first- and second-trimester abortions or trauma and has been reported to occur spontaneously at 20 weeks of gestation.[100]

The classic presentation of amniotic fluid embolism, seen in more than 50% of cases, is the abrupt onset of severe dyspnea, tachypnea, and cyanosis during labor or soon after delivery, frequently in association with cardiovascular collapse, hypoxemia, and seizures.[100] Shock and bleeding each are the initial presentation in 10% to 15% of cases. Bleeding secondary to DIC occurs in up to 50% of patients who survive the first 30 to 60 minutes. Most of the remaining patients will have evidence of DIC on laboratory tests. Amniotic fluid embolism is frequently complicated by pulmonary edema; it was found in 70% of the cases on chest radiograph.[100]

TABLE 105-11 Differential Diagnosis of Acute Respiratory Distress in Pregnancy

Disorder	Distinguishing Features	Chest Radiograph
Venous thromboembolism	Evidence of DVT, pleuritic chest pain, positive V/Q scan, leg Dopplers, angiogram	Normal/atelectasis/effusion
Amniotic fluid embolism	Hemodynamic collapse, seizures, DIC	Normal/pulmonary edema
Pulmonary edema secondary to preeclampsia	Hypertension, proteinuria	Pulmonary edema
Tocolytic pulmonary edema	Tocolytic adminstration, rapid improvement	Pulmonary edema
Aspiration pneumonitis	Vomiting, reflux, fever	Focal infiltrate/pulmonary edema
Peripartum cardiomyopathy	Gradual onset, cardiac gallop	Cardiomegaly, pulmonary edema
Pneumomediastinum	Occurs during delivery, subcutaneous emphysema	Pneumomediastinum, subcutaneous air
Air embolism	Profound hypotension, cardiac murmur	Normal/pulmonary edema
Other: asthma, pneumonia, cardiac disease, ARDS	AS for nonpregnant patient	As for nonpregnant patient

ABBREVIATIONS: ARDS, acute respiratory distress syndrome; DIC, disseminated intravascular coagulatoin; DVT, deep venous thrombosis, V/Q, ventilation-perfusion.

The mechanisms of respiratory and circulatory failure in amniotic fluid embolism remain controversial. Amniotic fluid and particulate matter (lanugo hairs, meconium, fat, or fetal squames) may enter the maternal venous circulation via endocervical veins or uterine tears or at the placental site itself.[11] In some animal studies, filtered amniotic fluid has been found to be relatively innocuous in less than massive amounts. This finding suggests that cellular and other debris present in the fluid embolism may either mechanically obstruct the maternal pulmonary vasculature, leading to the development of pulmonary hypertension, or trigger a maternal systemic reaction. Others believe that vasoconstrictor arachidonic acid metabolites present in the amniotic fluid itself may elicit pulmonary hypertension.[83] Circulatory failure has been ascribed to various pathophysiologic processes, and these may vary over time. Initially, acute right heart strain from acute pulmonary hypertension may occur. Acute elevation of pulmonary artery and central venous pressures with subsequent hypotension have been observed in animal models of amniotic fluid embolism.[100] Elevation of Ppw, minimal increase in the pulmonary vascular resistance, and depressed left ventricular performance have been observed in human patients with amniotic fluid embolism, suggesting that left ventricular dysfunction contributes to circulatory collapse.[99] In addition, a component of pulmonary capillary leakage must exist, as severe pulmonary edema occurs at a Ppw <19 mm Hg.[99]

Management

The treatment of patients with amniotic fluid embolism and cardiovascular collapse is supportive and is aimed at ensuring adequate oxygenation, stabilizing the circulation, and controlling bleeding. The initial management should include intubation, administration of 100% oxygen, and mechanical ventilation with a small tidal volume (4 to 6 mL/kg) and rapid rate (24 bpm). Early sedation and muscle relaxation may allow complete rest of the respiratory muscles and confer hemodynamic stability. PEEP is then added to achieve a Pa_{O_2} of >90 mm Hg at an FI_{O_2} <0.6. Pulmonary artery catheterization allows measurement of the cardiac output and Ppw, which can be used to guide hemodynamic adjustments aimed at minimizing Ppw (to reduce vascular leak) while providing an adequate cardiac output. Pulmonary arterial blood can be examined cytologically for evidence of abnormal amniotic fluid components—fetal squamous cells, lanugo hairs, etc. However, demonstration of these amniotic fluid elements in the maternal pulmonary circulation is not sufficient to make this diagnosis, since small numbers of fetal squamous cells have been observed in patients without clinical evidence of amniotic fluid embolism.[82] Vasoactive drugs are frequently necessary to reverse hypotension. Once DIC is established, factor replacement and heparin therapy, which are controversial, should be undertaken only in conjunction with a hematology consultant.[30] Intravenous corticosteroid therapy has been reported to be of benefit in limited case reports.[101]

TOCOLYTIC THERAPY

Pulmonary edema associated with β-adrenergic agents given to inhibit preterm labor is seen in as many as 4.4% of patients receiving these drugs.[102] Most of the reported cases have resulted from use of intravenous β-mimetics such as ritodrine, terbutaline, isoxuprine, and salbutamol. There is an increased incidence in women with multiple gestations, concurrent infection, and those receiving corticosteroid therapy.[3] Most women have intact membranes at the time of presentation. Pulmonary edema typically develops during tocolytic therapy or within 24 hours after the discontinuation of these drugs. When pulmonary edema develops postpartum, the vast majority of cases are encountered within 12 hours of delivery.[102]

The pathogenesis of this disorder remains unknown. Pulmonary edema has never been associated with similarly high doses of β-adrenergic agonists during the treatment of asthma. Therefore, some alteration related to pregnancy may predispose women to this complication. Left ventricular function was normal in those patients assessed with echocardiography and invasive monitoring.[102] The observation that Ppw is normal in most patients who have pulmonary artery catheters placed has led to speculation that these drugs or occult infection produce a pulmonary capillary leak.[3,102] Several facts suggest that increased circulatory volume may also play a major role: (1) large volumes of crystalloid are often given in response to the reflex tachycardia resulting from sympathomimetic drugs; (2) the intravascular volume expansion and reduced colloid oncotic pressure characteristic of pregnancy increase susceptibility to hydrostatic edema; (3) sodium and water excretion may be impaired in the supine pregnant patient; (4) tocolytic agents may increase arginine vasopressin secretion and thus impair water balance; and (5) the response to diuresis is prompt in these patients.[102]

Most patients complain of chest discomfort and dyspnea, manifest tachypnea, have tachycardia with crackles on lung auscultation, and have pulmonary edema on chest radiography (Table 105-12). A positive fluid balance is often noted in the hours to days preceding the onset of symptoms. In the largest collected series, the mean arterial P_{O_2} when breathing room air was 50.4 ± 2.9 mm Hg with a P_{CO_2} of 28.1 ± 2.1 mm Hg.[102] The history and clinical findings should help in distinguishing this disorder from acute thromboembolic disease, acid aspiration, and amniotic fluid embolism.

Management

The course of this disease is usually benign, and invasive hemodynamic monitoring is usually not required. In a large series there were only two maternal deaths (3%); fetal survival was 95%.[102] Treatment should consist of discontinuation of tocolytic therapy, oxygen administration, and diuresis. Response is usually rapid, with resolution of tachypnea and hypoxemia often occurring within hours.

ASPIRATION

Aspiration is an uncommon but well-described and ominous complication of the peripartum period.[84] Factors that increase the risk of aspiration in the pregnant woman

TABLE 105-12 Features of Tocolytic-Induced Pulmonary Edema

Most common cause of pulmonary edema in pregnancy
Associated with β-adrenergic agonist use
Dyspnea, tachypnea, and crackles are typical
Occurs <24 hours after tocolytic agents are stopped
Responds promptly to oxygen and diuretics

include the increased intragastric pressure that results from external compression by the enlarged uterus, relaxation of the lower esophageal sphincter due to progesterone, delayed gastric emptying during labor, and depressed mental status and vocal cord closure from analgesia. Injury due to aspiration of gastric contents is related to the volume of aspirated material, its acidity, the presence of particulate material, the bacterial burden of the aspirated material, and host resistance to subsequent infection. The early injury is a chemical pneumonitis, the severity of which is determined primarily by the acidity and volume of the aspirate. Diffuse lung injury with the development of ARDS may occur early in the course. A late complication of aspiration is the evolution to bacterial pneumonia, which tends to be focal and polymicrobial and occurs 24 to 72 hours after the event.

Management

Prevention of this dread complication should be the primary goal of all physicians assessing and managing the patient's airway. Once aspiration has occurred, treatment is supportive and is similar to that for the nonpregnant individual, as discussed elsewhere in this text (see Chap. 51). Antibiotics should be given only if bacterial pneumonia develops.

VENOUS AIR EMBOLISM

Although a rare occurrence, venous air embolism may account for 1% of all maternal deaths.[103] It occurs during normal labor, delivery of women with placenta previa, criminal abortions using air, orogenital sex, and insufflation of the vagina during gynecologic procedures.[103] Air is thought to enter subplacental venous sinuses, then to embolize through the venous circulation, and finally to obstruct pulmonary blood flow when it reaches the right ventricle. Two other mechanisms may be important in the pathophysiology of this disorder—the obstruction of pulmonary arterioles by fibrin microemboli and the recruitment and activation of polymorphonuclear leukocytes by aggregated proteins; both the fibrin microemboli and the aggregated proteins would be produced by the turbulent air-blood interface. Symptoms include cough, dyspnea, dizziness, tachypnea, tachycardia, and diaphoresis. Sudden hypotension is usually followed by respiratory arrest. A mill wheel murmur or bubbling sound is occasionally heard over the precordium. Right heart strain, ischemia, and arrhythmias have been noted on the electrocardiogram. Patients who survive the initial cardiopulmonary collapse may develop noncardiogenic pulmonary edema.

Management

When venous air embolism is suspected, the patient should be placed immediately in the left lateral decubitus position to direct the air embolus away from the right ventricular outflow tract. The patient should be ventilated with 100% oxygen in an effort to decrease the size of the embolus by removing nitrogen.[103] Hyperbaric therapy has been an effective way to treat air embolism in diving medicine. Anticoagulation with heparin to treat fibrin microemboli and administration of high-dose corticosteroids to decrease pulmonary edema formation have been proposed, but their usefulness in this disorder remains untested.[103]

RESPIRATORY INFECTIONS

The incidence of pneumonia in pregnancy may be increasing, reflecting a decline in the general health of a segment of the population of childbearing women and infection with human immunodeficiency virus (HIV).[104] In a large retrospective review of pneumonia during pregnancy, pneumonia complicated 1 out of every 1287 deliveries.[105] The incidence may be even higher in urban areas, with one study reporting pneumonia in 1 of every 367 deliveries at a large city hospital. Obstetric complications included preterm labor in 44% and preterm delivery in 36% in one large study of pneumonia during pregnancy.[105] In addition, 20% of the cases had respiratory failure requiring mechanical ventilation; maternal mortality was 4%, while fetal mortality was 12%. Underlying maternal disease, such as the acquired immunodeficiency syndrome (AIDS) and cystic fibrosis, were associated with maternal medical complications and preterm delivery. The spectrum of organisms that causes bacterial pneumonia is similar to that in the nonpregnant population (Table 105-13).[83,104] An increased incidence of influenza pneumonia was noted among pregnant patients during the 1918–1919 and 1957–1958 influenza pandemics. Autopsy reports noted the cause of death as respiratory insufficiency from fulminant influenza pneumonia rather than from secondary bacterial infection as is usually the case in the nonpregnant population.[103] However, pregnancy has not been demonstrated to be a risk factor for severe influenza infection except during those pandemic years. Primary infection with varicella zoster virus progresses to pneumonia more often in adults than in children. Some investigators have noted an increased rate of progression to pneumonia and an increased mortality in pregnant patients, but the validity of this claim has not been proved conclusively. Coccidioidomycosis is the fungal infection most commonly associated with increased risk of dissemination during pregnancy, especially if it is contracted in the third trimester or immediately postpartum.[104] The decreased cell-mediated immunity thought to occur during pregnancy may predispose the pregnant patient to disseminated varicella and coccidioidomycosis. Infection with *Mycobacterium tuberculosis* during pregnancy occurs. Whether pregnancy adversely influences the course of active tuberculosis is a matter of debate.[106] It is clear that with appropriate chemotherapy, the prognosis for pregnant women with tuberculosis is excellent. There is no evidence for increased activation of quiescent disease during pregnancy. In vivo studies

suggest that pregnancy does not affect the response to tuberculin skin testing, and this test can be performed safely during pregnancy.[106] Maternal and fetal mortality from advanced tuberculosis was high in the era before effective chemotherapy. At present, the outcome for mother and child is excellent except in rare cases of congenital or neonatal tuberculosis.

HIV infection in the pregnant patient is complicated by the risk of perinatal transmission to the fetus, preterm delivery, and opportunistic infection, especially pneumonia.[107] Testing for HIV infection and antiretroviral therapy to prevent vertical transmission are currently the standard of care in the pregnant patient. *Pneumocystis carinii* pneumonia (PCP) may complicate pregnancy and may be especially virulent in this setting. It is the most common cause of AIDS-related death in pregnant women in the United States, with respiratory failure requiring mechanical ventilation occurring in 59% of patients and with a mortality rate of 50%.[108] Fetal mortality is also high and appears to be worse if PCP occurs during the first or second trimester. The clinical presentation is not altered by pregnancy.

Management

The choice of antibacterial agents to treat pneumonia during pregnancy should take account of potential fetal toxicity. The penicillins, cephalosporins, and erythromycin (except for the estolate, which increases the risk of cholestatic jaundice in pregnancy) are considered safe.[103,104] Tetracycline and chloramphenicol are contraindicated, and sulfa-containing regimens should be avoided near term except for the treatment of PCP, as discussed below.[83,104] Amantadine has been shown to be teratogenic at very high but not at lower doses in animals; its use has not been studied in pregnant women.[103] Favorable results have been obtained using acyclovir to treat pregnant women with varicella pneumonia.[83] No teratogenic effects have been noted in animal studies of acyclovir.[103] It is important to initiate therapy with acyclovir early to affect outcome favorably. Thus acyclovir should be started at the first sign of respiratory system involvement in pregnant patients with cutaneous varicella infection.[103] Amphotericin B should be used to treat disseminated coccidioidal infections in pregnancy. Fluconazole and likely other azole antifungals are teratogenic and best avoided.[109] No adverse effects on the fetus have been reported for amphotericin. Active tuberculosis during pregnancy should be treated with isoniazid, rifampin, and ethambutol plus pyridoxine until drug susceptibility testing is complete.[110] All three of these medications cross the placenta, but none has been shown to have teratogenic effects. In patients with sensitive organisms, isoniazid and rifampin should be continued for 9 months. Although pyrazinamide is recommended for routine use in pregnant women by the World Health Organization, in which case the treatment duration is shortened to 6 months, the drug has not been routinely used in the United States due to lack of data regarding safety. Streptomycin is the only antituberculosis drug with documented harmful effects on the human fetus and it should not be used during pregnancy.[110] PCP should be treated with trimethoprim-sulfamethoxazole.[104] Treatment with trimethoprim-sulfamethoxazole, compared with other therapies, may result in improved outcome.[108] Corticosteroids are added if clinically indicated as for the nonpregnant patient.[104]

Other Disorders of Pregnancy

ACUTE RENAL FAILURE

The incidence of acute renal failure associated with pregnancy is between 0.02 and 0.05%.[20] The differential diagnosis of acute renal failure in pregnancy can be found in Table 105-14.[2] As discussed above, acute renal failure may complicate preeclampsia, the HELLP syndrome, and acute fatty liver of pregnancy. Acute tubular necrosis may occur from hemorrhage or sepsis. Acute cortical necrosis is associated with placental abruption, septic abortion, prolonged intrauterine retention of a dead fetus, hemorrhage, and amniotic fluid embolism.[20] Acute oliguric renal failure necessitating dialysis typically results. Arteriography may demonstrate loss of the cortical circulation, and renal biopsy can confirm the diagnosis. While renal function often improves, end-stage renal failure is the eventual outcome.[20] Idiopathic postpartum acute renal failure is an unusual complication of pregnancy and may occur days to weeks after a normal pregnancy and delivery.[20] The etiology is unknown. The disorder may be a variant of HUS or TTP, since it is clinically and pathologically similar to these entities although without hemolysis or thrombocytopenia, and many patients respond to treatment with prednisone administration and plasmapheresis.[2] In general, the treatment of acute renal failure in pregnancy is similar to that in the nonpregnant patient, with supportive care and dialysis as necessary. Renal dysfunction associated with preeclampsia and the HELLP syndrome should respond to delivery of the fetus, while TTP and HUS require plasmapheresis with fresh frozen plasma.[77]

ACUTE LIVER FAILURE

Acute liver failure is an uncommon complication of pregnancy.[65] The differential diagnosis and characteristics of liver diseases in pregnancy can be found in Table 105-15.[78] In pregnancy, de novo liver function test abnormalities are

TABLE 105-14 Differential Diagnosis of Acute Renal Failure in Pregnancy and the Postpartum Period

Prerenal
Hemorrhage
Hyperemesis gravidarum
Renal
Acute tubular necrosis (secondary to sepsis, hemorrhage, placental abruption, intrauterine fetal death, etc)
Bilateral renal cortical necrosis (secondary to abruption, hemorrhage, preeclampsia, septic abortion, etc)
Preeclampsia
HELLP syndrome
Acute fatty liver of pregnancy
HUS/TTP
Idiopathic postpartum renal failure
Acute glomerulonephritis (e.g., lupus flare precipitated by pregnancy)
Postrenal
Gravid uterus
Nephrolithiasis

ABBREVIATIONS: HELLP, hemolysis, elevated liver enzymes, low platelets; HUS, hemolytic uremic syndrome; TTP, thrombotic thrombocytopenic purpura.

TABLE 105-15 Characteristics of Liver Diseases in Pregnancy

Disease	Symptoms	Jaundice	Trimester	Incidence in Pregnancy	Laboratory Values[a]	Adverse Effects
Hyperemesis gravidarum	Nausea, vomiting	Mild	1 or 2	0.3%–1.0%	Bilirubin <4 mg/dL, ALT <200 U/L	Low birth weight
Intrahepatic cholestasis of pregnancy	Pruritus	In 20%–60%, 1–4 weeks after pruritus starts	2 or 3	0.1%–0.2% in U.S.	Bilirubin <6 mg/dL, ALT <300 U/L, increased bile acids	Stillbirth, prematurity, bleeding, fetal mortality 3.5%
Biliary tract disease	Right upper quadrant pain, nausea, vomiting, fever	With CBD obstruction	Any	Unknown	If CBD stone, increased bilirubin and GGT	Unknown
Drug-induced hepatitis	None, or nausea, vomiting, pruritus	Early (in cholestatic hepatitis)	Any	Unknown	Variable	Unknown
Acute fatty liver of pregnancy	Upper abdominal pain, nausea, vomiting, confusion late in disease	Common	3	0.008%	ALT<500 U/L, low glucose, DIC in >75%, increased bilirubin and ammonia late in disease	Increased maternal mortality (≤20%) and fetal mortality (13%–18%)
Preeclampsia and eclampsia	Upper abdominal pain, edema, hypertension, mental status changes	Late, 5%–14%	2 or 3	5%–10%	ALT <500 U/L (unless infarction), proteinuria, DIC in 7%	Increased maternal mortality (~1%)
HELLP syndrome	Upper abdominal pain, nausea, vomiting, malaise	Late, 5%–14%	3	0.1% (4%–12% of women with preeclampsia)	ALT <500 U/L, platelets <100,000/μL, hemolysis, increased LDH, DIC in 20%–40%	Increased maternal mortality (1%–3%) and fetal mortality (35%)
Viral hepatitis	Nausea, vomiting, fever	Common	Any	Same as in general population	ALT greatly increased (>500 U/L), increased bilirubin, DIC rare	Maternal mortality increased with hepatitis E

ABBREVIATIONS: ALT, alanine aminotransferase; CBD, common bile duct; DIC, disseminated intravascular coagulation; GGT, γ-glutamyl transferase; HELLP, hemolysis, elevated liver enzymes, and low platelets; LDH, lactate dehydrogenase.
SOURCE: Reproduced with permission from Knox et al.[78]

uncommon and occur in less than 5% of pregnancies in the United States.[65] Serum alkaline phosphatase increases during the first 7 months of pregnancy peaking at two to four times normal at term. As discussed above, serum albumin concentrations decrease in pregnancy. Levels of serum aminotransferases and bilirubin are unchanged in normal pregnancy.

Liver failure rarely complicates preeclampsia and the HELLP syndrome; subcapsular hematoma and rupture are more common complications, as discussed above. Acute fatty liver of pregnancy is estimated to occur in 1 of 13,000 deliveries.[65] Risk factors include male fetus, multiple gestations, and a first pregnancy. Mean onset is at 36 weeks' gestation, although the disorder can be seen as early as 26 weeks and postpartum. Patients present with nonspecific symptoms such as headache, nausea and vomiting (70%), right upper quadrant or epigastric pain (50% to 80%), malaise, and anorexia.[78] The onset of acute fatty liver of pregnancy may be similar to the onset of preeclampsia, with peripheral edema, hypertension, and proteinuria. Jaundice may follow 1 to 2 weeks later. Cholestasis with mild-to-moderate elevations in serum aminotransferases are the rule. Ultrasound may show increased echogenicity. Computed tomographic abdominal scans are more sensitive and may demonstrate decreased attenuation, although this imaging exposes the fetus to significant radiation. Liver biopsy is sometimes necessary to make the diagnosis but must be undertaken with caution because these patients often have a coagulopathy. The biopsy is characterized by microvesicular fatty infiltration detected only on frozen sections.[65] Acute fatty liver of pregnancy progresses to fulminant hepatic failure complicated by encephalopathy, renal failure, pancreatitis, hemorrhage, DIC, seizures, coma, and death.[78] Because deterioration may occur rapidly, expectant management is generally not advised. The treatment is delivery of the fetus. Jaundice, liver dysfunction, and DIC may worsen for a few days after delivery but then should improve. Maternal and fetal mortality has improved with early delivery and is less than 20%. Full maternal recovery is to be expected. Because long-chain 3-hydroxyacyl-coenzyme

dehydrogenase deficiency in the fetus has been reported to be associated with acute fatty liver of pregnancy in seven of ten women in a recent study, infants may have hypoglycemia, hypotonia, acute or chronic skeletal and cardiac muscle dysfunction, and sudden infant death syndrome.

Maintenance of the Internal Environment

While early mortality can be reduced in the critically ill gravid patient by the therapies outlined above, malnutrition, nosocomial infection, and gastrointestinal hemorrhage often complicate a prolonged ICU stay and account for much of the later morbidity and mortality. Several of these issues are discussed below with the aim of establishing the best milieu for recovery from critical illness.

ACID-BASE STATUS

As previously discussed, pregnancy results in a compensated respiratory alkalosis in which P_{CO_2} and bicarbonate concentration average 30 mm Hg and 18 to 20 mEq/L, respectively. During labor this respiratory alkalosis worsens because of maternal hyperventilation. Nonetheless, current evidence suggests that the resulting alkalemia is not clinically relevant. In one study, fetal oxygen delivery was not impaired when mothers hyperventilated in labor, as fetal P_{O_2} decreased by only 4 mm Hg despite significant increases in maternal and fetal plasma pH.[111] Fetal compensation may result from the facts that the alkalosis-induced leftward shift of the fetal hemoglobin saturation curve may preserve fetal oxygen-carrying capacity and that carbon dioxide diffuses rapidly across the placenta, allowing quick reestablishment of acid-base homeostasis. Unlike spontaneous hyperventilation, however, respiratory alkalosis from excessive mechanical ventilation can cause fetal asphyxia in animal models as a result of decreased uteroplacental blood flow.[86] Furthermore, maternal metabolic alkalosis has been shown in animal models to significantly decrease placental blood flow and fetal carotid P_{O_2}.[112] Since severe respiratory and metabolic alkaloses in the critically ill are often a result of medical treatment—excessive mechanical ventilation, nasogastric suction, diuretic use, and corticosteroid administration—close monitoring of maternal acid-base status should allow prevention or early correction of the alkalosis.

Acidosis may be detrimental to the fetus and should be avoided. Decreased ventilation, with elevation of P_{CO_2} even to prepregnancy levels, will result in respiratory acidosis. Early intubation and mechanical ventilation are indicated in gravidas before hypercapnia and severe respiratory acidosis develop.

Maternal metabolic acidosis occurs in normal labor and delivery, presumably as a result of hyperventilation and other muscle activity.[113] Lactic acid is produced, and these maternal fixed acids pass rapidly to the fetus. In early labor, fetal pH averages 7.30 and P_{CO_2} averages 45 mm Hg, with a fall in pH to 7.20 immediately after delivery.[114] The pH falls owing to a metabolic acidosis, which resolves over the first 60 minutes of neonatal life. When a maternal metabolic acidosis develops as a result of illness, treatment should be directed at the underlying process after it is determined whether the anion gap is normal or increased. The use of bicarbonate to correct pH is controversial for both pregnant and nonpregnant patients, as is discussed in Chap. 77. When bicarbonate is given, serum carbon dioxide levels rise, and carbon dioxide diffuses rapidly across the placenta. The rise in fetal bicarbonate levels is slower, because this charged species equilibrates more slowly across the placenta. Thus infused bicarbonate may increase acidosis intracellularly or in fetal tissue beds. For this reason, if correction of an underlying acidosis or delivery are likely to be achieved within hours, treatment with bicarbonate is not recommended. Controlled mechanical ventilation to correct metabolic acidosis is indicated when the patient cannot generate sufficient respiratory compensation or the work of breathing will further aggravate the acidosis. This measure should make it possible to provide enough ventilation to minimize acidosis.

PREVENTION OF GASTROINTESTINAL HEMORRHAGE

Pregnancy is not known to result in abnormal gastric acid secretion or to increase the vulnerability of the upper gastrointestinal mucosa to ulceration, but critical illness is often complicated by gastric erosion and severe bleeding. A number of interventions are currently used as prophylaxis against this common complication.

Antacids and sucralfate act by mixing with and neutralizing the gastric contents or by directly coating the gastric mucosa. Because the enlarging uterus may divide the stomach into antral and fundal pouches, complete mixing of gastric contents is unlikely.[115] Therefore these agents may fail to provide prophylaxis against gastric ulceration. Histamine-receptor blockers such as cimetidine and ranitidine are category B medications, as are the proton pump inhibitors, and are the medications of choice in pregnant critically ill patients to reduce the risk of gastrointestinal hemorrhage.

NUTRITION

Total parenteral nutrition (TPN) has been used in pregnant patients for extended periods for disorders such as inflammatory bowel disease, esophageal stricture, and malignancy. Its use in acute malnutrition associated with critical illness is less well described.[116] Animal studies find that the mother is favored over the fetus during starvation, and in human beings maternal body stores are maintained at the expense of fetal growth during semistarvation.[3] For these reasons, aggressive and early nutritional support should be instituted. Patients who have not resumed normal oral intake within 3 days of the onset of critical illness should receive nutritional support. The gut should be used if possible, and feedings given as a bolus by nasogastric tube or as infusions by a soft duodenal feeding tube. Caloric requirements during pregnancy are close to 40 kcal/(kg/d). Sepsis, trauma, burns, and recent surgery are likely to increase this requirement. If severe liver disease is not present, it is recommended that 1.5 g/(kg/d) of protein be given and that approximately 20% of calories be provided as lipids. A variety of enteral feeding supplements can meet these goals at tolerable infusion rates. Finally, electrolyte disorders are common in these patients, and careful attention must be paid to serum calcium, phosphate, and magnesium levels, with additional supplements given as necessary.

TABLE 105-16 Safety of Drugs Used in the ICU, according to the FDA Classification of Drug Safety in Pregnancy

Categories A and B	Category C	Categories D and X
Acyclovir	Albuterol	ACE inhibitors
Amphotericin	Atracurium	Acetylsalicylic acid
Cephalosporins	Atropine	Aminoglycosides
Cimetidine	Bretylium	Benzodiazepines
Clindamycin	β-Blockers	Midozolam
Erythromycin	Bupivacaine	Phenytoin
Glycopyrrolate	Dantrolene	Tetracyclines
Insulin	Digoxin	Warfarin
Lidocaine	Haloperidol	
Magnesium sulfate	Inotropes	
Meperidine	Flumazenil	
Methyldopa	Fluconazole	
Metronidazole	Furosemide	
Naloxone	Heparin	
Penicillins	Hydralazine	
Propofol	Labetalol	
Ranitidine	Meperidine	
Terbutaline	Nifedipine	
	Nitroglycerine	
	Nitroprusside	
	Pancuronium	
	Prednisone	
	Procainamide	
	Suxamethonium	
	Thiopental	
	Vecuronium	
	Vancomycin	

NOTE: Column 1 (categories A and B) represents drugs for which no fetal risk has been demonstrated in human and/or animal studies in the first trimester. Column 2 (category C) represents drugs for which animal studies have demonstrated adverse effects, or for which inadequate data exists. These may be used for clear indications where the benefit justifies the potential risks. Column 3 (categories D and X) represents drugs for which evidence of human fetal risks exist. Category D drugs may be used in exceptional circumstances for serious diseases where the expected benefit outweighs the risks.

Classification of some drugs differs in different reference. The physician should weigh the available evidence, or lack thereof, before using any drug in a pregnant woman. This table serves only as a general guide to the method of classification of drug safety in pregnancy.

SOURCE: From Lapinsky et al.[2]

ABBREVIATION: ACE, angiotensin-converting enzyme.

Patients who do not tolerate enteral feeding will require TPN. The same guidelines for total calories and for the distribution of calories among lipids, carbohydrates, and protein can be used. There is a theoretical concern that the use of intravenous fat emulsions in pregnancy could result in placental infarction due to fat emboli.[117] However, this complication has not been reported and fat emulsions are used in our institution.

FDA DRUG CLASSIFICATION

Since pregnant patients being treated for critical illness may require multiple pharmacologic interventions, intensivists in the United States should be aware of the Food and Drug Administration use-in-pregnancy ratings. Commonly prescribed medications in the intensive care unit are listed in Table 105-16. Category A drugs are those that have undergone adequate controlled studies in pregnant women and have not demonstrated a risk to the fetus. Category B drugs are those with no evidence of fetal risk in human beings (if animal studies demonstrate risk, human findings do not, or if human studies are inadequate, animal findings are negative). Category C agents are those in which risk cannot be ruled out (human studies are lacking, and animal studies are either positive for fetal risk or lacking; still, potential benefits may outweigh risk). Category D includes agents with positive evidence of fetal risk by virtue of investigational or postmarketing human data (still, in critical illness potential benefits may outweigh risks). Category X includes drugs contraindicated in pregnancy.

Chapter 106

ANAPHYLACTIC AND ANAPHYLACTOID REACTIONS

JONATHAN MOSS
PAUL-MICHEL MERTES

KEY POINTS

- *Mast cells or basophils release mediators of anaphylactic and anaphylactoid reactions as a result of direct drug actions or interaction of antigen with mast cell or basophil immunoglobin E.*
- *Agents that commonly cause hypersensitivity reactions are antibiotics, blood products, radiocontrast media, muscle relaxants, colloids, preservatives, protamine, and latex.*
- *Histamine, eosinophilic chemotactic factor of anaphylaxis, slow-reacting substance of anaphylaxis, platelet-activating factor, prostaglandins, and kinins are the six major pharmacologic mediators known to be released in anaphylactic and anaphylactoid reactions.*
- *Symptoms caused by these mediators are usually immediate but may be delayed by 2 to 15 minutes or, in rare cases, by as long as 2.5 hours after the parenteral injection of antigen.*
- *Because this reaction includes vasodilation and translocation of fluid from capillaries and postcapillary venules (resulting in loss of fluid and colloid from intravascular spaces), effective plasma volume and systemic vascular resistance is decreased, which can lead to shock.*
- *The sine qua non of anaphylaxis is severe cardiovascular or respiratory compromise; most conscious patients sense impending doom before the clinical event occurs.*
- *Tryptase is helpful in distinguishing between anaphylactic and anaphylactoid reactions.*
- *Although various drugs are used to treat anaphylactic and anaphylactoid reactions, discontinuation of the offending drug, maintenance of the airway, administration of oxygen, blood volume expansion, and administration of titrated doses of epinephrine (very large doses may be needed) are the mainstays of therapy.*
- *Anaphylactic and anaphylactoid reactions are acute, potentially fatal events, but their morbidity and mortality rates can be decreased by preparation, drills such as those done for cardiopulmonary resuscitation, and prompt recognition and aggressive treatment.*

Life-threatening hypersensitivity or pseudoallergic reactions to exogenously derived and administered agents in critical care environments can be, and usually are, treated successfully by a prepared intensivist.[1] These reactions are anaphylactic if immune mediated and anaphylactoid if chemically mediated. Data from multicenter studies of perioperative patients show an incidence of life-threatening reactions of 1 in 5000 anesthetics, half of which are immune mediated. Although chemically mediated reactions may be much more common, they usually are less severe.[2] Rapid recognition and treatment of such reactions can prevent much of the morbidity and mortality that would otherwise occur.

Life-Threatening Hypersensitivity Reactions

Anaphylaxis is a life-threatening allergic, immune-mediated reaction. The term *allergic* applies to immune-mediated reactions, as opposed to those caused by pharmacologic idiosyncrasy, direct toxicity, drug overdose, or drug interactions.[3] Anaphylactoid reactions produce the same clinical syndrome but are not immune mediated. Interaction of antigen with mast cell immunoglobin (Ig) E or direct drug actions cause mast cells to release mediators of anaphylactic and anaphylactoid reactions (Fig. 106-1). Vasoactive mediators of these reactions include histamine, eosinophilic chemotactic factor of anaphylaxis (ECF-A), slow-reacting substance of anaphylaxis (SRS-A; a mixture of three leukotrienes, including a potent coronary vasoconstrictor), platelet activating factor (PAF), kinins, and prostaglandins (see Fig. 106-1). Symptoms usually occur within 15 minutes of parenteral injection of the causative agent, although they may be delayed. The net effect of these agents is a marked decrease in systemic vascular resistance and the leakage of fluid from the capillaries and postcapillary venules. This excessive vasodilation and reduction in effective plasma volume can result in shock. Thus, volume replacement and administration of epinephrine are therapeutic mainstays. Common causes of such reactions are antibiotics, blood products, muscle relaxants, colloids, preservatives, latex, protamine, and radiocontrast medium.

Incidence and Prevalence

Anaphylactic and anaphylactoid reactions to drugs and adjuvants represent an important component of iatrogenic pathology responsible for significant morbidity, mortality, and medical care costs.[4,5] However, there is no existing comprehensive epidemiologic study of drug allergy in the general population because many reactions attributed to allergic events are not intensively investigated. Also, many authentic allergic events are not reported. However, several series from different countries have estimated the incidence of anaphylaxis during anesthesia[6–17] to be between 1 in 10,000 to 1 in 20,000.[9,12] Despite the fact that these reactions are witnessed and occur in a monitored setting, they have a mortality rate ranging from 3.5%[18] to 4.7%[19] even when appropriately treated.[9,12]

Skin testing overestimates the incidence of reactions. Although the occurrence of these events is well documented, the prevalence of sensitization to anesthetic drugs in the overall population remains poorly defined. For example, there is a 9.3% prevalence of sensitivity to neuromuscular blocking agents in the general population,[20] based on skin test positivity and/or detection of specific IgE to quaternary ammonium ions, although anaphylaxis to neuromuscular blocking agents occurs in only 1 in 6500 anesthetics.[9] Similarly, the prevalence of latex sensitization, a major cause of anaphylaxis during anesthesia, depends on the population studied. It ranges from 1% to 6.6% in the general population,[21,22] reaching 15.8% in

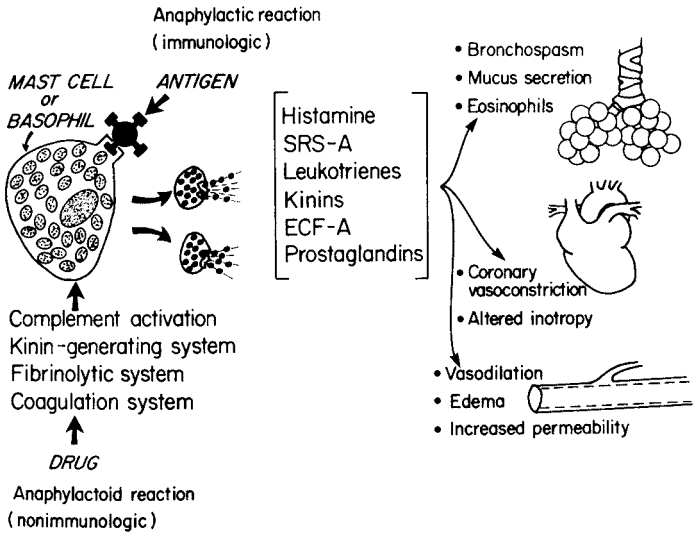

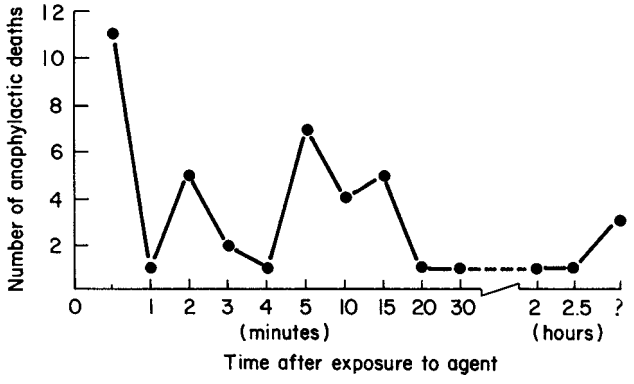

FIGURE 106-1 Summary of the pathophysiologic changes in anaphylactic and anaphylactoid reactions. ***Top*****. Anaphylactic reactions. The allergen enters the body and combines with immunoglobulin E antibodies on the surface of mast cells and basophils. The mast cells and basophils degranulate, releasing mediators (histamine, slow-reacting substance of anaphylaxis, leukotrienes, kinins, eosinophilic chemotactic factor of anaphylaxis, prostaglandins, platelet activating factor, and others). The release of these substances is associated with some of the signs and symptoms of anaphylaxis: bronchospasm; pharyngeal, glottic, and pulmonary edema; vasodilation; hypotension; decreased cardiac contractility and arrhythmias; subcutaneous edema; and urticaria.** ***Bottom.*** **Anaphylactoid reactions. The offending agent enters the body and works by nonimmunologically activating systems that cause degranulation of mast cells and basophils. These systems include the complement system, the coagulation and fibrinolytic systems, and the kinin-generating system. Activation of these systems can result in the release from basophils and mast cells of the same mediators as in anaphylaxis and in a syndrome that is clinically indistinguishable from anaphylaxis.**

an anesthesiology staff.[23] However, this IgE-dependent sensitivity does not necessarily indicate that an allergic reaction will occur in case of exposure to latex.

Clinical Presentation

The end-organ effects of different mediators produce the clinical syndrome of anaphylaxis. In a sensitized individual, the onset of the signs and symptoms caused by these mediators is usually immediate but may be delayed by 2 to 15 minutes or, in rare cases, by as long as 2.5 hours after the parenteral injection of antigen (Fig. 106-2).[24] After oral administration, manifestations occur at unpredictable times. True anaphylaxis requires immune-mediated release of some or all of the above vasoactive mediators. In contrast, other mechanisms can liberate the vasoactive substances that produce this clinical syndrome. Patients with anaphylactic or anaphylactoid reactions may manifest some or all of the signs and symptoms described in the following sections.[24,25]

FIGURE 106-2 Interval between exposure and reaction to the allergen in 43 cases of anaphylactic death. ***(Adapted with permission from Delage and Irey.[35])***

RESPIRATORY SYSTEM

Awake patients may complain of nasal stuffiness or itching, difficulty in breathing, or retrosternal tightness. Coughing, wheezing, tachypnea, laryngeal stridor, and cyanosis are other manifestations, as are acute respiratory distress and pharyngeal, epiglottic, or glottic edema. Respiratory symptoms under anesthesia occur but represented 75% of mortality rate in one series.[25a]

CARDIOVASCULAR SYSTEM

Conscious patients may complain of dizziness. They may also complain of chest tightness, sometimes due to myocardial ischemia. Electrocardiographic changes can vary from tachyarrhythmias and nonspecific changes of the ST segment or T wave, to ventricular fibrillation, electromechanical dissociation, and asystole. In anesthetized patients, hypotension, tachycardia, and cardiovascular collapse are the hallmarks of these reactions.

SKIN

Complaints range from itching, warmth, and minor swelling of the face or an extremity to itching of the eyes and nonpitting deep edema in the cutaneous tissue. Patients may manifest the characteristic urticaria or flare of histamine release. However, cutaneous manifestations alone may not be a harbinger of more severe reactions. The myorelaxant atracurium, known to stimulate histamine release, causes a skin rash in about 33% of patients. Antihistamines completely abolish the skin rash. However, the cutaneous manifestation is independent of hemodynamic effects or plasma histamine levels. Thus, the risk-benefit relation of discontinuing the use of a drug that induces a rash should be considered if that drug represents a needed therapy.[26] Conversely, even in severe reactions, cutaneous manifestations may not be present in many instances.

Other Manifestations

Perhaps most impressive in the awake patient is the expression of a sense of doom. Most conscious patients experiencing an anaphylactic or anaphylactoid reaction who were attended by the authors said something like "I feel horrible" or "I'm going to die" before any hemodynamic or pulmonary symptoms or signs were evident.

An anaphylactic or anaphylactoid reaction may involve any combination of these symptoms; however, the sine qua non of anaphylaxis is severe cardiovascular or respiratory compromise. Because this reaction includes vasodilation and translocation of fluid from capillaries and postcapillary venules (resulting in loss of fluid and colloid from intravascular spaces), there is a reduction in effective plasma volume and systemic vascular resistance followed by shock. Thus, fluid resuscitation is a first priority in treating this syndrome.

The most severe life-threatening reactions result from laryngeal edema, bronchospasm, and vascular collapse, which are probably end-organ responses to the release of vasoactive substances. The full variety of vasoactive mediators of anaphylactic and anaphylactoid reactions is not known. However, an understanding of the known pharmacologic mediators responsible for the clinical manifestations provides a rationale for therapy of anaphylaxis.

Mediators of Anaphylactic Reactions

HISTAMINE

Histamine is a low-molecular-weight amine that is stored predominantly in tissue mast cells and circulating basophils. It dilates capillaries and venules and promotes vascular permeability. Its actions on the histamine H_1 and H_2 receptors are thought to be responsible for decreased systemic vascular resistance and increased permeability in venules.[27] Through H_1-mediated effects on vascular smooth muscle, histamine is also a potent coronary vasoconstrictor.[28] Vascular responses of vasodilation and local cutaneous reactions (wheal and flare) are mediated by H_1 and H_2 receptors. H_2 receptors mimic β-adrenergic receptors in molecular biology function and role, and mediate chronotropic responses. Histamine has a complex array of effects on the vasculature, depending on the presence or absence of vascular endothelium. It is important to note that histamine is a potent constrictor if the endothelium is damaged.

EOSINOPHILIC CHEMOTACTIC FACTOR OF ANAPHYLAXIS

ECF-A, an acidic peptide with a molecular weight of 500 to 600, is stored in mast cell granules. It is chemotactic for eosinophils. The exact role of the eosinophil in the allergic response is unclear. During phagocytosis, eosinophils release histaminase, phospholipase D, and arylsulfatase, enzymes that can inactivate histamine and SRS-A.

PLATELET ACTIVATING FACTOR

PAF, acetyl glyceryl ether phosphorylcholine, causes platelet aggregation and bronchoconstriction, increases vascular permeability, and modulates leukocyte function.

LEUKOTRIENES

Leukotrienes are synthesized in response to antigens and are not stored intracellularly. Products of the oxidative metabolism of arachidonic acid through the lipooxygenase pathway, leukotrienes were once known as SRS-A (leukotrienes C_4, D_4, and E_4).[29] End-organ effects include potent constriction of bronchial smooth muscle. On a molar basis, leukotrienes are 4000 times more potent than histamine in causing bronchoconstriction in normal human beings. Other systemic effects of leukotrienes include cutaneous inflammation, chemotaxis of polymorphonuclear leukocytes, and promotion of lysosomal enzyme release from leukocytes.

PROSTAGLANDINS

Prostaglandins are unsaturated fatty acids that are synthesized at the time of the inflammatory stimulus. Like leukotrienes, they are products of the metabolism of arachidonic acid, but through the cyclooxygenase pathway. Their biologic activities are specific to the target organ on which they act. Prostaglandins are potent mediators of the inflammatory response and can increase capillary permeability and result in bronchospasm, pulmonary hypertension, and peripheral vasodilation.

KININS

Kinins are low-molecular-weight peptides that enhance capillary permeability, dilate certain blood vessels, contract certain smooth muscles, and are perhaps leukotactic. Bradykinin is a potent stimulus for the release of nitric oxide from vascular endothelium. Several processes independent of IgE can generate kinins.

Mediators of Anaphylactoid Reactions

There are multiple processes by which biologically active mediators can be generated to produce an anaphylactoid reaction.

Histamine, and to a lesser extent other vasoactive mediators described above, can be liberated independently of immune reactions to produce an almost identical clinical syndrome. Mast cells (usually derived from connective tissue) and basophils release histamine in response to chemicals or drugs.[30] Activation of the blood coagulation and fibrinolytic systems, the kinin-generating sequence, or the complement cascade can produce the same inflammatory substances as are produced in an anaphylactic reaction (see Fig. 106-1).

When given rapidly in large doses, morphine and meperidine can cause histamine release,[31] resulting in an anaphylactoid reaction. Such large doses are rarely administered fast enough to cause histamine release except when given to induce anesthesia. Sedative doses of opioids or slowly administered anesthetic doses usually do not cause the release of appreciable quantities of histamine. Radiographic contrast medium, *d*-tubocurarine, and vancomycin can also trigger histamine liberation and produce anaphylactoid reactions.[32] Interestingly, small variations in molecular structure can markedly alter histamine-releasing potential. Cisatracurium, the R-cis,R'-cis isomer of atracurium, is one of 10 isomers present in the commercial form of atracurium. It is only one-eighth as likely to cause histamine release as is the mixture.

However, the actual mechanisms for non–immune-mediated histamine release are not completely understood. Why some patients are prone to histamine release in response to drugs is unknown.

Common Causes of Anaphylactic and Anaphylactoid Reactions in the Critical Care or Operating Room Environment

NEUROMUSCULAR BLOCKING AGENTS

Neuromuscular blocking agents are responsible for up to 70% of anaphylactic reactions during general anesthesia.[33] In France in 1996, the incidence of anaphylaxis was estimated at 1 in 6500 anesthetics involving a muscle relaxant[9] and occurred whether or not the agents cause chemically mediated reactions. In most series, succinylcholine appears to be most frequently involved, although variations in practice patterns account for some differences. In the most recent French series, rocuronium, a steroidal relaxant devoid of chemically mediated histamine release, was the primary drug responsible for reactions.[10] Because the main antigenic determinants in the generation of specific IgE antibodies are substituted ammonium ions,[34] an 80% cross-reactivity between the different muscle relaxants is observed by skin tests. Cross-reactivity explains why many patients may exhibit allergic symptoms on first exposure to a neuromuscular blocking agent.[35] Details for skin testing of these agents are included in a recent article by Laxenaire et al[10] (Fig. 106-3).

ANTIBIOTICS

Although allergic reactions to β lactams are the most common cause of anaphylactic reactions in the population at large, they occur far less frequently in the operating room (12% of events). These reactions, classifiable as immediate or nonimmediate, can be produced by the four classes of β lactams (penicillins, cephalosporins, carbapenems, and monobactams), which share a common β-lactam ring structure. Cross-reactivity among cephalosporins and between cephalosporins and penicillins can occur.[36]

Immediate reactions (type I or mediated by IgE), usually within the first hour after drug administration, are characterized by diffuse erythema, pruritus, urticaria, angioedema, rhinitis, bronchospasm, hyperperistalsis, hypotension, cardiac arrhythmias, and anaphylactic shock alone or in combination. Anaphylaxis occurs in about 0.004% to 0.015% of penicillin[37] and 0.001% to 0.1% of cephalosporin[36] treatments. The fatality rate from shock after administration of penicillin is 0.0015% to 0.002%. Despite the fact that penicillin-induced anaphylaxis is rare, this drug remains the most common cause of anaphylaxis in human beings, accounting for approximately 75% of anaphylactic deaths in the United States each year.[38,39]

In many cases, a detailed history of a patient's reaction to penicillin may allow clinicians to exclude true penicillin allergy, thus allowing these patients to receive the drug.[40] Skin tests are the quickest and most reliable method for demonstrating the presence of β-lactam–specific IgE antibodies. Using the suspected β lactams themselves (in particular cephalosporins) in addition to penicillin major and minor determinants as test agents is highly desirable. Patients with a compelling history of type I penicillin allergy who require penicillin should undergo skin testing. Those with a negative skin test result can take penicillin without serious sequelae.[41] Only 10% to 20% of patients reporting a history of penicillin allergy are truly allergic when skin testing is performed. Conversely, many patients with positive skin tests have only vague penicillin allergy histories.[42]

Although serum-specific IgE assays can be used as complementary tests, negative test results should be interpreted in light of the time elapsed from the last exposure to the suspected β lactam because in vivo and in vitro test sensitivity decreases over time. In some diagnostic workups, patients with a strong history of type I β-lactam allergy and negative skin and in vitro tests undergo a controlled administration of the suspected β lactam.[41]

Strategies for dealing with penicillin-allergic patients are evolving and are institution specific. Patients who are allergic to penicillin have been reported to have a 5% to 30% incidence of cross-reactivity to cephalosporins. The recent trend in the United States is to use cephalosporins without a convincing history of penicillin allergy[36,41] because alternative antibiotics can cause severe anaphylactoid reactions. For example, chemically mediated red-man syndrome manifested as hypotension and flushing[3,43] occurs with rapid vancomycin administration.[44]

HYPNOTICS

The incidence of anaphylactoid reactions with thiopental is estimated to be 1 in 30,000.[33] Most of the generalized reactions are linked to direct leukocyte histamine release.

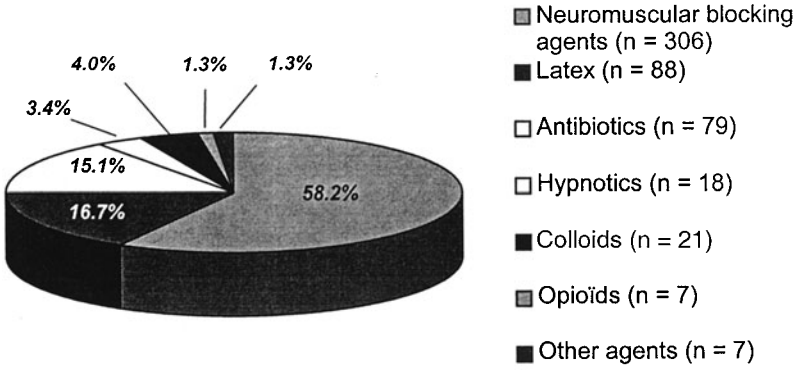

FIGURE 106-3 Agents involved in anaphylactic reactions observed during anesthesia in France between January 1, 1999 and December 31, 2000 (526 reactions). ***(Reproduced with permission from Mertes et al.[73])***

However, there is evidence for IgE-mediated anaphylactic reactions based on skin tests and specific IgE assay.[45]

Ever since Cremophor EL has been discontinued as a solvent for some non-barbiturate hypnotics, many previously reported anaphylactoid reactions have disappeared. Although less frequent, anaphylaxis to all induction agents has been observed.[46,47] However, in recent studies, induction agents caused only 3.7% of all anaphylactic cases during anesthesia.[10]

OPIOIDS

Although patients often relate anaphylactic reactions to opiates, immunologically mediated reactions to morphine, codeine phosphate, meperidine, fentanyl and its derivatives are quite rare, occurring only once in 100,000 to 200,000 anesthetics.[33] Because of the direct histamine-releasing properties and frequent non–histamine-related cutaneous manifestations, there is significant over-reporting of allergy to opiates. Most opioids (with the possible exception of the fentanyl family) may cause direct release of histamine, urticaria along the vein of administration, and vasodilation. Bronchospasm and angioedema have not been reported, even when large doses of these agents were used for anesthesia before cardiac procedures.[48] Codeine has been implicated in several cases of anaphylactoid reactions, but in all of the reported instances, more than one drug was used simultaneously. An anaphylactoid reaction to morphine and an inordinate sensitivity to histamine release have been reported, but skin testing in this patient produced negative results.[49]

Radiocontrast Medium

Anaphylactoid reactions during infusion of radiocontrast material occur in 1% to 2% of procedures.[50] Although the mechanism of such reactions remains unknown, anaphylactic treatment may diminish them. When repeated infusions of radiocontrast materials were given to patients with a history of an immediate anaphylactoid reaction to them, the incidence of repeat reactions was 17% to 35%. Pretreatment with prednisone, diphenhydramine, and ephedrine significantly decreased repeat reactions in these at-risk patients. Steroid pretreatment should be given at least 12 hours before administration of the contrast agent.

Local Anesthetics

True allergy to the para-aminobenzoic ester agents, such as procaine, is well documented, but documented allergic reactions to the amide local anesthetics are rare.[51] Methylparaben, a derivative of para-aminobenzoic acid and a preservative used in many multidose vials of local anesthetics, may well be the offending agent in anaphylactic reactions. With a true allergy to one amide local anesthetic agent, a potential for cross-reactivity exists. Although skin testing is used to identify safe local anesthetic agents, there is no support for applying this technique to humans. Clinical history appears to be a good discriminator. Most "reactions" in the dental chair appear to result from anxiety or epinephrine responses. For example, in a series of 71 patients who gave a history of possible allergic reaction to local anesthetics, only 15% had had history of clinical manifestations of a hypersensitivity response (i.e., urticaria, wheezing, or facial swelling).[52]

TABLE 106-1 Incidence of Anaphylactoid Reactions to Colloid Volume Expanders

Colloid	Incidence (%)
Plasma protein	
Plasma protein derivative	0.019
Human serum albumin	0.011
Dextran	
Dextran 60/75	0.069
Dextran 40	0.007

Volume Expanders

COLLOID

Anaphylactoid reactions to the clinically used colloids have been studied extensively in Europe (Table 106-1).[53,54] Because of kinin contaminants, the purified protein fractions are associated with a higher incidence of reactions than are other colloids. The complex polysaccharides can activate the complement system. These reactions do not depend on prior sensitization. The reported incidence of anaphylactoid reactions after purified protein fractions varies from 0.007% to 0.085%.

BLOOD PRODUCTS

Transfusion reactions can be classified as hemolytic or nonhemolytic. Hemolytic reactions result from ABO-antigen–incompatible transfusions in which IgG or IgM antibodies from the donor or recipient react with red blood cells, complement is fixed and activated, cells are destroyed, and complement anaphylatoxins are released.[55] Urticaria, hypotension, and bronchospasm may accompany activation of the clotting cascade. In a sedated and/or paralyzed patient, bleeding or severe hypotension may be the only sign of a transfusion reaction. The most common allergic reactions to transfusions are nonhemolytic, febrile reactions from leukoagglutinins. Unlike red blood cells, leukocytes and platelets contain HLA antigens of the human histocompatibility system. Antibodies of the IgG or IgM class to these antigens are known as *leukoagglutinins*. The precise relation of leukoagglutinins to anaphylactoid reactions remains unclear. Transfusion-related acute lung injury is produced by leukoagglutinin reactions.[3] Patients who lack serum IgA will generate antibodies to IgA and may have a severe anaphylactoid reaction with transfusion of IgA-replete normal blood.[56] In most cases of transfusion reaction, the magnitude of cell lysis, hypotension, bronchospasm, and increased capillary permeability probably relates directly to the rate and extent of complement activation.

PROTAMINE

Many case reports and studies have provided evidence that protamine reversal of the effects of heparin can cause a severe, life-threatening reaction with generation of anaphylatoxins (C5a) and thromboxane.[57] Multiple mechanisms

have been implicated in protamine reactions, including mechanisms that are immune mediated, mechanisms that are mediated otherwise, and mechanisms that combine immune-mediated and vasoactive-mediated reactions when vasoactive substances are displaced by protamine. Because protamine is a histone derived from salmon sperm, antigenic crossover with fish allergy is possible. Diabetics who have received protamine zinc insulin (25 U contains 0.7 mg protamine) appear to have an increased incidence of this reaction and of antibodies to protamine.[57,58] More than one mechanism may be involved; production of C5a anaphylatoxins by any mechanism generates thromboxane A_2, which causes pulmonary vasoconstriction, bronchoconstriction, and systemic hypotension. Substitutes for heparin and protamine are being developed, so that patients with known risk factors will be able to undergo safe cardiopulmonary bypass. Until then, dose modification, the use of hexadimethrine (Polybrene) for heparin reversal (obtained by an investigational drug request from the Food and Drug Administration) or ancrod for "anticoagulation" remain options.

LATEX

Allergy to latex has been increasingly recognized as an important cause of allergy in anesthesia and critical care.[59] Although latex allergy was first described in urologic patients in 1983, the role of latex as an allergen in the perioperative period was not described until 1988. Latex allergy currently represents 12% of life-threatening events, according to one recent French study.[60] This true allergy should be distinguished from the cutaneous reactions to the products of vulcanization. It is important to note that, in the same study population, latex allergy was largely unreported in a previous 5-year period. Approximately 1% of the general population has the IgE antibody to latex (vs. 8% of surgeons or nurses), but it is unclear whether the increase in latex allergy is related to the more widespread use of latex since the epidemic of acquired immunodeficiency syndrome or to prior lack of recognition of the allergy.[61–63] Clearly, some instances of allergy attributed to drugs were latex allergies. The first documented case of fentanyl allergy was reexamined and found to be an allergy to latex.[64]

Because of the ubiquity of latex in the operating room and intensive care units, allergies to latex are frequently difficult to distinguish from allergies to drugs. Epidemiologic studies report that patients with multiple latex exposures and a history of atopy are at particular risk. In a population of children with meningomyelocele and other midline disorders, antibodies to latex were detected in more than 35%. In the operative setting, this allergy typically occurs some 30 minutes after induction and is characterized by cutaneous, respiratory, and hemodynamic disturbances. This timing distinguishes latex allergy from reaction to induction agents. Diagnosis of this disorder can be made by radioallergosorbent test or enzyme-linked immunosorbent assay, with approximately 90% sensitivity and with specificity ranging from 60% to 90%.

Protocols for the management of patients with known or suspected latex allergy have been developed, but they are frequently difficult to carry out in the critically ill patient. Aside from the use of nonlatex gloves, masks, and catheters, exceptional vigilance must be paid to percutaneous and inhalational sources of latex.[65] In addition, cross-reactivity with ethylene oxide, often used to sterilize instruments, has been reported.

Anaphylaxis: Prevention, Recognition, and Treatment

There seems to be good evidence that preoperative preparation and physician training can decrease morbidity and mortality rates from anaphylaxis. The French Society of Anesthesiologists has suggested a comprehensive strategy for such preoperative evaluations.[33] An aggressive preoperative evaluation to identify patients at risk for latex allergy significantly decreased the frequency of these reactions in France. An allergic history is important, particularly for latex allergy.

The introduction of chymopapain into the armamentarium for treating herniated nucleus pulposus was highly instructive about prophylaxis and treatment of anaphylactic reactions. Before the introduction of IgE screening, a relatively high incidence (0.3% to 2%) of anaphylactic reactions was associated with chymopapain administration. Although now infrequently used, its introduction prompted a new prospective study of anaphylaxis. From the release of chymopapain by the Food and Drug Administration in November 1982 until September 1983, the incidence of anaphylactic reactions was similar to that in the phase II trial (i.e., approximately 0.4% in men and 1.3% in women for the first 30,000 patients treated).[66] Then the incidence decreased significantly (to 0.25% in men and 0.7% in women). The mortality rate from chymopapain anaphylaxis also decreased from 2 of 13 to 3 of 252. We believe that improved survival rate is attributable to awareness of the pathophysiology of such reactions, vigilance during administration of the drug, and pretreatment of the patient with H_1 and H_2 antihistamines. *Although prophylactic administration of antihistamines did not significantly decrease the overall rate of anaphylaxis, it significantly decreased mortality rate attributable to anaphylactic reactions.* Alternatively, increased physician awareness and treatment of anaphylaxis may be a significant factor in the decrease in mortality rates.

A subject of some interest is whether the patient with an atopic history is at special risk. It now appears that a history of generalized allergy does not predispose to anaphylactoid or anaphylactic reaction in the perioperative period. Thus, limiting histamine-releasing drugs in this population does not seem justified by current evidence. Populations at risk appear to be better categorized by concurrent illness. Older patients or those with myocardial ischemia present a special problem. They are at greater risk of complications than are other patients from pretreatment (especially vigorous hydration and steroid administration) and therapy for anaphylactic reactions. The possibility of triggering anaphylactic or anaphylactoid reactions in this group should be weighed against the clinical advantage of these drugs.

Aside from preoperative assessments, pretreatment with antihistamines remains an option for patients at risk. One might consider giving patients H_1- and H_2-receptor antagonists for 16 to 24 hours before exposure to a suspected allergen or agent known to cause histamine release. Some experts argue that large doses of steroids (2 g hydrocortisone) should also be administered to women before exposure to agents associated with a high incidence of anaphylactic or anaphylactoid reactions.[67]

The treatment plan for an anaphylactic or anaphylactoid reaction should be reviewed with other physicians and nurses caring for the patient, and, if anticipated, specific tasks should be assigned in advance (e.g., who starts the second

TABLE 106-2 Possible Therapy for a 70-kg Individual in the Event of an Anaphylactic or Anaphylactoid Reaction

A.	Pretreatment
	1. Consider desensitization
	2. Administer 50 mg diphenhydramine q 6 h for 24 h, and either 300 mg cimetidine q 6 h for 24 h, or 150 mg ranitidine q 9–12 h for 24 h; and 2 g hydrocortisone IV 1–6 h before anticipated exposure
	3. Establish large-bore IV line and prehydrate patient with maintenance fluid plus perhaps an additional 500 mL
B.	Plan for the worst and assign tasks in advance (e.g., who starts extra IV line, who turns patient, who gets crash cart, who draws blood for blood gas measurement)
C.	Initial therapy
	1. Stop administration of allergen
	2. Maintain airway with 100% O_2
	3. Stop negative inotropic and vasodilating agents
	4. Expand blood volume
	5. If indicated, administer 0.05–0.1 mg epinephrine (0.5–1 mL of 1:10,000 solution) q 1–5 min up to a total of 1–2 mg over 1 h or more often, if needed
D.	Secondary therapy (if indicated)
	1. Administer antihistamines (50 mg diphenhydramine, 300 mg cimetidine)
	2. Administer inhaled β_2-adrenergic agents for bronchospasm
	3. Administer drip infusion of catecholamines
	4. Administer steroids (2 g hydrocortisone IV)
E.	Evaluate airway for edema before extubating the trachea

ABBREVIATIONS: IV, intravenous; q, every.

intravenous infusion, who turns the patient supine). The fact that the chance of a serious reaction is slight does not justify lack of planning. If the worst is routinely expected and planned for, the rate of adverse outcomes of anaphylactic and anaphylactoid reactions is likely to decrease.

Although various drugs are used to treat anaphylactic and anaphylactoid reactions, discontinuation of the offending drug, maintenance of the airway, administration of oxygen, blood volume expansion, and administration of epinephrine are the mainstays of therapy (Table 106-2). These procedures are necessary to treat the sudden hypotension and hypoxia that result from vasodilation, increased capillary permeability, and bronchospasm. Establishing a plan beforehand for the successful therapy for these reactions will diminish the risk of unfavorable outcomes. Although a dogmatic treatment protocol is not warranted by the data, data are consistent enough to justify a proposed treatment protocol. Anaphylactic and anaphylactoid reactions are triggered by different mechanisms, but the mediators released and the treatment for these severe reactions are indistinguishable.

Identifying the Agent Involved

Testing for allergic reactions and the diagnosis of allergic disorders begins with a symptom history and physical examination, although many individuals will deny prior exposure. Thus, 20% of patients with allergies to neuromuscular blockers have not received these drugs previously. In addition, a time frame for reaction after the injection of the incriminated drug is very helpful. In chymopapain allergy, 90% of reactions were manifest within 10 minutes on the day of administration. When more than one drug has been injected or absorbed over a short period, a diagnostic strategy based on laboratory tests on samples taken during and shortly after the reaction and on tests carried out days to weeks later may be helpful. Early tests are mainly designed to determine whether or not an allergic mechanism is involved, whereas delayed testing attempts to identify the responsible drug.

TRYPTASE

Tryptase levels acquired during or immediately after a reaction can be helpful in determining whether the reaction is immunologically mediated. Mast cells activated during an IgE-mediated hypersensitivity reaction release proteases such as tryptase and prestored histamine and newly generated vasoactive mediators. Because tryptase content in basophils is 300- to 700-fold less than in mast cells in humans, tryptase levels in serum are a marker for systemic mast cell activation. Although it can be marginally elevated in different situations,[68] an elevated serum tryptase concentration above 25 μg/L strongly suggests an anaphylactic mechanism.[69,70]

Although a negative tryptase test does not completely rule out anaphylaxis, a 2-year survey of anaphylactoid reaction during anesthesia conducted in France between 1999 and 2000 confirmed its utility in clinical practice. There has been the suggestion that tryptase can distinguish between anaphylactic and anaphylactoid reactions, based on the observation that rapid infusion of vancomycin leads to a 40-fold increase in histamine levels without a change in tryptase.[71] The elevated histamine levels persist even when patients are pretreated with oral or intravenous H_1/H_2 antagonists, although the accompanying hypotension is attenuated, confirming the vancomycin reaction as chemically mediated.[72] A contrasting view emerged from a study demonstrating that pharmacologic concentrations of vancomycin can release histamine in isolated mast cell preparations. The most recent epidemiologic evidence demonstrates that an elevated tryptase is a reliable, although imperfect, sign of an immunologic reaction (Fig. 106-4).

The sensitivity of tryptase measurements for the diagnosis of anaphylaxis was estimated at 64%, the specificity at 89.3%, the positive predictive value at 92.6%, and the negative predictive value at 54.3%.[73] Peak serum tryptase levels are found between 30 and 60 minutes, and optimum sampling is 1 hour after the start of the reaction. The biological half-life of tryptase is estimated at 2 hours; therefore, increased levels can sometimes be detected for 1 to 6 hours or longer after the onset of anaphylaxis. Increased tryptase levels in sera after death suggest systemic anaphylaxis as a cause of death.[74]

Skin Testing

Skin testing is one of the most frequently used primary confirmatory tests for allergen-specific IgE antibody in the diagnosis of human allergic disease, although its reliability somewhat depends on which class of drug is being tested.

Application of an allergen extract to the skin may be accomplished through a prick puncture or an intradermal injection. Control tests using saline (negative control) and codeine or histamine (positive control) must accompany skin tests to determine whether or not the skin is able to release histamine and react to it. In the prick test, allergen is introduced into the epidermis by means of a puncture. The immediate reaction (wheal and erythema) is read at 15 to 20 minutes. A prick test is considered positive when the diameter of the wheal is at

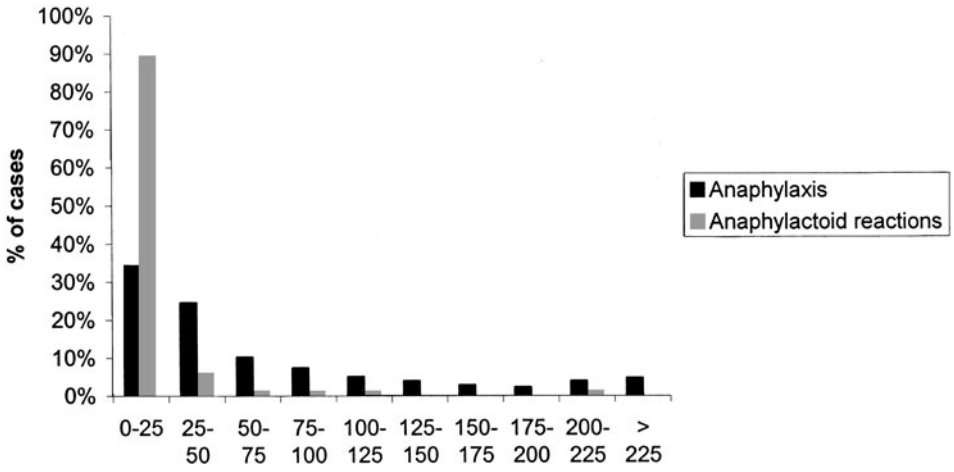

FIGURE 106-4 Tryptase levels for anaphylactic and anaphylactoid reactions. The percentage of cases that are of anaphylactic or anaphylactoid origin is presented at a predefined tryptase level. At levels lower than 25 μg/mL, both types of reactions can occur, but anaphylactoid reactions predominate. For patients exhibiting levels higher than 25 μg/mL, the etiology is far more likely to be anaphylactic.

least equal to half of that produced by the positive control and at least 3 mm larger than the negative control. Alternatively, allergen (0.01 to 0.05 mL) can be administered intracutaneously through a 26- to 27-gauge needle. In a skin test titration, the same volume of 10-fold serial dilutions of an allergen extract is injected. The objective of skin test titration is to determine the concentration of an extract that produces a wheal or erythema of a defined diameter (e.g., diameter of the wheal is at least twice that of the injection wheal).

Several factors may contribute to the variability of skin test results, including the individual's biologic responsiveness, the technique used to perform the test, the reagents (stability, vehicle, allergen concentration, and purity), and the method used to evaluate skin reactions. Despite the problems of possible false-positive and false-negative results, prick tests in case of suspected latex allergy and prick and intradermal tests in case of drug allergy are advised.[33,75] Recent guidelines concerning the maximal concentration to be used during skin testing for the diagnosis of anaphylaxis during anesthesia have been reported.[10] Although some controversy on the validity of skin test persists, the development of such standardized diagnostic protocols should facilitate interpretation.

Radioallergosorbent Test

Allergen-specific IgE antibody is also an important confirmatory test in the diagnosis of type 1 hypersensitivity reactions. The radioallergosorbent test was the first assay reported for the detection of allergen-specific IgE antibodies. This assay is a noncompetitive solid phase immunoradiometric assay. The allergosorbent assay is prepared by covalently coupling allergen onto cyanogen bromide-activated cellulose disks that are then incubated with the patient's serum. The amount of bound immunospecific IgE is determined by incubation with radioiodinated antihuman IgE Fc. Bound radioactivity is proportional to the amount of allergen-specific IgE in the initial patient's serum and is compared with an IgE antibody reference serum. This early allergen-specific IgE antibody assay was followed by second-generation assays with new matrix materials such as the cellulose sponge used in the Pharmacia CAP system, various polyclonal and monoclonal anti-IgE detection antibody combinations, and non-isotopic labels. Automation has improved assay precision and reproducibility.

Despite promising results as in the case of sensitization to neuromuscular blocking agents,[76–78] when maximal clinical sensitivity is needed, as in the case of drug allergies, intradermal skin tests are preferred. IgE antibody serologic results are viewed as complementary to skin tests.[76]

In Vivo Provocation

In rare instances, in vivo provocation tests may be performed to confirm the identity of an allergen that may be clinically necessary. These tests place the patient at some risk for a reaction because they involve a direct allergen challenge. Therefore, their indication will ultimately depend on whether one can identify a substitute therapy for the putative allergen.

If a patient must receive a drug that is likely to trigger an anaphylactic or anaphylactoid reaction, several steps should be taken. First, an allergist should be consulted. Second, repeated injections of small amounts of antigen or offending hapten may be given because this procedure decreases the amount of specific IgE antibody produced and may stimulate T-suppressor cells. At the same time, this procedure usually increases the amount of competitive IgG antibody (i.e., blocking antibody). Blocking antibody can compete with IgE for receptors on the surface of basophils and mast cells to decrease the mediators released from these cells. Third, small amounts of drug are injected, for example, 5 mg of lidocaine intravenously. This "test dose" hypothesis is verified by the chymopapain experience. Fourth, these tests are done in the post-anesthesia care unit or other setting where resuscitation equipment is available.

Treatment and Initial Therapy

1. Discontinue suspected allergen. This step prevents further recruitment of mast cells and release of mediators.
2. Maintain airway and administer 100% oxygen. Bronchospasm, pulmonary hypertension, and pulmonary capillary leakage may cause severe mismatching of ventilation and perfusion.[79] These changes can persist for several hours during anaphylactic reactions, producing hypoxemia. Therefore, the airway should be maintained, and supplemental oxygen (we recommend 100% oxygen)

should be administered until the situation improves. Intubation of the trachea should be considered, if it has not already been done.

3. Discontinue all sedative, vasodepressing agents. Agents that may have negative inotropic properties or that may decrease systemic vascular resistance should be discontinued because they may contribute to decreased vascular compensation and often interfere with the body's compensatory response to cardiovascular problems. Thus, we believe that these agents should be discontinued to avoid hypotension.
4. Expand blood volume. Because up to 40% of intravascular volume is rapidly lost into the interstitial spaces in an acute anaphylactic reaction during anesthesia,[80] effective therapy consists of rapid replacement of blood volume.[81] Rapid fluid loss and successful treatment with fluid replacement have been documented in the case of an anaphylactic reaction observed incidentally by transesophageal echocardiography.[82] Evidence does not indicate that colloid is more effective than crystalloid. Rapid administration of 1 to 2 L of lactated Ringer's solution or normal saline is important in the initial therapy for these reactions. Further blood volume expansion may be necessary, if hypotension persists.
5. Administer epinephrine. Epinephrine is a mainstay of therapy in acute anaphylaxis for several reasons. Its α_1-adrenergic effects make it useful for treating hypotension. Its β_2-adrenergic effects inhibit bronchoconstriction and the release of mediators from stimulated mast cells or basophils by stimulating the production of intracellular cyclic adenosine monophosphate.[83] For hypotension, 0.05 to 0.1 mg of epinephrine (0.5 to 1 mL of a 1:10,000 solution) should be given initially as an intravenous bolus and repeated every 1 to 5 minutes up to 0.015 mg/kg (or 10 mL of a 1:10,000 solution) for a 70-kg patient, as needed. In cardiac arrest or with a total loss of blood pressure or pulse, full cardiopulmonary resuscitative doses of epinephrine are indicated (0.01 mg/kg, not to exceed 1.0 mg total) in addition to rapid volume expansion. Larger, even massively larger, doses have been needed when titrated to effect, but we do not recommend them as initial doses, because hypertension and tachycardia resulting in myocardial cell death have been reported in such situations. Intramuscular or subcutaneous administration of epinephrine may be unreliable in a hypotensive patient who requires immediate therapy. Interactions with propranolol are possible, and care must be taken not to overdose the patient with epinephrine to the point of severe hypertension (unopposed α-adrenergic effects) and its consequence. Overdose can occur in the absence of propranolol. The major threat from chronic β-adrenergic blockade appears to be that responses to epinephrine may be insufficient to terminate the reaction, and increased doses of epinephrine may be required.[84] We believe that any amount of epinephrine is appropriate when titrated to effect; the doses indicated above provide a starting point.

Secondary Treatment

If the above treatment does not resolve symptoms and signs, additional treatment with antihistamines, aminophylline, catecholamines, corticosteroids, calcium, and endotracheal intubation may be indicated.

ANTIHISTAMINES

Histamine is one of the major mediators of the acute manifestations of anaphylactic and anaphylactoid reactions. Because the vasodilatory effects are mediated by H_1 and H_2 receptors, both types of receptor site must be blocked if all potentially harmful cardiovascular effects of histamine are to be antagonized. Studies in which patients were pretreated before histamine release demonstrate that adverse cardiopulmonary responses can be blunted or prevented when H_1- and H_2-receptor antagonists are used.[85] Although histamine is only one of the mediators released in anaphylactic and anaphylactoid reactions, it may account for many of the initial adverse manifestations. No clinical evidence indicates that administration of antihistamines is effective in treating anaphylaxis once mediators have been released. Administration of antihistamines is therefore recommended only as secondary treatment in acute reactions. (Suggested doses are 1 mg/kg diphenhydramine or 0.1 mg/kg chlorpheniramine as the H_1 blocker and 4 mg/kg cimetidine as the H_2 blocker.)

CATECHOLAMINES

INHALED β_2 AGONIST

If bronchospasm persists (and hemodynamic function is stable), terbutaline or albuterol may be administered as a bronchodilator.

INTRAVENOUS ISOPROTERENOL

If bronchospasm persists, isoproterenol may be useful as a pure β-adrenergic agonist and bronchodilator. This drug may also prove useful when combined with epinephrine in the patient taking β-adrenergic receptor blocking drugs. The β_2-adrenergic effects of isoproterenol cause vasodilation and possible hypotension, especially in patients already experiencing vasodilation or depletion of blood volume. Tachycardia is another possible unwanted effect. Because isoproterenol dilates the pulmonary artery, it may be useful for treating the increased pulmonary vascular resistance of severe anaphylactic reactions when oxygenation is a problem or right ventricular dysfunction occurs (but see Chap. 26 for cautions in this regard). (Starting doses for persistent bronchospasm are 0.5 to 1 μg/min per 70 kg.)

INTRAVENOUS EPINEPHRINE

When hypotension and bronchospasm persist, an intravenous epinephrine drip may be given after blood volume has been expanded and epinephrine boluses have been administered. The starting dose of epinephrine is 1 to 2 μg/min per 70 kg and should be titrated to the desired effect.

INTRAVENOUS NOREPINEPHRINE (LEVOPHED)

Blood pressure can be maintained in a hypotensive patient with norepinephrine until adequate volume expansion has been achieved. Although α-adrenergic drugs may theoretically potentiate the release of mediators, hypotension is deleterious to cerebral and coronary perfusions and must be treated aggressively.

STEROIDS

Corticosteroids should be given in severe reactions, such as shock with refractory bronchospasm and hypotension; there is no evidence to suggest an appropriate dose or preparation.[68,86] We believe 2 g of hydrocortisone phosphate (or its equivalent) is appropriate for severe cardiopulmonary dysfunction. Large doses of methylprednisolone (35 mg/kg) have been shown to inhibit complement-induced polymorphonuclear cell aggregation and lysosomal enzyme release in vitro. Corticosteroids may decrease release of vasoactive mediators and metabolites of arachidonic acid in anaphylaxis by stabilizing membrane phospholipids or by generating macrocortin, which inhibits phospholipid turnover.

AIRWAY EVALUATION

If laryngeal edema occurs in anaphylactic reactions, swelling can persist.[87] In such instances, the larynx can be examined on extubation.

CALCIUM

Because release of mediators is a calcium-dependent process, theory and experimental evidence indicate that administration of calcium may worsen an anaphylactic condition.[88]

Other Immunologic Considerations

Further study is necessary to confirm the effects of trauma and sedative-hypnotics on immunity and the mechanism of this alteration. For now, we know that the perioperative period interferes with innate immunity (e.g., by mucous and skin membrane transgressions), but the effect of alteration of acquired immunity is not clear.

Follow-up

An integral part of therapy is to communicate effectively to patients when an agent is responsible for a true allergic event, and to identify the responsible agent. Although anaphylactic reactions in the perioperative period remain uncommon, there has been a significant tendency to attribute perioperative hemodynamic and respiratory compromises to an anaphylactic origin without appropriate testing. *In our preoperative clinics, there is a 200-fold over-reporting by patients of anaphylaxis to opiates or local anesthetics*. It is important, medicolegally and for patient safety reasons, that patients be fully aware which agents are implicated.

Chapter 107

DERMATOLOGIC CONDITIONS

MARIO E. LACOUTURE
MICHAEL JUDE WELSCH
ANNE E. LAUMANN

KEY POINTS

- *In a patient with a dermatologic condition, observation and description of the lesions (morphology, distribution, and texture) are important for developing a differential diagnosis.*
- *Mucous membranes (oral, ocular, nasal, genital, and perianal) should be examined in all patients.*
- *The skin may provide clues to an underlying, life-threatening condition, such as endocarditis, graft-versus-host disease, bacterial sepsis, toxic shock syndrome, systemic vasculitis, or complications from the human immunodeficiency virus.*
- *Drug-related dermatoses are prevalent in the intensive care unit. Clues to diagnosis include a rapidly developing eruption; generalized, symmetrical, predominantly truncal distribution; maculopapular, urticarial, or acneiform morphology; and accompanying pruritus.*
- *Extensive skin disease can cause important fluid, electrolyte, and protein losses and predisposes the patient to life-threatening infections.*

Basics of Dermatology

APPLICATION OF STRUCTURE AND FUNCTION TO DERMATOSES

The basic anatomy of the skin is described in Fig. 107-1. The skin is a complex organ whose major function is to provide a barrier against the environment. Other major functions include temperature regulation and sensation. The skin is divided into three major layers: epidermis, dermis, and subcutaneous tissue. The outermost layer of the epidermis, the stratum corneum, is composed of dead, anucleate keratinocytes and serves as the first and major physical barrier. The stratum granulosum and stratum spinosum lie below the stratum corneum and are composed of keratinocytes in the process of differentiation. They are derived from the bottom layer of the epidermis, the basal cell layer. The epidermis is connected to the dermis by a complex of proteins and adhesion molecules in the basement membrane zone. Nutrients and products of metabolism are exchanged in the superficial and deep vascular networks located in the dermis. The dermis also contains nerve endings and supporting structures such as sebaceous glands, eccrine sweat glands, and hair follicles.

Alteration of any layer or structure of the skin can result in primary dermatologic disease. Often the skin is secondarily affected in underlying comorbid conditions and may serve as a window to internal disease processes. The stratum corneum can be damaged in the intensive care setting by tape, electrocardiographic leads, defibrillator devices, dry environments, pressure, or adhesives. Alteration may impair barrier resistance to infectious agents or allow passage of antigens to deeper layers of the skin. Preparing the skin for invasive procedures with topical solutions exposes the patient to potential sensitizers. Metabolically active cells in the suprabasal layers are susceptible to inflammatory and cytotoxic reactions from medications and toxins. Disruption in cell adhesion clinically manifests as blisters and may result from medications, toxins, pressure, extremes in temperature, or autoimmune diseases. Infections and inflammatory processes can occur at any level or in any structure, leading to conditions such as impetigo, folliculitis, cellulitis, fasciitis, or vasculitis.

BASIC MORPHOLOGIC APPROACH AND DESCRIPTIONS

When approaching a patient with skin disease, careful observation, palpation, and description are critical for developing a differential diagnosis. The morphology, or type, of lesion may be flat (macule), elevated (papule, nodule, plaque, cyst, vesicle, bulla, pustule, or hyperkeratosis), or depressed (ulcer or atrophy; Table 107-1). Shape, margination (well or poorly defined borders), and arrangement of the lesions are important. Color may be white (leukoderma or hypomelanosis); red (erythema), pink, violaceous (purple), brown (hypermelanosis or hemosiderin), black, blue, gray, or yellow. Particular attention should be paid to the distribution of the eruption (e.g., localized, systemic, truncal, acral, unilateral, or intertriginous). Palpation will help determine consistency, temperature, mobility, tenderness, and depth of lesion. When various lesions are present, one should attempt to determine the primary lesion.

Clinical history is essential. Symptoms (fever, malaise, arthralgias, myalgias, etc.) must be questioned, especially cutaneous symptoms (pruritus, pain, tenderness, burning, or stinging). Time course of the skin lesions should be determined, with particular attention to medication history (prescription and nonprescription, oral, topical, and alternative). Common diagnostic aids in dermatology are skin biopsy for hematoxylin and eosin or other special staining, direct immunofluorescence (DIF), or culture; potassium hydroxide preparation (for dermatophytic infections); mineral oil mounts (for scabies); Gram stain (for bacterial infections); fluid cultures; and Tzanck smears (for herpes simplex and varicella zoster virus infections).

TABLE 107-1 Basic Morphologic and Descriptive Terminology

Macule	Flat lesion of variable size
Papule	Elevated lesion less than 0.5 cm diameter
Plaque	Elevated lesion greater than 0.5 cm diameter
Nodule	Elevated, palpable lesion greater than 0.5 cm diameter
Vesicle	Fluid filled lesion less than 0.5 cm diameter
Bullae	Fluid filled lesion greater than 0.5 cm diameter
Pustule	Pus-filled lesion
Ulcer	Depressed lesion with loss of epidermis and variable levels of dermis
Wheal	Evanescent pale-red papule or plaque

Dermatoses Precipitated by Drugs

EPIDEMIOLOGY AND PROBABILITY OF ADVERSE DRUG REACTIONS

The World Health Organization (WHO) defines an adverse drug reaction (ADR) as any noxious, unintended, and undesired effect of a drug that occurs at diagnostic, prophylactic, or therapeutic doses used in humans.[1] This definition excludes untoward events due to noncompliance or errors in drug administration, therapeutic failures, intentional and accidental poisoning, and drug abuse. A meta-analysis of 39 prospective studies covering 32 years reported a 10.9% incidence of ADR in admitted hospital patients and a 4.7% incidence for patients admitted because of serious ADR.[2] In addition, fatal ADR ranked "between the fourth and sixth" leading causes of death in the United States in 1994, exceeding deaths due to pneumonia and diabetes.[2] The rate and severity of preventable ADRs in intensive care units (ICUs) is nearly twice that in non-ICUs,[3] and ADRs are responsible for lengthening the stay in medical and surgical ICUs.[4] It has been estimated that ADRs cost a 700-bed teaching hospital $5 million to $6 million a year[5] and $1.56 billion to $4 billion for all hospitals in the United States.[6,7]

Cutaneous ADRs (CADRs) are the most common type of ADR and occur in 2% to 3% of hospitalized patients.[8] One in 1000 patients has a serious CADR,[9] representing approximately 3% of all disabling injuries in hospitalized patients.[10]

Many commonly used drugs have reaction rates exceeding 1%.[11] The numbers of CADR may be higher in the ICU setting owing to the critical and compromised nature of the patient compounded by the multiplicity of drugs. Several factors influence the probability of a drug producing an adverse reaction: the size of the compound (larger compounds are more likely to act as haptens), drug-drug interactions (altered metabolism and protein displacement), the route of delivery (intravenous administration increases the incidence of reactions), and patient factors such as renal function, alcohol use, hepatic function, and severity of concomitant disease.[12,13] However, a recent nested case-control study showed severity of illness and length of stay as the only relevant risk factors.[14] A review of nine articles studying rates of CADR found that antibiotics (e.g., amoxicillin, penicillin, fluoroquinolones, sulfonamides, and cephalosporins), nonsteroidal anti-inflammatory agents (NSAIDs), and other analgesics were the leading culprits.[11] Another study found that antiepileptics (e.g., phenytoin and carbamazepine) were also common causal agents. The following medications only rarely cause CADR: digoxin, acetaminophen, meperidine, aminophylline, diphenhydramine, bisacodyl, prochlorperazine, spironolactone, prednisone, thiamine, ferrous sulfate, atropine, morphine, insulin, and spironolactone.

AN APPROACH TO CUTANEOUS ADVERSE DRUG REACTIONS

Cutaneous eruptions are the most frequent ADR in hospitalized patients, accounting for 97.5% of cases in a prospective study by Thong et al.[15] Maculopapular or morbilliform exanthems (Fig. 107-2, Plate 107-2) and urticaria are responsible for 95% and 5% of CADRs, respectively.[11] Onset of the exanthem is usually within 1 week of administration, with the notable

FIGURE 107-2 Maculopapular or morbilliform eruption. This is the most common presentation of a cutaneous adverse drug reaction. (Collection of Dr. Mario Lacouture.) See Plate 107-2.

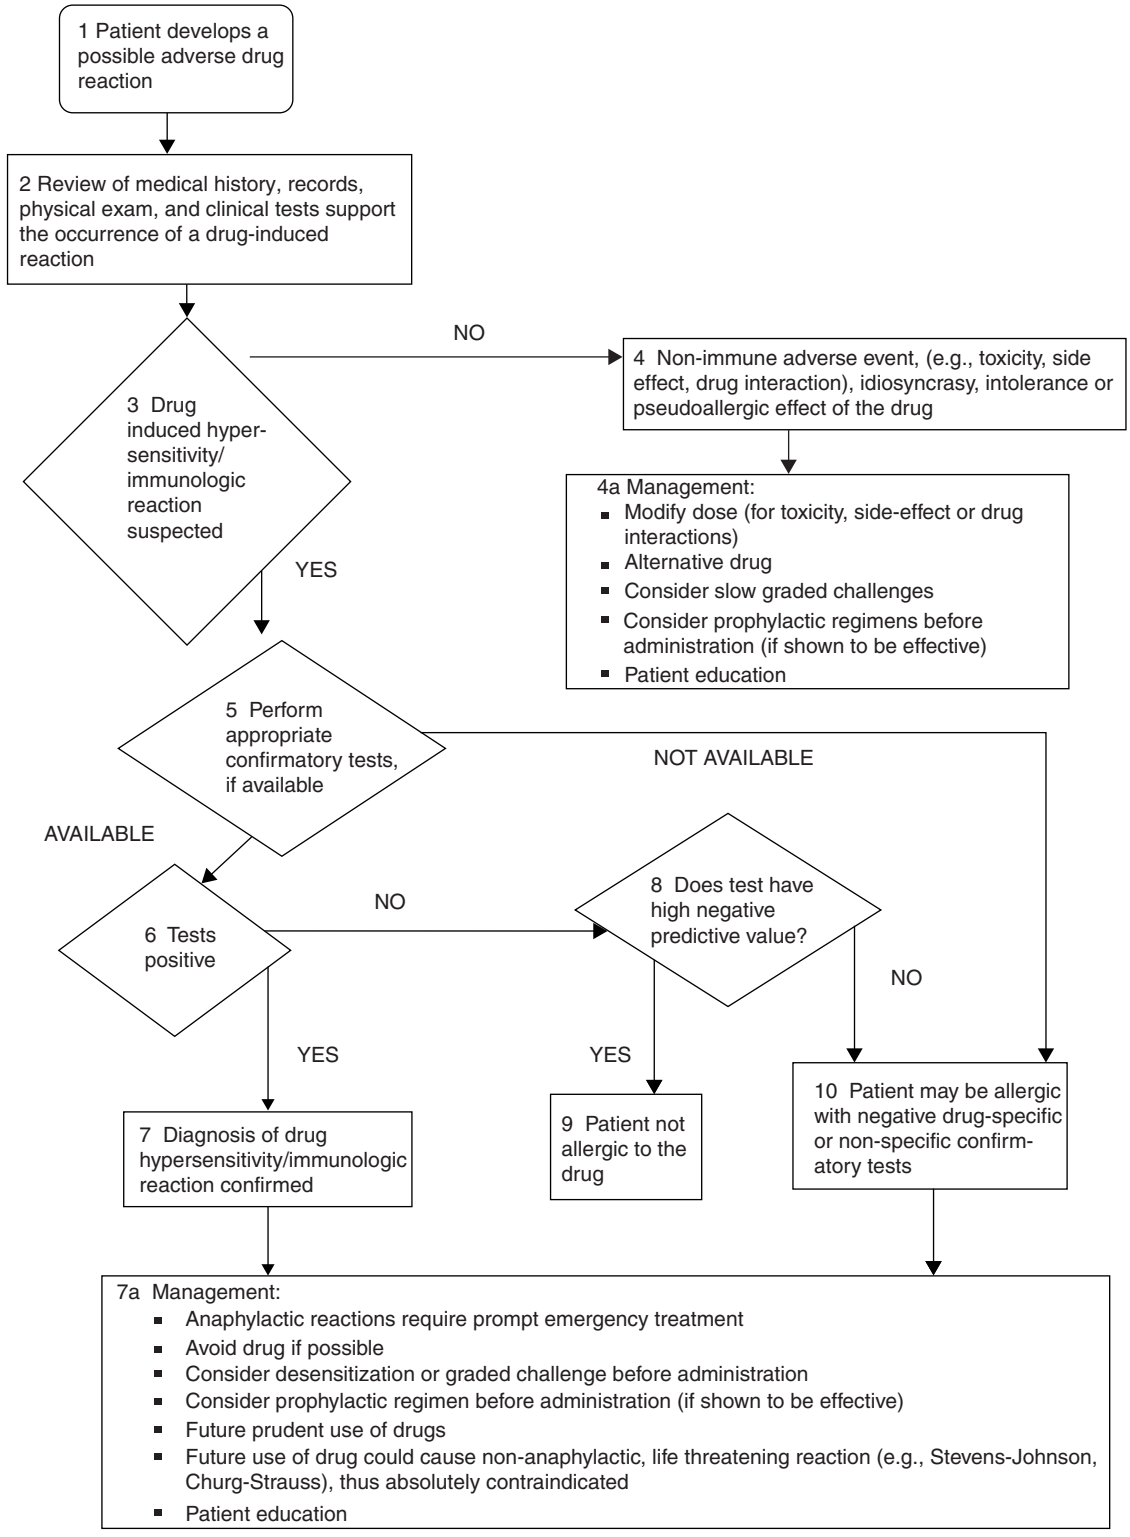

FIGURE 107-3 Algorithm for the management of adverse drug reactions. Adapted from Joint Task Force on Practice Parameters, the American Academy of Allergy, Asthma and immunology. Executive summary of disease management of drug hypersensitivity: A practice parameter. Ann Allergy Asthma Immunol 83:665, 1999. Used with permission.

exceptions of antibiotics and allopurinol. Clues to recognizing a CADR include a rapidly developing rash, with an onset temporally related to the administration of a drug. Medical history, physical examination, and laboratory findings may provide clues, although an extensive laboratory workup is usually unnecessary for diagnosis (Fig. 107-3). Identifying the causative agent in the ICU setting may be problematic due to the concurrent administration of multiple drugs and the inability of patients to recall important facts. Hence, all medical records and family members or close contacts should be

TABLE 107-2 Indicators that an Adverse Drug Reaction May Become Serious

Cutaneous Findings	Systemic Findings
Confluent erythema	High fever (>40°C)
Rash or edema involving the face	Lymphadenopathy

SOURCE: Ref. 9.

questioned. Important information includes (1) time of onset and course of the reaction; (2) dosage and time of initiation and/or discontinuation of any medications (including over-the-counter and alternative products); (3) the patient's previous exposure to this or other related medications; (4) any previous history of ADR, its management, and any measures taken to prevent future ADRs; (5) the patient's medical problems; and (6) any physical and/or laboratory abnormalities present with the ADR, with special attention to organ system(s) involved. Clues to diagnosis include (1) an eruption that develops very rapidly; (2) a generalized, symmetrical, predominantly truncal distribution; (3) an exanthematous (maculopapular), urticarial, fixed drug, or acneiform morphology; and (4) accompanying pruritus. Other less common drug-associated morphologies are lichenoid, photosensitive, vasculitic, or lupus-like patterns. With all this information in hand and knowing the reaction rate of various medications, identification of the cause of an eruption becomes more likely.

Despite the benign nature of the overwhelming majority of CADRs, it important to evaluate for increasing liver or renal dysfunction and for signs suggesting progression to severe skin disease (Stevens-Johnson syndrome [SJS] or toxic epidermal necrolysis [TEN]). Signs indicative of serious skin problems include mucosal involvement, blistering lesions, and a positive Nikolsky sign (Table 107-2).

CLASSIFICATION OF CUTANEOUS ADVERSE DRUG REACTIONS

The classification of CADRs can be problematic, largely due to the lack of data on molecular mechanisms underlying these reactions. The most widely used classification scheme for ADR was devised by Rawlins and Thomson[12] (Table 107-3): type A reactions are related to the pharmacologic effects of the drug, are consequently predictable, and occur with great frequency; type B reactions are unrelated to the pharmacologic actions of the drug and are therefore unpredictable and uncommon; type C reactions result from long-term use of a drug; and type D reactions relate to carcinogenicity and teratogenicity of a drug. Type A reactions are the most common (80%) and can occur at any dose. Type B reactions occur in susceptible individuals (6% to 10%) a few days after administration or with reexposure and are independent of dose. Type B comprises drug intolerance, idiosyncratic reactions, and allergic or hypersensitivity reactions (those having a well-defined immunologic mechanism). Allergic reactions can be categorized further into those that are mediated by drug-specific antibodies or drug-specific T lymphocytes. These include the four mechanisms identified in the Gell and Coombs classification: immediate, cytotoxic, immune complex, and delayed hypersensitivity.[16] Allergic CADRs are characterized by occurrence in a subset of people who have had a previous exposure to the same or similar drug. The reactions often develop rapidly with reexposure and produce clinical syndromes that are commonly associated with immunologic reactions. These may include systemic manifestations such as hepatitis, fever, and eosinophilia, which have been found in 30% of hospitalized patients with drug reactions, particularly in those induced by allopurinol or anticonvulsants.

TABLE 107-3 Classification of Cutaneous Adverse Drug Reactions (CADR)

Type A reactions (common, predictable)
- Toxicity or overdose (hepatic failure with high-dose isotretinoin)
- Side effects (dry skin with topical retinoids)
- Drug interaction (increased coumadin bleeding when a macrolide is administered)

Type B reactions (uncommon, unpredictable)
- Idiosyncratic reaction (the very rare cholestatic liver dysfunction occurring after 3–4 weeks of oral terbinafine therapy)
- Immunologic reactions
  Type I (immediate, IgE-mediated): anaphylaxis
  Type II (cytotoxic, IgG, complment-mediated): hemolysis
  Type III (immune complex): serum sickness
  Type IV (delayed-type hypersensitivity): contact dermatitis

Type C reactions
- Long-term use (blue discoloration with the use of hydroxychloroquine)

Type D reactions
- Carcinogenic or teratogenic effects (squamous cell carcinoma after ultraviolet A radiation therapy)

SOURCES: References 12, 16.

Anaphylaxis and urticaria are Gell-Coombs type I (immediate) hypersensitivity reactions. They usually occur within 1 hour of drug administration, although they may occur as late as 72 hours. These reactions are mediated by immunoglobulin (Ig) E antibodies specific to the causative drug, found on mast cells and peripheral blood basophils, and occur more frequently with parenteral administration. Urticaria may occur in the setting of the systemic manifestations of anaphylaxis, which comprise angioedema with laryngeal edema, bronchospasm, hypotension, diffuse erythema, hyperperistalsis, cardiac arrhythmias, and pruritus (see Chap. 106). Drug-induced anaphylaxis occurs in 1 of 2700 hospitalized patients and is most frequently induced by β-lactam antibiotics (including penicillin), radiocontrast medium, intravenous anesthetic drugs, aspirin, other NSAIDs, and opiates. In the United States, the most common cause of anaphylaxis is penicillin, accounting for 75% of 500 to 1000 anaphylactic deaths in 1 year.[17] Urticarial lesions are pruritic, erythematous or white, nonpitting, round or oval edematous papules or plaques surrounded by a clear or red halo, usually at different stages of formation. Penicillins, sulfonamides, and NSAIDs are the most common causal medications.[18] Angioedema refers to the same pathophysiologic process as urticaria with transudation of interstitial fluid into the dermis

or hypodermis. Treatment of urticaria consists of discontinuation of the offending drug and the administration of oral antihistamine H_1 blockers. These include diphenhydramine, hydroxyzine, and the nonsedating agents, loratadine, cetirizine, and fexofenadine. If anaphylaxis develops, emergency treatment is instituted with intramuscular or subcutaneous epinephrine, high-flow oxygen and airway management, intravenous diphenhydramine, steroids, fluids, vasopressors, and cardiopulmonary resuscitation, as needed. Skin testing with the offending agent is usually positive in IgE-mediated reactions.

Cytotoxic (type II) reactions are mediated by IgG and complement, usually occur longer than 72 hours after drug exposure, and manifest as increased clearance of red blood cells and platelets by the lymphoreticular system. Skin testing is not useful.

Type III reactions are serum sickness-like reactions, in which IgG and/or IgM immune complex deposition leads to diffuse tissue injury. Common clinical findings include fever, urticaria (often figurate or polycyclic), angioedema, malaise, arthralgias (particularly of the hands and feet with swelling), lymphadenopathy, and occasionally nephritis or endocarditis, usually starting after 1 to 3 weeks of drug administration. There is an associated eosinophilia. Heterologous antisera, xenogeneic antibodies, and drugs with a low molecular weight (e.g., penicillin) are common triggers. Systemic steroids are often used to treat this reaction, although large-scale controlled clinical trials are lacking.

Allergic contact dermatitis is the most common type IV, delayed-type hypersensitivity reaction, usually caused by topically applied medications. Sensitization is required and usually occurs over 5 to 7 days, after which the reaction can be elicited by topical or systemic administration of the same or a structurally similar agent. This means that a previous exposure is necessary, although a reaction may appear de novo after several days of contact with the offending agent. A pruritic, erythematous, vesicular, scaly eruption occurs at the site of contact, which, with time, may become lichenified (thickened with accentuation of skin markings) related to rubbing or scratching.

Diagnostic tests for CADR may be useful to determine the causative agent, the type of reaction, and the prognosis. Skin testing may be performed by a prick or intradermal administration of the suspected drugs to determine the presence of drug-specific IgE antibodies (type I Gell-Coombs reactions). Penicillin, muscle relaxants, and barbiturates are amenable to this type of testing because their epitopes are known. In some institutions, allergists and immunologists are able to purify the offending epitopes from other drugs. Medicines that undergo significant metabolism and those with undefined epitopes cannot be tested. An in vitro test to study the presence of circulating drug-specific IgE antibodies is the radioallergosorbent test. Penicillin, insulin, thiopental, protamine, latex, chymopapain, and selected muscle relaxants can be tested by radioallergosorbent test, with variable consistency.

When ADRs are mediated by drug-specific T cells (type IV; e.g., contact dermatitis), patch testing is a useful adjunct. It is performed by applying predetermined dilutions of the compound on intact skin for different periods and assessing for erythema, edema, or vesiculation, all indicative of specific T-cell reactivity. A skin biopsy aids in clarifying the pathophysiology of a reaction, for example, by the demonstration of immune complexes, leukocytoclastic vasculitis, or tissue eosinophilia. However, the biopsy often does not help in establishing whether or not the cutaneous reaction is drug induced. Blood eosinophil counts have been regarded as an indicator of ADR; however, recent studies have shown that this criterion carries a low sensitivity (22% to 36%, depending on arbitrarily defined cutoff rates), making routine eosinophil testing unhelpful.[19] Serum tryptase levels are useful in reactions caused by diffuse mast cell (anaphylactic or anaphylactoid) activation, especially when hemodynamic changes are present. Tryptase is a protease stored in the granules of mast cells and released with mast cell activation. Levels should be obtained within 2 hours of initiation of the episode. Serum tryptase concentrations are recommended over serum histamine concentrations due to the greater stability of tryptase.[20]

The clinical usefulness of in vitro diagnostic tests to detect the presence of drug-specific antibodies capable of eliciting basophil histamine release, lymphocyte blast transformation, or complement activation remains to be proven. These tests carry a low sensitivity, are currently used mainly as research tools, and therefore are not recommended for routine clinical use.

Despite the high prevalence of ADR to sulfonamides in the general population (3%) and those infected with the human immunodeficiency virus (HIV; 60%), there are no reliable diagnostic tests available for clinical use. If, however, there is certainty that a sulfa drug has caused a CADR, desensitization protocols have been developed for patients with the acquired immunodeficiency syndrome that allow for sulfonamide administration during treatment and prophylaxis of opportunistic infections.[21]

Despite the different proposed mechanisms, overlap is common, and one cannot infer the pathogenesis of an eruption by its morphology or causative drug alone. The diagnosis of a drug-related dermatosis encompasses a complex mental algorithm of probability, time and causality, alternative diagnoses, and plausibility.

CHEMOTHERAPY-INDUCED DERMATOSES

Cancer patients may be affected by cutaneous reactions of diverse etiologies, including infections, paraneoplastic pemphigus, dermatomyositis, graft-versus-host disease (GVHD), nutritional deficiency, metastases, cutaneous neoplasms, radiation reactions, and administration of chemotherapeutic agents.

The most common CADR to chemotherapeutic agents is alopecia (hair loss), which may present as anagen (hair growth phase) or telogen (hair resting phase) effluvium.[22] Anagen effluvium is usually caused by antineoplastic agents, which weaken the hair shaft, resulting in severe hair loss apparent 1 to 2 months after therapy. Telogen effluvium occurs secondary to acute physical or psychological stress, malnutrition, or drugs. Spontaneous regrowth with drug discontinuation is the norm for both types of alopecia. The most common causative agents include vincristine, cyclophosphamide, doxorubicin, daunorubicin, dactinomycin, and paclitaxel. Treatments are rarely successful. The effectiveness of 2% minoxidil has been inconsistent.[23,24]

Adverse effects in the oral mucosa occur in 40% of patients as a result of direct drug toxicity or indirectly via effects on the

TABLE 107-4 Antidotes used in chemotherapeutic agent extravasation

Agent	Antidote
Anthracycline	Topical DMSO
Mitomycin	Topical DMSO

bone marrow. Stomatitis is a frequent complication leading to erythema, edema, ulceration, pain, burning, and xerostomia. It is particularly common in individuals who are younger than 20 years, who have prior oral disease, or who have hematologic malignancies. Common culprits include topotecan, methotrexate, fluorouracil, doxorubicin, docetaxel, daunorubicin, dactinomycin, and bleomycin. Healing occurs within 2 to 3 weeks. Treatment consists of adequate oral hygiene and the use of topical agents such as attapulgite, magnesium/aluminum hydroxide, diphenhydramine elixir, benzocaine, and viscous lidocaine.

Candidiasis, with its white, adherent velvety plaques, and varicella zoster virus may also affect the inside of the mouth. Herpes simplex usually affects the vermilion border of the lips, but in the immunosuppressed may cause indolent intraoral ulcers.

Intravenous administration of chemotherapeutic agents may result in extravasation into surrounding tissues. Severity depends on type, quantity, and concentration of drug,[25] and disabling sequelae are uncommon. Agents may be irritants (e.g., bleomycin, carboplatin, cyclosphamide, doxorubicin, etoposide, fluorouracil, paclitaxel, or vinblastine), which cause sclerosis, hyperpigmentation, and tenderness along the vein, or vesicants (e.g., bleomycin, carmustine, cisplatin, doxorubicin, etoposide, fluorouracil, melphalan, mechlorethamine, mitomycin, paclitaxel, vinblastine, or vincristine), which cause burning, necrosis, and ulceration. Treatment consists of discontinuing the infusion, elevating the affected extremity, and applying local heat or cold. Heat should not be applied when extravasation of vinca alkaloids occurs because this may cause ulceration.[26] Surgical debridement and skin grafting may be needed in persistent ulcers. Antidotes are also recommended (Table 107-4).

Localized or diffuse hyperpigmentation is a common CADR, as a result of melanin, carotene, hemoglobin, or other pigment. Characteristic gingival bands occur with cisplatin; horizontal hyperpigmented bands on blond hair (flag sign) with methotrexate; flagellate streaks of hyperpigmentation with bleomycin; pigmented nail bands with bleomycin, cytarabine, cyclophosphamide, daunorubicin, doxorubicin, fluorouracil, hydroxyurea, idarubicin, mitomycin, tegafur, or vinblastine; and mucosal hyperpigmentation with busulfan, fluorouracil, tegafur, doxorubicin, hydroxyurea, cisplatin, or cyclophosphamide.[22]

Another well-described ADR to chemotherapeutic agents is acral erythema, occurring in 6% to 24% of patients,[27] mainly those treated with cytarabine, doxorubicin, and fluorouracil. This painful eruption consists of diffuse erythema and edema on the palms and soles. This resolves with exfoliation within 4 weeks of discontinuing the drug. It needs to be differentiated from acute GVHD in the appropriate clinical setting. Treatment is supportive, with elevation, cold compresses, analgesics, and pyridoxine 150 mg each day.[28]

ANTICOAGULANT-INDUCED DERMATOSES

Adverse reactions to anticoagulants can be localized or diffuse and mediated by various mechanisms. Unfractionated heparin, low-molecular-weight heparins, and vitamin K antagonists are drugs used routinely in the treatment and prophylaxis of thromboembolic disease. In addition to the well-known ADRs such as an increased bleeding tendency, these agents may cause CADR which necessitate institution of alternative therapies.

Heparin is a mucopolysaccharide that can induce various ADRs, including immediate reactions (e.g., urticaria, asthma and anaphylaxis), delayed-type reactions (e.g., erythematous plaques, skin necrosis, a generalized eruption, and thrombocytopenia).[29] Delayed-type reactions manifest as erythematous, vesicular, or pruritic plaques at the injection site within 2 to 5 days of therapy, whereas heparin-induced skin necrosis develops between 5 and 10 days of therapy. Cutaneous reactions have also been described related to the use of low-molecular-weight heparins and heparinoids.[30] In patients with skin necrosis, heparin must be discontinued due to the increased risk of developing heparin-induced thrombocytopenia II.[31] These patients usually have significant concurrent illnesses but no coagulation abnormalities. Histology shows fibrin deposition in venules and capillaries in the dermis and hypodermis, with necrosis. Intracutaneous testing is useful for the diagnosis of delayed reactions (erythematous plaques at heparin injection sites) but is contraindicated in the presence of skin necrosis. A positive skin test has been associated with heparin-induced IgG antibodies. There may be cross-reactivity between unfractionated heparin and low-molecular-weight heparins and heparinoids. Rates of 50% and 30%, respectively, have been reported.[32] Therefore, treatment consists of discontinuing heparin and administering one of the newly developed direct thrombin inhibitors (argatroban and lepirudin) to provide protection during warfarin initiation.

Warfarin, a racemic mixture of R and S enantiomers, inhibits the vitamin K–dependent clotting factors II, VII, IX, and X; it also inhibits the anticoagulant proteins C and S, thereby causing a transient hypercoagulable state.[33] On rare occasions, skin necrosis, which is potentially fatal (15% of cases), occurs with initiation of therapy before full anticoagulation is achieved. Three to 10 days after starting therapy, pain precedes the appearance of ill-defined erythematous plaques, which progress into edematous, blue-black plaques with hemorrhagic bullae in the center. The lesions necrose, leaving central eschars. Necrosis commonly affects the breasts, abdomen, and thighs in females and the abdomen and thighs in males. Histopathology shows fibrin occluding dermal and hypodermal veins, with diffuse necrosis.[34] This occurs more commonly in women. Other risk factors include a large loading dose, protein C deficiency, and the presence of the factor V Leiden mutation. Treatment consists of discontinuation of warfarin and administration of intravenous heparin. Some investigators have reported success with the use of protein C concentrate, prostacyclin, and factor VII.[35] Lesions are treated as any other skin ulcer; however, when they

TABLE 107-5 Commonly Used Herbal Remedies and Reported Adverse Reactions

Name of Plant/Constituent	Adverse Effect	Alleged Indications
Flavonoids	Hemolytic anemia chronic diarrhea, nephropathy, colitis	Antioxidant, edema
Germander	Hepatotoxicity	Choleretic, antiseptic, weight loss
Valerian root, skullcap, chaparral	Hepatotoxicity	Antioxidant
Momordica charantia	Hepatotoxicity	Diabetes
Sauropus androgynus	Bronchiolitis abliterans	Weight loss
Chinese herbal preparations		
Aconite	Arrythmias, abdominal pain	Various
Aristolochia fangchi/pistolochia	Nephrotoxicity	Weight loss
Jin Bu Huan	Hepatotoxicity	Sedative, analgesic
Bajiaolian	Hepatotoxicity	Eczema
Syo-saiko-to	Hepatotoxicity	Cold, liver disease
Shiitake mushroom	Dermatitis	Immunostimulant
Kombucha mushroom	Hepatotoxicity	Cancer, hair growth
Tripterygium wilfordii hook F	Lupus nephritis	Antiinflamatory
"Eternal life" tea	Hepatotoxicity	Variable
Ginseng	Mania, SJS, bleeding	Stimulant
Siberian ginseng	Increases digoxin levels	Stimulant
Ma Huang	Psychosis	Stimulant
Agnus castus	Increases risk of miscarriage	Gynecologic diseases
Guar gum	Intestinal obstruction, death	Weight loss
Licorice root	Hypokalemia, hypertension, arrythmias, edema	Various
Sparteine	Shock	Weight loss
Salicylates in oil of wintergreen, eamphor, peppermint, menthol eucalyptus	Salicylism	
Aloe, cascara, frangula, rhubarb senna	Colorectal Cancer	Laxatives
Capsaicin	Gastric Cancer	
Ayurvedic remedies	Heavy metal poisoning	Various
Pyrrolizidine alkaloids*	Hepatotoxicity	Various
St John's Wort (Hypericum perforatum)	↑ Sensitivity to sunlight, radiation therapy	Depression
Ginko biloba	Hematoma, hyphema	Dementia, pain
Ginseng	Bleeding	Various (mood, HTN)
Ginger	Inhibit coagulation	Motion sickness, vertigo
Echinacea	Hepatotoxicity	Immunostimulant (colds)

*Present in comfrey and other plants (e.g., borage, senecio, coltsfoot).

are extensive, surgical debridement, grafting, or occasionally amputation may be necessary to prevent the development of infection and sepsis. In one review, surgical treatment was found to be necessary in more than 50% of cases.[36]

ADVERSE REACTIONS TO ALTERNATIVE DRUGS

Botanical products are classified as dietary supplements. As such, they are exempt from the stringent evaluation and regulatory processes that drugs have to undergo to show efficacy, safety, and quality.[37,38] Although not allowed to make specific health claims, the manufacturers of these remedies are permitted to state they maintain good health. Herbal remedies account for a $1.5 billion per year industry in the United States, and it is estimated that 33% of Americans use these remedies, especially women and people of high socioeconomic status.[39] Eighty percent of the world population uses herbal remedies. In Taiwan, herbal remedies ranked third among culprits for ADR in a study of 2695 patients admitted to the medicine ward.[40] In a Hong Kong study, 0.2% of all admissions were due to adverse reactions to Chinese herbal drugs.[41] Another survey found that 8% of 400 users of complementary medicine experienced adverse herbal reactions (AHRs).[42]

It is not uncommon for patients admitted to the ICU to have been taking herbal medicines, or "supplements." Contrary to popular belief, herbal products may result in clinically significant adverse reactions and herbal-drug interactions, which may alter diverse organ systems and drug metabolism (Table 107-5).

In addition to AHRs due to the major compounds present, contaminants are a significant source of adverse reactions. Contamination of herbal remedies is abundant, due in part to lack of regulation. Lead, arsenic, and other heavy metals have been found in numerous herbal remedies. Autoimmune thrombocytopenia has been reported in a patient receiving kelp tainted with arsenic. In addition, some remedies have been found to contain traditional drugs, such as aspirin, paracetamol, mefenamic acid, diazepam, and triamcinolone, with corresponding adverse reactions.

There are some herbal remedies not yet reported to cause adverse reactions: camomile (anti-inflammatory), garlic (cholesterol lowering, and antihypertensive, although it may

TABLE 107-6 Interactions Between Herbal Products and Drugs

Name of Botanical Constituent/Drug	Effect
Shankhapushpi/Phenytoin	Decreases phenytoin levels
Grapefruit juice/Cyclosporin, Ca channel blockers	Increases levels
Chinese herbal:danshen, MS oil/warfarin	Coagulation abnormality
Glycyrrhizin*/Prednisone	Altered prednisolone metabolism
St John's Wort/SSRIs	Serotonin syndrome (sweating, hyperreflexia, and shivering); seizures; coma
Kava-Kava/SSRIs	Serotonin syndrome (sweating, hyperreflexia, and shivering); seizures; coma
Garlic/anticoagulants	↑bleeding
Ginger/anticoagulants	↑bleeding
Ginko biloba/anticoagulants	↑bleeding
Ginseng/anticoagulants	↑bleeding
Echinacea/ketoconazole/phenytoin	Hepatotoxicity

*Found in licorice and the following Chinese herbs: Sho-saiko-Tok, Sai-boku-To, and Sairei-To.
SSRIs, selective serotonin re-uptake inhibitors (paroxetine, trazodone, sertalin).
SOURCES: References 38, 43.

cause a contact dermatitis when topically applied), *Ginkgo biloba* (increases blood flow), peppermint (analgesic), Sabal (anti-inflammatory), and saw palmetto (antiandrogenic, estrogenic, anti-edema). Underreporting is prevalent; therefore, it should not be assumed that these medicines are free of adverse reactions.

Similarly, interactions with traditional drugs are a significant cause of concern in individuals taking herbal remedies concurrently with traditional medicines[43] (estimated at 18% of the population; Table 107-6). Components in herbal remedies such as St. John's Wort and Kava-Kava, used for depression and anxiety, respectively, have been shown to inhibit monoamine oxidase activity. Interactions with drugs affecting the metabolism of neuroactive amines, such as the selective serotonin-reuptake inhibitors, are a potential problem. Therefore, coffee, tea, and foods containing tyramine (aged cheese, soy sauce, smoked meats, bananas, and avocados) should be avoided.

Because many of the mechanisms underlying AHR are unclear, a careful history and evaluation is necessary. In addition, because the half-life of many of these components is not known, they should be discontinued immediately on admission to the hospital or the critical care unit.

VASOPRESSIN-INDUCED SKIN NECROSIS

Vasopressin, a nonselective vasoconstrictor, is used in the treatment of vasodilatory septic shock, hypotension unresponsive to catecholamines,[44] and variceal hemorrhage.[45] Uncommon adverse reactions to large-dose (0.2 to 0.4 U/min), centrally administered vasopressin include cardiac arrhythmias, ischemia, infarction, and bowel ischemia.[46] When peripheral intravenous administration is used, accidental extravasation of the drug may result in skin necrosis and gangrene. This CADR may occur even at small doses (0.04 U/min) or when small quantities that are undetectable by the occlusion pressure monitor infiltrate the tissue. Interestingly, this skin necrosis does not occur with large-dose subcutaneous administration, as performed for diabetes insipidus. Treatment consists of stopping the vasopressin infusion, surgically débriding the ischemic tissue, and applying wet dressings or grafting. Administration through a central venous catheter is encouraged, even for small doses, to minimize the occurrence of this adverse reaction.

Diffuse ischemic skin lesions, defined as new areas of mottled or livid skin, have been found to occur in approximately 30% of patients during infusion of arginine-vasopressin, an alternative powerful vasopressor agent that is increasingly used in catecholamine-resistant vasodilatory shock. Sepsis and arterial occlusive disease are predisposing factors. These lesions, often seen on the limbs and trunk but also on the tongue, may lead to gangrene, necessitating débridement and amputation.[47]

Severe Cutaneous Adverse Drug Reactions

STEVENS-JOHNSON SYNDROME AND TOXIC EPIDERMAL NECROLYSIS

CADRs are classified by the WHO as severe when they are life-threatening, require hospitalization, or lead to permanent disability. Stevens-Johnson Syndrome (SJS) (Fig. 107-4,

FIGURE 107-4 Stevens-Johnson syndrome/toxic epidermal necrolysis. Erosive involvement of lips and oral mucosa. ***(Courtesy Dr. Iris K. Aronson collection.)*** **See Plate 107-4.**

FIGURE 107-5 Toxic epidermal necrolysis: >30% of the body surface area involved. Necrotic epidermis sloughs, revealing moist, bright red dermis. ***(Courtesy Dr. Iris K. Aronson collection.)*** **See Plate 107-5.**

Plate 107-4) and toxic epidermal necrolysis (TEN) (Fig. 107-5, Plate 107-5) are rare, serious CADRs, with calculated incidences of 1 to 6 and 0.4 to 1.2 cases per million person-years, respectively.[48] SJS and TEN are histopathologically identical diseases that are differentiated by the extent of epidermal detachment: less than 10% in SJS, 10% to 29% in transitional SJS/TEN, and greater than 30% in TEN. In addition to the hypersensitivity syndrome/drug reaction with eosinophilia and systemic symptoms, SJS and TEN constitute the major groups of severe CADRs[49] (Table 107-7).

Fever, sore throat, cough, and burning eyes may precede painful skin eruptions resembling burns for 1 to 3 days. Lesions usually appear within 3 weeks of drug administration and begin as irregularly defined, painful erythematous macules with purpuric centers that tend to coalesce. Within a few hours or days, blisters appear and epidermal detachment extends over the body. Lesions in the mucosae are characteristic, occasionally preceding skin lesions by several days. However, initial presentation of SJS and TEN may be very similar to less serious CADR, that is, a maculopapular rash. Involvement of the epithelium of the trachea, bronchi, or gastrointestinal tract increases morbidity rate.

TEN is the most severe form of drug eruption known, with a mortality rate of approximately 30%.[50] Mortality is mainly a result of respiratory complications or sepsis. Prognosis is influenced by age (>60 years), the presence of comorbidities, sepsis, and extent of body surface area involved.[9,50,51] TEN is caused almost exclusively by medications, although it may be a manifestation of severe acute GVHD.[52] The implicated medication is usually started within 3 weeks of the eruption. An increased risk for SJS and TEN has been found with the use of the following drugs: anticonvulsants (phenytoin, valproic acid, phenobarbital, and carbamazepine), antibiotics (sulfonamides and aminopenicillins), NSAIDs (oxicam derivatives), chlormezanone, allopurinol, and, interestingly, corticosteroids.[48] Drugs with long-half lives, known to be frequent culprits, have been associated with higher fatality rates.[53] TEN occurs more frequently in HIV-infected individuals, especially those receiving sulfonamides and/or nevirapine. This may be related to the concurrence of the glutathione S-transferase M1 null and the slow acetylator genotypes.[54] Precipitation of SJS and TEN by infectious agents is much less common. Infection with *Mycoplasma pneumoniae* is the best documented[55] (Table 107-8).

The pathogenesis of SJS and TEN remains unclear. Humoral and cell-mediated cytotoxicities, drug metabolites, and apoptotic mechanisms have been implicated, with inconsistent data. Experimental data suggest that activation of Fas (CD95) through its ligand, FasL (CD95L), results in caspase-mediated keratinocyte apoptosis, possibly an important pathophysiologic mechanism in TEN.[56] Fas (CD95) is a cell surface receptor expressed on keratinocytes and most cells and can be activated by FasL, which is expressed by natural killer cells and activated T lymphocytes.[57] FasL can also exist in a soluble form (sFasL), capable of inducing apoptosis.[58] Soluble FasL results from metalloproteinase-mediated cleavage

TABLE 107-7 Classification of Severe Cutaneous Adverse Drug Reactions

	SJS	TEN	Hypersensitivity/DRESS
Mucous membrane	>90%	>90%	<30%
BSA involvement[a]	<10%	>30%	<10%
Erosions	Several sites	Several sites	Mouth and lips
Detachment of epidermis	Yes	Yes	No
Hyperkeratosis/desquamation	No	No	Usual
Neutropenia	No	30%	No
Eosinophilia	No	No	90%
Atypical lymphocytes	No	No	30–40%
Respiratory tract	Bronchial erosions/ARDS	Bronchial erosions/ARDS	Interstitial pneumonitis
Liver	Hepatitis 10%	Hepatitis 10%	Hepatitis 60%
Heart	No	No	Myocarditis
Lymph node enlarged	No	No	Usual

[a] When detachment involves 10%–29% of BSA, we classify the case as SJS-TEN overlap. ARDS, adult respiratory distress syndrome; BSA, Body surface area; DRESS, drug reaction with eosinophilia and systemic symptoms; SJS, Stevens-Johnson syndrome; TEN, toxic epidermal necrolysis.

of cell surface FasL and stimulation of peripheral blood mononuclear cells by an offending drug results in upregulated sFasL expression. Sera from SJS and TEN patients can induce Fas-FasL–mediated keratinocyte apoptosis in vitro and contain elevated concentrations of sFasL when compared with control patients.[59]

Initially, patients develop pain, tenderness, or a burning sensation in the skin. These symptoms often begin abruptly and are associated with fever and general malaise. Over the next 1 to 3 days, ill-defined erythematous macules or a diffuse erythema develop over the trunk and extremities. As the red areas enlarge, central dusky necrotic sites develop with subsequent bullae formation. Bullae result from edema occurring beneath the necrotic epidermis. As the disease progresses, sheets of full-thickness epidermis slough off, revealing dark red, moist dermis (resembling severe second-degree burns). The Nikolsky sign (separation of the skin with lateral traction) is positive and an important diagnostic clue.

Mucous membrane involvement occurs in 85% to 95% of patients and may be the presenting sign.[60] The oropharynx and conjunctivae are most affected, resulting in severe erosions and pain. Keratitis, ocular erosions, and symblepharon may result in blindness. Dysuria is a sign of urethral involvement. Erosions in the lower respiratory tract and the intestine have also been described.[61]

Hematologic studies may show anemia, eosinophilia, neutropenia, lymphopenia, thrombocytopenia, and an elevated erythrocyte sedimentation rate. Lymphopenia is seen early in the course of disease in up to 90% of cases and is a result of depletion of CD4 T lymphocytes. Neutropenia is seen in up to 30% of cases and carries a poor prognosis.[62] Serum chemistries show evidence of extensive fluid and protein loss, hypoalbuminemia, and hypocalcemia.[63] Taking a small piece of tender erythematous skin for frozen section may help make a rapid diagnosis. This will show the level of the separation within the skin and, in TEN, reveals full-thickness necrosis of the epidermis, with an intact dermis with little or no inflammation. Alternatively, a skin biopsy in an area immediately adjacent to and overlapping a blister may be sent for routine histology. The irregular presence of necrotic keratinocytes along the dermal-epidermal junction is a hallmark of early lesions, whereas diffuse epidermal necrosis with subepidermal clefting is present in late lesions. There is minimal dermal inflammation. Immunofluorescence findings are nondescript, with no significant complement or antibody deposition, suggesting that cell-mediated cytotoxicity is an important mechanism.

The clinical differential diagnosis includes staphylococcal scalded skin syndrome, acute GVHD, scarlet fever, erythema multiforme, and pemphigus vulgaris. In all these cases, full-thickness epidermal necrosis is rare (except in GVHD, in which epidermal necrosis is accompanied by an abundant lymphocytic infiltrate).

Erythema multiforme (previously referred to as erythema multiforme minor), is an acute, self-limited reaction characterized by asymptomatic, annular erythematous, or urticarial plaques with central areas of blistering and necrosis, resulting in the so-called target lesions. Lesions usually develop on the extensor surfaces of the extremities and mucosae and cover less than 10% of the body surface area. Outbreaks last for 1 to 4 weeks. Relapses are frequent. It is associated with recurrent herpes simplex virus infections in the great majority of cases and with *M. pneumoniae* infection in a smaller subset.

Treatment for SJS and TEN includes pain management and prompt withdrawal of any agents that are not essential for the maintenance of life. This latter has been shown to decrease mortality rate in TEN by about 30% per day, despite some progression of the mucocutaneous involvement.[64] Fluid resuscitation, treatment of infections, and meticulous skin and eye care are most appropriately managed in an isolation room in a burn unit, where the staff is trained in topical wound and skin care. Severe airway involvement may necessitate intubation and ventilation. An ophthalmologic consultation should be obtained to assess eye involvement, which is usually treated with topical antibiotics and lubricants. If symblepharon occurs, early lysis must be performed. Fluid and electrolyte imbalances are related to the percentage of body surface area involved; however, fluid loss tends to be less than in severe burn patients. Topical therapy includes gentle debridement of necrotic skin followed by the application of nonadherent dressings to the areas of skin erosion, a wrapping of a thin silver-impregnated dressing, and an outer linen covering to hold all in place. Antibiotic ointments are widely used, although their value is unproved. It is important to avoid the sulfonamide derivatives (silver sulfadiazine cream, topical mafenide acetate, and ophthalmic sodium sulfacetamide) because of potential significant absorption and the possibility of inducing SJS.[65] A variety of other dressings may be used to decrease fluid loss and pain and promote wound healing, and may be useful adjuncts to therapy. These include porcine xenografts[66] and synthetic dressings such as Omniderm, OpSite, Vigilon, Mepitel, and Biobrane. Systemic antibiotics should be used only when there is documented infection or neutropenia.

The use of corticosteroids and immunosuppressive agents in the treatment of TEN is controversial. The rationale for such an approach is based on the assumption that TEN is an immune-mediated event. There are no case-controlled studies supporting the use of corticosteroids; however, several case reports have advocated their use.[67,68] In most cases in which steroids were found effective, they were started very early in the course of the disease. More recent literature has

indicated a higher mortality rate, increased time to recovery, and increased length of hospital stay in patients treated with systemic corticosteroids.[69,70] Patients undergoing long-term glucocorticoid therapy who develop TEN may have a delay in onset, but the severity of disease is unaffected.[71] Based on this information, corticosteroids should not be used routinely in TEN and should only be considered in patients who present early in the course of disease. Intravenous immunoglobulin therapy in TEN aims to decrease Fas-mediated keratinocyte apoptosis by sequestering Fas available for binding to CD95. Four nonrandomized, uncontrolled studies have shown that large-dose intravenous immunoglobulin decreases mortality rate and progression of TEN,[72–75] whereas one prospective study showed no benefit.[49] Hence, there is no consensus, and controlled, randomized trials are needed. The use of plasmapheresis and immunosuppressive drugs remains controversial due to the lack of strong clinical data.

HYPERSENSITIVITY SYNDROME/DRUG REACTION WITH EOSINOPHILIA AND SYSTEMIC SYMPTOMS

A severe hypersensitivity syndrome consisting of fever, rash, lymphadenopathy, and variable organ (usually liver) involvement may appear after several weeks of drug ingestion. When associated with eosinophilia and systemic symptoms, the term *drug reaction with eosinophilia and systemic symptoms* is used (see Table 107-7). The most common precipitants are the aromatic anticonvulsants (e.g., phenytoin, phenobarbital, and carbamazepine). Faulty metabolism of these drugs is thought to precipitate the disease process, which has also been associated with the initiation or reactivation of infection with human herpes virus type 6.[76] There is a 75% incidence of cross-reactivity between these anticonvulsants; therefore, once one of these drugs has caused a reaction, further exposure to any of them should not be attempted. Other medications known to cause this syndrome include dapsone, sulfonamides, allopurinol and minocycline.[77]

The cutaneous component of this ADR varies from a maculopapular eruption to frank erythroderma. Discontinuation of the offending agent and the administration of moderate to large doses of systemic steroids are the treatments of choice and have shown benefit in multiple case reports. Supportive care, similar to that for SJS and TEN, in an ICU or burn unit, must be instituted when life-threatening visceral manifestations are present, whereas topical steroids alone may be sufficient for mild disease.

Medical Dermatoses

PEMPHIGUS VULGARIS

Pemphigus vulgaris (PV) is an autoimmune, mucocutaneous, blistering disease characterized by an intraepidermal split that results in superficial flaccid bullae. Autoantibodies directed against intercellular adhering junction antigens lead to bullae formation. Circulating IgG directed toward intercellular desmogleins 3 and 1, which interact with plakoglobin in the dense plaque of the desmosome, can be detected in the serum and skin biopsies from perilesional skin.[78,79] The stimulus for the circulating autoantibodies is unknown. PV has been described in association with autoimmune diseases, malignancy, and medications.[80] The medications most often cited have thiol groups in their molecules, such as penicillamine and captopril.[81] PV occurring in association with an underlying neoplasm is termed paraneoplastic pemphigus. Paraneoplastic PV is seen primarily with lymphomas. Patients develop flaccid bullae on normal or slightly erythematous skin. The bullae rupture easily, leaving superficial and crusted erosions (Fig. 107-6, Plate 107-6). The presence of Nikolsky's sign (lateral extension of an intraepidermal split with application of pressure to small intact bullae) is a characteristic feature. Blisters may occur anywhere on the body, with a predilection for the trunk, groin, scalp, and face. Mucous membrane involvement is characteristic. The oral mucosa is involved in more than 95% of patients and is the initial manifestation in up to 70%.[82] Intact bullae are rarely seen due to their superficial location. PV occurs primarily in the middle and older age groups.

FIGURE 107-6 Pemphigus vulgaris. Flaccid, superficial bullae which rupture easily leaving superficial erosions. ***(Courtesy Dr. Anne Laumann collection.)*** **See Plate 107-6.**

The diagnosis of PV is made using routine (hematoxylin and eosin) dermatopathologic analysis of a biopsy from the border of an active lesion in addition to direct immunofluorescence (DIF: patient's skin and anti-immunoglobulin) of a biopsy specimen from perilesional skin and indirect immunofluorescence (IIF) of a serum sample (patient's serum incubated with monkey esophagus and then with anti-immunoglobulin). Histologic examination shows loss of adhesion between keratinocytes (acantholysis) above the basal layer, resulting in an intraepidermal split. DIF reveals IgG and complement deposition between keratinocytes within the epidermis. IIF reveals intercellular IgG deposition on monkey esophagus. The IIF titer may be quantified and loosely reflects disease activity.

Before the advent of corticosteroids, PV carried a high mortality rate. At present, patients are typically started on doses of at least 1 to 2 mg/kg per day of prednisone to halt progression of the disease. Azathioprine may be started concurrently at a dose of 50 to 100 mg/day. The dose is calculated based on the red blood cell concentration of thiopurine methyltransferase, an enzyme involved in the metabolism of the thiopurine drugs, because low concentrations of this enzyme may lead to serious side effects, such as excessive myelosuppression, and high concentrations may lead to rapid metabolism of azathioprine and potential underdosing.[83] Immunosuppressants should be initiated early in the course of the disease to allow time for their immunosuppressant

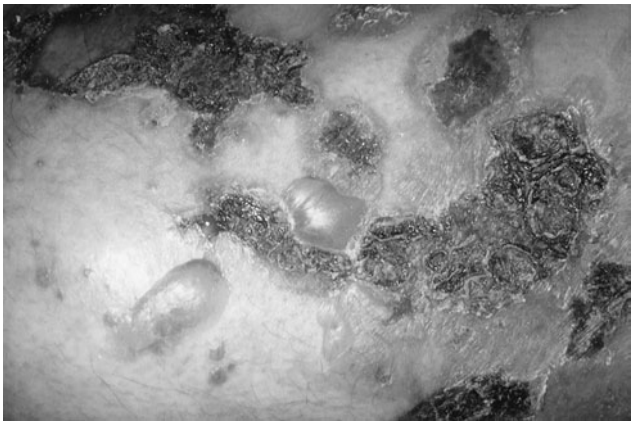

FIGURE 107-7 Bullous pemphigoid. Tense bullae arising on an erythematous plaque. ***(Courtesy Dr. Anne Laumann collection.)*** **See Plate 107-7.**

actions to take effect as this may take up to 6 weeks. Current therapeutic regimens also include parenteral gold, dapsone, plasmapheresis, intravenous immune globulin, and other immunosuppressant agents, such as cyclosporine, cyclophosphamide, and mycophenolate mofetil.[84,85]

BULLOUS PEMPHIGOID

Bullous pemphigoid (BP) is a self-limited autoimmune blistering disease characterized by tense, subepidermal bullae (Fig. 107-7, Plate 107-7). Autoantibodies develop to portions of the hemidesmosome complex in the basement membrane zone. The resulting disruption in adhesion leads to a subepidermal split from the dermis. These antigens are identified by their molecular weights, 230 kDa (BPAGI) and 180 kDa (BPAG2). Table 107-9 lists the characteristics that distinguish BP from PV.

BP has an estimated incidence rate of 7 per million per year. It occurs equally in men and women usually between 60 and 80 years of age. Approximately 50% of treated patients will go into remission within 2.5 to 6 years of onset of disease; however, individuals may have active disease for as long as 10 years. There is a predilection for tense blisters on normal or erythematous skin to occur in the groin, axillae, and flexural areas. Nikolsky sign is negative. Mucous membranes are involved in approximately 20% of patients. In addition to the bullae, patients may have urticarial weals and serpiginous erythematous plaques. Lesions heal without scarring, although there may be significant pigmentary change.[86]

Histopathologic sections show a split between the epidermis and the dermis, with an infiltrate consisting predominantly of eosinophils. Lymphocytes and neutrophils may also be present in the superficial and deep dermis. DIF of perilesional skin shows a linear deposition of IgG and complement along the basement membrane zone. Although the titer does not reflect disease activity, indirect immunofluoresence (IIF) studies show circulating antibasement membrane zone IgG antibodies in 70% to 80%.[87]

Corticosteroids, at smaller doses ($\leq$1 mg/kg per day) than those used for pemphigus vulgaris (PV), have been the mainstay of treatment for widespread disease. Localized or mild disease may respond to antibiotics at anti-inflammatory doses such as tetracycline 1 to 3 g/day or erythromycin 1 to 3 g/d with nicotinamide 1 g three times daily and/or high-potency topical steroids. Other therapies include dapsone and immunosuppressants such as azathioprine, cyclophosphamide, chlorambucil, mycophenolate mofetil, and methotrexate.[88]

PSORIASIS

Psoriasis is a chronic, recurrent skin condition that affects 1% to 3% of the population. Both sexes are equally affected. Well-defined circular or oval plaques with adherent silver scale characterize the lesions. Lesions have a predilection for extensor surfaces, especially the knees, elbows, scalp, and the superior end of the gluteal fold. Psoriatic lesions often develop at sites of physical trauma such as scratched areas, surgical incisions, and tape removal. This finding is referred to as the Köbner phenomenon. Initial psoriatic episodes that may occur 2 to 3 weeks after a streptococcal infection sometimes appear as widespread, asymptomatic, small red papules with a silvery scale. This is called guttate psoriasis and usually resolves over 2 to 3 months with no specific treatment. Drugs may also precipitate or exacerbate preexisting psoriasis. Well-known culprits include the withdrawal of systemic or strong topical steroids or other immunosuppressive agents and the administration of β blockers, antimalarials, or lithium.

TABLE 107-9 Comparison of Pemphigus Vulgaris and Bullous Pemphigoid

	Pemphigus Vulgaris	Bullous Pemphigoid
Age at onset	40–60 y	50–80 y
Clinical appearance	Superficial *flaccid* bullae erosions	Large *tense* bullae, urticarial wheals and serpigenous plaques
Nikolsky sign	Positive	Negative
Mucous membrane involvement	$\geq$95% (often is initial sign of disease)	$\leq$20%
Histology	Intraepidermal split	Subepidermal split
Direct immunofluorescence	IgG and complement (C3) deposition between keratinocytes	Linear deposition of IgG and C3 along basement membrane zone
Antigen	Desmoglein 3 (130 kDa), plakoglobin (85 kDa)	BP Ag I (230 kDa), BP Ag II (180 kDa)
Course	Mild to severe, may require large doses of steroids to control	Mild, tends to respond readily to systemic steroids

ABBREVIATION: Ag, antigen; BP, bullous pemphigoid; IgG, immunoglobulin G.

Alcohol abuse and HIV infection are associated with extensive and resistant psoriasis.[89]

Many clinical variants of psoriasis exist. Generalized pustular psoriasis, also referred to as von Zumbusch psoriasis, is a rare but serious variant that is characterized by diffuse pustules on erythematous plaques. Erythematous skin rapidly develops crops of pustules that coalesce to form "lakes of pus." Nails, palms, and soles are often affected. Fever, hypocalcemia, and leukocytosis may accompany the outbreak. The average age of onset is 50 years, with no sexual predilection. Precipitating factors include drugs, infection, pregnancy, exertion, and menstruation. The differential diagnosis in a patient with diffuse pustules and fever includes infection, drug reaction, acute generalized exanthematous pustulosis, pustular psoriasis, and subcorneal pustular dermatosis.[90,91]

Psoriasis may be treated initially with a variety of topical medications. These include corticosteroids, calcipotriene, tar, anthralin, and topical retinoids. These agents are used as monotherapy or in combination. Systemic drugs are reserved for extensive or disabling disease and include methotrexate, cyclosporine, and oral retinoids. Ultraviolet (UV) light therapy is often used in combination with topical and/or systemic agents. UV light therapy has been a mainstay of treatment for years. This includes natural sunshine, broadband UVB (280 to 320 nm), UVA (320 to 400nm), and a single-wavelength light narrowband UVB (311 nm). Psoralen, a photosensitizer, is used to potentiate the UVA effects in a regimen called PUVA. Acitretin, a systemic retinoid, may be used alone or in combination with phototherapy. Biologic therapy that targets specific cytokines and intercellular adhesion molecules has recently been introduced. At the time of writing three of these agents have been approved by the Food and Drug Administration for the treatment of psoriasis. Alefacept is a recombinant protein containing human leukocyte function-associated antigen 3 and human IgG1. IG binds to CD2 on memory-effector cells. Efalizumab is a humanized monoclonal antibody to CD11a, a subunit of LFA-1. IG inhibits trafficking of T-cells to the skin and T-cell reactivation in the skin. Etanercept is a soluble recombinant human tumor necrosis factor 2 receptor that binds the circulating inflammatory stimulator tumor necrosis factor 2. Each is administered parenterally using unique dosing regimens.[92,93] The long-term affects of these therapies are not yet known. Acitretin, narrowband UVB, PUVA, methotrexate, and cyclosporine have been used effectively in the treatment of generalized pustular psoriasis.[94]

ERYTHRODERMA

Erythroderma or *exfoliative dermatitis* is a descriptive term for a clinical condition characterized by total body diffuse erythema and scaling (Fig. 107-8, Plate 107-8). The skin is initially red and warm. Scaling and exfoliation, often accompanied by fever, chills, and lymphadenopathy, follow. The percutaneous absorption barrier is lost and blood flow to the skin increases, which may lead to serious complications such as hypoalbuminemia, peripheral edema, loss of muscle mass, and high-output cardiac failure, with as much as 8% of the total cardiac output being directed at the inflamed cutaneous vasculature. Causes of exfoliative dermatitis include inflammatory conditions, drug eruptions, cutaneous T-cell lymphoma, and systemic neoplasms (Table 107-10). Common inflammatory

FIGURE 107-8 Erythroderma. Generalized erythema, edema, and scaling. ***(Courtesy Dr. Anne Laumann collection.)*** **See Plate 107-8.**

conditions include psoriasis, atopic dermatitis, contact dermatitis, and pityriasis rubra pilaris. Antiepileptic medications (carbamazepine, phenobarbital, or phenytoin), antihypertensive medications (captopril or chlorothiazide), antibiotics (cephalosporins, dapsone, isoniazid, or minocycline), and calcium channel blockers have been associated with exfoliative erythroderma.[95] Lymphomas and hematologic malignancies are common systemic neoplasms that may cause erythroderma. Sézary syndrome is the leukemic form of cutaneous T-cell lymphoma, which is characterized by circulating atypical lymphocytes with hyperconvoluted nuclei (Sézary cells). These atypical cells are identified on blood smear or in skin biopsies. Internal malignancies occasionally cause erythroderma.

The erythrodermic patient should be monitored with specific attention to fluid and electrolyte balance, temperature regulation, and nutritional status. Skin biopsy may help identify the underlying cause of the dermatosis and thus direct specific treatment. Initial management includes the use of medium potency topical steroid ointments covered with a

bland ointment, such as zinc oxide ointment and wrapped with clean cloths, or topical steroids applied directly under a plastic sauna suit. It is important to avoid topical irritant agents, such as tar-containing ointments. Wet dressings may help weeping or crusted areas. Pruritus and anxiety typically respond to the sedating antihistamines. Alternatively, doxepin at doses of 25 to 50 may be given at bedtime.

PURPURA

Purpura is a clinical term that represents the extravasation of blood into surrounding tissues.[96] Purpura is a common skin condition that has many causes. An approach to the patient with purpura focusing on the dermatologic decision-making algorithm is discussed (Fig. 107-9). The type of lesion depends on the depth of the vascular plexus involved, the size of the vessel injury, precipitating factors, and coextravasated circulating substances. Visual and tactile assessments of a lesion are crucial. Lesions are placed into two main categories, palpable or nonpalpable (Fig. 107-10, Plate 107-10). The patient's underlying conditions, potential precipitating events, current and past laboratory values, and medication history are analyzed.

Nonpalpable (macular), nonblanching purpura arises from simple hemorrhage into tissue. The dermal vascular network consists of superficial and deep vascular plexuses. The superficial plexus possesses arteriovenous loops that ascend into the dermal papilla. Petechiae are lesions smaller than 0.2 cm in diameter that result from superficial vascular hemorrhage. Larger areas are termed *ecchymoses*. Nonpalpable purpura is most commonly attributed to fragility of the vascular tissue or defects in hemostasis. Examples include actinic or solar purpura (owing to the age-related loss of collagen in the basement membrane of blood vessels) and purpura secondary to systemic corticosteroids (related to inhibition of lysyl oxidase that is required for synthesis of type IV collagen, the principal collagen associated with blood vessel basement membrane integrity). Cutaneous amyloid, primary or secondary resulting from myeloma, may be deposited in endothelial cells.[97] Deposition results in vascular fragility so that nonpalpable lesions representing common bruises, sometimes called *pinch purpura*, may occur after minor trauma. This occurs mainly on the face, especially periorbitally. Other common causes of flat purpura include platelet disorders (thrombocytopenia, thrombocytopathia, and thrombocytosis), disseminated intravascular coagulation (DIC), and warfarin-associated necrosis. If the diagnosis cannot be made on clinical grounds, a skin biopsy may be helpful. Flat purpura in neutropenic patients is approached as if it were palpable purpura, because these patients are unable to mount the appropriate

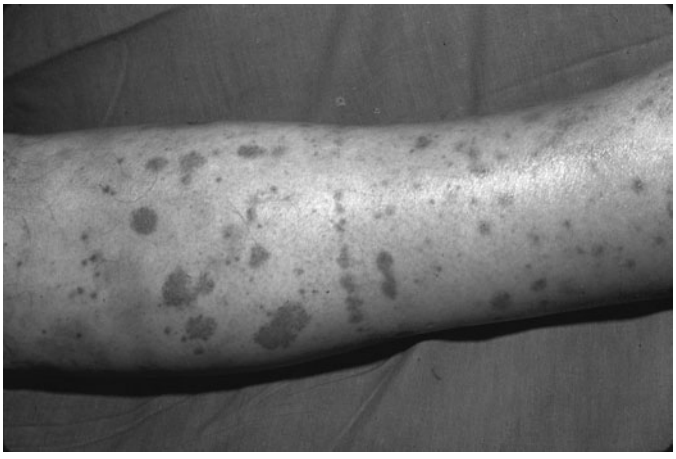

FIGURE 107-10 Palpable purpura (leukocytoclastic vasculitis). Erythematous to violaceous plaques on the lower extremity, which do not blanch with pressure. ***(Courtesy Dr. Denise Rubenstein collection.)*** **See Plate 107-10.**

immune response to cause dermal inflammation. In such patients, biopsy is important to assist with diagnosis.

Palpable purpura indicates underlying vasculitis (also called *cutaneous necrotizing venulitis* or *leukocytoclastic vasculitis*). For the first 24 to 48 hours, the lesions are a deep erythematous color that eventually becomes violaceous. The pathologic process results from segmental vascular inflammation, swelling and necrosis of endothelial cells, and neutrophilic infiltration of vessel walls with fragmentation of nuclei.

As outlined in Fig. 107-9, many factors may lead to vasculitic injury. Precipitating factors include infections, drugs, autoimmune diseases, and immunoglobulin-mediated complement activation. Common infectious agents include *Staphylococcus aureus*, hepatitis B, and hepatitis C. Drugs commonly associated with vasculitis include ampicillins, thiazides, phenytoin, sulfa-containing compounds, allopurinol, hydralazine, and propylthiouracil.

Workup includes identification of a potential primary cause and evaluation for systemic involvement. In addition to a biopsy, a complete blood count, chemistry panel, liver function tests, urinalysis, stool guaiac, hepatitis B and C viral serologies, cryoglobulins, and complement levels are evaluated. Antinuclear antibody titers are evaluated in patients with suspected connective tissue diseases. In patients with a fever and heart murmur, blood cultures and echocardiography should be performed.[98]

Retiform purpura is referred to as *purpura fulminans*, a pattern usually indicative of micro-occlusion. In contrast to inflammatory purpura, this type immediately manifests as violaceous purpura that may or may not be palpable. Lesions appear abruptly and display a retiform or jagged edge, sometimes blending into a livedo pattern at the periphery. The major causes of micro-occlusive disease include disseminated intravascular coagulation, meningococcemia, acquired protein C or S deficiency, warfarin-induced skin necrosis, antiphospholipid antibody syndrome, sepsis of various causes, cryoglobulinemia, cryofibrinogenemia, paroxysmal nocturnal hemoglobinuria, and cholesterol emboli.[99]

GRAFT-VERSUS-HOST DISEASE (GVHD)

GVHD is a complex syndrome which occurs after allogeneic bone marrow transplantation. The skin is often the first and is the most frequent organ involved. Biopsy may help distinguish GVHD from other causes of erythema such as drug eruptions or viral exanthems. Acute GVHD usually occurs between days 10 and 30 after transplantation, but may appear at anytime.[100]

Skin changes consist of a generalized morbilliform eruption progressing to extensive redness, blistering, or skin necrosis. The earliest sign is pruritus and tenderness of the palms and soles, with reddening of the dorsal aspects of the fingers and periungual skin. Diffuse erythema of the hands and feet soon follows. In addition, the ears are commonly affected. Unusual clinical patterns may be seen due to the polymorphous nature of this disease. Confluence of lesions occurs on the trunk as the disease progresses. Blisters (with a positive Nikolsky sign) and generalized desquamation portend a poor prognosis. The palmar and plantar erythemas of acute GVHD need to be differentiated from those of palmar-plantar erythrodysesthesia due to chemotherapeutic agents. This syndrome may occur with GVHD or in similar clinical situations. The erythrodysesthesia begins as spotty erythema on the thenar and hypothenar eminences and progresses to severe pain and swelling.

The original grading system for GVHD was described in 1974 and is still in use today.[101] Several features of GVHD are recognized: (1) 72% of transplanted patients develop clinically recognizable GVHD; (2) an increase in the serum aspartate aminotransferase concentration is related to the onset or worsening of the skin erruption; (3) cutaneous symptoms precede systemic involvement by 2 to 3 days; and (4) the severity of GVHD does not correlate with the underlying disease process, the conditioning regimen, or the day of onset after grafting. The initial management strategy when GVHD is suspected includes obtaining a skin biopsy to look for the characteristic changes. Unfortunately, the diagnostic yield of skin biopsies for GVHD is only 50% to 65%. When biopsies show nonspecific changes, additional biopsies are recommended in 24 to 48 hours. Tissue cultures to look for bacteria, mycobacteria, and fungi should be performed in febrile patients.

Factors associated with a high risk of developing GVHD include an HLA mismatch, an unrelated donor, older age of the recipient or donor, a sex mismatch, T-cell replete grafts, donor allosensitization, regimen toxicity, and compromised delivery of GVHD prophylaxis.[102] splenectomy, bone marrow cell dose, and ABO match. Polymorphism of minor determinants such as the adhesion molecule CD31 may account for the risk of GVHD between HLA identical donor and transplant recipients.[103] Future testing for minor and major determinants may help decrease the risk and severity of GVHD.

GVHD has also been described after autologous and syngeneic transplantation. This phenomenon has stimulated much interest because it indicates that factors other than donor reactivity against recipient antigens may be involved in allogenic GVHD. In autologous GVHD, only the skin is involved, and lesions typically resolve within 7 days. The combination of total body irradiation (which causes failure of the peripheral autoregulatory mechanisms) and cyclosporine (which blocks clonal deletion of autoreactive T cells that escape from the thymus) are believed to be important factors.[104] Treatment for acute GVHD includes modifying the original immunosuppressive prophylactic regimen (cyclosporine, tacrolimus, or mycophenolate mofetil) and adding methylprednisolone at 2 mg/kg. Treatment protocols differ and may include anti-thymocyte globulin, intravenous immunoglobulin (IVIG), and monoclonal antibodies. Topical treatment is mainly supportive, with emollients and topical steroids. Erythrodermic and severe blistering patients deserve close monitoring and aggressive immunosuppression. Other therapies reported to be beneficial in the treatment of GVHD include ultraviolet light therapy (PUVA, broad band or narrow band UVB) extracorporeal photochemotherapy (photopheresis), pentoxifylline, and thalidomide.

Dermatoses Precipitated by Infection

BACTERIAL INFECTIONS

Infectious organisms can involve the skin via a primary or secondary route. Primary infections begin as a localized exogenous invasion that can spread superficially or invade to the deeper subcutaneous tissue, depending on host and virulence factors. Secondary infections occur by hematogenous dissemination of the organism or portions of the organism and may be accompanied by immune complex deposition.

IMPETIGO

Impetigo is a primary bacterial infection that occurs in two forms: impetigo contagiosa (caused by staphylococci and, less commonly, streptococci), and bullous impetigo (caused by a toxin released from *S. aureus*). Impetigo usually appears on exposed areas such as the face and extremities in children, the elderly, and the immunosuppressed. Impetigo begins as an erythematous plaque with scattered vesicles that subsequently rupture to form honey-colored crusts. The infection often begins after minor trauma allows bacterial invasion of the superficial epidermis. Constitutional symptoms are generally absent but regional lymphadenopathy is common. Bullous impetigo is characterized by large flaccid bullae that have a positive Nikolsky sign. Bullous impetigo is caused by a toxin-producing strain of phage group II *S. aureus*. Bullous impetigo may be considered a localized form of staphylococcal scalded skin syndrome.

The diagnosis of impetigo is made based on clinical findings. Culture and sensitivity may be useful to confirm the diagnosis or when resistant or nephritogenic strains are suspected. Anti-DNAase B and antihyaluronidase titers rise significantly after streptococcal skin infection, but there is no change in the antistreptolysin titer.[105] Bullous impetigo is a toxin-mediated process and culture of blister fluid is often negative. Serious secondary infections related to pyoderma include osteomyelitis, septic arthritis, and pneumonia.

The prevalence of erythromycin-resistant streptococci and staphylococci has been increasing in recent years, so erythromycin is no longer a treatment of choice. Treatment includes room temperature tap water compresses in conjunction with topical mupirocin or a β-lactamase–resistant penicillin (dicloxacillin or cloxacillin) or a first-generation cephalosporin (cephalexin). Azithromycin may be given to penicillin-allergic patients. Up to 15% of individuals, usually children between the ages of 2 and 4 years, with impetigo caused by a group A streptococcal nephritogenic strain (usually M-49 serotype) develop acute poststreptococcal glomerulonephritis 1 to 5 weeks (median = 10 days) after infection. Occasionally, a group C streptococcus is involved.[106] The overall incidence of nephritis related to impetigo is 2% to 5%. The use of antibiotics does not appear to decrease the incidence of poststreptococcal glomerulonephritis, despite prompt clinical and bacteriologic responses.[107]

NECROTIZING FASCIITIS

Necrotizing fasciitis (NF) is a rapidly progressive suppurative bacterial infection of the superficial and deep fascia that, if left unchecked, progresses to gangrene, sepsis, and death (see Chap. 55). Classically, this has been associated with group A streptococcus alone or with concomitant facultative and anaerobic bacteria (clostridium, bacteroides, Enterobacteriaceae, *Vibrio* species, and non–group A streptococci).[108]

NF occurs in adults of any age who may be otherwise healthy. Predisposing factors include any condition that may cause a break in the skin, such as varicella, cuts, burns, surgical procedures, and child birth. Diseases such as diabetes and cirrhosis, immunosuppression, and drugs such as infliximab may also increase the risk of infection.[109] The patient's use of NSAIDS may delay diagnosis and allow for rapid progression of infection owing to attenuation of the early inflammatory host response and alteration of the humoral immune response.[110]

Patients present with skin erythema, edema, warmth, and tenderness often localized to one limb. Other areas such as the face are affected less often.[111] Within 24 hours there is rapid spread proximally and distally along the limb, and there may be a bluish necrotic hue and bullae appearing within the affected area. The key features that distinguish NF from cellulitis are rapid spread and significant tenderness.

The diagnosis of NF is primarily clinical. Computed tomography or magnetic resonance imaging may help locate the site and extent of infection. In mixed anaerobic infections, plain radiographs may detect gas in the soft tissues. In evaluation of a swollen painful extremity, compartment pressure measurements may be useful. If pressures are elevated (>40 mm Hg), immediate fasciotomy is indicated. A superficial skin biopsy does not aid in the diagnosis. Tissue sampling that extends to the fascia is required.

Surgical debridement or incisional drainage is essential for treatment. Concomitant treatment with antibiotics should not delay surgical management. Antibiotics alone are ineffective owing to the amount of vascular occlusion in the affected area and to the slower growth rate of streptococci in large inocula.[112] After debridement, tissue should be Gram stained

and cultured for aerobes and anaerobes. Empiric antibiotic therapy includes penicillin and/or clindamycin.

TOXIC SHOCK SYNDROME

Toxic shock syndrome (TSS) is characterized by fever, shock, desquamating rash, and multiorgan system failure in association with toxins mediated from group A streptococcal or *S. aureus* infections. Streptococcal TSS (STSS) is seen most often in association with soft tissue infection, including necrotizing fasciitis (NF). The syndrome appears to be mediated by one or more of the streptococcal pyrogenic exotoxins (types A, B, or C). Type A exotoxin has the most potent inflammatory and cytotoxic properties and is most closely associated with STSS.[113] These toxins may act as superantigens by directly linking the major histocompatibility complex of antigen presenting cells to the V-β portion of the T-cell receptor, thus bypassing the limiting step of antigen processing and resulting in massive T-cell activation.[114] Up to 80% of patients with this syndrome present with soft tissue infections.[115] Other access sites include the mucous membranes, such as the vagina, intravenous drug use, and burn wounds.[116,117] In patients with no identifiable portal of entry, seeding of infection is thought to occur by a transient bacteremia originating in the pharynx. Symptomatic sore throat may occasionally precede STSS. Patients, who tend to be young and in good health, present with influenza-like symptoms (fever, myalgias, malaise, headache, nausea, vomiting, or diarrhea) often in conjunction with pain and erythema of an area such as an extremity. Approximately 20% of patients will develop a generalized blanching erythema that desquamates at days 7 to 14.[118]

The criteria for diagnosis of STSS are presented in Table 107-11. Laboratory data that support the diagnosis of STSS include a normal or moderately elevated white blood cell count with a profound left shift, azotemia, hypocalcemia, hypoalbuminemia, thrombocytopenia, hematuria, and an elevated creatine kinase. It is interesting to note that evidence of renal impairment precedes hypotension in approximately 50% of patients at the time of admission to the hospital and develops in all others within 4 to 8 hours after admission.

TSS caused by *S. aureus* begins with a scarlatiniform eruption. There may be flexural accentuation, erythema and edema of the palms and soles, hyperemia of the conjunctivae and mucous membranes, and a strawberry tongue.[119] In contrast to STSS, which tends to present with a localized soft tissue infection, signs of infection are often absent in TSS mediated by *S. aureus*–producing toxin. Both syndromes tend to occur in young healthy adults, but TSS may be associated with staphylococcal overgrowth of occluded mucosal surfaces (e.g., superabsorbent tampons or nasal gauze packing).

Treatment of STSS and TSS consists of supportive care, vasopressors, and antibiotics. Adequate antimicrobial coverage for *Staphylococcus* and *Streptococcus* should be initiated with clindamycin alone or in combination with penicillin.[120] Treatment with intravenous γ globulin may be considered in patients who present hypotensive and with a cellulitis.[121] Hyperbaric O_2 and plasmapheresis have also been used in STSS.[41,122]

TABLE 107-11 Definition of Streptococcal Toxic Shock Syndrome (Proposed)

Isolation of group A streptococci from a normally sterile site[a] (e.g., blood, pleural fluid, cerebrospinal fluid, tissue biopsy) or from nonsterile site[b] (e.g., oral, vaginal, and rectal mucosa).
Systolic blood pressure < 90 mm Hg in adults
At least two of the following
Renal impairment
Disseminated intravascular coagulation
Elevated liver enzymes
Adult respiratory distress syndrome
Generalized cutaneous erythema
Severe soft tissue inflammation and necrosis.

STAPHYLOCOCCAL SCALDED SKIN SYNDROME

Staphylococcal scalded skin syndrome (SSSS; Fig. 107-11, Plate 107-11) is a desquamative exanthem that occurs in conjunction with infection of toxin-producing *S. aureus* phage group II types 3A, 3C, 55, and 71.[123] The desquamation is mediated by exfoliative toxins A and B.[124] Most patients are younger than 5 years, and adults are only rarely affected. The major risk factors for developing SSSS in adults are renal failure (owing to decreased filtration of toxin), hematologic malignancies, and immunosuppression. The concurrent use of NSAIDs may predispose to SSSS.[125]

Several factors make SSSS an important consideration in the ICU setting. Nasal carriage of *S. aureus* is three times higher in hospital personnel and dialysis patients than in the general population. Approximately 6% of the coagulase-positive *S. aureus* strains randomly isolated from hospitalized patients are toxigenic. Patients in the ICU may be immunosuppressed and/or have renal failure, thereby increasing their risk for acquiring SSSS.

The disease process is similar to bullous impetigo but is generalized rather than localized. Patients may have a preceding upper respiratory infection with rhinorrhea, pharyngitis, and conjunctivitis. The exanthem begins abruptly with diffuse tender erythema and subsequent superficial desquamation. The erythematous skin has a rough sandpaper-like texture often accentuated in the flexural and periorificial area. Because the split occurs in the granular layer (superficial) of the epidermis, intact bullae are rarely seen although when present, the Nikolsky sign may be positive. The skin appears bright pink, moist, and eroded skin after desquamation. The clinical presentation sometimes may be difficult to separate from that of toxic epidermal neurolysis (TEN).

Cultures are taken from all orifices (eye, nose, throat, vagina, and rectum) and blood. The diagnosis of SSSS is supported by the isolation of *S. aureus*. Rapid distinction from TEN may be made by frozen section of the exfoliated skin and histopathologic examination to determine the level of cleavage. Biopsy at the border of a blister and normal skin should also be sent for routine processing. Cultures from blisters are negative owing to the toxin-mediated nature of the disease.

Treatment of SSSS requires appropriate antibiotics and vigilant monitoring of fluids and electrolytes. Antibiotic choice usually includes penicillinase-resistant semisynthetic penicillins (nafcillin, methicillin, or dicloxacillin) or a

FIGURE 107-11 Staphylococcal scalded skin syndrome. Superficial desquamation of non-necrotic epidermis. ***(Courtesy Dr. Denise Rubenstein collection.)*** **See Plate 107-11.**

first-generation cephalosporin. Monotherapy is usually adequate because multiresistant strains of *S. aureus* are rarely encountered among the toxigenic strains. Adjunctive measures include the application of bland lubricants for the patient's comfort. Healing occurs in 7 to 10 days.

PSEUDOMONAS BACTEREMIA

Different skin manifestations of pseudomonas bacteremia have been described. These have been divided into four categories.[126] The first is ecthyma gangrenosum, which is characterized by a localized, erythematous, tender plaque or bulla that subsequently develops central necrosis leaving a gangrenous eschar with an erythematous annular border. The lesions can occur anywhere but are usually found in the anogenital region, buttocks, or axilla.[127] Ecthyma gangrenosum occurs in approximately 5% of patients with pseudomonas bacteremia and has been described in association with localized pseudomonas infection without bacteremia. The second category includes vesicles or bullae that can occur anywhere and may occur singly or in clusters. These lesions frequently become hemorrhagic and take on the appearance of ecthyma gangrenosum lesions when ruptured. The third category is a cellulitis with a sharply demarcated border. This contrasts with cellulitis caused by staphylococcal or streptococcal infection, which tends to have ill-defined borders. The fourth category of lesion are small pink, round plaques or subcutaneous nodules that are concentrated on the trunk and proximal extremities. The nodules are considered a form of nodular cellulitis and, when incised and drained, grow *Pseudomonas aeruginosa* in culture. *Pseudomonas aeruginosa* bacteremia carries a high mortality rate and treatment should be initiated early. This requires dual therapy with an aminoglycoside in conjunction with ticarcillin, piperacillin, ceftazidime, or imipenem.

VIBRIO VULNIFICUS BACTEREMIA

Vibrio vulnificus is a gram-negative rod that is found in salt water and in shellfish. The main portals of entry in humans are via ingestion (gastroenteritis) or direct inoculation into the skin (cellulitis). There may be an associated septicemia. The other *Vibrio* species (e.g., cholerae and parahaemolyticus) primarily cause gastroenteritis. *Vibrio vulnificus* infection is seen most commonly in association with underlying hepatic disease (cirrhosis or fatty liver), diabetes mellitus, chronic renal insufficiency, or underlying immune suppression. Most of the case reports in the United States involve patients with cirrhosis who injured themselves while in salt water or who ate raw oysters.[128]

A patient will present with an erythematous painful swollen limb with overlying hemorrhagic bullae and fever. Thirty-three percent of patients are in shock within 12 hours of presentation. The incubation period after ingestion is 4 to 96 hours. There may be a history of an abrasion occurring while in salt water or the recent ingestion of raw shellfish. The presence of hemorrhagic bullae overlying a cellulitis with the appropriate clinical history is highly suspicious for *V. vulnificus* septicemia. The clinical picture may be very similar to that of NF.

Aspiration of blister fluid for Gram stain and culture is essential, and biopsy for culture may be useful. Elevated creatine phosphokinase levels are often present in this condition and in STSS. This is in contrast to the normal creatine phosphokinase levels usually found in the less rapidly progressive conditions of cellulitis and erysipelas, and may be a helpful distinguishing feature.[129] The laboratory should be alerted when *Vibrio* infection is suspected so that the material is set up for culture on thiosulfate-citrate-bile salt-sucrose agar. On thiosulfate-citrate-bile salt-sucrose agar, *V. vulnificus* yields large green colonies within 24 hours of aerobic incubation.[130]

Fortunately, *V. vulnificus* is sensitive to most antibiotics. Because of the high mortality and morbidity rates, effective treatment includes early search for and recognition of the infection, aggressive antibiotic therapy, supportive care, and, in cases of wound infections, débridement.[131] Empiric therapy includes doxycycline or minocycline with an aminoglycoside or cephalosporin.

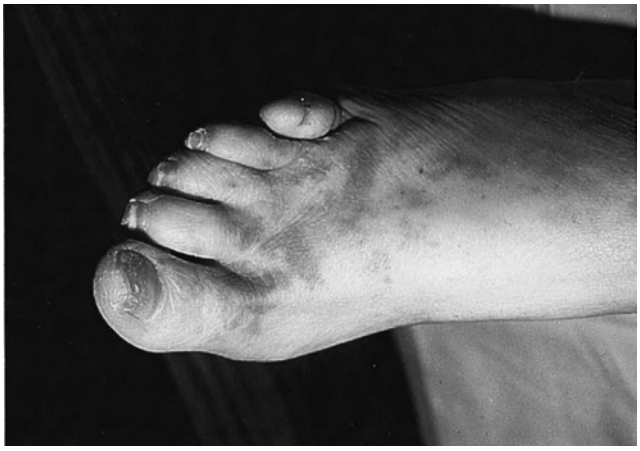

FIGURE 107-12 Meningococcemia. Purpuric lesions with irregularly angulated borders. See Plate 107-12.

MENINGOCOCCEMIA

Acute infection with the gram-negative diplococcus *Neisseria meningitidis* is associated with characteristic cutaneous findings, which may aid in the early diagnosis of this rapidly fatal disease. Characteristic findings are petechiae, ecchymoses, or palpable purpura. Petechiae may be preceded by an urticarial, rubella-like, papular, or generalized scarlatiniform eruption for 2 days. Petechiae may have a smudged appearance and tend to be concentrated on the trunk, proximal extremities, and mucosal surfaces (Fig. 107-12, Plate 107-12). The number of petechiae correlates with the degree of thrombocytopenia and is indistinguishable from other causes of petechiae such as diffuse intravascular coagulation (DIC). A late finding may be hemorrhagic vesicles or bullae centrally located within a purpuric patch. Patients with deficiency of late-acting complement factors (C5 to C8) are at particular risk for severe or recurrent meningococcal infections.[132]

The purpura seen in meningococcemia is mediated by two events. The first is thrombosis precipitated by meningococcus, fibrin, and leukocytes with a corresponding leukocytoclastic vasculitis. Thrombi are concentrated in the lung, skin, spleen, heart, and liver. The second is DIC precipitated by meningococcal endotoxin.[133] Fibrin thrombi within a vessel and a corresponding vasculitis are seen on histology.

The diagnosis is aided by a skin smear for Gram stain and biopsy for culture. Blood polymerase chain reaction is a sensitive test for confirming meningococcal disease.[134] Mortality rates are high and fewer than 30% with septic shock survive. Mortality rate is higher with increasingly extensive skin hemorrhage (purpura fulminans). Prompt antibiotic treatment is essential to decrease mortality rate, and drotrecogin-alpha (recombinant human activated protein C) may be particularly valuable. High-dose penicillin is still the drug of choice despite evidence of some less susceptible strains of meningococcus.[135] Cefotaxime and ceftriaxone have the advantages of being safe with a rapid onset of action and also being excellent antibiotics for *Streptococcus pneumoniae* and *Haemophilus influenza*, pending confirmatory diagnosis. Chloramphenicol is an acceptable alternative in penicillin-allergic patients.

The differential diagnosis of the purpuric lesions of meningococcemia includes gonococcemia, rickettsial infection, allergic vasculitis, bacterial endocarditis (with *S. aureus* or viridans streptococci), and DIC. Patients with gonococcemia usually have an associated arthritis and tenosynovitis with a very few scattered petechiae, each surmounted by a tiny pustule occurring in an acral distribution. Symmetric petechiae of the palms and soles are highly suggestive of Rocky Mountain spotted fever (infection with *Rickettsia rickettsii*).

INFECTIVE ENDOCARDITIS

The most common cutaneous finding in patients with infective endocarditis is petechiae. Petechiae are found in approximately 30% of patients and may be secondary to microemboli; however, bacteria are rarely cultured from skin specimens. Petechiae may appear on conjunctiva, buccal mucosa, palate, and retina (Roth spots). Petechiae on fingers or nail beds manifest as red to brown streaks termed *splinter hemorrhages*. Splinter hemorrhages are also seen in the elderly or related to trauma. The lesions are most suggestive of infective endocarditis when they occur on the proximal nail beds.

Petechiae occurring on the palms and soles with a nodular character are termed *Janeway lesions* (Fig. 107-13, Plate 107-13). Janeway lesions are characteristically nontender.[136] The lesions result from septic emboli consisting of bacteria, neutrophilic infiltration, and subcutaneous hemorrhage. Janeway lesions persist for several days and occur commonly in staphylococcal endocarditis. Osler nodes are small (2 to 15 mm) painful nodules.[137] The lesions are commonly found on the pads of the fingers, toes, or thenar eminences. They tend to occur in crops, are frequently multiple and evanescent, and disappear within hours to days. Osler nodes are seen in 5% to 15% of patients with streptococcally induced infective endocarditis but may also be seen in systemic lupus erythematosus, endocarditis due to fungal or gram-negative bacilli, typhoid fever, gonococcemia, and on the arms of patients with cannulated radial arteries. Microscopic examination shows microemboli in adjacent arterioles. Janeway lesions and Osler nodes resolve with appropriate antibiotic therapy. Clubbing of the digits is a nonspecific finding found in 10% to 20% of cases of infective endocarditis, especially when the disease is of long duration.

FIGURE 107-13 Subacute bacterial endocarditis. Nontender, purpuric macules with irregular borders scattered on the toes (Janeway lesions). See Plate 107-13.

Viral Infections

HERPES SIMPLEX

Cutaneous herpes infection is associated with herpes simplex virus (HSV) types 1 and 2 that can occur on any cutaneous area. In general, HSV-1 causes orofacial infection and HSV-2 causes anogenital infection, although this distinction is changing with HSV-1 causing up to one-third of new genital infections. HSV-2 genital infection recurs six times more frequently than HSV-1 genital infection.[138] Any stress on the immune system increases the likelihood of expression of HSV in a previously infected individual. The classic appearance of recurrent HSV infection is a cluster of vesicles or shallow erosions over the lips, genitals, and lumbosacral region (Fig. 107-14, Plate 107-14). It is not uncommon for the vesicles to go undetected, so the patient presents with punched-out erosions or shallow ulcerations. In the ICU, recurrent infections are extremely common and related to the stress of illness or the degree of immunosuppression. The patient may not have been aware of any previous outbreaks, but in the immunosuppressed, if early lesions go undetected, large, erosive areas of ulceration may occur. Chronic perianal HSV ulcers are easily mistaken for decubitus ulcers. Scalloped borders and small circular ulcerations at the periphery of the ulcer may be helpful distinguishing signs.

Rapid diagnosis in 30 minutes to 2 hours may be done by DIF on cells that have been smeared on a glass slide with saline and dried or by direct fluorescent antibody (DFA) testing with monoclonal antibodies on cultured specimens.[139,140] This highly sensitive test distinguishes HSV-1 from HSV-2. Bedside diagnosis is aided by performing a Tzanck smear. The vesicle is unroofed, and the base of the lesion is scraped with a blade. The scraping is spread evenly on a glass slide and then allowed to air dry or is fixed with alcohol. The slide is then stained with Giemsa, Toluidine blue, or Diff-Quik stain and examined for multinucleated giant and/or balloon cells. If no vesicles are present, a scraping from a moist erosion may be helpful (crusted lesions generally will not yield a positive result). An early vesicle should be chosen for biopsy to avoid secondary changes that might obscure the characteristic features. These include an intraepidermal bulla with ballooning degeneration of keratinocytes at the base of the vesicle. Balloon cells develop intracellular edema and subsequently break their desmosomal attachment to adjacent cells and float up into the bulla cavity. These cells are often multinucleated (2 to 15 nuclei) and correspond to the multinucleated giant cells seen on the Tzanck smear. Culture of the vesicle fluid will allow identification of HSV or varicella zoster virus (VZV). HSV usually grows within 48 hours in tube cell cultures, whereas VZV may take 7 to 14 days to grow. Antibodies to HSV are found in 50% to 90% of adults. Testing is generally unhelpful for a diagnosis of a particular outbreak. The presence of IgM or a fourfold or greater rise in IgG titer reflects recent infection. The presence of IgG indicates prior exposure.

FIGURE 107-14 Severe recurrent herpes simplex infection associated with systemic steroid administration. Grouped vesicles and pustules on an erythematous base. ***(Courtesy Dr. Anne Laumann collection.)*** **See Plate 107-14.**

All HSV and VZV infections encountered in the ICU should be treated promptly with an antiviral agent such as acyclovir, famciclovir, or valacyclovir usually intravenously, although the medications are effective orally. These medications are converted to triphosphorylated purine analogues via viral thymidine kinase and host cell enzymes. Acyclovir triphosphate is an inhibitor and a substrate for viral DNA polymerase and becomes incorporated into the growing DNA chain. Acyclovir triphosphate lacks a hydroxyl group in the 3′ position and further chain synthesis is halted. In the setting of immunosuppression, strains of acyclovir-resistant HSV and VZV have developed. Resistance occurs when viral thymidine kinase no longer phosphorylates acyclovir (or famciclovir). Foscarnet is a second-line agent for treatment of HSV and VZV in cases where resistance occurs. Foscarnet attaches to the pyrophosphated binding sites of viral DNA and RNA polymerases, causing reversible inhibition of enzyme activity. Foscarnet does not require viral thymidine kinase for activation. Foscarnet is administered intravenously at a dose of 60 mg/kg twice daily or 40 mg/kg three times daily. HSV and VZV resistance to acyclovir can be determined in the laboratory.[141]

Local care consists of 0.5% silver nitrate or Burrow compresses applied for 20 minutes three to four times daily to alleviate swelling, inflammation, maceration, and crusting of extensive erosions. Topical acyclovir in general is not useful but may speed the healing of erosive HSV in immunosuppressed individuals. Topical penciclovir applied every 2 hours for 4 days has been shown to decrease clinical healing time by about 1 day in primary infections.

An important complication of HSV infection is eczema herpeticum. This is disseminated cutaneous HSV infection that occurs in patients with an underlying dermatitis such as atopic dermatitis, seborrheic dermatitis, contact dermatitis, or Darier disease. Patients present with diffuse crusting that may or may not be preceded by typical herpetic lesions. Intact vesicles are rarely seen. Diffuse eczema herpeticum is a severe and potentially life-threatening condition that may require therapy with intravenous acyclovir.[142]

VARICELLA ZOSTER

The varicella zoster virus belongs to the herpesvirus family (DNA-enveloped viruses). Varicella (chicken pox) is the primary disease, and zoster (shingles) is a recrudescence of the latent form. Primary infection occurs via aerosolized

respiratory droplets (most common) or direct contact with vesicle fluid. After primary infection, the virus lies dormant in the dorsal root ganglion until reactivation occurs. Reactivation results in spread of the virus down the nerve root, causing pain, erythema, and vesicles in a dermatomal distribution.

The classic cutaneous finding in varicella is a generalized eruption of discrete vesicles, each on an erythematous base ("dew-drop on a rose petal"). These appear after an average incubation period of 14 days (range = 9–21 days) and are usually seen in association with prodromal symptoms of fever and malaise. The patient is contagious from 2 days before the eruption until all lesions have crusted. The vesicles first appear on the trunk and spread to the extremities. Lesions commonly occur in the mouth and vagina and tend to rupture rapidly, leaving small ulcers (aphthae). The cutaneous lesions progress from an erythematous papule to a vesicle to a hemorrhagic crust. There may be lesions at various stages of development at any one time. Varicella infection in adults and the immunosuppressed can be life-threatening. The most common complication is varicella pneumonia. Pneumonia generally appears 1 to 6 days after the onset of the rash. The symptoms may be out of proportion to chest radiographic findings. Encephalitis may be seen in patients with a persistent viremic state and appears to correspond to direct infection of the central nervous system. An immune complex vasculitis may lead to pancreatitis, myocarditis, arthritis, and palpable purpura.

Herpes zoster presents with a prodrome of intense pain affecting a dermatome before the onset of an erythematous, urticarial plaque in which the characteristic vesicles are seen. The eruption is generally unilateral, but spread across the midline and "spillover" into adjacent dermatomes may be seen. After several days the vesicles appear purulent or hemorrhagic. A crust subsequently forms. Occasionally, the only symptom is unilateral severe pain because the associated rash does not occur or goes undetected.

The most common dermatomes affected are in the thoracic (55%) and trigeminal (15% to 20%) distribution. Varicella zoster rarely occurs distal to the elbows or knees. Involvement of the eye is caused by infection of the ophthalmic branch of the trigeminal nerve. This may lead to conjunctivitis, keratitis, and iridocyclitis. The nasociliary branch innervates the tip and side of the nose. This branch also supplies the globe of the eye. Vesicles occurring in this area (Hutchinson sign) may be a clue to potential eye involvement. Ophthalmologic consultation is mandatory.

In patients who are immunosuppressed, disseminated herpes zoster may occur. The rash is initially limited to a few contiguous dermatomes and spreads to involve large areas of the body over several days. Patients should receive full doses of intravenous antiviral therapy.

Varicella zoster and HSV infection are diagnosed by Tzanck smear, histology, culture, DIF, and DFA. Tzanck smear and histology do not distinguish between VZ and HSV. Culture will identify the virus but may be delayed up to 14 days. DIF or DFA is recommended when rapid diagnosis is required.

SMALLPOX (VARIOLA)

The WHO declared the world free of smallpox in 1980. The last case of naturally acquired smallpox occurred in Somalia in 1977 and the last case in the United States occurred in 1949. The threat of smallpox as a potential agent of terror has brought the disease back into focus (see Chap. 61). The cause is one of two Orthopoxviridae , variola major or variola minor. We have not seen the natural disease for more than 25 years, so the following description is based on old experience. The disease is spread through droplets during face-to-face contact by coughing or by contact with body fluids such as vesicle or conjunctival fluid, urine, or saliva. It enters the body through the respiratory tract.[143] Infectiousness starts 1 day before the onset of the rash, peaks during the first week of the rash, and continues until the lesions are completely healed across. Incubation time is typically 7 to 17 days. Malaise, fever, and backache are followed by the exanthem in 2 to 4 days. Case fatality rate may be as high as 60% in an unvaccinated population with variola major and is due to pulmonary edema from heart failure.

The Center for Disease Control and Prevention (http://www.bt.cdc.gov/agent/smallpox/index.asp) has defined three major criteria for smallpox: (1) febrile prodrome occurring 1 to 4 days before rash onset, fever with a temperature higher than 101°F, and at least one of the following: prostration, headache, backache, chills, vomiting, or severe abdominal pain; (2) classic smallpox lesions consisting of deep-seated, firm, round, well-circumscribed vesicles or pustules that may become umbilicated or confluent; and (3) all lesions are in the same stage of development on any one part of the body, such as the face or the arm. Minor criteria include: (1) a centrifugal distribution of lesions with a predilection for the face and distal extremities; (2) lesions first appearing on the oral mucosa/palate, face, or forearms; (3) a toxic- or moribund-appearing patient; (4) slow evolution of lesions from macules to papules to pustules, with each stage lasting 24 to 48 hours; and (5) lesions on the palms and soles. The lesions scab at about 9 days and often leave pink, depressed pock marks that become permanent scars. The presence of many confluent or hemorrhagic lesions is correlated with the severity of the disease and portends a poor prognosis.

Varicella is the most likely condition to be confused with smallpox. The lesions of varicella are more superficial and are not preceded by a prodrome. They appear in crops, evolve rapidly, and have different stages of evolution, with papules, vesicles, and erosions appearing on any individual body segment at the same time. Other conditions to consider include disseminated herpes zoster, molluscum contagiosum, bullous impetigo, morbilliform drug eruptions, contact dermatitis, erythema multiforme, Stevens-Johnson syndrome, enteroviral infections, especially hand-foot-and-mouth disease, disseminated herpes simplex, scabies, and insect bites including flea bites.

No curative treatment is known for smallpox. Supportive care and treatment of secondary infections, often staphylococcal, are mainstays of therapy. Vaccination within 4 days of exposure may prevent or lessen the severity of the illness. Vaccinia immune globulin, which is in limited supply but can be obtained from the Centers fro Disease Control and Prevention, may be helpful if given early enough. There is no experience with antiviral agents.

HEPATITIS C VIRUS

Infection with the hepatitis C virus (HCV) is associated with several dermatologic conditions. These include vasculitis (secondary to cryoglobulinemia), porphyria cutanea tarda,

lichen planus, polyarteritis nodosa (rare), and generalized pruritus (common). Necrolytic acral erythema is associated with acute hepatitis C.

Two types of vasculitis have been associated with hepatitis C: leukocytoclastic vasculitis (which affects postcapillary venules) and necrotizing arteritis (which affects arteries in the subcutaneous tissue). The vasculitis is secondary to a mixed cryoglobulinemia. Palpable purpura, urticarial weals, or livedo reticularis (a mottled net-like pattern of blue-brown macules) characterize the vasculitis. The prevalence of mixed cryoglobulinemia in HCV-positive patients is 2% to 5% and is probably twice this in patients with hepatitis C–related chronic active hepatitis. Leukocytoclastic vasculitis may be the presenting sign of HCV infection. Rheumatoid factor is an extremely sensitive serologic marker for mixed cryoglobulinemia in HCV-infected patients.

Porphyria cutanea tarda (PCT) is a rare disease that is characterized by a defect in the enzyme uroporphyrinogen decarboxylase, which is essential to the production of protoporphyrin. Protoporphyrin is the precursor of heme, which is an important component of hemoglobin, myoglobin, cytochromes, peroxidases, and catalases. Two types of PCT exist: acquired and familial (autosomal dominant). Acquired PCT has been classically associated with liver disease. HCV may be the factor that links PCT and liver disease. The prevalence of HCV may be as high as 95% in patients with acquired PCT. The cutaneous manifestations of PCT include bullae and hyperpigmentation over sun-exposed areas of the body. Scarring, milia, and hypertrichosis, often seen on the sides of the face, develop as lesions resolve. The bullae of PCT are induced by visible light in the 400- to 410-nm wavelength (Soret band).[144]

A 24-hour collection of urine will show elevated levels of uroporphyrin and coproporphyrin. Quick screening for excess urinary porphyrins using a Woods lamp (blue light) on an acidified urine sample will demonstrate a characteristic coral-pink fluorescence.

Skin biopsy of a bulla shows characteristic histologic findings of a subepidermal separation of the epidermis from the dermis, with festooning of the dermal papillae into the base of the bulla related to the presence of hyaline-like material around the blood vessels and in the upper dermis. Laboratory data demonstrate excess total body iron stores.

The treatment of PCT is focused on decreasing the patient's iron load. Periodic phlebotomy to maintain a hemoglobin level of 10 g/dL or until the serum iron drops to 50 to 60 μg/dL. In cases in which phlebotomy is contraindicated or ineffective, small doses of chloroquine (125 mg twice weekly) may be effective. The response of PCT in patients treated with pegylated interferon α and ribavirin for hepatitis C has not been determined.

Lichen planus (LP) is an inflammatory cutaneous eruption characterized by purple-violaceous, polygonal, pruritic papules that have a predilection for the flexor surfaces of the forearms and wrists. Mucosal involvement manifests as a lacy white reticulate pattern on the buccal mucosa and gingiva. The prevalence of hepatitis C in patients with LP is variably estimated to be from 4% to 38%. LP also may occur secondary to medications such as thiazide diuretics, β blockers, gold, and antimalarials. Most cases are idiopathic.[145,146]

Other skin manifestations are a consequence of treatment with interferon α. These include erythema at injection sites, transient alopecia, excessive skin dryness, and sweating. Psoriasis may flare, and cutaneous necrosis has occurred due to the accidental injection of interferon α into an artery. There appears to be a high incidence of lichenoid cutaneous reactions with the combination of interferon α and ribavirin.

HUMAN IMMUNODEFICIENCY VIRUS

The cutaneous manifestations of HIV infection are protean. An acute nonspecific exanthem in association with influenza-like symptoms is seen in up to 66% of patients soon after initial infection. Subsequent cutaneous manifestations of HIV can be divided into three broad categories: inflammatory, infectious, and malignant.[147]

The most common inflammatory cutaneous manifestation of HIV-1 infection is seborrheic dermatitis. Seborrheic dermatitis is characterized by erythema and greasy scales over the scalp, eyebrows, nasolabial folds, chin, chest, and groin areas. The etiology of seborrheic dermatitis is unclear, but infection with the yeast *Pityrosporum ovale* has been proposed as the underlying cause. Psoriasis is also commonly seen in HIV-1 infection. Psoriasis is characterized by erythematous, well-demarcated plaques with a silvery scale that has a predilection for the extensor surfaces of the extremities, scalp, and trunk. Psoriasis may be seen alone or in association with Reiter syndrome (classic triad of conjunctivitis, urethritis, and arthritis). The rash associated with Reiter syndrome is also referred to as *keratoderma blenorrhagicum* (psoriasis of the soles) and *balanitis circinata* (psoriasis of the glans penis). The initial lesions are dull red macules that become papular and pseudovesicular. The roofs thicken to form hyperkeratotic plaques, and scaly collarettes may be seen. The mature lesions may stand out 1 cm or so from the skin. Reiter syndrome may be a reaction pattern seen in association with gastrointestinal infection (*Salmonella*, *Shigella*, or *Yersinia*) or *Chlamydia* infections.

The infections seen in patients with HIV-1 range from common conditions that take on a more aggressive and recalcitrant course (common warts, molluscum contagiosum, herpes simplex (HSV), varicella zoster, candidiasis, and dermatophyte infections) to rare conditions seen more commonly in the immunocompromised host (*Mycobacterium tuberculosis*, atypical mycobacteria, *Mycobacterium avium intracellulare*, *Cryptococcus neoformans*, and deep fungal infections). Infectious diseases may have atypical appearances. The classic flesh-colored papules with central umbilication seen in molluscum contagiosum closely resemble the cutaneous manifestations of *C. neoformans* and histoplasmosis. Chronic cutaneous ulceration may be the result of an underlying infection such as HSV, bacteria, fungus, mycobacteria, and atypical mycobacteria. Oral hairy leukoplakia (OHL; secondary to Epstein-Barr virus) and mucous membrane candidiasis are commonly seen. White plaques of OHL appear on the sides of the tongue, and the white patches due to colonization by *Candida albicans* may occur on any mucosal surface. Rubbing the white plaques removes candidal colonies, but OHL lesions are adherent.

The most common malignancies seen in association with HIV-1 infection are Kaposi's sarcoma (KS) and lymphomas. KS is almost always associated with human herpes virus 8 infection, although other factors, such as immunosuppression, may be necessary for its induction. HIV-associated KS is seen almost exclusively in homosexual males. It is rarely seen

in patients who contracted the virus by nonsexual means. Cutaneous findings in KS vary from violaceous macules to plaques or nodules. Lesions may appear anywhere and at any time during the course of HIV infection. They tend to be symmetrically distributed, form oval patches along skin tension lines, and are often seen on the palate and tongue.[148] Individuals with HIV have a 200-fold increased risk of non-Hodgkin's lymphoma compared with the general population. Most of these lymphomas are of the B-cell variety and are associated with aggressive disease. The pathogenesis is not known but probably involves HIV, immune dysfunction, cytokine dysregulation, and other viral antigens (e.g., human herpes virus 8 and Epstein-Barr virus). Extranodal disease is the norm, and skin involvement is not unusual. Clinically, this includes variably distributed erythematous to flesh-colored papules or nodules.[149]

Fungal Infections

SUPERFICIAL FUNGAL INFECTIONS

Fungi are ubiquitous. Geophilic fungi inhabit soil and are frequently isolated from the hair of small wild animals and birds. Zoophilic fungi are parasitic on animals, whereas anthropophilic fungi primarily live on human beings. Dermatophytes are specialized saprophytic fungi that use keratin and establish an equilibrium with the host, causing an ongoing toxic or allergic reaction. Yeasts are unicellular fungi. Dermatophytes (*Epidermophyton*, *Microsporum*, and *Trichophyton*) and yeasts (*Candida* species and *Pityrosporum*) cause superficial fungal infections. Dermatophyte infection may occur on any cutaneous surface including the hair and nails. Classic lesions are polycyclic, erythematous, scaling and have central clearing and a raised border. Pruritus is common. A raised, pustular, boggy inflammatory lesion is more likely to occur when a zoophilic fungus causes a human infection (e.g., a kerion in the scalp caused by *Microsporum canis*). Infections are named according to site of infection: tinea capitis (scalp and hair), tinea manuum (hand), tinea corporis (body), tinea cruris (groin), and tinea unguium (nail). All these conditions are common. For instance, tinea capitis occurs predominantly in prepubertal inner city children with a classroom prevalence rate 15% or higher in some areas, and toenail onychomycosis is variously estimated to have prevalence rates of 2% to 13% in the United States population, 15% to 20% in persons 40 to 60 years old, and higher than 50% in persons older than 70 years.

A bedside diagnosis can be made by demonstrating septate hyphae in potassium hydroxide mounts of scales or in material obtained from debris under an infected nail. The addition of chlorazol black E may enhance the visibility of the hyphae.[150] Culture for accurate identification of a fungus may be done on Sabouraud dextrose agar with cycloheximide and chloramphenicol. The fungus may take 4 weeks to grow. For more rapid confirmation that a dermatophyte is present, dermatophyte test medium (turns red by 2 weeks when a dermatophyte is present) is often used. This test does not allow separation of one dermatophyte species from another.

Twice-daily topical treatment with allylamines (naftifine or terbinafine) or imidazoles (ketoconazole, econazole, or clotrimazole) is usually curative for skin infections. Despite a relative lack of sensitivity of trichophyton tonsurans, the common cause of tinea capitis, to oral griseofulvin, this agent is still in general use for scalp and hair infections. It is likely that one of the newer oral agents (e.g., terbinafine) will soon become the preferred treatment. Topical therapy has only limited success for nail involvement. A 3- or 4-month course of oral terbinafine or pulsed itraconazole is necessary to clear toenails. Fingernails require only 6 weeks of oral therapy. Other possible agents include fluconazole and ketoconazole.[151,152] Primary cutaneous infection with *C. albicans* occurs in moist, warm environments such as intertriginous areas. Patients develop bright red, moist plaques with satellite pustules. The differential diagnosis includes dermatophyte infection, erythrasma (caused by *Corynebacterium minutissimum*), seborrheic dermatitis, and psoriasis. The diagnosis is supported by the typical pseudohyphae on potassium hydroxide mount or culture.

During the past two decades, the incidence of candidemia in patients in ICUs has soared from 1.5 to 60 infections per 10,000 adult ICU admissions and from 23 to 123 infections per 10,000 neonatal ICU admissions. Even with antifungal therapy, the mortality rate approaches 30%. Most cases occur in patients who have central venous lines placed. *Candida* species on the skin of the patient or caregivers can insinuate their way into these catheters, adhere to the inside of the tubing, and form biofilms.[153] Disseminated candidiasis presents with the characteristic cutaneous finding of widespread papules and pustules. In neutropenic patients with candidiasis, the skin lesions may not develop until the white count begins to recover.[154] Neutropenia and immunosuppression are the greatest risk factors for disseminated candidiasis. The differential diagnosis includes steroid-induced acne, which may develop in conjunction with chemotherapy. In steroid acne, the pustules arise from the hair follicle, are all in the same stage of development, and tend to concentrate on the face, shoulders, and upper trunk.

Diagnosis can be attempted by culturing the blood, the pustule contents, or tissue obtained from a skin biopsy, but the yield may be as low as 50%. Biopsy specimens may be stained with periodic acid-Schiff (PAS) or silver methenamine stain to visualize yeast forms. There is a need for better technology to identify disseminated candidiasis. Detection of anti-*Candida* antibodies, *Candida* metabolites, *Candida* DNA or the release of β glucan into the blood have not proved to be of general clinical use thus far.[155]

Colonization with *Pityrosporum ovale* or *orbiculare* may cause the very common tinea versicolor or it may lead to *Pityrosporum folliculitis*. Tinea versicolor presents with hypo- or hyperpigmented, regularly colored tan macules superimposed with a very fine scale, often on the upper trunk and limbs. It is seen in adolescents and young to middle-age adults. Typical hyphae and spores ("spaghetti and meatballs") are seen on potassium hydroxide mounts. Treatment with topical antifungals, such as selenium sulfide or ketoconazole, is effective, but the pigmentary change may persist for some months. Recurrence is common.

Pityrosporum folliculitis presents with asymptomatic or slightly itchy follicular papules and pustules on the face, chest, and back of mainly young women. Predisposing factors include antibiotic ingestion, steroid treatment, diabetes, Hodgkin disease, and living in the tropics, where men and women are equally affected. The involvement of the periphery of the face, the nape of the neck, the lower trunk, buttocks,

and thighs distinguishes this infection from acne vulgaris. Resolution follows the use of topical antifungals as for tinea versicolor or the use of oral ketoconazole and topical keratolytic agents.

DEEP FUNGAL INFECTIONS

Deep cutaneous fungal infections are uncommon in the immunocompetent host. Opportunistic infections occur in patients who are immunocompromised by malignancies, systemic agents, or medical conditions, including the acquired immunodeficiency syndrome. Hematogenous seeding to the skin from the lung is the most common route for aspergillosis, histoplasmosis, blastomycosis, cryptococcosis, and zygomycosis (including the frequently fatal infections caused by *Mucorales*).[156] Direct inoculation may occur but is less common. Lesions present as inflammatory plaques, ulcerations, nodules, and papules. Differentiation cannot be made on clinical grounds alone. Umbilicated papules resembling lesions of molluscum contagiosum are characteristically seen in disseminated cryptococcosis, but they have also been reported in disseminated aspergillosis and histoplasmosis. Biopsy and culture of the lesions is imperative. Under the microscope with the appropriate stains, rounded refractile spherical cells with broad-based buds are seen in blastomycosis (potassium hydroxide mounts of pus smears), macrophages containing tiny yeast-like spores in histoplasmosis (hematoxylin and eosin, Gram stain, or a Giemsa stain), round to ovoid spores usually with large capsules in cryptococcosis (India ink mounts of pus smears), branching septate hyphae in aspergillosis (hematoxylin and eosin, PAS or silver methenamine stains), and vascular invasion by very large, long, nonseptate hyphae in mucormycosis (hematoxylin and eosin, PAS, or silver methenamine stains). Systemic treatment with itraconazole, fluconazole, amphotericin B, or caspofungin is required to control each of these diseases, as is extensive debridement of all necrotic tissue.[157]

Selected Dermatoses

MILIARIA

Miliaria, sometimes referred to as heat rash, is caused by obstruction of the eccrine (sweat) ducts at a variety of levels causing sweat retention. Miliaria can be classified into three groups, based on the levels of ductal obstruction: miliaria crystalline, miliaria rubra, and miliaria profunda.[157]

Miliaria crystallina (also known as sudamina), presents as crops of 1 to 2 mm asymptomatic, clear fluid-filled vesicles (”dew drops”) on the skin, which develop after an episode of increased termperature (e.g., fever, increased ambient temperature), or after increased sweating (e.g., fever or drug-induced), increased ambient humidity (particularly in babies and the bedridden).

Miliaria rubra (also known as prickly heat) represents the same pathologic process o sweat duct obstruction and sweat retention, but in the stratum granulosum, resulting in 1–2 mm paroxysmally pruritic or stinging erythematous papules or macules. This type of miliaria is characteristic of hot and humid climates, affecting up to 30% of the population. Resolution of lesions is followed by variable periods of anhidrosis. The eruption often occurs on the trunk and neck, but it ca occur anywhere except the face and volar areas. Treatment consists of reducing the ambient temperature and humidity, and emollient application. When there is bacterial overgrowth, miliaria pustulosa may occur.[158]

Miliaria profunda (also known as mamillaria) is less frequent than the other types, and is characterized by asymptomatic 1 to 3 mm pink papules usually located on the trunk, that result from sweat duct obstruction at or below the dermal-epidermal junction. This type of miliaria results from multiple episodes of miliaria rubra, as occurs in tropical climates. It may lead to extensive anhidrosis, predisposing the individual to malaise, dyspnea, tachycardia, hyperpyrexia, heat exhaustion, and in prolonged cases, to tropical anhidrotic asthenia.[159]

DRY SKIN

Xerosis (dry skin, asteatosis) is one of the most common dermatologic conditions, and is characterized by a dry, scaly noncompliant, and rough appearance of the skin. Although most individuals will experience some degree of xerosis, prevalence increases with age (>75% of individuals over 64).[160] Most commonly affected areas are the hands, the shins, the posterior upper arms, and the back.

In spite of its generally benign course, systemic causes must be taken into consideration, especially if the condition is severe and associated with inflammation: malignancies (usually lymphoproliferative), renal disease (uremic frost), obstructive biliary disease, hypothyroidism, drugs (lithium, isotretinoin), chronic diseases, and malnutrition leading to hypovitaminosis. Aggravating factors such as cold, dry, windy climates, air-conditioning, as well as organic solvents, harsh detergents, excessive bathing, or hot baths result in decreased water content in the stratum corneum and an increase in transepidermal water loss (TEWL). Erythema and pruritis are indicators of inflammation, present when the condition is sever. Rubbing and scratching can lead to dermatitis or thickened skin with accentuated markings (lichenification).

Treatment consists in restoring the epidermal water barrier, in order to minimize TEWL.[162] This can be achieved by avoiding aggravating factors (see above), only using emollient soaps or soap substitutes, and lipid-based agents (e.g., emollients) that reduce water evaporation (petrolatum, mineral oil, dimethicone, cyclomethicone); humectant agents that attract water into the stratum corneum (glycerin, propylene glycol, urea, sodium lactate, sorbitol). In addition, skin roughness can be decreased with the use of the keratolytic alpha- or beta-hydroxy acids.

PRESSURE ULCERS

Continuous pressure over a bony site obstructs microcirculation, leading to tissue ischemia and necrosis. Pressure ulcers result, constituting a major problem in the ICU, with reported incidences of 1% to 56% and prevalences of 14% to 41%, which are two- to threefold higher than in other hospitalized patients.[158,159] Altered circulation and ventilation and the use of vasoactive drugs may decrease peripheral oxygen delivery to tissues, thereby increasing the risk of pressure ulcers. The development of pressure ulcers leads to increased mortality rates, costs, and lengths of hospital stays.

A National Pressure Ulcer Advisory Panel in 1998 developed the most widely used staging system of pressure ulcers.[160] It encompasses four grades.

STAGE I

A stage I pressure ulcer is an observable pressure-related alteration of intact skin whose indicators, as compared with the adjacent or opposite area on the body, may include changes in one or more of the following: skin temperature (warmth or coolness), tissue consistency (firm or boggy feel), and/or sensation (pain, itching). The ulcer appears as a defined area of persistent redness in lightly pigmented skin, whereas the ulcer may appear with persistent red, blue, or purple hues in darker skin tones.

STAGE II

A stage II ulcer is defined as partial-thickness skin loss involving epidermis, dermis, or both. The ulcer is superficial and presents clinically as an abrasion, blister, or shallow crater.

STAGE III

Stage III ulcer is characterized by full-thickness skin loss involving damage to, or necrosis of, subcutaneous tissue that may extend down to, but not through, underlying fascia. The ulcer presents clinically as a deep crater with or without undermining of adjacent tissue.

STAGE IV

This ulcer is characterized by full-thickness skin loss with extensive destruction, tissue necrosis, or damage to muscle, bone, or supporting structures (e.g., tendon, joint capsule). Undermining and sinus tracts also may be associated with stage IV pressure ulcers.

Given the right set of circumstances, pressure ulcers can develop within 2 to 6 hours. Many risk factors have been described in the literature, but the risk assessment scales have not been specific for the ICU.[161] Notwithstanding the limitations of the studies, risk factors include the duration of previous surgeries and number of operations, preoperative protein and albumin concentrations, skin moisture, use of inotropic drugs, fecal incontinence or diarrhea, altered circulatory status, diabetes mellitus, decreased mobility, and a high score on the Acute Physiology and Chronic Health Evaluation II (APACHE II). Preventive strategies should be implemented from the moment of entry into the ICU. These include the use of risk assessment scales, repositioning the patient every 2 hours, provision of dynamic or static support surfaces that redistribute pressure, and proper nutrition.[162] A critical aspect of the topical treatment is the maintenance of a moist environment. This can be achieved by the use of any one of many different dressings: transparent films, hydrocolloids, alginates, foams, hydrogels, or hydrofibers marketed for pressure ulcer care. These dressings require few changes, so they result in less need for nursing care, faster healing, and decreased infection. Gauze dressings, particularly wet to dry dressings, are to be avoided because they allow the wound to dry and, as such, slow healing.[163] Surgery may be attempted for recalcitrant, full-thickness ulcers. However, recurrence rates are high.

Chapter 108

SICKLE CELL DISEASE

GREGORY J. KATO
MARK T. GLADWIN

KEY POINTS

- *Sickle cell disease causes a chronic hemolytic anemia associated with acute and chronic vaso-occlusion.*
- *Baseline hemodynamic and laboratory values in patients with sickle cell disease can be confused with sepsis.*
- *Serum creatinine levels of 1 to 1.5 mg/dL often indicate significant renal dysfunction.*
- *The most common intensive care management problems in patients with sickle cell disease include the acute chest syndrome, very severe anemia, sepsis, stroke, priapism, and splenic sequestration.*
- *Secondary pulmonary hypertension occurs in 30% of patients with sickle cell disease, often unrecognized.*
- *Red cell transfusion is an important treatment for most patients with sickle cell disease requiring intensive care management.*
- *Rapid exchange transfusion is indicated for central nervous system events, serious respiratory disease, or multiorgan failure.*
- *Transfusion management in patients with sickle cell disease requires investigation of alloimmunization history.*
- *Preoperative red cell transfusion and detailed supportive care are advisable for significant surgery in patients with sickle cell disease.*

Sickle cell disease is a highly prevalent disease in the United States, affecting 1 in 500 African American infants. It is common in individuals of African, Caribbean, Mediterranean, Arab, and other Middle Eastern descent. It is a genetic disorder with an autosomal recessive inheritance pattern. Sickle cell disease is often called "the first molecular disease" because the biochemical alteration in sickle hemoglobin described by Linus Pauling in 1948 was one of the first lesions identified at the molecular level for a human disease. Sickle hemoglobin forms rod-like polymers in deoxygenated red cells in areas of the circulation, with low oxygen tension, acidosis, or hyperosmolarity. Sickle hemoglobin polymerization causes a host of secondary molecular and cellular changes, many of which impair blood flow and contribute to tissue damage. The microcirculation can be acutely or chronically impaired in virtually any organ in the body, resulting in the characteristic crisis pattern of intermittent pain and acute organ injury superimposed on the gradual development of chronic organ failure.

Despite the early progress in a molecular understanding of sickle cell disease, its treatment remained largely palliative for many decades. In recent years, the longevity of patients with sickle cell disease has been prolonged by the institution of prophylactic penicillin treatment and immunization to decrease mortality rate from pneumococcal sepsis. Chronic transfusion therapy for selected patients has improved outcome, and acute transfusion therapy is the central intervention for most complications requiring admission to the intensive care unit (ICU). Hydroxyurea, the first treatment approved by the Food and Drug Administration for sickle cell disease, decreases disease severity and mortality rate.[1,2] Most recently, new paradigms have emerged regarding the pathophysiology of secondary complications of sickle cell disease, with much of this involving impairment of normal intravascular signaling via the nitric oxide (NO) pathway[3–5] (Fig. 108-1). These new paradigms have triggered a wave of research seeking to translate these basic science advances into clinical practice.[6] This chapter reviews general aspects of the genetics and pathophysiology of sickle cell disease, common clinical problems with an emphasis on those faced in a critical care setting, and contemporary therapeutic approaches to these complications of sickle cell disease.

General Background

In 1910, James Herrick first reported the observation of sickle-shaped red cells from the blood of an anemic Chicago dental student from Grenada. Subsequently, in 1949, Linus Pauling and his colleagues demonstrated a difference in the electrophoretic pattern of sickle hemoglobin compared with normal hemoglobin and introduced the label of "molecular disease." Marotta and colleagues in 1977 showed that the hemoglobin alteration was due to a single nucleotide change in the gene encoding the β subunit of hemoglobin A.

Genetics and Epidemiology

Sickle cell disease is inherited in a classic Mendelian autosomal recessive pattern, with homozygous individuals demonstrating complications of hemolytic anemia and impaired microvascular blood flow. Usually the heterozygous carrier state, sickle trait, is completely asymptomatic, although rarely vaso-occlusive events, splenic infarction, renal papillary necrosis, or sudden death can occur, usually under high-altitude hypoxic conditions. Several other mutant β-globin alleles can induce sickling disorders when inherited in combination with the sickle trait, the most common of which are β thalassemia and hemoglobin C. Although the homozygous state typically results in severe disease, the sickle trait appears to confer resistance to severe malaria, leading to an evolutionary selection for this carrier state in geographic regions with a high prevalence of malaria.[7] The sickle trait allele appears to have independently arisen at least three times in Africa and once in the Arab-Indian region. Migration from these regions has brought sickle cell disease to all parts of the world, particularly the Caribbean, Mediterranean, and the North and South American regions. Some variation in disease severity has been attributed to distinct haplotypes surrounding these alleles; additional polymorphisms in several other genes appear to modify disease severity, including those affecting expression of the α- and β-globin (thalassemia mutations) and γ-globin (fetal hemoglobin) genes.

Homozygous sickle cell disease is also referred to as *SS disease* or *sickle cell anemia*, to distinguish it from *hemoglobin SC disease*, a compound heterozygous combination of sickle trait and hemoglobin C trait. Hemoglobin SC disease is clinically similar in scope to SS, but hemoglobin SC disease on average presents milder or less frequent vaso-occlusive

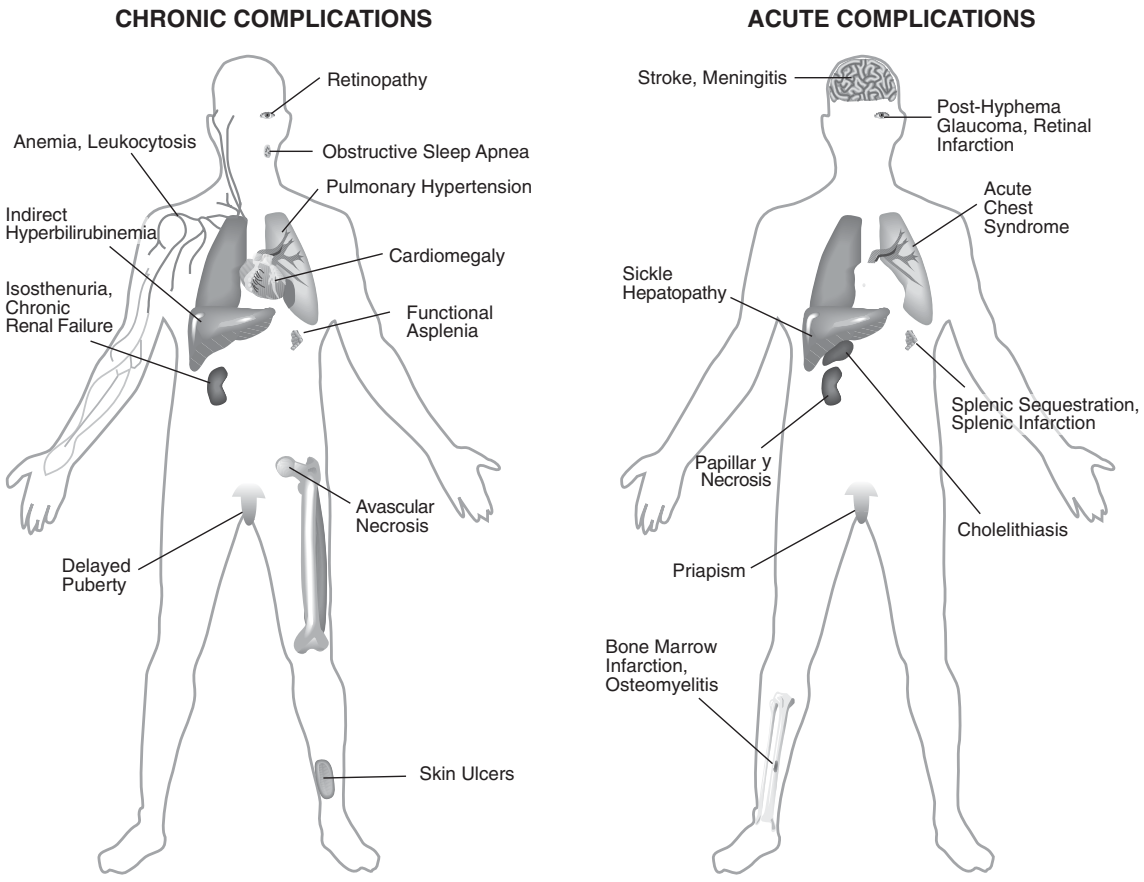

FIGURE 108-1 Chronic and acute complications of sickle cell disease. Sepsis is an additional potential acute complication of sickle cell disease.

complications. The spectrum of SC disease overlaps considerably with SS. Another compound heterozygous form of sickle cell disease is that of S-β-thalassemia. A combination of a β-globin S allele with a nonexpressing β-globin allele, called *S-β^0-thalassemia*, results in production of only hemoglobin S, and the clinical phenotype closely resembles SS. If the thalassemia allele of β globin permits partial expression of a normal β-globin protein, the combination is called *S-β^+-thalassemia*, and like hemoglobin SC, the disease tends to be milder. There are several additional combinations of the β-globin S allele with rare variant hemoglobins that can result in different severities of sickle cell disease.

Pathophysiology

The single nucleotide mutation in the sixth codon of the β-globin gene changes the corresponding amino acid in β globin from valine to glutamic acid. This induces a conformational change in the hemoglobin tetramer that renders it susceptible to polymerization with deoxygenation in hypoxic, hyperosmolar, or acidic regions of the circulation. The rod-like polymer bundles distort the red cell membrane into the characteristic sickle shape. Intracellular hemoglobin S polymerization and "sickling" are associated with a complex combination of pathophysiologic changes (Table 108-1 and Fig. 108-2). It is likely that adhesion of erythrocytes and leukocytes to endothelial receptors such as vascular cellular adhesion molecule 1 (VCAM-1) combines with physical rigidity and distortion ("sickling") of the red blood cells to occlude the microvascular circulation. Additional involved cell adhesion molecules include intercellular adhesion molecule 1, E selectin, and P selectin. The resulting tissue ischemia-reperfusion drives tissue and organ injury, generalized inflammation, and ultimately produces tissue infarction. These pathophysiologic events produce clinical and biochemical perturbations, such as fever and leukocytosis, which can mimic sepsis. Tissue ischemia and infarction produce severe pain attacks called *acute pain crisis* or *vaso-occlusive crisis* (VOC) and specific end-organ pathophysiology, such as the acute chest syndrome (ACS), an acute lung injury syndrome similar to acute respiratory distress syndrome (ARDS), discussed in greater detail below.

Steady-state sickle cell disease is characterized by intense inflammation that accelerates during VOC, likely secondary to nearly constant tissue ischemia-reperfusion. This is illustrated by frequent fever during VOC and the ACS and by increased leukocyte, platelet, and endothelial cell activation, with increased circulating mediators and markers of oxidant stress and inflammation. Examples of these inflammatory markers include elevated levels of C-reactive protein, cytokines (tumor necrosis factor α, interleukin 1β, and granulocyte-macrophage colony-stimulating factor), chemokines (interleukin 8), integrins ($\alpha_4\beta_1$), selectins (E and P), adhesion molecules (VCAM-1 and intracellular adhesion molecule 1), markers of oxidant stress and inflammation

TABLE 108-1 Pathogenesis of Sickle Cell Anemia

Mechanism	Modifying factors
RBC sickling	
Hemoglobin polymerization (crystal-solution equilibrium)	Hemoglobin deoxygenation-degree and duration of hypoxia
	Hemoglobin concentration-cellular dehydration
	Inversely proportional to hemoglobin F concentration
RBC interactions with vascular endothelial cells	Supporting evidence
Disturbance of vasoregulation	Transcriptional induction of endothelial cell genes encoding endothelin 1, a potent vasoconstrictor, after contact with sickled RBCs
	Endothelin 1 levels are elevated during VOC and ACS
	Cell-free plasma hemoglobin impairs nitric oxide bioavailability
Activation of the coagulation system	Central nervous system vascular thrombosis
	Pulmonary in situ thrombosis and thromboembolia from distant sources
	Elevated whole blood tissue factor procoagulant activity
Increased adhesion of RBCs and WBCs to vascular endothelium	Increased expression of adhesion molecules results in RBC-endothelial cell adhesion and endothelial cell damage
	Association between clinical severity and in vitro adhesion of sickled RBCs to endothelial cells
	Increased expression of adhesion molecules after activation by inflammatory cytokines (TNF α and IL-1 β)
	Reticulocyte integrin complex, $\alpha_4\beta_1$, binds to plasma fibronectin and endothelial cell VCAM-1
	Sickle red blood cell CD36 and endothelial cell CD36 bind to thrombospondin secreted by activated platelets
	Increased numbers of circulating microvascular endothelial cells in sickle cell disease, particularly during VOC
	Increased endothelial cell activation as evidenced by increased ICAM-1, VCAM-1, E selectin, P selectin

ABBREVIATIONS: ACS, acute chest syndrome; ICAM-1, intercellular adhesion molecule 1; IL-1β, interleukin 1β; RBC, red blood cell; TNFα, tumor necrosis factor α; VCAM-1, vascular cellular adhesion molecule 1; VOC, vaso-occlusive pain crisis; WBC, white blood cell.

(isoprostanes and tyrosine nitration), and vasoconstrictors (endothelin 1).[4,5]

Associated with this inflammation is a state of endothelial dysfunction, with impaired NO bioavailability. Strong evidence points to intravascular consumption of NO by cell-free plasma hemoglobin liberated from red cells by intravascular hemolysis and by radical-radical inactivation reactions with superoxide produced by xanthine oxidase.[8,9] Impairment of NO signal transduction leads to many adverse consequences, including increased inflammation and impaired microcirculatory blood flow.[10,11] It may also lead to platelet activation and acute and chronic pulmonary hypertension.[12,13]

Baseline Physiology

Sickle cell disease is fundamentally a severe hemolytic anemia. This is characterized by a normocytic, normochromic anemia with reticulocytosis at baseline. Characteristic laboratory profiles for patients with SS and SC without hydroxyurea treatment are presented in Table 108-2. Hemolysis is mostly but not exclusively extravascular and is due primarily to mechanical injury and destruction of erythrocytes rendered rigid by intracellular hemoglobin S polymerization. Baseline leukocytosis is commonly present and should not necessarily be construed as evidence of infection. Nucleated red blood cells commonly are miscounted in the complete blood count as white cells, although the overall counting error is usually relatively small. The diminished oxygen-carrying capacity due to chronic anemia is compensated by increased cardiac output (Table 108-3). Cardiomegaly and biventricular chamber dilation due to constant increased cardiac output are common (Table 108-4). Splenic dysfunction due to subclinical infarction is almost universal by late childhood in patients with homozygous sickle cell disease; on computed tomography, the spleen appears typically as a small calcified mass (Fig. 108-3). As discussed below, patients with SC disease or S thalassemia may retain their spleens and present with acute splenic sequestration or infarction. Likewise, gradual infarction of the renal medulla by adolescence leads to isosthenuria (iso-osmolar urine), with increased urination because of diminished urinary concentrating capacity, mimicking a nephrogenic diabetes insipidus phenotype. Aside from increasing maintenance fluid requirements, these changes mean that urine specific gravity is not closely indicative of hydration status. The increased cardiac output and higher plasma content of each milliliter of blood present the renal glomeruli with a volume of plasma per minute up to twice

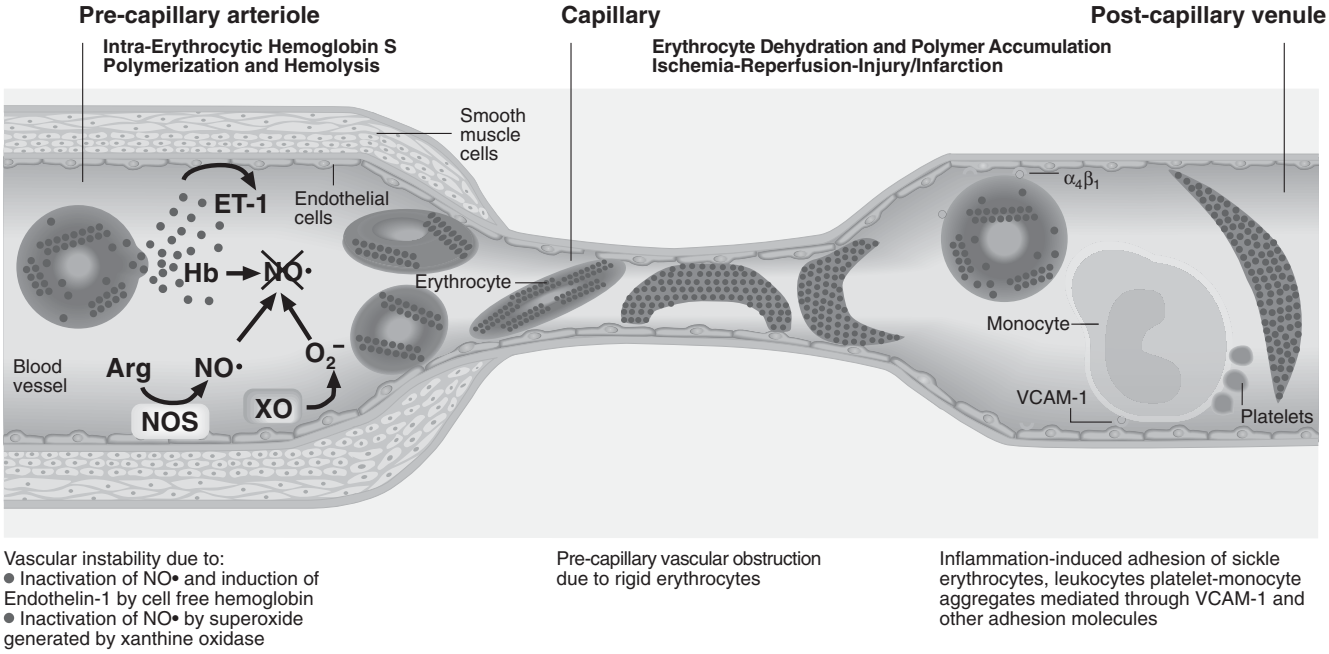

FIGURE 108-2 Model of pathophysiology of sickle cell disease. This model reflects a summary of pathophysiologic events for which there is substantial supportive evidence. Nitric oxide (NO·) is normally synthesized from L-arginine by isoforms of NO synthase (NOS). Recent findings have implicated vascular instability due to inactivation of endogenous NO by free plasma hemoglobin released from lysed red cells and by superoxide (O_2^-) generated possibly by xanthine oxidase (XO), which is strongly expressed in the plasma of patients with sickle cell disease. NO deficiency leads to vasoconstriction and inflammation. Cell-free hemoglobin also induces the expression of endothelin 1 (ET-1), an extremely potent vasoconstrictor. The best characterized mechanism of vaso-occlusion occurs due to extensive hemoglobin S polymerization, leading to dense, poorly compliant red cells that cannot readily traverse capillaries. More recent evidence has indicated the adhesion of immature red cells and leukocytes to cell adhesion molecules (*green arcs*) expressed on endothelial luminal surfaces of postcapillary venules in response to NO deficiency, tumor necrosis factor α and other inflammatory cytokines, commonly found to be in patients with sickle cell disease. Activated monocytes and platelet-monocyte aggregates have been described in patients with sickle cell disease, and these appear to secrete inflammatory cytokines. The resulting sluggish flow of desaturated red cells in the venules may promote sickling, leading to multifactorial vaso-occlusion.

TABLE 108-2 Ranges of Laboratory Values in Normal Adults with Sickle Cell Disease[a]

Parameter	SS	SC	General Population
Oxygen saturation (%)	95.4 ± 3.3	98.3 ± 1.2	95–98
Leukocyte count (K/μm^3)	11.3 ± 3.2	8.7 ± 4.0	4.5–11.0
Hemoglobin (g/dL)	8.3 ± 1.1	11.6 ± 1.2	M: 13.5–17.5 F: 12.0–16.0
Platelets (K/μm^3)	401 ± 119	268 ± 117	150–450
Urea nitrogen (mg/dL)	9 ± 6	9 ± 5	6–20
Creatinine (mg/dL)	0.7 ± 0.3	0.8 ± 0.2	0.7–1.2
Alkaline phosphatase (U/L)	115 ± 91	95 ± 51	25–100
Bilirubin, total (mg/dL)	3.5 ± 1.8	1.7 ± 1.1	0.3–1.2
Bilirubin, direct (mg/dL)	0.5 ± 0.3	0.4 ± 0.6	0–0.2
Lactate dehydrogenase (U/L)	437 ± 154	247 ± 80	208–378
Ferritin (ng/mL)	656 ± 1058	253 ± 395	M: 20–250 F: 10–120
Iron (μg/dL)	94 ± 41	87 ± 57	M: 65–175 F: 50–170
Transferrin (mg/dL)	215 ± 57	249 ± 46	200–400

[a] Ranges are mean ± standard deviation for sickle cell patients not on hydroxyurea treatment.[50] Laboratory values are included only for those common tests in which sickle cell patient values often differ from the general population. Additional data are available from the cooperative study.[51] The ranges for the general population are adapted from other sources.[52]

that of patients without sickle cell disease. This leads to baseline glomerular hyperfiltration (up to 200 mL/min) and a low baseline serum creatinine range of approximately 0.5 to 0.6 mg/dL (see Table 108-2). Serum creatinine levels above this level actually imply renal insufficiency. A serum creatinine level of 1.0 mg/dL may often be associated with other consequences of renal insufficiency, such as hyperkalemia, hyperuricemia, and increased anemia due to a partial defect in erythropoietin secretion. Importantly, these features of renal insufficiency may arise even when the glomerular filtration rate may be in the 80-mL/min range.

These baseline physiologic perturbations result in a hyperdynamic cardiovascular state with relatively low blood pressure, low systemic and pulmonary vascular resistances, high cardiac output. and renal hyperfiltration (see Tables 108-3 and 108-4). These findings are similar to other high cardiac output states such as pregnancy and thyrotoxicosis. These hemodynamic parameters combined with significant baseline inflammation in patients with sickle cell disease, characterized by leukocytosis and increased serum ferritin, often can be mistaken for sepsis in the absence of a true infectious insult (see Table 108-4).

Common Clinical Problems

Common and significant clinical problems in patients with sickle cell disease are summarized in Fig. 108-1.

VASO-OCCLUSIVE PAIN CRISIS

VOC is perhaps the most characteristic manifestation of sickle cell disease. These severe painful attacks, most commonly affecting the extremities and back, result from acutely impaired microvascular blood flow. Most commonly affected are bones, due primarily to ischemia and infarction of the bone marrow and inflammation of the periosteum, with intense bone pain due to the resulting edema and tissue swelling in the inelastic compartment of the bone marrow medulla. Most often, pain affects the lumbosacral vertebrae and the long bones, although any bone may be affected. Joint effusions of the elbows and knees are common. At times, especially in children, there is difficulty in distinguishing painful crisis from osteomyelitis. The mainstays of treatment for pain crisis are analgesics, in particular nonsteroidal anti-inflammatory drugs and opioids. Correction of dehydration or hypoxemia is important, as is careful monitoring for development of ACS (see below). Clinicians frequently undertreat the severe pain of sickle cell crisis. Opioid tolerance due to recurrent or chronic opioid treatment may dramatically increase the dosage required in individual patients. There is little, if any, risk for developing opioid dependency with short courses of large-dose opioids for VOC.

STROKE

Ischemic stroke is a frequent complication of sickle cell disease, occurring at any age, but mainly in children. This topic is discussed in detail below in the section on special problems in the ICU.

EYE DISEASE

A proliferative retinopathy develops in 10% of patients with SS disease and at least twice as often in patients with

TABLE 108-4 Cardiac Catheterization Data for Adults with Sickle Cell Disease[a]

Parameter	Without Pulmonary HTN	With Pulmonary HTN
Pulmonary artery systolic (mm Hg)	30.3 ± 5.77	54.3 ± 12.26
Pulmonary artery diastolic (mm Hg)	11.7 ± 4.86	25.2 ± 7.72
Pulmonary artery mean (mm Hg)	17.8 ± 4.86	36.0 ± 7.78
Cardiac output (L/min)	8.62 ± 3.03	8.60 ± 1.76

This is typical in adults with homozygous sickle cell disease. The stomach is visualized by oral contrast material.**

SC disease. This chronic complication may be treated with laser photocoagulation. Two acute complications present ophthalmologic emergencies. The first is vision loss due to acute occlusion of the central retinal artery. This may resolve with emergency exchange transfusion before retinal infarction occurs. The second emergency is traumatic hyphema in a patient with sickle cell disease or sickle trait. The environment of the anterior chamber of the eye promotes sickling, and this can readily cause acute glaucoma. Evacuation of the blood should be undertaken for hyphema without delay to avoid vision loss.[14]

LUNG DISEASE

Sickle cell disease is associated with a high incidence of acute and chronic lung complications. The ACS is a lung injury syndrome and, in cases of extensive lung involvement, is similar to ARDS. It is defined by a new pulmonary infiltrate secondary to alveolar consolidation, not atelectasis, in a patient with sickle cell disease accompanied by chest pain, fever, tachypnea, wheezing, or cough. It is caused frequently by pulmonary fat embolism syndrome from severe vaso-occlusion of the bone marrow or by an excessive pulmonary inflammatory response to common respiratory pathogens. Its pathogenesis and treatment are discussed in detail in the section on special ICU problems. Chronic complications can include the development of restrictive lung disease, pulmonary fibrosis, or pulmonary hypertension, with the latter occurring in up to 30% of adults with sickle cell disease.[15] Pulmonary hypertension appears to be the most serious risk factor for early mortality in adult patients with sickle cell disease and, in the past, may have been under-recognized by clinicians. Reactive airway disease or asthma occurs with increased frequency in children with sickle cell disease.[16]

HEART DISEASE

Although vaso-occlusion of the coronary microcirculation can produce myocardial infarction, acute wall motion abnormalities, and cardiac enzyme release, coronary atherosclerosis is essentially nonexistent in patients with sickle cell disease for reasons that are poorly understood, possibly owing to low levels of low-density lipoprotein cholesterol, early mortality of males, and increased heme oxygenase activity. Cardiomegaly and biventricular chamber dilation are nearly universal due to a long-term high cardiac output state as compensation for severe chronic anemia. High-output cardiac failure, diastolic dysfunction, and pulmonary hypertension are common cardiac complications of sickle cell disease (see Tables 108-3 and 108-4).

HEPATOBILIARY

Up to 42% of patients with sickle cell disease have calcium bilirubinate gallstones by age 18 years, although only a fraction of these patients are symptomatic. Stones develop due to the very high rate of bilirubin excretion in bile as a breakdown product of hemoglobin turnover. In cases of acute cholecystitis, awaiting its resolution decreases perioperative complications. Acute vaso-occlusion in the liver can cause pain, elevated transaminases, and extreme hyperbilirubinemia, generally responding well to supportive care. Rarely, the liver may acutely sequester peripheral blood cells, clinically analogous to splenic sequestration syndrome (see Special Problems in the ICU).

SPLENIC

Nearly all patients with sickle cell disease develop progressive loss of splenic function secondary to its microvascular

vaso-occlusion and infarction, beginning at birth and complete by age 10 years. This manifests primarily as a marked susceptibility to sepsis and meningitis due to encapsulated organisms, particularly in children younger than 5 years. The incidence of serious infection is dramatically decreased by penicillin prophylaxis and immunization against *Haemophilus influenzae* and *Streptococcus pneumoniae*. However, splenic dysfunction still causes a modest lifelong risk of overwhelming sepsis. The spleen is atrophic and nonfunctional in 98% of adults with SS sickle cell disease (see calcified spleen in Fig. 108-3B). A dramatic acute complication of sickle cell disease is splenic sequestration crisis, described in detail in the section on special problems in the ICU. This complication occurs frequently in pediatric patients with functioning spleens, primarily young children with homozygous SS disease, and adults with hemoglobin SC sickle cell disease or S-β^+-thalassemia because approximately 50% of these patients retain their spleen into adulthood. It is conceivable that hydroxyurea therapy in children with sickle cell disease might lead to prolongation of splenic function.

RENAL

Isosthenuria develops in most patients by age 10 years, with increasing maintenance fluid and sodium requirements. Hematuria due to papillary necrosis is an occasional complication, usually self-resolving. A nephropathy with nephrotic-grade proteinuria can frequently progress to uremia. Early signs include the normally low serum creatinine exceeding 0.6 mg/dL, progressively severe anemia, and a rise in the serum uric acid level. Angiotensin-converting enzyme inhibitors can decrease proteinuria and potentially slow progression of renal insufficiency. Uremia has been treated with dialysis and with renal transplantation.

SKELETAL

Bone marrow infarcts are frequent causes of pain. These may be detected on magnetic resonance imaging or radionuclide imaging with technetium sulfur colloid, although it is not normally clinically helpful to ascertain these by imaging. The heads of the femur and humerus are susceptible to avascular necrosis, a potential source of constant pain and disability. Ischemic bone becomes susceptible to bacterial osteomyelitis. *Staphylococcus aureus* is the most common organism in sickle cell osteomyelitis episodes. *Salmonella* species are frequently encountered, which very rarely cause bone sepsis in patients without sickle cell disease. Joint effusions and occasionally hemarthrosis may be seen adjacent to infarcted bones. Septic arthritis is seen less commonly.

SKIN

Leg ulcers, a clinical feature of this and other hemolytic disorders, are usually limited to adolescence and adulthood. They heal very slowly and can cause very severe pain. They rarely develop acute cellulitis. They are best treated with scrupulous wound care.

Special Problems in the ICU

The demographics of adult patients with sickle cell disease admitted to the medical ICU at a single institution over a 10-year span are presented in Table 108-5. Specific issues in management of patients with sickle cell disease admitted to the ICU are discussed in detail below.

TABLE 108-5 Demographics of MICU Admissions for Patients with SCD[a]

SCD hospitalizations resulting in MICU admission (range)	1.5–2.9%
MICU stay, days (mean ± standard deviation)	5.0 ± 6.5
MICU mortality rate	13%
MICU diagnosis:	
Acute chest syndrome (including pneumonia)	43%
Severe anemia	36%
Sepsis	20%
Pulmonary hypertension	9%
Left heart failure	4%
Multiorgan failure	3%

ACUTE CHEST SYNDROME

The ACS of sickle cell disease is an all-inclusive lung injury syndrome, akin to ARDS. The largest clinical study of ACS defined ACS on the basis of the finding of a new pulmonary infiltrate involving at least one complete lung segment that was consistent with the presence of alveolar consolidation but excluding atelectasis. In addition, the case definition required chest pain, a temperature higher than 38.5°C, tachypnea, wheezing, or cough. [17] Implicit in this definition is the acknowledgment that lung injury from a wide variety of causes can induce pulmonary microvascular sickling to a greater or lesser extent.

Identified etiologies of the ACS include infection, vascular infarction, and fat emboli (Table 108-6). Vichinsky and colleagues found that infections account for about one-half of cases with identified etiologies, with identified pathogens in order of frequency: *Chlamydia*, *Mycoplasma*, respiratory syncytial virus, *Staphylococcus aureus*, *Streptococcus pneumoniae*, and Parvovirus (Table 108-7). Approximately one-third of cases were presumed due to pulmonary infarction from vaso-occlusion.[17] Some of these cases may have resulted from pulmonary atelectasis due to hypoventilation caused by painful infarction of ribs or vertebrae. Localized hypoxemia due to ventilation-perfusion mismatch of any cause may result in intrapulmonary sickling and vaso-occlusion (see Table 108-6).

Fat embolism appears to play a large role in episodes of ACS developing after the onset of a pain crisis. In the study by Vichinsky et al, oil droplets in pulmonary macrophages were found in bronchoalveolar lavage fluid from approximately one-sixth of all cases, indicative of fat embolism.[18] The mechanism appears to involve infarction of bone marrow, with sloughing of fat droplets from necrotic marrow into the venous circulation, resulting in pulmonary fat emboli resembling those classically seen in patients with femur and pelvic fractures after trauma (Figs. 108-4 and 108-5). Serum levels of secretory phospholipase A_2 rise before the clinical onset of ACS associated with painful crisis.[19] This enzyme can hydrolyze phospholipids into potent inflammatory mediators

TABLE 108-6 Pathogenesis of the Acute Chest Syndrome

Mechanism	Supporting Evidence
Bone infarction leads to atelectasis and regional hypoxia	Rib, vertebral, and sternal bone infarctions result in pain, hypoventilation, atelectasis, and subsequent hypoxia Incentive spirometry decreases radiographic atelectasis in patients with sickle cell anemia and VOC
Fat emboli	Evidence of bone marrow embolization found in 9%–75% of autopsy series Lipid-laden alveolar macrophages can be recovered from 20%–60% of patients with ACS; $sPLA_2$ levels are elevated in ACS; $sPLA_2$ may liberate free fatty acids from bone marrow lipid, releasing arachidonic acid and promulgating inflammation
Infection	Microbiological, serologic, or PCR evidence of pathogens[a]

Pathogen	Episodes	Pathogen	Episodes
Chlamydia pneumoniae	29%	*Haemophilus influenzae*	2%
Mycoplasma pneumoniae	20%	Cytomegalovirus	2%
Respiratory syncytial virus	10%	Influenza A virus	2%
Staphylococcus aureus	5%	*Legionella pneumophila*	2%
Streptococcus pneumoniae	4%	*Escherichia coli*	1%
Mycoplasma hominis	4%	Epstein-Barr virus	1%
Parvovirus	4%	Herpes simplex virus	1%
Rhinovirus	3%	Pseudomonas species	1%
Parainfluenza virus	2%	Miscellaneous	6%

Vascular occlusion	Increased adherence of erythrocytes to endothelial cells In animal models, regional pulmonary hypoxia results in entrapment of sickle erythrocytes Vascular obstruction indicated by ventilation/perfusion scan Pulmonary emboli documented by autopsy series
Vascular injury and inflammation	Endothelin 1 levels are elevated during VOC and ACS Elevated levels of inflammatory mediators such as $sPLA_2$ Clinical progression to adult respiratory distress syndrome (noncardiogenic pulmonary edema)

[a] From Vichinsky et al.[17]

ABBREVIATIONS: ACS, acute chest syndrome; $sPLA_2$; secretory phospholipase A_2; PCR, polymerase chain reaction; VOC, vaso-occlusive pain crisis.

such as free fatty acids and lysophospholipids. Liberation of arachidonic acid may lead to production of leukotrienes, thromboxanes, and prostaglandins, all of which mediate inflammation and affect endothelial function. Inflammation leads to endothelial cell surface expression of cell adhesion molecules, especially VCAM-1. Expression of VCAM-1 may be further increased by depletion of NO and its precursor arginine, which normally suppress VCAM-1 expression.[20,21] This receptor, normally involved in the recruitment of inflammatory cells, may bind erythrocytes and leukocytes, contributing to pulmonary vaso-occlusion. This pulmonary microvascular obstruction worsens ventilation-perfusion mismatch, thereby aggravating hypoxemia, which increases sickling and leads to a vicious cycle (see Fig. 108-5). The ACS can evolve to a common end point of acute lung injury resembling that of ARDS, regardless of the initial etiology.[22]

TABLE 108-7 Causes of Acute Chest Syndrome[a]

Cause	Cases with Identified Etiology
Fat embolism	16%
Chlamydia	13%
Mycoplasma	12%
Virus	12%
Typical bacteria	8%
Mixed infections	7%
Legionella	1%
Miscellaneous infections	1%
Infarction	30%

[a] Only those cases with complete analysis for the indicated potential infectious causes by culture, serology, and polymerase chain reaction are reported. Cases without any defined infectious etiology were presumed to be due to infarction without infection.

SOURCE: Vichinsky et al.[17]

The clinical severity of ACS is highly variable. Common physical findings include fever, tachypnea, rales, and wheezing. Laboratory findings often include leukocytosis, an acute decrease in hemoglobin level (~1.6 g/dL), and hypoxemia. Pulmonary infiltrates are often found in the upper lobes in children and lower lobes in adults. Multilobar disease suggests a worse prognosis. In addition to a new pulmonary infiltrate or consolidation, pleural effusions develop in up to half of the episodes during the course of hospitalization (see Fig. 108-4). In the study by the National Acute Chest Syndrome Study Group, 22% of ACS episodes in adults and 10% of episodes in children required management with mechanical ventilation. Risk factors for requiring mechanical ventilation were decreased platelet count ($<200{,}000/mm^3$), multilobar disease, a history of cardiac problems, and neurologic complications. Total mortality rates were 9% in adults but lower than 1% in children. Other than pain (especially abdominal pain), the most common complications are neurologic (11% of episodes), including seizures or stroke. Cardiac, gastrointestinal, or renal complications are infrequent. Mean duration of hospitalization was 10.5 days, as compared with 3 to 4 days for uncomplicated ACS.[17]

Treatment of ACS involves careful supportive care, empiric antibiotic therapy, and transfusion therapy (Table 108-8). Pain should be treated aggressively, and often patient-controlled analgesia is best. Relief of chest pain may improve tidal volume and improve oxygenation, although it is important to avoid excessive sedation and respiratory suppression.

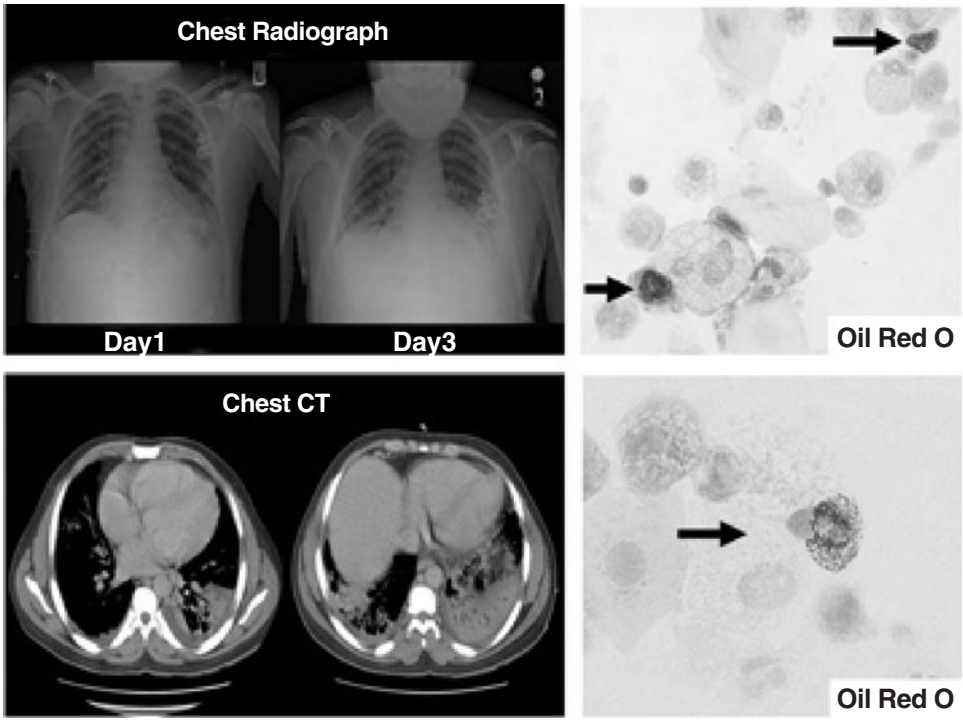

FIGURE 108-4 Acute chest syndrome of sickle cell disease. A 27-year-old male with sickle cell disease presented with fever, shortness of breath, and vaso-occlusive crisis with left chest wall pain. A chest radiograph on day 3, initially normal on day 1, demonstrates the development of a bilateral lower lobe infiltrate and bilateral pulmonary volume loss. Chest computed tomographic images on day 3 show bilateral basilar infiltrates, with dense consolidation of left lower lobe, and small bilateral pleural effusions. Micrographs after oil red O staining (which stains fat red) of specimens obtained by bronchoalveolar lavage showed lipid-laden macrophages consistent with the acute chest syndrome caused by bone marrow fat embolism to lung. ***(Haley M, Gladwin MT, unpublished observations.)***

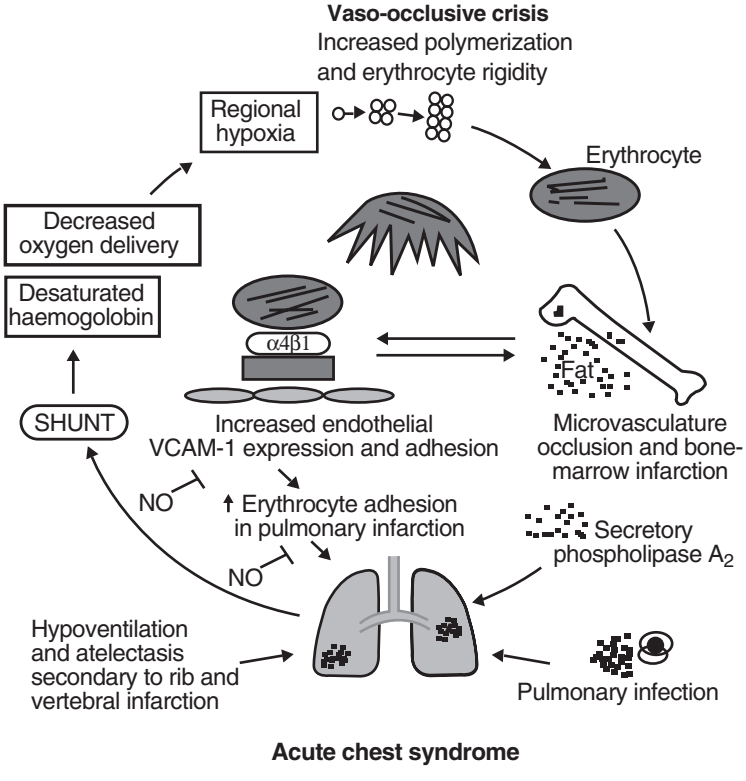

FIGURE 108-5 Model of acute chest syndrome pathophysiology. Vaso-occlusive crisis mediated though increased polymerization of hemoglobin S, erythrocyte rigidity, deformation, mechanical obstruction, and blood cell adherence to vascular cell adhesion molecule 1 (VCAM-1) leads to infarction of a variety of tissues, most characteristically the marrow of bones, causing severe bone pain. In some cases, fat droplets from necrotic marrow appear to slough into the venous circulation of the bone medulla, where the droplets embolize to the pulmonary circulation and increase the amount of secretory phospholipase A_2 in blood plasma. Hydrolysis of these fat emboli releases proinflammatory free fatty acids that can induce VCAM-1 expression in the pulmonary microvasculature, leading to adhesion of red and white blood cells. The pulmonary microvascular occlusion can lead to ventilation-perfusion mismatch, generalized hypoxemia, and increased systemic hemoglobin S polymerization. Alternatively, the cycle may be initiated by hypoventilation due to chest wall pain, causing localized hypoxia and pulmonary microvascular hemoglobin S polymerization, or by a pulmonary infection, which generates local hypoxia with shunting and inflammation to induce VCAM-1. The cycle may be broken by exchange transfusion or possibly by glucocorticoids. The potential therapeutic effect of inhaled nitric oxide on ventilation-perfusion matching, which decreases pulmonary artery pressure and inhibits adhesion events, is currently being studied. ***(Reproduced with permission from Gladwin and Rodgers.*[22]**)

TABLE 108-8 Therapy of the Acute Chest Syndrome of Sickle Cell Disease

Judicious hydration
1–1.5 times daily requirement; fluid restriction may be indicated in patients with severe acute chest syndrome and capillary leak or in renal insufficiency
Oxygen
Indicated to maintain adequate oxygenation; does not offer benefit for vaso-occlusive crisis in the absence of hypoxemia
Pain management
Mild pain
Oral codeine, acetaminophen or ibuprofen
Moderate to severe pain
Medication can be administered on a fixed time schedule with interval analgesics to obtain adequate pain control (see Table 108–9)
Consider patient controlled analgesia (see Table 108–10)
Prevent atelectasis
Incentive spirometry: 10 maximum inspirations q 2 h while awake
Empiric antibiotics
Cephalosporin to cover *Streptococcus pneumoniae*
Include macrolide or quinolone for coverage of atypical pathogens *Chlamydia pneumoniae* and *Mycoplasma pneumoniae*
Cultures should include nasal washings for viral pathogens (influenza, respiratory syncytial virus, adenovirus, parainfluenza virus, cytomegalovirus, and parvovirus)
Diagnose and treat reactive airways disease
Consider occult lack of positive end-expiration pressure and its complications
Consider exchange transfusion or simple transfusion (see Table 108–12)
Inhaled nitric oxide
May prove efficacious but cannot be recommended routinely at this time

Incentive spirometry also helps to reduce atelectasis. Because an infectious etiology in practice can rarely be ruled out, initial management should include empiric antibiotic coverage for *Chlamydia pneumoniae*, *Mycoplasma pneumoniae*, and *Streptococcus pneumoniae*, frequently encountered organisms in ACS.[17] Commonly a third-generation cephalosporin is combined with a macrolide or quinolone antibiotic. Patients may respond to inhaled bronchodilator therapy, especially if they have a history of reactive airway disease.[16]

Pulse oximetry is a useful tool to monitor the severity of hypoxemia. Due to difficulties in interpretation caused by sickle cell disease, the data from pulse oximetry is only approximate.[23–25] Pulse oximetry while the patient is on room air should be followed, with consideration of arterial blood gas sampling while the patient is on room air if the oxygen saturation is below 92%. An increase in the alveolar-arterial oxygen gradient is the best predictor of ACS severity. The magnitude of the gradient and rate at which it develops determine the need for ICU admission, emergency transfusion, and aggressive respiratory support.[26]

Transfusion therapy is an important consideration in any case of ACS. Simple transfusion of 2 to 4 U of packed red blood cells should be considered early when ACS is diagnosed. Simple transfusion appears to be as effective as a more complete red blood cell exchange, but hemoglobin must be maintained below 10 g/dL.[27] This is usually possible because hemoglobin levels decrease during ACS. In the event of rapid progression of respiratory distress, more severe hypoxemia, multilobar disease, or requirement for mechanical ventilation, exchange transfusion is more definitive and the current standard of care (see section on transfusion therapy). Simple transfusion can be performed as a temporizing maneuver until manual or automated exchange transfusion can be performed.

Other treatments for ACS have been reported in the literature. Dexamethasone pulse therapy (0.3 mg/kg intravenously every 12 hours in four doses) has been reported to be effective in decreasing the severity of ACS in children. However, the rate of rebound pain or ACS progression when dexamethasone is stopped may exceed 25%, thus preventing widespread acceptance of this treatment.[28] Our own anecdotal experience indicates that a steroid taper does not alleviate this rebound. Dexamethasone may be useful in clinical settings in which transfusion therapy is not available or as a temporizing measure pending definitive therapy with exchange transfusion. Two case series have suggested that inhaled NO might provide clinical benefit, but this cannot be recommended without further clinical investigation in patients with sickle cell disease.[28a,28b]

PULMONARY HYPERTENSION

This frequent but previously underreported complication of sickle cell disease is associated with a high mortality rate. In a current prospective study of the prevalence and severity of pulmonary hypertension in adult patients with sickle cell disease, our group found a prevalence of 33%, and affected patients had a significantly lower survival rate at 21 months of follow up than did patients with sickle cell disease without pulmonary hypertension.[28c] A retrospective analysis suggested a 2-year mortality rate of 50%, comparable to that of primary pulmonary hypertension.[15] Sudden death from sickle cell disease may be linked to pulmonary hypertension. Severity of pulmonary hypertension in patients with sickle cell disease in steady state is mild to moderate and associated with a high cardiac output and low pulmonary vascular resistance compared with control subjects with sickle cell disease without pulmonary hypertension (see Tables 108-3 and 108-4). In our experience, pulmonary vasculature remains vaso-responsive to prostacyclin and NO in approximately 80% of patients.

Our data indicated that endogenous NO is consumed in the plasma of patients with sickle cell disease by the cell-free

hemoglobin liberated from red cells by intravascular hemolysis.[8] The increase in plasma hemoglobin commonly observed during VOC may heighten NO consumption during crisis and cause decompensation of previously moderate pulmonary hypertension. This is exacerbated by an apparent depletion of the substrate for NO synthesis, the amino acid L-arginine.[29,30] Elevated plasma levels of endothelin 1, an extremely potent vasoconstrictor, are found in patients with sickle cell disease during VOC, potentially increasing pulmonary artery pressures in VOC.

SEPSIS AND MENINGITIS

Due primarily to splenic dysfunction, patients with sickle cell disease are at particular risk for sepsis. Children younger than 6 years are at greatest risk, especially for meningitis. Advances in immunizations are improving these risks, but these patients remain at higher risk for sepsis and meningitis than the general population. Although sepsis and meningitis may be caused by any organisms pathogenic in the general population, patients with sickle cell disease are particularly susceptible to infection with encapsulated organisms, especially *Streptococcus pneumoniae*. This organism may be resistant to β-lactam antibiotics due to long-term penicillin prophylaxis or recurrent courses of empiric antibiotics. Empiric antibiotic coverage with ceftriaxone or cefotaxime should be considered for fever in children younger than 6 years and in patients of all ages who appear toxic or have fever with high-grade leukocytosis. These antibiotics have rarely been associated with immune-mediated hemolytic anemia, and appropriate caution and monitoring should be undertaken. Cerebrospinal fluid pleocytosis or strongly suspected bacterial meningitis should be treated initially with vancomycin in addition to large doses of ceftriaxone or cefotaxime. Antimicrobial management of ACS was discussed earlier.

STROKE

Approximately 7% of patients with sickle cell disease will develop clinically detected cerebral infarction, with much of this risk occurring in early childhood. Young children are at risk of ischemic stroke, with a peak incidence between ages 2 and 5 years, and another peak is seen in adults older than 53 years.[31] These strokes are commonly in large vessel distributions, in contrast to the microvascular infarcts incurred in other organs. The infarctions are commonly multifocal and can be clinically overt or subclinical in nature. Population screening with transcranial Doppler ultrasonography is performed prospectively to identify those at high risk for strokes because prophylactic transfusion therapy can prevent these strokes. Patients at risk are those with time-averaged mean blood flow velocity over 200 cm/second in the internal or middle carotid arteries.[32] Clinical strokes can manifest during acute illness or as isolated neurologic events. Children with acute neurologic events should be rapidly assessed clinically for the likelihood of ischemic stroke versus bacterial meningitis, with the latter normally presenting with features of sepsis. Ischemic clinical stroke mandates rapid treatment with exchange transfusion to limit the extent of the infarction and prevent recurrences. Emergency exchange transfusion should be considered in children with sickle cell disease and acute neurologic disability even before neuroimaging studies. Without continued chronic transfusion, two of three patients will have a recurrence. The required duration of long-term transfusion remains unclear, although most children with stroke are transfused into adulthood. Issues in stroke in sickle cell disease have recently been reviewed.[33]

Hemorrhagic stroke predominates over nonhemorrhagic stroke in adults with sickle cell disease, primarily during the third decade.[31] They are usually intracerebral hemorrhages but may occur as subarachnoid hemorrhages, with the latter often following rupture of aneurysms. Hemorrhages occur apparently due to chronic vasculopathy, and there is no published evidence to indicate whether or not its course is modified by transfusion therapy. Unfortunately, there is a dearth of published experience to guide therapy in these patients, and treatment is largely supportive, with consideration of exchange transfusion. Surgical intervention may be indicated for aneurysms.

SPLENIC SEQUESTRATION AND INFARCTION

Splenic sequestration involves acute engorgement of the spleen, presumably due to obstruction of its venous outflow by sickled erythrocytes.[34] The volume of blood acutely sequestered from the circulation can cause severe anemia and life-threatening hypotension. Because most patients with homozygous sickle cell disease have splenic atrophy by age 10 years due to gradual microinfarction, this complication occurs only in those patients with significant residual splenic parenchyma, namely young children with sickle cell disease and individuals at all ages with less severe sickling syndromes, such as hemoglobin SC disease and hemoglobin S-β-thalassemia. Splenic sequestration when acute and severe should be treated with rapid red cell transfusion, analogous to the treatment of acute severe traumatic blood loss. Overtransfusion should be avoided because, during resolution, sequestered red cells can be abruptly released, potentially causing hyperviscosity. When this syndrome occurs in adolescents or adults with hemoglobin SC disease, it may be associated with acute splenic infarction. This clinically impressive syndrome can present with very high-grade fever, extraordinary splenic pain and tenderness, and enormous splenomegaly. Sonography or computed tomography may depict inhomogeneity representative of hemorrhagic infarction, which should be differentiated from possible splenic abscess. Patients with acute splenic infarction can be managed medically with transfusions and supportive care.[35]

Recurrence of splenic infarction indicates a risk of multiple future recurrences, and some have recommended splenectomy. If this is done, it should probably be done electively after medical management and clinical resolution of the acute episode to avoid undue operative risk.

PRIAPISM

Priapism refers to pathologically prolonged erection of the penis, which is often extremely painful.[36] Although its pathophysiologic mechanism remains to be elucidated, it seems likely that penile venous outflow is obstructed by sickled erythrocytes. Case reports of many therapeutic approaches have been proposed based on experience in limited numbers of patients, but these have rarely proved to be of benefit in larger clinical experiences. The most widely recommended acute treatment for severe episodes is exchange transfusion, although evidence of its efficacy is limited. Therapies of

questionable value have included adrenergic agonists, nitrates, and a surgical approach known as a Winter shunt. Only one therapy has shown some benefit in a relatively large single-institution study involving percutaneous drainage and irrigation of the corpus cavernosum initiated within 3 hours of onset.[37] The value of this approach has not been validated in other institutions, but it may have the clearest evidence of benefit in absence of a well-established standard of care. One very interesting, counterintuitive approach has been reported. Sildenafil, normally used clinically to treat erectile dysfunction, given in single 50-mg doses as needed, rapidly relieved several episodes of priapism in three patients with sickle cell disease.[38] Because of the possibility that this drug might also be capable of inducing priapism, its use cannot be recommended until further research is conducted.

PERIOPERATIVE MANAGEMENT

Patients with sickle cell disease have a high risk of perioperative complications, with 10% to 50% developing a VOC or ACS postoperatively. Careful preoperative anesthesiology consultation should be undertaken. Many sickle cell centers have traditionally performed serial transfusion or exchange transfusion preoperatively with a goal of preventing postoperative complications by reducing the hemoglobin S fraction to less than 30%, with a final total hemoglobin level of at least 10 gm/dL. A randomized study by Vichinsky et al showed that preoperative simple transfusion with a goal of raising the total hemoglobin concentration to 10 gm/dL, without a specific goal for hemoglobin S percentage, has similar efficacy. However, this study included predominantly patients with less invasive surgical procedures, such as tympanostomy tube placement or laparoscopic cholecystectomy. Some centers still prefer to perform exchange transfusion before major surgery in patients with sickle cell disease, although many transfuse less aggressively. A careful risk-benefit evaluation must be applied to each case, especially in patients with a history of red blood cell alloimmunization.

Supportive care should include careful attention to avoiding dehydration, overhydration, deoxygenation, vascular stasis, low temperature, acidosis or infection. The operating room should be kept warm, and warming devices should be used for the patient. Oxygenation status should be closely monitored intraoperatively and postoperatively, and incentive spirometry should be prescribed postoperatively. The literature regarding perioperative management of patients with sickle cell disease has been reviewed in more detail by Marchant and Walker.[39]

Treatments

OXYGEN AND FLUIDS

Because hypoxemia and dehydration can trigger sickling, it is important to prevent these from developing. Contrary to traditional teaching in many medical training programs, there is no indication of benefit from aggressive hydration in patients who are not dehydrated or from oxygen therapy in the absence of hypoxemia. Excessive fluid resuscitation may even compromise some older patients who have some degree of congestive heart failure or renal insufficiency.

ANALGESICS

At times, acetaminophen can suffice for mild pain. More severe pain often requires addition of an oral opioid analgesic such as codeine, hydromorphone, morphine, or oxycodone; morphine and oxycodone are available as short-acting or sustained-release preparations (Table 108-9). Severe pain episodes are best treated with intravenous opioids, usually morphine or hydromorphone, with considerable added convenience to patient and clinician when administered via a patient-controlled analgesia pump (Table 108-10). Patients with severe pain may also benefit from the parenteral nonsteroidal anti-inflammatory drug ketorolac, although questions have been raised about potential impairment of renal blood flow. Ketorolac also presents a risk of gastrointestinal hemorrhage, particularly if used for 5 days or longer. We recommend that nonsteroidal anti-inflammatory agents be withheld in patients with sickle cell disease with pulmonary hypertension or serum creatinine level above 0.8 mg/dL. Clinicians should consider the baseline narcotics the patient is using for determining an adequate dose of narcotics. Opioid tolerance due to previous chronic or frequent opioid administration may be an indication for much larger doses of opioids for acute pain control. Elderly or debilitated patients may require smaller doses of opioids to reduce toxicity. Opioid therapy may result in constipation, nausea, or pruritus. A laxative such as Senokot should be administered prophylactically. Nausea may be treated with diphenhydramine, hydroxyzine, promethazine, ondansetron, or dolasetron. Pruritus may be treated with diphenhydramine or hydroxyzine. Very severe pruritus may respond to naloxone

TABLE 108-9 Parenteral Analgesics Commonly Used in Painful Crisis of Sickle Cell Disease[a]

Class	Agent	Adult Dose	Pediatric Dose	Notes
NSAID	Ketorolac	30 mg IV q 6 h	0.5 mg/kg IV q 6 h	After 3 d, change to oral ibuprofen due to risk of gastrointestinal bleeding; omit in patients with known pulmonary hypertension
Opioid	Morphine	5–20 mg IV q 3 h	0.1–0.2 mg/kg IV q 3–6 h	Usually use morphine as opioid except in cases of previous morphine intolerance
	Hydromorphone	1–4 mg IV q 3–6 h	0.015–0.03 mg/kg IV q 3–6 h	

[a] Most patients will require midrange doses. Use a lower dose range in elderly or debilitated patients or consider an upper dose range in opioid-tolerant patients. Highly tolerant patients at times may require even larger doses than the ranges listed. The use of meperidine is generally discouraged, due to seizures occasionally seen as a complication of its use. Most patients can obtain satisfactory analgesia with morphine or hydromorphone. Opioid-induced side effects often require medical management (see text).

ABBREVIATIONS: IV, intravenously; NSAID, nonsteroidal anti-inflammatory drug.

TABLE 108-10 Approaches for Patient-Controlled Analgesia[a]

Agent	ADULT DOSE		PEDIATRIC DOSE	
	Continuous	Demand	Continuous	Demand
Morphine	1–2 mg/h	1–2 mg	0.01–0.03 mg/kg per hour	0.01–0.03 mg/kg
Hydromorphone	0.2–1 mg/h	0.2–1 mg	0.003–0.005 mg/kg per hour	0.003–0.005 mg/kg

[a] In adults and children, common parameters include 6- to 10-minute lockout, limited to five demand doses per hour. Meperidine should never be administered by continuous infusion. Most patients will require midrange doses. Use a lower dose range in elderly or debilitated patients or consider an upper dose range in highly opioid-tolerant patients. Highly tolerant patients at times may require even larger doses than the ranges listed. Opioid-induced side effects often require medical management (see text).

1 μg/kg per hour as a continuous intravenous infusion. This small dose can block opioid receptors associated with pruritus without blocking those associated with analgesia. Detailed recommendations for analgesia in patients with sickle cell disease have been published.[40]

INCENTIVE SPIROMETRY

Bedrest during a pain crisis may lead to pulmonary atelectasis. This can trigger ACS (see below). Bedside incentive spirometry during pain crisis has been shown to prevent the development of pulmonary infiltrates.

TRANSFUSION

Although there is probably no indication for treatment of the acute pain crisis, most other acute serious complications of sickle cell disease can be stabilized through the use of transfusions to diminish the percentage of circulating hemoglobin S. Table 108-11 lists indications for transfusion therapy. It is clear from reviewing this list that almost any patient who requires an ICU visit is likely to require a simple or exchange transfusion. As such, the intensivist must be well versed in the indications, complications, and pitfalls of transfusion therapy in this population.

Patients with sickle cell disease have severe chronic anemia, and they generally tolerate transient episodes of at least a 20% decrease in their baseline hemoglobin level quite well, if the reticulocyte count remains high. Knowledge of a given patient's baseline parameters can help to determine the need for transfusion for exacerbation of anemia. The most severe and life-threatening anemia and reticulocytopenia occurs during aplastic crisis resulting from infection with the parvovirus B19, otherwise known as erythema infectiosum, fifth disease, or slapped-cheek disease. Life-threatening anemia and hypovolemia due to splenic sequestration are other such indications, discussed in more detail below.

There are several important transfusion issues unique to patients with sickle cell disease to consider. First, transfused red cells should be negative by Sickledex or another rapid screening test to exclude blood from sickle trait donors. Second, the detailed red cell phenotype should be ascertained in the blood bank, particularly for patients who will be chronically transfused, such as children with a new stroke. This permits more directed management of alloimmunization to red cell antigens, although the actual approach is controversial. The rate of alloimmunization to red cell antigens in patients with sickle cell disease is 18% to 36%, most often involving the D, C, and E antigens in the Rh system and less often the Kell, Kidd and Duffy blood groups. This is attributable in large part to discrepancy in allele frequency between these patients of African descent and the blood pool from donors of mostly European descent. One workshop report has recommended the use of red cell units prophylactically matched to prevent sensitization to the Rh antigens D, C, and E and the Kell antigen K.[41] However, others have advocated matching these antigens only after the patient has become immunized to antigens.[42] The high rate of alloimmunization in patients with sickle cell disease promotes a higher incidence (3%) of delayed hemolytic transfusion reactions. These are defined as premature clearance of transfused red cells, usually several days after transfusion. In some cases, the hemoglobin level may decrease to below the pretransfusion level, with the immune reaction to transfused cells apparently generalizing to also involve the patient's

TABLE 108-11 Acute Indications for Transfusion in Patients with Sickle Cell Disease

Indication	Transfusion Form
Severe anemia associated with high output cardiac failure, dyspnea, postural hypotension, angina, or cerebral dysfunction	Simple
Sudden reduction in hemoglobin concentration (splenic or hepatic sequestration, aplastic crisis)	Simple
Acute or suspected stroke	Exchange
Multiorgan failure syndrome	Exchange
Acute chest syndrome with severe hypoxia	Exchange
Acute chest syndrome with acute anemia	Simple
Preoperative preparation, hemoglobin SS	Simple
Preoperative preparation, hemoglobin SC, major surgery	Partial exchange
Acute severe priapism	Exchange

ABBREVIATIONS: SC, hemoglobin sickle cell disease; SS, homozygous sickle cell disease.

own red cells, a phenomenon that has been called "bystander hemolysis."

Because of this complication, it is critical to obtain a transfusion antibody history from blood banks where a patient was previously transfused. Over several months, alloantibody titers to red blood cell antigens may become undetectable on a routine type and cross-match but remain capable of mediating a transfusion reaction. The resulting delayed transfusion reaction in an acutely ill hospitalized patient can be catastrophic, with hemoglobin levels decreasing to 2 to 3 g/dL.

Simple transfusion is sufficient for correcting severe anemia, but exchange transfusion can more rapidly dilute sickle hemoglobin to less than 40% of circulating hemoglobin, which is desirable in acute life-threatening sickle cell complications, in particular stroke, ACS, and multiorgan failure syndrome. Exchange transfusion may be accomplished rapidly and isovolumetrically by erythrocytapheresis, when this procedure is available (Table 108-12). This requires upper extremity veins sufficient for two large-bore needles, placement of a Quinton or similar apheresis, or hemodialysis venous catheter in a central vein (femoral, internal jugular, or subclavian). Alternatively, manual exchange transfusion may be performed by using one of several protocols, with a goal of replacing 70% of the sickle red cell mass with transfused red cells. One simplified approach for adults is presented in Table 108-12. Another approach useful in children and adults is to exchange the red cell mass twice, as calculated below:

$$\text{volume transfused} = \frac{2\times(\text{patient hematocrit, decimal, not \%})\times(\text{patient weight in kg})\times(70\ \text{mL/kg})}{\text{average hematocrit of transfused packed red blood cells, usually 0.55}}$$

This volume may be transfused while whole blood is being withdrawn from a high-flow site, often an arterial or central venous line. The transfusion may be accomplished as rapidly as the inflow and outflow catheters allow, as long as care is taken to maintain balanced hourly inflow and outflow rates for the duration of the procedure. If the hemoglobin level exceeds 10 gm/dL or hematocrit exceeds 30% during the first half of the exchanged volume, the red cell hourly infusion rate should be halved, and the reduced red cell rate replaced with normal saline, so that the hourly inflow rate continues to equal the outflow rate. The final target hemoglobin level should be 10 gm/dL. Higher hemoglobin levels can cause hyperviscosity problems at the microvascular level in patients with sickle cell disease.

HYDROXYUREA

This agent was first widely used to treat chronic myeloid leukemia and has found a place in the prophylactic treatment of sickle cell disease. At least in adults with more severe than average sickle cell disease, it decreases the incidence of significant pain episodes, ACS, and transfusions by approximately 50% and significantly prolongs lifespan. Its favorable effects are mediated through its elevation of fetal hemoglobin, which inhibits sickle hemoglobin polymerization. Its use may be complicated by myelosuppression, and administration is commonly interrupted during sepsis or serious infection, although it is unclear whether this is truly necessary in the absence of drug-induced neutropenia. Hydroxyurea is contraindicated in pregnancy due to its potential teratogenicity, and a potential carcinogenic effect after long-term use has not been completely excluded.

GLUCOCORTICOIDS

Methylprednisolone (15 mg/kg per day intravenously IV in two doses) and dexamethasone (0.3 mg/kg every 12 hours intravenously in four doses) have produced statistically significant improvements in painful crisis and ACS, respectively, but this treatment is troubled by significant rebound symptoms in at least 25% of patients. The partial success of these

TABLE 108-12 Exchange Transfusion in Sickle Cell Disease

Indications
Patients with extensive pulmonary infiltrates (especially multilobar)
Rapidly progressive respiratory disease
Signs of respiratory distress
Pa_{O_2} <60 mm Hg in an adult breathing supplemental oxygen (70 mm Hg for children) or a decrease >25% from baseline in a patient with known hypoxemia.
Patient requiring ICU admission for ACS
Before major surgery (controversial)
Priapism and other severe symptoms.
Goals
Increase hematocrit to 10 gm/dL (do not exceed 12 g/dL to avoid hyperviscosity)
Decrease percentage of hemoglobin S to <30% (i.e., replace >70% of red cell mass)
Methods of exchange transfusion
Exchange transfusion is preferred if there is concern about volume overload, initial hemoglobin is >9–10 g/dL, or a significant rapid reduction in hemoglobin S is required (which is often the case in the ICU)
Remove 500 mL of whole blood from an arterial line or freely flowing venous line while infusing into another venous line simultaneously; repeat until the goals are met
Alternatively, remove 500 mL of blood, infuse 500 mL of normal saline, remove another 500 mL of blood, then transfuse 2 U of packed red cells; repeat until the goals are met
Automated apheresis devices can also be used; a typical adult will require 6–8 U of blood for apheresis exchange

ABBREVIATIONS: ACS, acute chest syndrome; ICU, intensive care unit; Pa_{O_2}, arterial pressure of O_2.

agents indicates the probable role that inflammatory pathways play in acute vaso-occlusive phenomena.

INVESTIGATIONAL

Inhaled NO at 80 ppm for 4 hours produces a trend toward significant improvement in the duration of crisis and pain scores in a preliminary study in children with VOC.[43] Case reports have documented its effect on increasing arterial oxygenation and decreasing pulmonary pressures during the ACS.[28a,28b] Its use in secondary pulmonary hypertension in sickle cell disease is being studied. The natural NO donor L-arginine often is depleted from the blood of patients with sickle cell disease in crisis, and its supplementation is being evaluated.[44] Inhibitors of the red cell Gardos channel enhance water transport into normally dehydrated sickle cells, thereby decreasing hemoglobin S polymerization, and these are in clinical trial.[45] Poloxamer 188 (Flocor) is a rheological agent that has shortened the duration of VOC under some circumstances.[46]

Chapter 109

THE OBESITY EPIDEMIC AND CRITICAL CARE

BRIAN GEHLBACH
JOHN P. KRESS

KEY POINTS

- *Morbid obesity presents unique cardiorespiratory challenges in the intensive care unit and frustrates the delivery of routine care. Whether or not obesity itself influences the outcome of critical illness is unclear.*
- *Morbid obesity leads to heart disease through a number of diverse mechanisms. Therefore, a high index of suspicion for its presence is warranted in the critically ill patient.*
- *An increased risk of venous thromboembolism in obesity merits an aggressive approach to prophylaxis.*
- *Cor pulmonale occurs in individuals with nocturnal and diurnal hypoxemia related to the obesity hypoventilation syndrome or coexisting obstructive sleep apnea and obstructive lung disease.*
- *Although simple obesity has relatively minor effects on pulmonary function, morbid obesity may be associated with reductions in forced vital capacity, forced expiration volume in 1 second, and total lung capacity. An increase in mid to late expiratory flow may be seen.*
- *Morbid obesity is associated with a significant increase in the percentage of oxygen consumption attributable to the work of breathing. This decreased respiratory reserve results in a predisposition to the development of respiratory failure even after trivial insults.*
- *Atelectasis is common in the morbidly obese postoperative patient and, in addition to any accompanying sleep-disordered breathing, may lead to respiratory failure. Although conclusive data are lacking, the early use of noninvasive ventilation in the high-risk postoperative patient may prevent the development of respiratory failure.*
- *Intubation of the morbidly obese patient may be technically challenging because of poor visibility of the glottis and decreased oxygen stores in alveoli from a reduced functional residual capacity.*
- *Morbidly obese patients should be ventilated in the upright or semi-upright position to improve respiratory system compliance and reduce the work of breathing. Positive end-expiratory pressure between 8 and 15 cm H_2O may be necessary to prevent atelectasis.*
- *Because the compliance of the chest wall is diminished in morbid obesity, a high plateau pressure does not necessarily indicate alveolar overdistention. When using low tidal volume ventilation in the management of the acute respiratory distress syndrome, a plateau pressure of 35 to 40 cm H_2O may be acceptable in some patients.*
- *Ultrasound guidance may be useful in establishing vascular access in the morbidly obese patient.*
- *Numerous unpredictable alterations in pharmacokinetics have been described in obesity. Reference to published guidelines for individual drugs and close monitoring of clinically available serum drug levels are recommended.*
- *Attempts by clinicians to accelerate a program of weight loss during the course of critical illness are misguided and may interfere with immune function, wound healing, and respiratory muscle strength. Carefully balanced hypocaloric regimens may be safe.*

An ever-increasing percentage of the inhabitants of developed countries is obese or overweight. This trend includes men and women and spans all age groups, including children. Obesity is associated with diabetes mellitus, cardiovascular disease, hypertension, and cancer and confers a reduced life expectancy, particularly in younger and severely obese individuals. Extreme obesity is frequently associated with life-threatening cardiopulmonary disease and presents substantial obstacles to the delivery of routine care. We present a summary of the challenges inherent in the care of the morbidly obese critically ill patient and highlight physiological principles important to the care of such patients.

The Obesity Epidemic

DEFINING OBESITY

Due to the impracticality of determining body fat composition in the clinical setting, obesity is typically defined as excessive weight relative to body surface area as determined by calculation of the body mass index (BMI), calculated as weight in kilograms divided by height in square meters. The correlation between BMI and obesity in most middle-age adults is very good, although using BMI as a proxy for body fat is misleading in individuals engaged in weight training who have increased muscle mass, and when significant edema is present. The World Health Organization and National Institutes of Health recommend the following definitions of overweight and obesity: overweight is defined as a BMI greater than 25 kg/m^2, obesity is defined as a BMI greater than 30 kg/m^2, and morbid obesity is defined as a BMI greater than 40 kg/m^2. Some authorities have extended the definition of morbid obesity to individuals with a BMI greater than 35 kg/m^2 if they have serious medical comorbidities.

THE MAGNITUDE OF THE PROBLEM

Data from the 1999–2000 National Health and Nutrition Examination Survey show a continued increase in the prevalence of overweight and obesity in the United States over the past 15 years. Relative to the 1988–1994 survey, the prevalence of overweight individuals has increased from 55.9% to 64.5%, obesity has increased from 22.9% to 30.5%, and morbid obesity has increased from 2.9% to 4.7%.[1] Non-Hispanic black women have the highest prevalence of obesity and overweight, but increases were found across all ethnic groups and in men and women. Perhaps of greatest concern is an increase in the prevalence of overweight and obesity among children, particularly Mexican American and non-Hispanic black adolescents.[2,3]

There are many potential explanations for the increasing number of persons who are overweight or obese. Technologic advances have decreased the cost of food production, thereby making food more affordable, and decreased the energy

expended by the typical worker.[4] Leisure time is increasingly dominated by sedentary activities such as watching television or using the computer. Television viewing is associated with increased food intake and a decrease in metabolic rate even when compared with other sedentary activities such as reading or sewing.[5] The risks of obesity and type II diabetes mellitus have been positively correlated with the amount of television watched,[6] and children randomized to an intervention discouraging television viewing had significant reductions in relative BMI compared with controls.[7] Other possible explanations for the obesity epidemic include an increased percentage of meals eaten outside the home, the serving of larger portions at commercial establishments, and the widespread consumption of diets low in vegetables and fibers and high in refined sugars. Individual susceptibility to these influences is poorly understood but likely includes a genetic component.

Unfortunately, the obesity epidemic is not confined to highly developed countries. The World Health Organization estimates that 1 billion people worldwide are overweight or obese. Worse, most indications are that the epidemic has not yet peaked: obesity is increasing in prevalence in developing countries coincident with decreased physical activity and the replacement of traditional fruits and whole grains in the diet with calorie-dense, processed foods.

Physiologic Effects of Morbid Obesity

Obesity is associated with a shortened life expectancy, particularly in severely obese younger individuals.[8] This section summarizes important physiologic derangements associated with obesity, with an emphasis on those germane to the care of the morbidly obese critically ill patient.

CARDIOVASCULAR EFFECTS

The risk of death from cardiovascular disease rises steeply above a BMI of 30 kg/m^2.[9] There are several mechanisms through which obesity can cause cardiovascular disease. First, obesity increases the risk of coronary atherosclerosis by inducing several risk factors in parallel. For example, obesity is associated with hypertension, insulin resistance, dyslipidemia, and coagulation abnormalities, which separately and collectively promote the development of cardiovascular disease.

There are other mechanisms through which obesity causes heart disease. Obesity may impair cardiac function through chronic pressure and volume overload.[10] Cardiac output is increased in obesity as a result of increased extracellular volume and increased blood flow to most tissue beds. This increased cardiac output is associated with increased preload and cardiac dilatation, with the subsequent development of eccentric left ventricular hypertrophy. This chronic volume-overloaded state, when combined with increased left ventricular afterload from concurrent hypertension, may result in marked left ventricular hypertrophy. Over time, left ventricular hypertrophy leads to impaired ventricular filling and diastolic heart failure. Systolic heart failure may result from ischemic heart disease, microvascular disease from diabetes mellitus, longstanding hypertension, or, in severe, longstanding obesity, a decrease in mid-wall fiber shortening and ejection fraction.[9]

Pulmonary hypertension with right ventricular hypertrophy and dilation may accompany obesity. When not caused by left ventricular failure, pulmonary hypertension in these patients typically arises from conditions that cause nocturnal and diurnal hypoxemia. A relatively common presentation of this problem is that of the patient with obstructive sleep apnea who has coexisting chronic obstructive pulmonary disease. Cor pulmonale may also develop in patients with the obesity hypoventilation syndrome (OHS). This poorly understood disorder is associated with daytime hypercapnia and hypoxemia, with the latter arising from alveolar hypoventilation and poor ventilation of the basal lung due to airway closure and atelectasis. Hypercapnia and hypoxemia elicit pulmonary vasoconstriction. Eventually, this may lead to vascular remodeling with resulting irreversible pulmonary hypertension and cor pulmonale. Individuals with the OHS frequently, but not always, have coexisting obstructive sleep apnea.

Plasminogen activator inhibitor I and fibrinogen levels are elevated in most patients with obesity, suggesting a role for hypercoagulability and impaired fibrinolysis in cardiac and cerebrovascular diseases. Elevated proinflammatory cytokines, for example, interleukin 6 and C-reactive protein, potentially indicate the presence of a low-grade inflammatory state in this condition.[9]

What are the clinical implications of this susceptibility to such a range of cardiovascular disorders? First, the intensivist caring for the morbidly obese patient should have a high index of suspicion for the presence of ischemic heart disease from coronary artery or microvascular disease. Second, abnormal cardiac function, diastolic or systolic, may be present, even if other risk factors for heart disease are absent. Particular sensitivity to changes in intravascular volume may result. Third, pulmonary hypertension and right ventricular failure should be suspected when obstructive lung disease and/or daytime hypoxemia or hypercapnia are present. The diagnosis of these conditions is complicated by poor sensitivity of physical examination and transthoracic echocardiography in morbidly obese individuals. In selected patients, transesophageal echocardiography or invasive hemodynamic monitoring may be necessary.

PULMONARY EFFECTS

MECHANICS OF THE RESPIRATORY SYSTEM

The effect of obesity on pulmonary function varies considerably between individuals, ranging from trivial to profound impairment, but generally increases in severity with the BMI.[11,12] The overall compliance of the respiratory system is reduced, mildly so in simple obesity and as low as 45% of normal in patients with OHS. Some studies have suggested that decreased chest wall compliance from the mechanical effect of adipose tissue on the thoracic cage is the principal cause of this abnormality, whereas other investigators have implicated reduced lung compliance as an additional factor, probably from a decrease in functional residual capacity. Airway resistance has been found to be increased, and a reduction in mid to late expiratory flows has been noted; because the ratio of forced expiratory volume in 1 second (FEV_1) to forced vital

capacity (FVC) is typically normal or even elevated in obesity, a reduction in small airway caliber is likely responsible.

PULMONARY FUNCTION

The most frequent abnormality in pulmonary function in obesity is a decrease in the expiratory reserve volume attributable to cephalad displacement of the diaphragm by adipose tissue. In severely obese individuals and in those with the OHS, total lung capacity and vital capacity may be reduced. In such patients, the residual volume may actually be increased relative to total lung capacity because of small airway closure and gas trapping. This is supported by the finding of larger total lung capacity by body box plethysmography than by helium dilution.[13] Similarly, spirometry is typically normal in simple obesity, whereas severely obese individuals or those with the OHS may exhibit reductions in FEV_1 and FVC, even though the ratio of these two variables is preserved or even increased.

Why do some individuals exhibit diminished pulmonary function and/or the OHS, whereas comparably overweight individuals may be little affected? Some, but not all, data suggest that the distribution of body fat may be an important determinant of pulmonary function; simply put, adipose tissue that is more centrally located is more likely to negatively influence pulmonary function. There are also important differences in respiratory muscle strength between patients with simple obesity and those with the OHS, with the latter exhibiting decreased inspiratory muscle strength. Weakness may be considered absolute, a result of mechanical disadvantage from diaphragm malposition, and relative, when the increased work of breathing from morbid obesity is considered (see below).

GAS EXCHANGE

Morbid obesity causes closure of small peripheral airways in the dependent regions of the lung, resulting in mismatching of ventilation and perfusion.[14] The result may be a widened alveolar to arterial oxygen gradient and mild to moderate hypoxemia that worsens in the supine position. Severe hypoxemia may be present in individuals with the OHS because of the additional contribution of hypoventilation. The diffusing capacity for carbon monoxide is typically normal and may be elevated when indexed to alveolar volume.

CONTROL OF BREATHING

Ventilatory drive is increased in simple obesity as assessed by the mouth occlusion pressure and diaphragm electrical activity in response to carbon dioxide inhalation. In contrast, mouth occlusion pressure response to carbon dioxide is reduced in OHS compared to normal individuals and to patients with simple obesity. Diaphragm electrical activity in response to carbon dioxide is inappropriately low in OHS.

PERIOPERATIVE AND OTHER PULMONARY CONSIDERATIONS IN OBESITY

The reduced functional residual capacity associated with severe obesity encroaches on the closing capacity, the lung volume at which small airways in the lung bases begin to close. This places severely obese patients at significant risk for atelectasis in the perioperative period, particularly where upper abdominal or thoracic operations are concerned. Hypoxemia may result and may be marked in the setting of a relatively unremarkable chest radiograph. Pulmonary embolism should always be considered in the differential diagnosis of such patients. Treatment involves adequate analgesia, avoidance of oversedation, early mobilization, and vigorous pulmonary toilet. Sleep-disordered breathing may worsen in the postoperative period, thereby increasing the risk of respiratory failure. Early application of noninvasive ventilation may decrease the incidence of postoperative pulmonary complications. The risk of aspiration of gastric contents is generally felt to be increased in obesity, and efforts to minimize this occurrence should be taken at the time of intubation (see below).

Not surprisingly, the risk of obstructive sleep apnea increases significantly with obesity, to as high as 40% when the BMI exceeds 40 kg/m^2. Patients who successfully lose a significant amount of weight, usually via surgical approaches to weight reduction, may exhibit significant improvements in lung volumes, gas exchange, and work of breathing, and sleep-disordered breathing may improve or even resolve.

OTHER EFFECTS OF OBESITY

An intriguing association between obesity and progressive renal insufficiency is becoming apparent.[10,15] Obesity is associated with increased renal blood flow, glomerular filtration rate, and microalbuminuria. Glomerular hyperfiltration may subsequently lead to glomerular sclerosis in a manner analogous to diabetes, even in obese patients without this diagnosis. Several potential mechanisms for this process have been suggested, ranging from hyperleptinemia to insulin resistance to a chronic state of low-grade inflammation induced by obesity. Apart from the direct effects of obesity on the kidney, a significant proportion of cases of end-stage renal disease may be attributable to the diabetes and hypertension associated with obesity.

The risk of venous thromboembolism is greatly increased in obese patients (BMI > 30 kg/m^2). Inactivity, venous stasis, and hypercoagulability likely contribute to this risk. The risk of death from cancer is substantially increased in individuals with a BMI greater than 40 kg/m^2.[16]

Management of Respiratory Failure

PATHOPHYSIOLOGY OF RESPIRATORY FAILURE IN MORBID OBESITY

Morbidly obese patients may be particularly susceptible to respiratory failure. Under normal conditions, very little (<5%) of the body's total oxygen consumption (V_{O2}) is attributable to the work of breathing. Emphysema and other forms of chronic lung disease increase the oxygen consumed by the respiratory muscles (V_{O2RESP}) by increasing the load on the respiratory muscles. In such conditions, the strength of the respiratory system may be just adequate for the load on the system, and further insults, however trivial, may provoke respiratory failure.

Evidence suggests that morbidly obese patients may be similarly compromised. Baseline V_{O2RESP} averaged 16% in a group of morbidly obese (average BMI = 53 kg/m^2) patients scheduled for gastric bypass surgery.[17] Further, obesity is associated with a disproportionate rise in V_{O2RESP} for a given

increase in minute ventilation, similar to emphysema.[18] Together these data suggest reduced respiratory reserve in morbid obesity, thereby increasing the risk of respiratory failure even from seemingly trivial insults (e.g., viral infection or, particularly in the postoperative patient, atelectasis) in a manner analogous to emphysema or other chronically compensated forms of respiratory failure.

EVALUATION OF RESPIRATORY FAILURE

The evaluation of morbidly obese patients with critical illness and with respiratory failure, in particular, is challenging. Physical examination is difficult, and chest radiography is commonly unhelpful. Computed tomography or other similar diagnostic studies are impossible if the patient exceeds the weight limit or width of the scanner table. Even when such studies are possible, there are enormous technical and safety challenges that accompany the transfer of such patients throughout the hospital. Frequently, diagnoses must by necessity be made on the basis of other clinical criteria.

The diagnosis of pulmonary edema is often frustrated by uncertainty regarding the presence of edema on the chest radiograph. Soft tissue shadows on portable chest radiographs are often difficult to distinguish from airspace edema. When suspected, other clinical signs may assist in making a diagnosis. For example, abundant frothy secretions from the endotracheal tube commonly accompany pulmonary edema. Analysis of the protein content of the initial secretions may permit a distinction between high- and low-pressure edema, as the latter is associated with a protein content greater than one-half that of serum.[19] Measurement of a frankly elevated pulmonary capillary wedge pressure usually indicates that pulmonary edema is present. Similarly, pulmonary edema may be diagnosed in the patient with hypoxemia refractory to high-flow oxygen who also has an elevated right atrial pressure and abnormal left ventricular systolic or diastolic function, although this approach also makes an inference that pulmonary edema necessarily results from abnormal pump function. Acute lung injury may be diagnosed on the basis of appropriate setting (e.g., aspiration after the administration of sedation) and hypoxemia refractory to high-flow oxygen. Although differentiating this condition from atelectasis can be difficult, noting abundant protein-rich endotracheal secretions may be helpful.

Pulmonary embolism is another serious condition that is particularly difficult to diagnose in the morbidly obese patient. Computed tomography of the chest and pulmonary angiography may be technically unfeasible. Serial lower extremity Doppler examinations should be performed, although pulmonary embolism is not disproved solely through this approach. A normal D-dimer as determined by enzyme-linked immunosorbent assay reliably excludes the diagnosis, but such a result is unlikely in the critically ill population, given the multitude of conditions associated with elevations in D-dimer levels. Echocardiography may suggest the diagnosis by demonstrating acute right heart dysfunction, but this finding lacks specificity given the range of disorders precipitating respiratory failure (e.g., acute lung injury or severe, untreated sleep disordered breathing) that cause this. Because there are no good data to guide the clinician, our approach is to initiate therapeutic anticoagulation in the setting of significant pulmonary hypertension (mean pulmonary artery pressure >40 mm Hg), if acute right heart dilation without another satisfactory cause is present, or when historical features (e.g., acute onset of chest pain and dyspnea) suggest the diagnosis.

MANAGEMENT OF RESPIRATORY FAILURE

Noninvasive positive pressure ventilation has several potential benefits in the initial management of morbidly obese patients with respiratory failure, including unloading the respiratory muscles, decreasing atelectasis, and treating any underlying sleep-disordered breathing. It may also have a role in preventing respiratory complications in the postoperative period. Joris et al demonstrated the utility of noninvasive positive pressure ventilation in reducing the postoperative decrease in FVC and FEV_1 when applied to morbidly obese patients in the first 24 hours after gastroplasty.[20] We recommend the early use of noninvasive positive pressure ventilation in morbidly obese patients who have developed respiratory failure. Extubation to noninvasive ventilation may also be considered for morbidly obese patients at high risk for respiratory failure after thoracic or abdominal surgery, although this approach is unproven. Noninvasive ventilation is discussed in greater detail in Chap. 33.

Intubation of the morbidly obese patient can be problematic.[21] The view afforded the operator may be suboptimal because of extensive soft tissue in the hypopharynx. Reduced functional residual capacity from morbid obesity and from sedation diminishes the oxygen stores available for the patient during apnea. The risk of aspiration of gastric contents may be increased in this population, and obese patients should be considered to have "full stomachs" during airway manipulation. For these reasons, we recommend that intubation be performed in the presence of an experienced operator, if possible. Once the decision has been made to intubate, appropriate planning should commence without delay. Early planning allows for the consultation of an experienced operator and an opportunity to perform an awake intubation, with or without fiberoptic assistance. If the patient is too unstable to attempt this, we recommend the routine use of cricoid pressure to minimize the risk of aspiration.

Several factors promote the development of atelectasis in the morbidly obese patient who is intubated for respiratory failure. These include the supine position, administration of sedatives and narcotics, and translaryngeal intubation. As a result, extremely obese patients frequently require increased levels of positive end-expiratory pressure to prevent atelectasis and maintain adequate oxygenation, even in the absence of acute lung injury. In our experience, a positive end-expiratory pressure of 8 to 15 cm H_2O is frequently necessary. Because of atelectasis, significant hypoxemia may be present at the time that the patient is otherwise ready to sustain spontaneous breathing. Extubation to noninvasive positive pressure ventilation (NIPPV) may facilitate this transition and may maintain upper airway patency when residual sedation promotes obstructive respiratory events, although the routine use of NIPPV for post-extubation respiratory failure cannot currently be supported.[21a] If possible, morbidly obese patients should be ventilated and undergo spontaneous breathing

trials in the reverse Trendelenburg position, a maneuver that improves respiratory system compliance by shifting the abdominal contents off the chest wall.

Lung protective ventilatory strategies are challenging to apply in the morbidly obese patient with acute lung injury because of the difficulty in diagnosing alveolar overdistension in this population. The plateau pressure represents the pressure required to inflate the lung against the elastic recoil of the lung and chest wall. Because the compliance of the chest wall is diminished in morbid obesity, a high plateau pressure does not necessarily indicate alveolar overdistension. Thus, when using low tidal volume ventilation in the management of acute lung injury or the acute respiratory distress syndrome, the delivery of a tidal volume of 6 mL/kg *ideal body weight* may result in a plateau pressure easily exceeding 30 cm H_2O but not necessarily overdistend alveoli. Given the lack of convincing utility of pressure-volume curves in the management of acute lung injury, we do not advocate their use in such cases. We recommend measurement of the plateau pressure in the upright or semi-upright position to minimize the contribution of increased intraabdominal pressure from obesity and at times accepting an arbitrarily higher plateau pressure, for example, up to 35 to 40 cm H_2O in the extremely obese patient, if necessary.

TRACHEOSTOMY

Although firm data are lacking, we have found early tracheostomy to be useful in the management of many morbidly obese patients with respiratory failure. We recommend that consideration be given to early tracheostomy in the following settings: (1) when severe obstructive sleep apnea that is refractory to medical therapy is present, (2) when long-term nocturnal ventilation for the treatment of obesity hypoventilation syndrome is planned, and (3) when the course of recovery is expected to be prolonged.

Other Problems in the Delivery of Critical Care

ESTABLISHING VASCULAR ACCESS

Establishing intravenous access may be particularly difficult in the morbidly obese patient, beginning with the frequent inability to place a peripheral intravenous line. The increased distance from skin to blood vessel makes any attempt to cannulate a central vein more difficult, and the sharp angle required, particularly to enter the subclavian vein, may make it impossible for the operator to pass the wire and/or dilator. In some patients, the needle and the introducer may be too short for the subclavian site. The femoral site should be used as a last resort because of the increased risk of infection and thrombosis associated with this site; in addition, this site is frequently inaccessible because of intertrigo. The internal jugular vein is therefore generally the site of choice for extremely obese patients, even with the difficulties imposed by a short, thick neck.

There is very little information regarding the practice of central venous catheterization in the morbidly obese. Because bedside ultrasound has been shown to decrease the risk of insertion complications in high-risk patients,[22] we recommend its use in the morbidly obese patient with poor landmarks.

NUTRITIONAL SUPPORT

Critically ill obese patients exhibit less lipolysis and fat oxidation than nonobese subjects.[23] This decreased ability to mobilize fat increases protein breakdown to fuel gluconeogenesis and, hence, ensure adequate carbohydrates for energy. An increased risk for protein malnutrition results, with potentially detrimental effects on immune function, wound healing, and lean muscle mass. Thus, the clinician should avoid the temptation to starve the patient in a misguided attempt to accelerate a program of weight loss during the course of critical illness. In contrast, several trials of carefully controlled hypocaloric nutritional support in which adequate protein was supplied demonstrated that chronically critically ill patients receiving such a regimen had nitrogen balance comparable to those patients receiving conventional total parenteral nutrition.[24]

We recommend the provision of not less than 60% of the measured energy expenditure with 1.5 to 2.0 g /kg ideal body weight as protein, or less if renal insufficiency is present, to ensure adequate carbohydrates for energy and prevent protein malnutrition. Indirect calorimetry should be used to guide nutritional support because of the unreliability of conventional equations in this setting.

DRUG DOSING

Different alterations in pharmacokinetics have been described in obese patients.[25] In general, the volume of distribution for drugs with greater lipophilicity is increased. There are notable exceptions, however, thus illustrating the importance of other factors, such as plasma protein binding, in the distribution of drugs. Some studies have shown an increase in protein binding of some drugs because of increased levels of α_1-acid glycoprotein in obesity, whereas other studies have shown decreased protein binding related to elevated triglycerides, lipoproteins, cholesterol, and free fatty acids.[23] Variable alterations in enzymatic and antioxidant systems have been described, and increased and decreased renal clearance rates have been found.

This tremendous intersubject variability, combined with important differences between drugs make generalizations about the dosing of individual medications impossible. Drugs with a narrow therapeutic window such as theophylline and digoxin may confer toxicity when dosed according to total body weight. Reference to published guidelines for individual drugs is recommended, as is close monitoring of clinically available serum drug levels. Because of data indicating an increased volume of distribution and prolonged half-life for midazolam in obese subjects and an apparent lack of accumulation for propofol when given as a general anesthetic, we prefer propofol as a continuous intravenous sedative, when this method of administration is indicated.[26,27] A strategy to prevent any potential accumulation of this sedative or the accompanying analgesic is still desirable, whether it be by daily interruption of continuous intravenous sedation or conversion to a validated regimen of intermittent sedative administration.

MINIMIZING COMPLICATIONS OF CRITICAL ILLNESS

Because of the significantly elevated risk of venous thromboembolism in obesity, we recommend an aggressive approach to prophylaxis. Unfortunately, data on this subject are lacking, and a survey of surgeons who perform bariatric surgery showed wide variation in practice.[28] Without good data to guide the clinician, we suggest the joint use of pneumatic compression boots and increased-dose subcutaneous heparin (7500 U twice per day).

Most studies suggest that the risk of aspiration of gastric contents is increased in the obese patient due to increased intraabdominal pressure and the high volume and low pH of gastric contents in such patients. This has implications not only for intubation (see above) but also for routine nursing and feeding. We recommend that all morbidly obese patients be fed and nursed in the semi-upright position.

NURSING ISSUES

The patient should be nursed in the semi-upright position to improve respiratory function and decrease the risk of aspiration. Special beds are available that accommodate extremely large patients. Hoists can be obtained that assist in lifting and turning the patient. The services of a lift team, if available, should be employed whenever moving the patient to minimize the risk of injury to staff members. Careful attention to the development of bed sores should be paid, because of patient immobility and the difficulty of examining and moving the patient.

Weight Loss

Recovery from critical illness related to morbid obesity provides an opportunity to engage the patient in a long-term plan to achieve weight loss. Referral to a weight-loss specialist is indicated. In addition to dietary counseling and physical activity (insofar as possible), available medical therapies include a variety of appetite-suppressant and anti-absorptive medications. Unfortunately, although short-term success is frequent, significant long-term weight loss is uncommon in this population. Therefore, careful consideration should be given to the option of surgical therapy for obesity. Currently favored techniques such as the Roux-en-Y gastric bypass and the biliopancreatic diversion with duodenal switch combine gastric restriction with different degrees of malabsorption. Improvement in or resolution of insulin resistance, obstructive sleep apnea, hypertension, left ventricular systolic dysfunction, and left ventricular hypertrophy have been reported.[29] Properly selected patients have a low ($\leq$ 1%) perioperative mortality rate, although anemia and vitamin deficiency are common in the first year after the procedure. Mean excess weight loss exceeded 50% at 14 years after surgery in a large cohort of patients who had undergone gastric bypass.[30] A randomized trial comparing open versus laparoscopic Roux-en-Y gastric bypass surgery demonstrated less deterioration in pulmonary function postoperatively when using the laparoscopic approach.[31] Noninvasive positive pressure ventilation may be useful in preventing postoperative respiratory failure in patients with marginal pulmonary function.

Until a large trial comparing medical with surgical approaches to morbid obesity is performed, we believe that properly motivated morbidly obese patients who have failed nonsurgical attempts at weight loss should be considered for bariatric surgery. Careful preoperative evaluation is necessary to exclude patients in whom the potential benefit is exceeded by the risk (e.g., older patients with cor pulmonale).

Does Obesity Influence the Outcome of Critically Ill Patients?

Obesity has obviously detrimental effects on health across many domains, including an increase in the rate of malignancies and an increase in mortality rate. The influence of obesity on outcome of patients undergoing intensive care is less clear. Whereas some investigators have found an increased mortality rate with morbid obesity,[32] others have not.[33] Conceivably, increased nutritional reserve could provide a protective effect from overweight in the setting of prolonged critical illness, although further studies are needed to reconcile the different reports of outcome from the studies to date.

Chapter 110
HYPOTHERMIA

NICOLA A. HANANIA
JANICE L. ZIMMERMAN

KEY POINTS

- *Accidental hypothermia results from the unintentional decrease in core body temperature to lower than 35°C (95°F) and can be classified as mild (32.2°C to 35°C, or 90°F to 95°F), moderate (28°C to 32.2°C, 82°F to 90°F), or severe (<28°C, 82°F).*
- *Although hypothermia from environmental exposure is very common, several medical conditions may also predispose to hypothermia necessitating hospitalization and admission to the intensive care unit.*
- *Individuals at highest risk for hypothermia include the homeless, the mentally ill, trauma victims, outdoor workers, those at the extremes of age, those with serious underlying medical conditions, and those with ethanol or drug intoxication.*
- *Several organ systems are affected by hypothermia: clinical manifestations depend on the underlying cause and core body temperature. Below 30°C (86°F), shivering ceases, level of consciousness progressively declines, and cardiac arrhythmias become more common.*
- *In the initial stages, wet clothing should be removed promptly, continued heat loss must be prevented, and the underlying illness should be identified and treated.*
- *Rewarming is the primary treatment for moderate to severe hypothermia. For patients with a core body temperature above 32°C (90°F), passive and active external rewarming and supportive therapies are preferred; for patients with lower temperatures and those with hemodynamic instability, active core rewarming using body cavity lavage or extracorporeal blood warming may be considered.*
- *In addition to rewarming, all patients with hypothermia need continuous monitoring of cardiac status, intensive fluid resuscitation, and circulatory support.*

Hypothermia is defined as a core body temperature lower than 35°C (<95°F). The severity of hypothermia is indicated by the degree to which the core body temperature is lowered and is classified as mild, moderate, or severe. Several medical conditions may increase the risk of hypothermia. Individuals at the extremes of age are at greatest risk. Risk of death from hypothermia is related to age, preexisting illnesses, nutritional status, and alcohol and drug intoxication.[1] In cases of severe hypothermia, prompt intervention with rapid rewarming is crucial and may be life saving. This chapter discusses the pathophysiology, risk factors, clinical diagnosis, and management of hypothermia. The use of hypothermia as a treatment, such as after cardiac arrest, is covered in Chap. 16.

Regulation of Body Temperature

Body temperature is closely regulated through a balance between heat production and heat dissipation.[2] The majority of endogenous heat production results from metabolic activity in the heart and liver. The skin accounts for 90% of heat loss and the lungs contribute the rest. Radiation cooling is the primary method of thermal load dissipation. The preoptic nucleus of the anterior hypothalamus is the thermal control center, which maintains body temperature at a given set value. In response to a decrease in core body temperature, the hypothalamus initiates mechanisms to conserve heat by cutaneous vasoconstriction and stimulation of muscular activity in the form of shivering.[2,3] In a conscious individual, the appreciation of cold induces the individual to exercise, wear more clothes, or move to a warmer environment.

As the core temperature decreases below 35°C (95°F), the coordinated systems responsible for thermoregulation begin to fail because the physiologic responses to minimize heat loss are very limited.[4] *Primary hypothermia (accidental hypothermia)* refers to a spontaneous decrease of core body temperature, usually as result of exposure to cold environments without adequate protection. Environmental hypothermia results from a combination of heat loss by convection (degree of wind exposure), conduction, and radiation to the surrounding ambient air. *Secondary hypothermia* represents a complication of an underlying disorder. Some of the disorders and conditions that may predispose an individual to hypothermia by decreasing heat production, increasing heat loss, or interfering with the central or peripheral control of thermoregulation are listed in Table 110-1.[1–9]

Epidemiology

From 1979 through 1995, 12,368 deaths were reported in the United States for which hypothermia was the underlying cause (an annual average of 723 and a rate of 0.3 deaths per 100,000 population).[10] Approximately half of the deaths from hypothermia occurred in persons older than 65 years; the annual death rate from hypothermia in this age group was 1.2 per 100,000. The age-adjusted death rate for men was almost triple that for women. In addition, for persons older than 65 years, the death rate for men and women of black and other races was much higher than that for white men and women.[11] Race-specific differences may reflect differences in socioeconomic determinants for factors that are important in the prevention of hypothermia, such as access to protective clothing, shelter, and medical care. Hypothermia may occur in any climate and during any season of the year. Hypothermia is most common among the elderly, the homeless or mentally ill, trauma victims, outdoor workers, children, and individuals with certain medical conditions as mentioned above.

Clinical Presentation

DIAGNOSIS

Historical facts do not always suggest hypothermia. When exposure to cold is obvious by history, the diagnosis is simple. Measurement of core body temperature is important in diagnosis of less overt presentations. Core temperature is best measured by using a cold-recording rectal probe thermometer capable of measuring temperatures as low as 25°C (77°F). Clinical manifestations differ with the severity of hypothermia, which is classified based on core temperature as mild

TABLE 110-1 Causes of Hypothermia

Mechanism	Clinical Disorder
Decreased heat production	Endocrinologic failure
	Hypopituitarism
	Hypoadrenalism
	Hypothyroidism
	Insufficient fuel
	Extreme exertion
	Hypoglycemia
	Malnutrition
	Neuromuscular inefficiency
	Age extremes
	Impaired shivering
	Inactivity
Increased heat loss	Environmental exposure
	Induced vasodilation
	Drugs, including alcohol
	Toxins
	Skin disorders
	Burns
	Psoriasis
	Exfoliative dermatitis
	Iatrogenic
	Cold infusion
	Emergent deliveries
Impaired thermoregulation	Peripheral failure
	Neuropathies
	Spinal cord transection
	Diabetes
	Central failure
	Metabolic
	Drugs: barbiturates, tricyclic antidepressants, sedatives, alcohol
	Trauma
	Cerebrovascular accident (CVA), subarachnoid bleed
	Parkinsonism
	Hypothalamic dysfunction
	Multiple sclerosis
	Anorexia nervosa
Miscellaneous	Sepsis
	Pancreatitis
	Carcinomatosis
	Uremia
	Vascular insufficiency

(35°C to 32.2°C, 95°F to 90°F), moderate (<32.2°C to 28°C, <90°F to 82°F), and severe (<28°C, <82°F).[2,3,5,7,12,13] This classification has implications for management because appropriate treatment depends on severity of the disorder, as described below. The onset of hypothermia is often insidious. Initial symptoms may be vague and include hunger, nausea, dizziness, chills, pruritus, or dyspnea. Extremity stiffness, weakness, and shivering may also be prominent. As core body temperature decreases, many patients no longer complain of cold, shivering disappears at temperatures below 32°C (<90°F), and muscles become rigid.[5,14] At this point, the level of consciousness becomes markedly altered and systemic manifestations are readily evident. A severely hypothermic victim has a markedly decreased metabolic rate. As a consequence, the cerebral ischemic tolerance during cardiocirculatory arrest is considerably longer in contrast with the normothermic state.[5,15,16] Therefore, one has to be very careful in assessing brain death while a patient remains hypothermic. Low temperatures cause the myocardium to become irritable and cardiovascular abnormalities are common.[15] These may include initial tachycardia followed by progressive bradycardia with an increase in systemic vascular resistance. Arrhythmias are common at core temperatures below 32°C (90°F), and ventricular fibrillation may occur spontaneously when the temperature is below 28°C (82°F).[14] Systemic blood pressure is often decreased in patients with severe hypothermia. Other clinical manifestations of hypothermia are listed in Table 110-2.

LABORATORY EVALUATION

Initial laboratory evaluations should be obtained to assess metabolic status and organ dysfunction. Recommended tests include blood glucose, electrolytes, renal and hepatic functions, complete blood count, and coagulation profile. Arterial blood gases should be obtained, and correction for temperature is not necessary.[5,17,18] Electrolytes, hematocrit, and coagulation status change with rewarming, so frequent monitoring is necessary. Other laboratory tests such as thyroid function studies, cardiac isoenzymes, toxicologic screen, and cultures should be used selectively based on the clinical history and examination. Chest and abdominal radiographs should be obtained with the need for other radiographs dictated by the clinical situation. The following are common laboratory findings in patients with hypothermia.

ARTERIAL BLOOD GASES

Typically, pH values increase as body temperature decreases (0.0147 and 1°C). Arterial pressures of O_2 and CO_2 also decrease with a decrease in temperature (7.2% and 4.4% and 1°C decrease in temperature), and the oxyhemoglobin dissociation curve is shifted to the left. However, because all arterial blood gas samples are warmed to 37°C (98.6°F) before values are measured, simply comparing uncorrected values measured at 37°C with the normal reference values at 37°C yields an accurate interpretation. Respiratory acidosis and metabolic acidosis are common findings in patients with moderate and severe hypothermia.[17]

COMPLETE BLOOD COUNT

An increase in hematocrit secondary to decrease in plasma volume is common (2% for each 1°C decrease in temperature). White blood cell and platelet counts may decrease as temperature decreases.[2,5]

COAGULATION PROFILE

A physiologic increase in coagulation occurs with hypothermia, and disseminated intravascular coagulation may occur with rewarming. Prolonged bleeding and clotting times are common. Prothrombin time and partial thromboplastin time may initially appear normal despite the presence of clinical coagulopathy because the values are measured after warming the blood sample to 37°C. Blood viscosity may be exacerbated in patients with cryoglobulinemia or cryofibrinogenemia, which is more common in elderly patients.

TABLE 110-2 Clinical Manifestations of Hypothermia

System	Mild Hypothermia	Moderate Hypothermia	Severe Hypothermia
CNS	Confusion, slurred speech, impaired judgment, amnesia	Lethargy, hallucinations, loss of pupillary reflex, EEG abnormalities	Loss of cerebrovascular regulation, decline in EEG activity, coma, loss of ocular reflex
CVS	Tachycardia, increased cardiac output and systemic vascular resistance	Progressive bradycardia (unresponsive to atropine), decreased cardiac output and BP, atrial and ventricular arrhythmias, J (Osborn) wave on ECG	Decline in BP and cardiac output, ventricular fibrillation (<28°C) and asystole (<20°C)
Respiratory	Tachypnea, bronchorrhea	Hypoventilation (decreased rate and tidal volume), decreased oxygen consumption and CO_2 production, loss of cough reflex	Pulmonary edema, apnea
Renal	Cold diuresis	Cold diuresis	Decreased renal perfusion and GFR, oliguria
Hematologic	Increased hematocrit and decreased platelet, white blood cell count, coagulopathy, and DIC		
GI	Ileus, pancreatitis, gastric stress ulcers, hepatic dysfunction		
Metabolic endocrine	Increased metabolic rate, hyperglycemia	Decreased metabolic rate, hyper- or hypoglycemia	
Musculoskeletal	Increased shivering	Decreased shivering (<32°C, 90°F), muscle rigidity	Patient appears dead, "pseudo-rigor mortis"

ABBREVIATIONS: BP, blood pressure; CNS, central nervous system; CVS, cardiovascular septem; DIC, disseminated intravascular coagulation; ECG, electrocardiogram; EEG, electroencephalogram; GFR, glomerular filtration rate; GI, gastrointestinal.

SERUM ELECTROLYTES

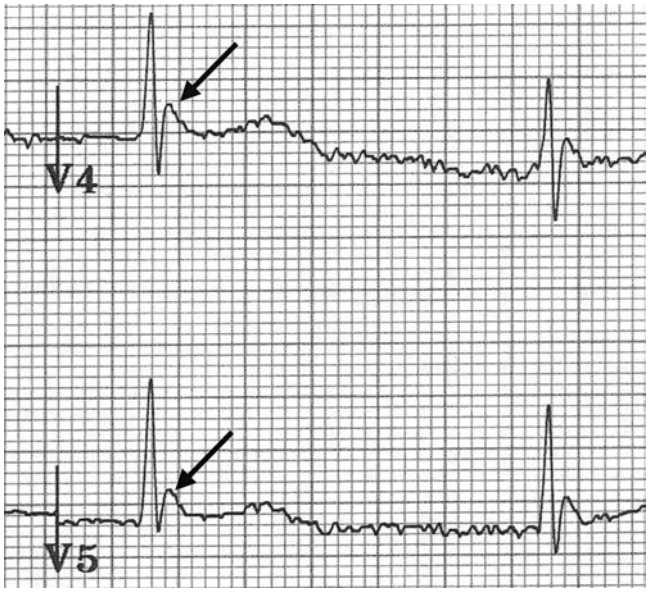
Recurrent evaluation of electrolytes is essential during rewarming because no consistent effect is present. Hypo- and hyperkalemia may complicate the course of hypothermia and either should be promptly corrected.

SERUM UREA NITROGEN AND CREATININE

These are almost always elevated because of decreased urinary clearance and decreased renal perfusion.

BLOOD GLUCOSE

Especially when core body temperature is above 30°C (86°F), acute hypothermia may be associated with an initial elevation of blood glucose due to catecholamine-induced glycogenolysis, whereas subacute and chronic hypothermia produce glycogen depletion with subsequent hypoglycemia. Nevertheless, hypoglycemia is one of the most common causes of mild hypothermia in a hospitalized patient.



OTHER LABORATORY ABNORMALITIES

Hyperamylasemia is common and may be related to a preexisting pancreatitis or pancreatitis induced by hypothermia. Hyperamylasemia correlates with the severity of hypothermia and with mortality rate. Variable elevation in creatine phosphokinase levels may reflect underlying rhabdomyolysis.

ELECTROCARDIOGRAPHIC ABNORMALITIES

PR, QRS, and QT intervals may be prolonged. When body temperature decreases below 33°C (91.4°F), the J (Osborn) wave may be noted as a positive deflection in the left ventricular leads at the junction of the QRS and ST segments in 25% to 30% of patients.[2,19–21] The presence of this wave is not pathognomonic and has no prognostic implication (Fig. 110-1).

FIGURE 110-1 The J (Osborn) wave (*arrows*) appears on electrocardiograms of approximately 80% of hypothermic patients. In general, the amplitude and duration of the Osborn wave are inversely related to core temperature.

Management

The severity of hypothermia, clinical findings, and comorbid conditions of the patient are important factors for determining the aggressiveness of resuscitation techniques (Fig. 110-2). Actions in all patients should include prompt removal of wet clothing, protection against continued heat loss, continuous monitoring of cardiac status, and avoidance of rough movement and excess activity, which can precipitate ventricular fibrillation.[20–25] Patients received in the hospital with moderate or severe hypothermia should be resuscitated until adequate rewarming has occurred or efforts are deemed unsuccessful.[13,23,24]

INITIAL STABILIZATION

Hypothermia should be confirmed by an accurate assessment of core temperature with a low reading thermometer. A rectal temperature is most practical, even though it may lag behind core changes. The probe should be inserted to an adequate depth but avoid cold fecal material. An esophageal temperature is an alternative to monitoring of rectal temperature, but readings may be falsely elevated in the intubated patient ventilated with warmed gas. In patients with moderate to severe hypothermia, temperature should be assessed continuously. The reliability of tympanic temperature devices has not been established in hypothermia.[5] Other vital signs may be difficult to evaluate, but evidence of a spontaneous pulse or blood pressure should be aggressively sought. The use of a Doppler ultrasound device may be necessary. Pulse oximetry is unlikely to be accurate in the setting of hypothermia and poor perfusion.

Supplemental oxygen should be administered pending assessment of oxygenation. Endotracheal intubation is indicated unless the patient is alert and has intact airway reflexes. Orotracheal intubation is preferred due to the risk of traumatic bleeding with the nasal route. However, muscle rigidity of the jaw in moderate to severe hypothermia may preclude use of the oral route. Neuromuscular blockers are unlikely to be effective at temperatures below 30°C (86°F) and should be avoided. Topical vasoconstrictors and the use of a smaller endotracheal tube may facilitate blind nasotracheal intubation in the patient with some spontaneous respirations. Intubation is unlikely to induce dysrhythmias in hypothermic patients.[8]

A nasogastric or orogastric tube should be placed in patients with moderate or severe hypothermia to relieve gastric distention. A urinary catheter is also essential to monitor urine output and assess volume resuscitation efforts. Peripheral

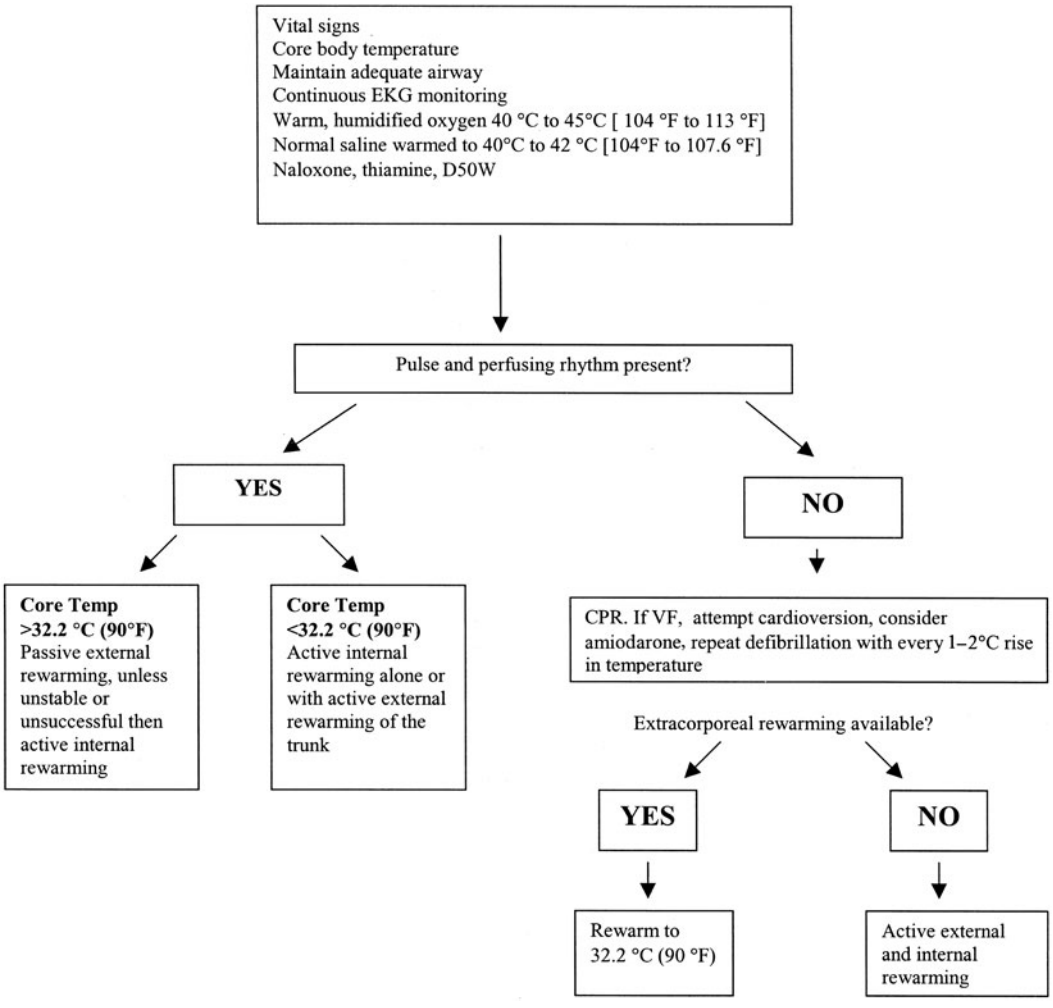


FIGURE 110-2 A systematic approach to a patient with hypothermia.

venous catheters are preferred over central venous access due to the potential to precipitate dysrhythmias. Needle electrodes are preferred for electrocardiographic monitoring. Intraarterial catheters for pressure monitoring should be used selectively. Pulmonary artery catheters are avoided due to potential dysrhythmias and the risk of vascular perforation. After rewarming, invasive monitoring may be warranted in complicated cases. Patients with moderate or severe hypothermia should be handled gently because movement and manipulation may precipitate dysrhythmias. Associated conditions requiring urgent intervention, such as traumatic injuries, hypoglycemia, or endocrinologic insufficiency, should be sought.

VOLUME RESUSCITATION

Patients with moderate or severe hypothermia are volume depleted and require rapid assessment of volume status and administration of fluids. A reasonable approach is to administer a 250- to 500-mL fluid challenge of warmed 5% dextrose in normal saline until further evaluation can be completed. During rewarming, increased fluid requirements are often necessary to prevent or treat hypotension. It has been recommended that lactated Ringer solution be avoided due to decreased ability of the liver to metabolize lactate.

In moderate or severe hypothermia, intravenous fluids heated to 40°C to 42°C (104°F to 107.6°F) should be administered. Heated intravenous fluids add little heat (unless very large volumes are infused) but do avoid the cooling effect of fluid therapy. Crystalloids can be heated in a microwave or commercial fluid warmer and should be mixed adequately before administration. Conductive heat loss can be minimized by using short segments of intravenous tubing and administering fluid as intermittent boluses.[26] Alternatively, fluids can be heated to higher temperatures (60°C, 140°F) when long lengths of tubing cannot be avoided.

Hemoconcentration is usually present in the severely hypothermic patient. A low initial hematocrit suggests acute hemorrhage or preexisting anemia. Occasionally, transfusion of packed red blood cells may be necessary as part of acute resuscitation. Different blood warming devices are available to deliver warm red cell products. The patient should be monitored closely for clinical signs of fluid overload during rewarming.

CIRCULATORY SUPPORT

Cardiopulmonary resuscitation is indicated in any patient with moderate to severe hypothermia in whom no pulse is present after appropriate evaluation or who has a nonperfusing rhythm such as ventricular fibrillation or asystole. The patient with a bradycardic pulse does not require pharmacologic manipulation of heart rate. Chest wall compressions are difficult and require more force in the hypothermic patient due to decreased chest wall elasticity. Frequent change of personnel performing chest compressions is necessary to prevent fatigue and ineffectiveness.

Initial defibrillation should be attempted for ventricular fibrillation or ventricular tachycardia without a pulse, although attempts may be unsuccessful at temperatures below 30°C to 32°C (86°F to 90°F). If initial defibrillation is unsuccessful, rewarming is instituted and defibrillation is attempted again after every 1°C to 2°C increase in temperature or when core temperature rises above 30°C to 32°C. Antiarrhythmic and vasoactive drugs are usually ineffective at temperatures below 30°C (86°F). These drugs should be avoided until rewarming to above 30°C (86°F), and then the lowest effective dose should be used. Excessive administration of resuscitation drugs may result in toxicity with rewarming due to altered metabolism.

Most hypothermia-induced dysrhythmias will convert spontaneously with rewarming. Atrial fibrillation is seen frequently and does not usually require specific treatment because the ventricle generally responds slowly. The best approach to ventricular dysrhythmias has not been determined. Bretylium tosylate has been effective in animal studies but is not currently used in resuscitation.[27,28] Lidocaine appears to be less effective, and procainamide may increase the incidence of ventricular fibrillation. The effects of amiodarone in hypothermic patients have not been evaluated. The optimal dose and infusion rate of bretylium and other vasoactive drugs are unknown in severe hypothermia.

Hypotension should be treated initially with volume replacement. Vasopressor agents have minimal effect on constricted vessels in moderate or severe hypothermia but may increase the risk of dysrhythmias.

REWARMING METHODS

Although rewarming is the primary treatment for moderate or severe hypothermia, controversy exists as to the optimal method, duration, and rate of rewarming. No controlled studies comparing rewarming methods exist, and rigid treatment protocols cannot be recommended. Rapid rates of rewarming have not proved to improve outcome in patients with severe hypothermia. The clinical circumstances, availability of resources, and advantages and disadvantages of available methods should be taken into account when selecting specific interventions for the patient.[3,5–7,13,14,18,23,29]

PASSIVE EXTERNAL REWARMING

Passive external rewarming involves covering the patient with an insulating material to prevent further heat loss. This method is the treatment of choice for most patients with mild hypothermia and is used as an adjunct in patients with moderate or severe hypothermia. Patients must be able to generate heat to rewarm themselves. Rewarming rates with passive external rewarming in mild hypothermia vary between 0.5°C to 2.0°C per hour.[4]

ACTIVE REWARMING

Active rewarming involves the transfer of exogenous heat to the patient by using external or internal techniques. Indications for active rewarming include cardiovascular instability, poikilothermia (<32°C), inadequate rewarming with other methods, endocrinologic insufficiency, and traumatic peripheral vasodilation (i.e., spinal core injury). Patients with endocrinologic diseases may have insufficient glycogen stores or insufficient endogenous thermogenesis.

ACTIVE EXTERNAL REWARMING

Different methods have been used for active external rewarming (AER), including immersion in a 40°C bath, warming blankets, heating pads, radiant heat, and forced air rewarming.

Indications for use of these devices remain controversial. Concerns have been raised regarding AER because vasodilation in the extremities may facilitate transport of colder peripheral blood to the warmer core, thereby lowering the core temperature ("afterdrop"). Peripheral vasodilation may also potentially worsen hypotension. Immersion in a warm water bath can impede monitoring and active resuscitation. Thermal injury can occur with heating pads, warming blankets, and radiant heat sources. The most practical technique for AER is forced air rewarming, which transfers heat convectively and prevents heat loss. These devices are usually readily available from postoperative care units. They enable greater contact of warm air with the patient's body than traditional warming blankets. Successful use of forced air as the primary rewarming method in patients with severe hypothermia with and without cardiac arrest has been reported.[30] Additional forced air warming systems are being evaluated.[31]

Warming rates of 1°C to 2.5°C per hour have been reported with AER after accidental hypothermia without any evidence of afterdrop.[30,32] Circulatory problems may be minimized if AER is applied only to the trunk. Truncal AER may be combined successfully with other methods of active core rewarming such as warmed intravenous fluids and heated humidified oxygen. The advantages of AER are ease of institution, availability, low cost, and noninvasiveness.

ACTIVE CORE REWARMING

Numerous alternatives are available for active core rewarming. Airway rewarming using heated humidified oxygen is relatively simple to institute and should be a part of management of most patients with moderate or severe hypothermia.[33] The delivery of heated oxygen is more effective through an endotracheal tube than by mask. Oxygen should be warmed to 40°C to 45°C (104°F to 113°F) through modification of humidifier devices.[34] A rewarming rate of 1°C to 2.5°C per hour can be expected.[5] Although there are several proposed advantages of airway rewarming that include decreased respiratory heat loss, increased heat donation to the respiratory tract, and direct heat transfer to the hypothalamus, brain stem, and medulla, its efficacy remains equivocal.[35]

Heated irrigation has been used to transfer heat from fluids to internal areas with a variety of techniques. Peritoneal dialysis or lavage is probably the most widely recognized method of heated irrigation. Peritoneal dialysis can deliver fluid heated to 40°C to 45°C (104°F to 113°F) to the peritoneal cavity with flow rates of approximately 6 L/h. Potential advantages of this technique are hepatic rewarming, use during chest compressions, and the capability to simultaneously provide renal replacement when a dialysate is used. Rewarming rates average 1°C to 3°C per hour.[4] This technique is not routinely advocated for stable patients but may be considered in combination with other rewarming methods for the patient with no evidence of perfusion.

Closed thoracic lavage also has been proposed for treatment of hypothermia.[36–38] This technique uses a large thoracostomy tube inserted into the anterior second or third intercostal space in the midclavicular line. A second tube is inserted in the posterior axillary line in the fifth or sixth intercostal space. Sterile normal saline heated to 40°C to 42°C (104°F to 107.6°F) is infused through the anterior tube and allowed to drain passively from the posterior tube. This technique may have the advantage of warming the heart and great vessels. However, clinical experience is limited. Mediastinal irrigation and myocardial lavage could be considered in patients with severe hypothermia and no spontaneous perfusion. These techniques require expertise for thoracotomy and clinical experience is limited.

Irrigation of the stomach, bladder, or colon has limited utility because the surface area available for heat transfer is small. In addition, gastric lavage may predispose to aspiration and must be discontinued during chest compressions. Special double lumen esophageal tubes or modified Sengstaken tubes have had limited evaluation and use.[39,40] These techniques are warranted only if no other methods are available for rewarming.

Four methods are available for extracorporeal blood rewarming. These include hemodialysis, arteriovenous rewarming, venovenous rewarming, and cardiopulmonary bypass (CPB). Hemodialysis uses a two-way flow catheter with percutaneous cannulation of a single vessel. The femoral vein is preferred over the subclavian vein to avoid myocardial irritation with the guidewire. This technique may be most appropriate in the patient without severe hemodynamic instability, although it has been used in unstable patients.[41,42] Hemodialysis may be the preferred rewarming method when hypothermia is associated with severe renal dysfunction or intoxication with dialyzable substances. Relatively new alternatives to hemodialysis are arteriovenous and venovenous rewarming.[43] These techniques use countercurrent fluid warming. Arteriovenous techniques depend on the patient's blood pressure to support flow, whereas venovenous techniques use a roller pump.

CPB using standard access through the femoral artery or femoral vein is the most invasive and labor-intensive technique for rewarming.[44] It has the advantages of providing complete hemodynamic support during rewarming and rapid rewarming rates.[15] Core temperature can increase 1°C to 2°C every 3 to 5 minutes with femoral flow rates of 2 to 3 L/min.[4] Unfortunately, CPB may require considerable time to institute and is not available in all institutions. Systemic anticoagulation may be contraindicated in trauma victims or contribute to hypothermic coagulopathy. Heparin-bonded tubing, portable circuits, and methods using venovenous access may overcome some of these problems.[45,46] These advances have allowed the institution of CPB in emergency departments and intensive care units.[47] Long-term outcomes of patients with severe hypothermia treated with CPB have been favorable.[48]

FUTURE TECHNIQUES

Techniques such as the use of very high-temperature intravenous fluids and diathermy are being explored for the treatment of moderate or severe hypothermia. Intravenous fluids heated to 65°C (149°F) have been used in animal studies and resulted in rewarming rates of 2.9°C to 3.7°C per hour with minimal intimal injuries.[49,50]

Diathermy involves the conversion of energy waves into heat. Ultrasound or low-frequency microwave radiation can deliver large amounts of heat to deep tissues. Although animal studies are promising, further investigation is needed to determine optimum clinical use.[4,35]

SUPPORTIVE CARE

Numerous complications are associated with moderate and severe hypothermia and should be anticipated by the clinician. Continuous monitoring and frequent reassessment of metabolic and hemodynamic parameters are essential to successful outcome. Rhabdomyolysis is frequent and may result in electrolyte disturbances and renal dysfunction. Compartment syndromes may become apparent several days after initial treatment. Acute respiratory distress syndrome, acute tubular necrosis, and disseminated intravascular coagulation may require intensive interventions.

Prognosis

The prognosis for hypothermia is improved by prompt recognition of the clinical presentation and institution of appropriate management strategies.[51] The risk of death from hypothermia is related to age, preexisting illnesses, nutritional status, and alcohol and drug intoxication. Outcome from severe hypothermia is difficult to predict. Mortality rates vary in several cohorts between 40% and 75%.[18] Clearly, resuscitation will be successful only if cardiac arrest is due to hypothermia and not a consequence of anoxia or other injuries. Underlying diseases, precipitating events, and duration and severity of exposure are important factors to be considered.[52] Although the treatment dictum has been that "no one is dead until warm and dead," clinical judgment is necessary for determining the most appropriate treatment and termination of efforts.[18] Proposed indicators of prognosis on arrival include severe hyperkalemia (>10 mEq/L), which may indicate death before severe hypothermia, a venous pH below 6.5, and severe coagulopathy.[33,53]

Prevention

Many episodes of severe hypothermia may be preventable by implementing public health strategies that include education programs targeting high-risk individuals such as the elderly and the homeless. Specific preventive measures include wearing adequate protective clothing, maintaining fluid and calorie intake, avoiding fatigue, ensuring heated shelter, and avoiding excessive alcohol consumption. Emergency departments and intensive care units should be prepared to manage victims with hypothermia especially in the winter months. Social services should be adequately staffed to provide counseling and shelter to homeless persons during periods of extreme cold. Family members, home health care workers, and social service providers should closely monitor the elderly and patients with medical conditions that may predispose to hypothermia.

Chapter 111 HYPERTHERMIA

JANICE L. ZIMMERMAN
NICOLA A. HANANIA

KEY POINTS

- *Heat stroke is distinguished from less severe forms of environmental hyperthermia by higher body temperature and the presence of severe central nervous system dysfunction.*
- *Classic (nonexertional) heat stroke affects the elderly and the chronically ill and is associated with high morbidity and mortality rates.*
- *Exertional heat stroke affects younger individuals who exercise in hot environments, and it develops over a short period.*
- *Immediate conductive or evaporative cooling should be instituted for heat stroke victims with a core temperature above 41°C.*
- *Malignant hyperthermia is a rare syndrome of hyperthermia, muscle contractions, and cardiovascular instability triggered by succinyl choline and inhaled anesthetics.*
- *Management of malignant hyperthermia includes the prompt recognition of the syndrome, discontinuation of the inciting drug, administration of dantrolene, and supportive care.*
- *Neuroleptic malignant syndrome is an idiosyncratic reaction to neuroleptic drugs characterized by hyperthermia, muscle rigidity, alterations in mental status, autonomic dysfunction, and rhabdomyolysis.*
- *Treatment of neuroleptic malignant syndrome includes discontinuation of the triggering drug, administration of dantrolene for muscle rigidity and hyperthermia, administration of dopaminergic drugs such as bromocriptine and amantadine, and supportive care.*

Hyperthermia is defined as a core body temperature above 38.2°C (101.8°F) and is commonly present in patients in the intensive care unit. In most cases, hyperthermia is a consequence of the presence of pyrogens that reset the hypothalamic thermoregulatory mechanism to a higher temperature.[1] This response, referred to as *fever*, is part of the individual's immune response to infection, malignancy, inflammation, or autoimmune disease.

The disorders discussed in this chapter, environmental hyperthermia, malignant hyperthermia, and the neuroleptic malignant syndrome, are not part of the body's immune response and result from a failure of homeostatic thermoregulatory mechanisms. Prompt recognition and appropriate treatment of these syndromes are critical to prevent irreversible cellular and organ injury.

Environmental Hyperthermia

PATHOPHYSIOLOGY

Environmental hyperthermia is related to endogenous heat production, high ambient temperatures, and/or high humidity. Humans produce approximately 50 to 60 kcal/m^2 per hour of heat, or approximately 100 kcal/hour.[2] Minimal activity can increase heat production two- to fourfold, and strenuous exercise may increase heat production as much as 20 times the baseline level. Normally, most heat loss (50% to 70%) occurs from the skin and lungs through radiation in neutral environments. Conduction of heat through direct contact with cooler objects or loss of heat due to convection accounts for a smaller percentage of heat loss. Evaporation of sweat from the skin is a major mechanism of heat loss in a warm environment.

The preoptic nucleus of the anterior hypothalamus receives information from temperature-sensitive receptors in the skin, viscera, and great vessels and initiates physiologic responses to temperature increases. Increased temperatures result in cutaneous vasodilation, decreased muscle tone, and increase in sweating. As ambient temperature nears 37°C (98.6°F), the body relies primarily on evaporation of sweat as a cooling mechanism. Evaporation can result in the loss of 580 kcal/L of evaporated sweat. Conditions of high humidity (>75%) impair the loss of heat through evaporation and increase the risk of heat injury.

An acute phase inflammatory response may cause or contribute to the pathophysiology of heat stroke. Increased concentrations of endotoxin, tumor necrosis factor, soluble tumor necrosis factor receptor, and interleukin 1 have been demonstrated in patients with classic heat stroke (CHS).[3,4] Interleukin 6 and nitric oxide metabolite concentrations correlate with the severity of illness. Endothelial cell activation or injury is suggested by findings of increased concentrations of circulating intracellular adhesion molecule 1, endothelin, and von Willebrand factor antigen.[5] Altered expression or blocked activity of protective heat shock proteins may also contribute to injury in heat stroke.[6]

PREDISPOSING FACTORS

Environmental hyperthermia results from increased heat production and/or decreased heat loss (Table 111-1). Environmental heat stress includes high heat and humidity that contribute to heat production and limit heat loss. Numerous drugs interfere with the thermoregulatory process. Sympathomimetic drugs, such as amphetamines, cocaine, phencyclidine, ecstasy and ephedrine, increase muscle activity and heat production and may also disrupt hypothalamic regulatory mechanisms.[7] Drugs with anticholinergic effects, such as cyclic antidepressants, antihistamines, and antipsychotics, inhibit cholinergically mediated sweating and disrupt hypothalamic function. Ethanol may contribute to heat stroke by several mechanisms: vasodilation resulting in heat gain from the environment, impaired perception of the environment, and diuresis. β-Adrenergic blockers may impair the cardiovascular compensation of increased output needed to compensate for cutaneous vasodilation and decrease cutaneous blood flow. Patients with stroke or head injury may also have impaired regulatory mechanisms. Dehydration by itself has been documented to increase core body temperature. Obese individuals have a lower ratio of body surface area to mass than do the nonobese, which limits radiant heat loss. Loss of apocrine sweat glands due to skin conditions such as burns or scleroderma is a much less common risk factor for heat injury. Factors that increased the risk of death in the July 1995

Hypothalamic dysfunction	Dehydration
Drugs (sympathomimetics)	Anticholinergic drugs
Hyperthyroidism	Obesity
	Skin disease
	Ethanol
	β Blockers

heat wave in Chicago included being confined to bed due to medical problems and living alone.[8]

SPECTRUM OF HEAT INJURY

The most commonly described types of heat injury include heat cramps, heat exhaustion, and heat stroke. Heat cramps are unlikely to result in the need for critical care. Heat cramps usually occur in individuals who work or exercise for long periods in hot environments, sweat heavily, and consume large quantities of hypotonic fluid.[9] Heat cramps often occur after exertion in abdominal, thigh, and calf muscles. The etiology is thought to be due to shifts of electrolytes and water between intracellular and extracellular spaces. Many patients experiencing heat cramps never present for medical care. Management includes rest and hydration (intravenously or orally) with a salt solution.

Heat exhaustion also does not usually require intensive care, but it is an important syndrome to distinguish from heat stroke. It may complicate other critical illness such as myocardial infarction and stroke. Patients with heat exhaustion usually experience salt or water depletion as a result of heat stress. Temperatures can be mildly elevated ($<40^{\circ}$C), but other clinical manifestations are nonspecific. Patients may complain of malaise, weakness, irritability, nausea, vomiting, and heat cramps. Although patients may have headache and/or mild confusion, severe disturbances of central nervous system (CNS) function are not present. Tachycardia and orthostatic hypotension may suggest significant dehydration. Treatment includes rest in a cool environment and fluid replacement based on clinical and laboratory parameters.

Heat stroke is the syndrome most likely to require intensive care, and it results from failure of normal homeostatic thermoregulatory mechanisms. The diagnosis of heat stroke requires a history of exposure to a heat load (external or internal), severe CNS dysfunction, and elevated temperature (usually $>40^{\circ}$C, or $>104^{\circ}$F). The absolute temperature may not be critical because cooling measures are often instituted before the patient is admitted to a health care facility. An alternative definition for heat stroke has been proposed that takes into account the current understanding of the pathophysiology: "A form of hyperthermia associated with a systemic inflammatory response leading to a syndrome of multiorgan dysfunction in which encephalopathy predominates."[6] The presence of severe CNS abnormalities distinguishes heat stroke from less severe forms of heat injury such as heat exhaustion. The absence of sweating is not a useful diagnostic criterion. If the history is inadequate, other disorders associated with hyperthermia must be considered in the differential diagnosis, such as infection, hypothalamic injury, thyrotoxicosis, neuroleptic malignant syndrome, and malignant hyperthermia.

HEAT STROKE SYNDROMES

Two syndromes of heat stroke occur: classic (nonexertional) heat stroke (CHS) and exertional heat stroke (EHS). CHS typically affects elderly individuals with underlying chronic illness and tends to occur when environmental heat stress is maximal for several days. This syndrome usually develops over several days and results in significant dehydration and absence of sweating.

EHS typically occurs in young, healthy individuals such as amateur athletes and military recruits who exercise in hot environments. This syndrome occurs sporadically depending on initiation of significant activity in a hot environment. These individuals usually have no chronic illness and are more likely to be nonacclimated individuals. Exertional heat stroke can occur over a short period. Dehydration may be mild, and approximately 50% of individuals will have profuse sweating on presentation.

CLINICAL MANIFESTATIONS

Heat stroke is a multisystemic disorder, and the manifestations in an individual depend on rapidity of onset, severity of exposure (temperature and duration), and comorbid conditions.[10] CNS dysfunction may range from bizarre behavior, delirium, and confusion to decerebrate rigidity, cerebellar dysfunction, seizures, and coma. Cerebellar abnormalities are often the first to appear and the last to resolve. These changes are potentially reversible, although permanent deficits such as cerebellar dysfunction, hemiparesis or dementia can occur. Lumbar puncture in patients with heat stroke may reveal increased protein, xanthochromia, and lymphocytic pleocytosis.

Tachycardia is an almost universal cardiovascular finding in heat stroke unless the patient is receiving β-adrenergic blockers or calcium channel blockers. Tachycardia occurs in response to peripheral vasodilation and the need for increased cardiac output. Supraventricular tachycardia and atrial fibrillation may also occur. The systemic vascular resistance is usually low unless severe hypovolemia is present.[11] Compensatory vasoconstriction occurs in the splanchnic and renal vascular beds. If the patient is unable to increase cardiac output, hypotension develops. Reversible myocardial dysfunction has been described in heat stroke,[12] and a variety of electrocardiographic changes have been described, including conduction defects, prolonged QT interval, nonspecific STT changes, and STT changes consistent with myocardial ischemia.[13] Additional physical examination findings may include ileus, gastric distension, diarrhea, decreased muscle tone, and tachypnea.

LABORATORY FINDINGS

The acid-base status in patients with heat stroke may be difficult to predict. Tachypnea may result in significant respiratory alkalosis, but most patients also have a metabolic lactic acidosis.[10,14,15] The etiology of the lactic acidosis differs with the type of heat stroke syndrome. In CHS, lactic acidosis more

commonly results from hypoperfusion and is often mild. In EHS, lactate is produced as a consequence of anaerobic muscle metabolism and acidosis may be severe. Hypoglycemia may be present in patients with EHS due to increased glucose use and impaired hepatic gluconeogenesis. Rhabdomyolysis with elevation of creatine kinase and renal failure occur more commonly with EHS. Renal failure occurs in approximately 25% of patients with EHS and 5% of patients with CHS. Renal injury may be due to myoglobinuria, direct thermal parenchymal damage, or decreased renal blood flow due to hypotension. Hematologic effects of heat stroke include leukocytosis and hypocoagulability that may progress to disseminated intravascular coagulation (DIC). Coagulation abnormalities may peak hours to days after heat injury.[10] Hepatic heat injury results in elevation of bilirubin and transaminase levels. Electrolyte concentrations are variable in heat stroke.[14] Hyperkalemia can result from rhabdomyolysis, but hypokalemia occurs more commonly. Hypocalcemia can occur, particularly with rhabdomyolysis, but usually does not require specific therapy.

TREATMENT OF HEAT STROKE

In addition to resuscitative measures, immediate cooling should be instituted for any patient with a temperature above 41°C (>105.8°F). Diagnostic testing such as computed tomography should be performed after cooling. Two methods of cooling have been used: conductive cooling and evaporative cooling. Although specific methods are promoted by individual clinicians, definitive human studies are lacking and the optimal cooling method remains controversial. Available resources and personnel may dictate the exact method used. Most patients can be effectively cooled in 30 to 45 minutes with either technique.

Direct cooling by enhancing conduction of heat from the body is accomplished by immersion of the patient in cold water. Skin massage to counter cutaneous vasoconstriction in the limbs has been recommended. Shivering can result in an undesirable increase in heat production, and chlorpromazine has been recommended to prevent this response. However, chlorpromazine may lower the seizure threshold and impair sweating. This method requires considerable staff time and may interfere with other resuscitative measures such as intubation and intravenous access. Variants of this method include ice-water soaks and application of ice packs to the axillae, groin, and neck, where the great vessels are closer to the skin surface. A protocol used by the U.S. Marine Corps training base for EHS has been described as follows[16]:

- A stretcher holding the victim is placed on top of a bathtub containing water and ice.
- One liter of normal saline is administered intravenously as a bolus.
- Sheets are dipped into the ice water and used to cover and drench the patient.
- Ice is added to the top of the sheet for further cooling and skin is massaged is improve skin blood flow.
- The head is constantly irrigated with more ice water and a fan is directed at the patient.

Evaporative cooling is a widely used cooling method based on a body cooling unit developed in the Middle East for treatment of individuals with heat stroke during the annual pilgrimage to Mecca.[17] Optimum cooling was achieved with unclothed volunteers suspended on a net sprayed with 15°C water and warm air at 30°C to 35°C (at the skin surface). A practical adaptation for hospital use is to place the unclothed patient on a stretcher and spray with warm (not cold) water. High-flow air currents are created with the use of fans to enhance evaporative cooling. This method allows personnel to institute other resuscitative measures while cooling occurs.

Other cooling methods such as peritoneal lavage, iced gastric lavage, or cardiopulmonary bypass have not been effectively tested in humans. Dissipation of heat by lavage of body cavities is limited by the small surface area available for conductive heat transfer. Gastric lavage may also predispose to aspiration. Antipyretics are not indicated, and dantrolene is ineffective.[18]

A thermistor probe (esophageal or rectal) should be used for monitoring core temperature during cooling efforts. Cooling should be stopped at 38.0°C to 38.8°C (100.4°F to 102°F) to prevent hypothermic overshoot. Continued monitoring is needed to detect a subsequent increase in core temperature. In addition to cooling, many patients will require intubation for airway protection. Supplemental oxygen should be instituted for all patients. The type and quantity of intravenous fluids should be individualized based on an assessment of electrolytes, volume status, and urine output. Overaggressive hydration during cooling may result in cardiac decompensation, especially in the elderly as vasodilation corrects. Significant rhabdomyolysis indicates the need to achieve urine outputs of 100 to 200 mL/hour with fluid therapy. Hypotension usually responds to fluid administration and cooling as peripheral vasodilation decreases. Vasopressor agents may result in vasoconstriction and an undesirable decrease in heat exchange. Invasive hemodynamic monitoring may be warranted in patients with refractory hypotension or suspected cardiac impairment. Significant electrolyte abnormalities should be corrected and monitored closely. Benzodiazepines should be used to control any seizure activity. Bleeding secondary to DIC may require transfusion of fresh-frozen plasma and/or platelets.

OUTCOME FROM HEAT STROKE

The survival rate from heat stroke approaches 90% with appropriate management. However, morbidity rate is related to the duration of hyperthermia and to underlying conditions. Advanced age, severe hypotension, coagulopathy, hyperkalemia, acute renal failure, and prolonged coma are associated with a poor prognosis.[14] Elevated lactate levels are associated with a poor prognosis in CHS but not in EHS.[19] In a retrospective study, rapid cooling (<1 hour) was associated with decreased mortality rate.[20]

Malignant Hyperthermia

Malignant hyperthermia (MH) is an inherited drug- or stress-induced hypermetabolic syndrome characterized by hyperthermia, muscle contractures, and cardiovascular instability. The incidence of MH in patients who receive anesthesia with a triggering agent varies in different populations and age groups. The incidence in adults is approximately 1 in 20,000 to 50,000. The syndrome is genetically transmitted as an

autosomal dominant trait. Although a similar syndrome in swine is caused by a single-point mutation of the ryanodine receptor, MH in humans is believed to result from a more heterogeneous group of mutations. The syndrome results from defects in calcium transport in skeletal muscle. The primary defects are postulated to be impaired reuptake of calcium into the sarcoplasmic reticulum, enhanced release of calcium from the sarcoplasmic reticulum, and a defect in the calcium-mediated excitation-contraction coupling mechanism. The resultant intracellular hypercalcemia leads to hypermetabolism.

Diagnostic testing for susceptibility to MH is problematic. Currently, a muscle biopsy sample from the patient is exposed in vitro to halothane and caffeine in selected laboratories.[21–23] The muscle of an affected individual contracts rather than relaxes in the presence of caffeine or halothane. A normal contracture test does not completely rule out the possibility of MH susceptibility, but no alternate tests are available. This limitation of the test probably reflects the heterogeneous nature of the underlying mutations.

TRIGGERS OF MALIGNANT HYPERTHERMIA

Halothane and succinylcholine have been implicated in most reported cases of MH. The combination of the two agents is more commonly involved than either agent alone. Additional potentiating agents include potent inhalational anesthetics, ethanol, caffeine, sympathomimetics (vasopressors), parasympathomimetics (atropine), cardiac glycosides, and quinidine analogues. Less commonly, MH can be precipitated by infection, physical or emotional stress, anoxia or high ambient temperatures. Nondepolarizing neuromuscular blockers, etomidate, nitrous oxide, ketamine, opiates, barbiturates, benzodiazepines, propofol, and local anesthetics are considered safe in patients with MH.

CLINICAL MANIFESTATIONS

Manifestations of MH usually occur within 30 minutes of the initiation of anesthesia in 90% of cases. However, the syndrome may occur at any time during anesthesia and the recovery period. The spectrum of presentations ranges from minor symptoms to a fulminant crisis. A clinical grading scale has been devised for diagnosis of MH but is not readily applicable at the bedside, and required data may not be available.[24] Muscle rigidity begins in muscles of the extremities or the chest. In patients receiving succinylcholine, the stiffness most commonly begins in the jaw. The development of masseter muscle rigidity after administration of a neuromuscular blocker should be considered an early sign of possible MH.[25,26] In the North American MH Registry, masseter muscle rigidity was the first sign in 30% of likely cases.[27] However, muscle rigidity may not be present in all cases. Monitoring of arterial blood gases or end-tidal CO_2 levels by capnography may detect an increase in CO_2 that may be the earliest sign of MH. Tachycardia is an early, although nonspecific, sign. Hypertension and mottling of the skin also occur. The increase in temperature usually occurs later but is followed rapidly by metabolic acidosis, ventricular arrhythmias, and hypotension. Temperature may increase as rapidly as 1°C every 5 minutes. Laboratory abnormalities include increased levels of sodium, calcium, magnesium, potassium, phosphate, creatine kinase, and lactate dehydrogenase and the presence of myoglobinuria. Lactate levels increase, and arterial blood gases indicate hypoxemia and hypercapnia if minute ventilation is constant.

TREATMENT

Once the diagnosis of MH is considered, the inciting drug should be discontinued immediately and the patient should be ventilated with 100% O_2. The most effective and safe therapy is dantrolene, a drug that blocks calcium release from the sarcoplasmic reticulum without inhibiting its reuptake.[28] Uncoupling of the excitation-contraction mechanism in skeletal muscle decreases thermogenesis. Dantrolene should be administered by rapid intravenous push at a dose of 2.5 mg/kg and repeated every 5 minutes as needed until the symptoms subside or the maximum dose of 10 mg/kg has been reached. Dantrolene is poorly water soluble and using 40°C water as the diluent may facilitate reconstitution.[29] A decrease in muscle rigidity should be evident within minutes. Subsequent doses of 1 mg/kg every 4 to 6 hours should be continued for 36 to 48 hours. If dantrolene is ineffective or slowly effective, evaporative or conductive cooling can also be used. Calcium channel blockers are of no benefit in MH and should not be used to treat arrhythmias. Sodium bicarbonate administration is often recommended to treat the acidosis, but evidence of efficacy is lacking. Urine output, vital signs, and blood gases should be monitored to guide ventilation and fluid therapy. A urine output of 100 to 200 mL/hour may be needed for treatment of rhabdomyolysis and myoglobinuria. Significant hyperkalemia should be treated with intravenous insulin and glucose. The coagulation profile should be followed to assess for the presence and severity of DIC.

OUTCOMES AND PREVENTION OF MALIGNANT HYPERTHERMIA

Several measures can be taken to prevent the occurrence of MH or limit the severity of the syndrome. The preoperative history may suggest a family history of anesthetic problems or neuromuscular disorders. Known MH triggers should be avoided in known susceptible individuals. Temperature and end-tidal CO_2 monitoring should be used during all general anesthesia procedures lasting longer than 30 minutes. Masseter muscle rigidity and increases in heart rate, CO_2 levels, and temperature should be evaluated as possible signs of MH. Dantrolene should be readily available in adequate doses. Prophylactic administration of dantrolene is not recommended.

The Malignant Hyperthermia Association of the United States provides a hot line for assistance in managing MH (1-800-MH-HYPER, 1-800-644-9737, or 1-315-464-7079 if outside the United States). The organization also maintains a Web site with useful information online (www.mhaus.org).

The mortality rate from MH, which was 50% to 70% decades ago, has decreased to lower than 10% because it is more appropriately recognized and treated. Death may result early in the clinical course from hyperkalemia, acidosis, or hypotension. Later deaths are often related to DIC, renal failure, and multiple organ dysfunction.

Neuroleptic Malignant Syndrome

Neuroleptic malignant syndrome (NMS) is an idiosyncratic reaction, usually to neuroleptic drugs, characterized by hyperthermia, muscle rigidity, mental status changes, autonomic dysfunction, and rhabdomyolysis. It may occur in up to 1% of all patients on neuroleptic agents and affects males more than females and the young more than the old.[30] The pathogenesis of NMS is unknown but is thought to be related to CNS dopamine-2 receptor antagonism or dopamine deficiency in the basal ganglia and hypothalamus resulting in altered temperature set point.[31]

TRIGGERS OF NEUROLEPTIC MALIGNANT SYNDROME

Most cases of NMS have been associated with high-potency neuroleptics such as haloperidol and thiothixene. However, the list of potential triggers includes butyrophenones (e.g., haloperidol), phenothiazines (e.g., chlorpromazine and fluphenazine), thioxanthenes (e.g., thiothixene), dopamine-depleting agents (e.g., tetrabenazine), dibenzoxazepines (e.g., loxapine), and withdrawal of levodopa/carbidopa or amantadine. The newer atypical antipsychotic drugs such as clozapine, risperidone, olanzapine, ziprasidone and quetiapine have also been reported to induce NMS. NMS can be associated with antiemetics (prochlorperazine), peristaltic agents (metoclopramide), anesthetics (droperidol), and sedatives (promethazine).[32] Rechallenge with the inciting drug may not result in recurrence of NMS. Other factors suggested to contribute to the development of NMS include lithium therapy, ambient heat, dehydration, psychomotor agitation, and underlying brain injury.[33,34]

CLINICAL MANIFESTATIONS

NMS usually occurs 3 to 9 days after initiating a neuroleptic agent or changing the dose. The reaction is not related to dose and may occur after a single dose. The syndrome may last for a period of 1 to 3 weeks, especially with depot drug forms. A similar onset occurs with dose reduction or withdrawal of dopaminergic agents in patients with Parkinson disease. The onset of symptoms can be insidious or fulminant. Symptoms often begin with mental status changes followed in sequence by muscle rigidity, hyperthermia, and autonomic dysfunction, but variability exists.[35] Hyperthermia is universally present, and the average maximum temperature is 39.9°C (103.8°F).[36,37] However, NMS has been reported to occur without temperature elevation.[38] Autonomic dysfunction includes tachycardia, diaphoresis, blood pressure instability, and arrhythmias. Autonomic dysfunction may precede changes in muscle tone. A general increase in muscle tone, "lead pipe" rigidity, or tremors occurs in more than 90% of patients. Early manifestations of changes in muscle tone include dysphagia, dysarthria, or dystonia that may be mistaken for extrapyramidal side effects of the drug. Altered mental status occurs in 75% of patients and can range from agitation to coma. The rigidity, tremors, and confusion of NMS may be attributed to the underlying disease in patients with Parkinson disease and delay the diagnosis. Rhabdomyolysis occurs frequently.

TABLE 111-2 Diagnostic Criteria for Neuroleptic Malignant Syndrome[a]

Major criteria
Fever
Muscle rigidity
Elevated creatine kinase
Minor criteria
Tachycardia
Abnormal blood pressure
Tachypnea
Altered consciousness
Diaphoresis
Leukocytosis

[a] Diagnosis of neuroleptic malignant syndrome is suggested by presence of all three major criteria or two major criteria with four minor criteria.
SOURCE: Mann et al.[42]

Laboratory findings include elevated creatine kinase levels and myoglobinuria. White blood cell counts are often increased (10,000 to 40,000/mm^3) and may demonstrate a left shift.[30] DIC has also been reported. Volume depletion or renal injury from rhabdomyolysis results in elevated levels of serum urea nitrogen and creatinine. Significant rhabdomyolysis may lead to serious electrolyte abnormalities.

Various diagnostic criteria have been proposed (Table 111-2), but NMS remains a clinical diagnosis based on exposure to neuroleptic agents or other dopamine antagonists in association with characteristic clinical manifestations.

TREATMENT OF NEUROLEPTIC MALIGNANT SYNDROME

Recommendations for treatment of NMS are based primarily on case reports and retrospective analyses because no controlled trials have been conducted in humans and no animal model exists. The patient should be admitted to an intensive care unit, and the precipitating medication should be discontinued. Treatment then involves three aspects: stopping thermogenesis, repletion of dopamine in the CNS, and general support.[32] Specific therapy should be individualized to each patient. The Neuroleptic Malignant Syndrome Information Service (www.nmsis.org) maintains a hotline for medical professionals (1-888-667-8367) if assistance is needed. Dantrolene is the most effective agent for decreasing muscle rigidity and temperature, although its role in NMS is less well defined than in MH. It can be given in the same doses as described for MH. Neuromuscular blockers and sedation may be infrequently needed for rigidity refractory to dantrolene. Dopamine agonists have been reported to have beneficial effects in NMS,[39,40] but results have been inconsistent.[41] These drugs include bromocriptine (2.5 to 5 mg orally three times daily, <30 mg/day), amantadine (100 mg orally three times daily), and levodopa/carbidopa. In severe cases, use of all three dopamine agonists may be considered. Benzodiazepines (lorazepam 1 to 2 mg every 8 hours) may be helpful in catatonia and for control of agitation. Electroconvulsive therapy has been used successfully in NMS, but indications are not well established. It may be considered when the clinical presentation overlaps with lethal catatonia.[32,42] Supportive therapy is crucial to successful management of NMS because patients typically die of complications such as

arrhythmias or aspiration. Intravascular volume should be optimized to replace increased insensible losses and maintain renal blood flow and urine output. Tachycardia and hypertension may respond to β blockers. External cooling may be required, and prophylaxis for venous thromboembolism should be instituted. Complications may include respiratory failure, cardiovascular collapse, renal failure, arrhythmias, or thromboembolism. Mortality rates are lower than 10% if recognition is prompt and appropriate treatment provided.

Chapter 112

DIVING MEDICINE AND NEAR DROWNING

CLAUDE A. PIANTADOSI
STEVEN D. BROWN

KEY POINTS

- *Immersion and diving produce physiologic effects from increased hydrostatic pressure and its effects on the behavior of gases.*
- *When diving with compressed air or other breathing gases, the body takes up extra nitrogen or other inert gas, which must be allowed to leave through the lungs gradually to avoid decompression sickness (DCS). DCS occurs when gas comes out of solution and forms bubbles in body tissues, which causes pain or neurologic symptoms by obstruction of blood flow and initiation of secondary inflammatory events.*
- *DCS is treated by prompt administration of high-flow O_2 and hydration. Oxygen recompression therapy is definitive treatment for symptom resolution and avoiding recurrence, even if delayed 1 or 2 days.*
- *Arterial gas embolism is usually the result of pulmonary overpressurization during ascent from diving with compressed gas and may occur at shallow depths. Arterial gas embolism is the second leading cause, after drowning, of fatalities in recreational diving.*
- *Near drowning (ND) is caused by asphyxia underwater, which may or may not be associated with aspiration. The primary injuries are to the brain, heart, lungs, and kidneys.*
- *In young adults, ND is often associated with drug or alcohol ingestion and may be accompanied by traumatic injuries.*
- *ND may be complicated by acute respiratory distress syndrome; its onset may be delayed or aggravated by aspiration of gastric contents or other foreign debris and pneumonia.*
- *ND may be complicated by pneumonia (or sepsis) caused by unusual pathogens present in contaminated water. Prophylactic antibiotic treatment is not indicated.*

Recreational activities involving water are enjoyed by millions of swimmers, boaters, and divers of all ages with various degrees of physical skill and judgment. However, the water environment is deceptively hazardous, and too often, swimmers or divers venture into peril with deadly results. In many situations, they ignore their physical limitations or impair their faculties with alcohol or other drugs. In other situations, such as with young children, the encounter with water is unsupervised or unexpected and frequently results in death by drowning. There are millions of recreational divers and many more recreational swimmers in the United States, which translates to thousands of diving accidents, drowning, and near drowning (ND) episodes each year. The exact number of such aquatic incidents and their effect on the health care system are difficult to estimate, but there may be more than 80,000 episodes per year in the United States. Victims often survive the incident only to die hours or days later in the hospital. Thus, the intensive care specialist should be knowledgeable about the clinical consequences and management of diving accidents and ND.

The Physics of Underwater Environments

Underwater environments produce physiologic changes as a result of the direct effects of increased hydrostatic pressure and its effects on the physical behavior of gases. Pressure is measured in units of force per area, which is expressed commonly in several convenient forms (Table 112-1). The pressure of the atmosphere at sea level is approximately 760 mm Hg (14.7 pounds per square inch). Underwater, the pressure of the water changes directly with depth, and this pressure must be added to atmospheric pressure to obtain total pressure, usually expressed in atmospheres absolute (ATA). Table 112-1 shows that a seawater column 33 ft deep (fsw) exerts a pressure equivalent to 1 atmosphere at sea level. Thus, a diver immersed at 33 fsw is exposed to a total pressure of 2 ATA.

When diving with compressed breathing gases, for the diver to inhale, the inspired gas pressure must be increased in proportion to the absolute pressure. Therefore, a larger number of gas molecules must be contained in the lungs (or other gas-filled body cavities) to maintain constant volume at a given temperature. The relation of pressure (P), volume (V), temperature (T) to number of moles of gas (n) is described by the *ideal gas law*:

$$PV = nRT \qquad (112\text{-}1)$$

where R is the universal gas constant. The ideal gas law gives rise to the special gas laws important in diving. Three relevant special gas laws in which one of the three variables is held constant are shown in Table 112-1. In diving the most important of these is the Boyle law, which explains the need to equilibrate pressure inside gas-containing spaces in the body, such as the middle ear space and lungs, to avoid barotrauma of descent (e.g., ear squeeze) or ascent (e.g., gas embolism).

Air and other breathable gases are mixtures of different molecules in which the total pressure is equal to the sum of the partial pressures of each gas. This expresses the Dalton law of partial pressures, which means that each gas in a mixture behaves as though it alone occupies the entire space. The uptake of gases by tissue is determined primarily by diffusion of gas from the alveolar spaces into blood and by transport of gas to tissues by the circulation (perfusion). The amount of a gas dissolved in liquid at any temperature, such as blood or tissues of the body at 37°C (98.6°F), is also proportional to its partial pressure (Henry law). The gas concentration in tissue at equilibrium is related to the partial pressure of the gas multiplied by its solubility coefficient. The physiologic effects of diving gases, such as nitrogen narcosis or the risk of decompression sickness (DCS), generally correlate with the partial pressure of the gas in the tissues of the body.

Immersion and Breath-Hold Diving

Water immersion produces adjustments by the respiratory, cardiovascular, renal, and endocrine systems.[1] Immersion produces three main physiologic effects: a decrease in thoracic gas volume, an increase in cardiac output, and a diuresis, which may lead to dehydration. These responses are caused

TABLE 112-1 Pressure Equivalents and Gas Laws

Pressure Condition	fsw	mm Hg	psig	ATA
Sea level	0	760	0	1.0
Sea water	33	1520	14.7	2.0
Sea water	66	2280	29.4	3.0
Sea water	330	8360	147.0	11.0
Boyle law $P_1V_1 = P_2V_2$				
Charles law $V_1/T_1 = V_2/T_2$				
Gay Lussaac law $P_1/T_1 = P_2/T_2$				

ABBREVIATIONS: ATA, atmosphere absolute (depth in ATA = [fsw + 33]/33); fsw, feet sea water; psig, pounds per square inch gauge, (a pressure gauge at sea level reads zero).

by hydrostatic pressure and the high density of water relative to air. During immersion, the blood vessels outside the thorax are supported by water, and an upright body is exposed vertically to a hydrostatic pressure gradient. The pressure around the body compresses the abdomen relative to the thorax, thereby causing negative pressure breathing (approximately –20 cm H_2O). The diaphragm is displaced upward, which decreases thoracic gas volume and expiratory reserve volume. The pressure gradient across the diaphragm, coupled to a hydrostatic decrease in venous capacitance in the legs, increases the volume of blood in the thorax, including the heart, by about 20%. Blood volume may be increased further by arterial vasoconstriction if the water is cooler than the thermoneutral point (~34°C, 93.2°F).

During immersion, cardiovascular distention activates mechanoreceptors that normally respond to hypervolemia. The apparent hypervolemia is detected in the hypothalamus via vagal afferents and leads to an immersion response. This response consists of diuresis and natriuresis, which have time profiles that suggest they operate by different mechanisms. Peak diuresis occurs rapidly (1 to 2 hours), whereas peak natriuresis occurs later (4 to 5 hours). Immersion diuresis but not natriuresis can be prevented by fluid restriction and vasopressin administration. The distention of the heart correlates with urinary sodium excretion. The mechanism of the immersion response is suppression of antidiuretic hormone release, also known as the *Gauer-Henry response*. The mechanism of natriuresis is related to a decrease in tubular reabsorption of sodium and not to an increase in filtered sodium. Natriuresis involves aldosterone suppression via decreased renin-angiotensin activity, increased release of atrial natriuretic factor, release of renal prostaglandins, and decreased renal sympathetic activity.

The increase in thoracic blood volume in immersion distends the heart and enhances ventricular diastolic filling (preload), which increases cardiac output.[2] Cardiac output increases almost entirely due to an increase in stroke volume, which may double. The elevated cardiac output is sustained and not accompanied by an increase in oxygen consumption.

Immersion has important implications for the physiology of the breath-hold.[3] In a breath-hold maneuver, the lungs are a reservoir for the exchange of O_2 for CO_2. During breath-hold in air, mean alveolar partial pressure of O_2 (P_{O_2}) decreases linearly as a function of the decrease in the mixed venous P_{O_2}. As alveolar P_{O_2} decreases, body O_2 consumption eventually decreases and anaerobic metabolism increases. CO_2 enters the lungs in proportion to pulmonary blood flow and the gradient for CO_2 diffusion between mixed venous and alveolar partial pressure of CO_2 (P_{CO_2}). The CO_2 transfer rate is high initially but then decreases because the diffusion gradient decreases as alveolar P_{CO_2} approaches the mixed venous P_{CO_2}. Further CO_2 production increases mixed venous P_{CO_2}, which causes alveolar P_{CO_2} to increase again. When the rising P_{CO_2} causes breathing to resume, the break point is reached. The time to the break point can be extended by maneuvers that lower P_{CO_2} or raise P_{O_2} such as hyperventilation or O_2 breathing. Hyperventilation does not increase the body's O_2 store appreciably because the increase in alveolar P_{O_2} resulting from a decrease in alveolar P_{CO_2} increases blood O_2 content only slightly. Thus, hyperventilation extends breath-hold time, but profound hypoxia may develop before the CO_2 reaches the break point.

Alveolar gas exchange during breath-holding is altered by underwater descent when thoracic compression decreases lung volume and the partial pressures of O_2, CO_2, and N_2 increase in the lungs (Fig. 112-1). On descent, alveolar O_2 and CO_2 concentrations decrease because of greater transfer of those gases to pulmonary capillary blood in relation to inert gas (N_2). Alveolar P_{O_2} increases during breath-hold diving compared with simple breath-holding (due to the increase in ambient pressure) and the transfer of CO_2 during early descent is opposite normal, that is, CO_2 moves from alveoli to pulmonary capillary blood. During ascent, the lung re-expands and alveolar P_{O_2} and P_{CO_2} decrease (as pressure decreases). Near the surface, the alveolar P_{O_2} may be almost as low as mixed venous P_{O_2}. In strenuous dives, expansion of hypoxic alveoli during ascent may result in reverse O_2 transfer from mixed venous blood to alveoli (see Fig. 112-1). Carbon dioxide retained in the blood during the dive also leaves during ascent as alveolar P_{CO_2} decreases. Carbon dioxide elimination continues after the dive, in addition to the small amount of N_2 that entered the blood during the dive.

Hyperventilation before breath-hold diving is a dangerous way to extend the dive. During the dive, compression of the lungs causes the alveolar P_{O_2} to increase. Thus, the primary signal to return to the surface is the P_{CO_2}. When the diver hyperventilates before the dive, the arterial P_{CO_2} begins at a lower level, and the time to the breath-hold break point is extended. However, alveolar O_2 concentration decreases to lower levels during the longer dive, and life-threatening hypoxia may occur as the diver approaches the surface. Loss of consciousness by this mechanism, known as *shallow water blackout*, causes many drowning episodes.

The body's response to breath-hold diving can be modified by a diving response induced by apnea and facial immersion,

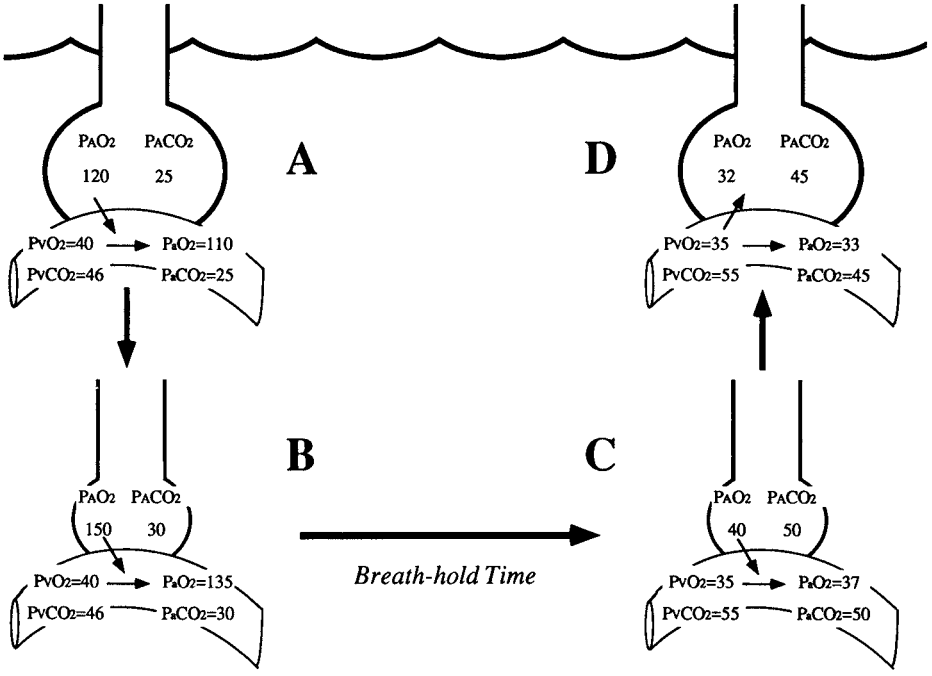

FIGURE 112-1 Mechanism of shallow water blackout. All values are expressed in millimeters of mercury. *A*. The breath-hold diver hyperventilates before the dive. *B*. At depth, arterial partial pressures of CO_2 (Pa_{CO_2}) and O_2 (Pa_{O2}) increase as the alveoli are compressed by hydrostatic pressure. *C*. At the end of the breath-hold dive, CO_2 increases toward the break point, and the diver begins to ascend. Note the decreased Pa_{O_2} and Pa_{O_2} at this point. *D*. When approaching the surface, Pa_{CO_2} and Pa_{O_2} decrease as the alveoli reexpand; O_2 leaves the pulmonary capillaries and enters the alveoli. This may result in profound hypoxemia and produce unconsciousness.

particularly in cold water. This diving response, manifested primarily as bradycardia, is most pronounced in young children. The diving response has been interpreted as an O_2-conserving response that redistributes blood flow from organs resistant to hypoxia to organs with continuous O_2 needs such as heart and brain. This interpretation is controversial for humans, although a diving response may contribute to survival of children resuscitated successfully after submersion in cold water.

Diving with Compressed Gases

The limitations of breath-hold diving are precluded by underwater breathing apparatuses that provide the diver with a continuous supply of breathing gas at any depth. In shallow water, for instance, 0 to 135 fsw, diving is usually carried out by using compressed air because it is inexpensive and readily available, even at remote locations. Air divers are usually free swimming, that is, they use a self-contained underwater breathing apparatus (SCUBA). The maximum safe depths are considered to be 135 fsw for SCUBA divers and approximately 200 fsw for divers tethered to a safety line.[4] Safety concerns are brought about by three factors: nitrogen narcosis, safe decompression, and oxygen toxicity. The problems of greatest importance to the intensive care specialist are caused by decompression and are discussed below. The other problems are covered in standard textbooks on diving medicine.

To dive beyond the practical range of compressed air, special gas mixtures, such as helium-oxygen (heliox) or oxygen-enriched air (nitrox) must be supplied. In heliox operations, inspired oxygen pressure is usually maintained at a constant 0.4 to 1.0 ATA, and the helium may be recycled by gas reconditioning equipment. Surface-supplied heliox diving is expensive but effective and relatively safe to depths of 400 fsw. Most dives deeper than 400 fsw require saturation of the diver with inert gas at the approximate working depth of the dive. Divers can live and work for weeks after saturation and then undergo a single slow decompression.

PRINCIPLES OF DECOMPRESSION

The use of compressed gases in diving produces physiologic problems during ascent because of the escape of inert gas from tissues. Elimination of inert gas from the body as the pressure decreases during ascent from diving or to altitude is known as *decompression.* The rate of uptake or elimination of inert gases from the body after a change in pressure is determined primarily by gas solubility in blood and tissue, blood flow, and the volume of tissue. Inert gas exchange usually follows an exponential function with respect to time. Tissues that behave this way are perfusion limited, and the characteristics of their inert gas exchange are defined by a half-time. Because the body tissues receive different amounts of blood flow and nitrogen is more soluble in fatty tissues, half-times for different tissues vary considerably. The principle of multiple tissues was used to calculate the first safe decompression tables, with the assumption that gas bubbles and, hence, DCS would occur only if the tissues were supersaturated to allow a nitrogen partial pressure of about twice the absolute pressure. Modern decompression tables are still based on multiple parallel exponential models, but other concepts have been used with success.[5] The variable that most affects inert gas uptake and elimination is tissue perfusion, but diffusion may limit tissue gas exchange under some conditions. Diffusion limitation may occur if the rate of inert gas exchange by perfusion is extremely rapid, if tissue perfusion is very low, or if a tissue barrier such as capillary endothelium has a high diffusion resistance.

Diffusion also may be important when two adjacent tissues have very different rates of perfusion. In such conditions, elimination of inert gas from the faster tissue may allow more inert gas to diffuse from the slower tissue. Thus, a faster tissue may remain supersaturated for longer than expected.

Diffusion is also important after gas bubbles have formed in a tissue during decompression. Gas bubbles contain large amounts of N_2 gas that can be removed by perfusion only after the N_2 diffuses back into the tissue. The rate at which N_2 diffuses away from a gas bubble is determined by the bubble surface area, the intrabubble pressure, and the difference in partial pressure between bubble and tissue.

During decompression, bubbles form in specific places in the body called *nucleation sites*. Microscopic gas nuclei remain stable for a long time at hydrophobic sites in the body and grow into bubbles during decompression. The number of nucleation sites and their location and propensity to form macroscopic bubbles differ according to physiologic conditions. For example, exercise may increase the number of bubbles formed by *tribonucleation*, a mechanism whereby large negative pressures can generate bubbles by traction between surfaces lubricated by a liquid, such as joints. Bubbles created by tribonucleation may arise from preexisting gas nuclei or by de novo formation.

DECOMPRESSION SICKNESS

There is little doubt that gas bubbles cause DCS, but some bubbles are clinically silent. However, there is uncertainty about the exact mechanisms of bubble growth and precisely how bubbles trigger the diverse features of DCS. The factors that govern bubble formation in "aqueous" tissues have been used to develop tables for safe decompression. Decompression tables usually assume that DCS will not occur unless the inert gas tension exceeds some threshold of critical supersaturation. The assumption of such a threshold conflicts with data indicating that DCS occurs as a stochastic event.[6] Therefore, even appropriate use of well-tested decompression tables or a decompression computer is associated with a finite risk of DCS for dives of approximately 25 fsw or deeper. However, most serious cases of DCS are due to omitted decompression.

The clinical manifestations of DCS are attributed to growth of bubbles in body tissues. Primary sites of bubble growth are the joint spaces, tendon sheaths, and periarticular tissues, including peripheral nerves. Bubbles in these locations produce pain that is known as *type I DCS*, or *bends*. Bubbles also form in the spinal cord and other areas of the central nervous system. This is called *type II* or *serious DCS*. Other serious forms of DCS involving the audiovestibular system (staggers) and pulmonary system (chokes), although relatively rare, also occur. The common clinical manifestations of DCS are presented in Table 112-2.

DCS in military and commercial divers occurs with a predominance of type I symptoms. Altitude bends, or dysbarism, is generally accompanied by mild to moderate type I DCS. Tunnel workers have a reported incidence of DCS of 0.7% to 1.5%, primarily consisting of type I symptoms of the knee and lower leg.[7] In contrast, some survey data have suggested a predominance of type II symptoms in recreational divers.[8] The reasons for this difference in DCS in recreational diving are not clear, although underreporting of type I DCS and overdiagnosis of type II DCS are likely. In some cases, long delays in the diagnosis and treatment of type I DCS may allow more severe manifestations to evolve. Recreational divers are more likely to omit decompression than are professional divers, thus increasing the probability of serious DCS.

TABLE 112-2 Clinical Manifestations of DCS

Type I (mild DCS)
Limbs
Pain (bends), niggles, lymphatic obstruction, numbness, and paresthesias usually involving the large joints, e.g., shoulders, elbows and knees
Skin
Mottling, itching, rash, pallor, urticaria, edema
Type II (serious DCS)
CNS
Brain
Headache, seizures, loss of consciousness, visual disturbances, hemiparesis, aphasia, tremor, ataxia (staggers)
Spinal cord
Low back or pelvic girdle pain, paraparesis, urinary retention, incontinence
Audiovestibular DCS
Tinnitus, vertigo, nystagmus, decreased hearing, nausea and vomiting
Cardiopulmonary DCS (chokes)
Dyspnea, cough, wheezing, hemodynamic collapse

ABBREVIATIONS: CNS, central nervous system; DCS, decompression syndrome.

One of the most serious forms of DCS is spinal paralysis.[9] Spinal cord DCS is not fully understood, but in some animals the injury has been related to intravascular bubbles that form in the low-pressure, epidural venous plexus of the spinal cord.[10] Because of its slow blood flow, the plexus is susceptible to bubble formation. Bubble-induced thrombi can obstruct venous outflow, leading to ischemic injury of the spinal cord. Despite evidence for bubble formation in the spinal venous plexus, intravascular formation of bubbles appears to be otherwise uncommon. Most intravascular bubbles probably originate at the tissue-blood interface and stream into the circulation to be absorbed by the lungs. Bubbles arising in the body of the spinal cord (autochthonous) have also been implicated in the etiology of spinal DCS.[11]

Once bubbles enter the circulation, surface activity at the blood-to-bubble interface produces changes in blood proteins. These include complement activation, activation of coagulation and fibrinolysis, platelet and neutrophil aggregation and destruction, and release of inflammatory mediators. Precise roles for these events have not been determined in DCS pathogenesis.

If a large number of bubbles is released into the venous system during decompression, they may obstruct the pulmonary circulation and cause sore throat, cough, chest pain, and shortness of breath. This syndrome, known as *the chokes*, if untreated, may lead to cardiovascular collapse and death. Some bubbles may also cross pulmonary capillaries as small gas emboli or pass into the arterial circulation through right-to-left cardiac shunts, for example, patent foramen ovale (PFO).[12] However, PFO is present in about 20% of normal individuals, and its presence probably leads to more severe rather than more frequent episodes of DCS.[13]

Divers with the chokes develop symptoms minutes to hours after decompression, which may be progressive. Physical examination reveals tachypnea, tachycardia, crackles, wheezing, cyanosis, and gasping in severe cases. The chest radiograph may show diffuse pulmonary infiltrates similar to acute respiratory distress syndrome (ARDS). Should

bubbles pass into the arterial circulation, neurologic findings may appear, primarily involving cerebral symptoms and signs. Arterial blood-gas determinations often show hypoxemia and respiratory alkalosis.

PULMONARY BAROTRAUMA

Pulmonary barotrauma of ascent, also known as *pulmonary overpressurization*, is a potentially serious consequence of failure of expanding gas in the lung to escape from alveoli. Overstretching of lung regions may rupture acini or alveoli and cause pulmonary interstitial emphysema. Disruption of the pulmonary parenchyma may cause mediastinal or soft tissue emphysema, pneumopericardium, pneumothorax, or arterial gas emboli (AGE). Pulmonary overinflation occurs during ascent while diving with compressed breathing gases. It is most likely to occur with breath-holding, loss of consciousness underwater, or airway obstruction that traps gas. Pulmonary overinflation also may occur after explosive decompression of aircraft at altitude.

Lung rupture during ascent also depends on physiologic factors such as pulmonary compliance, transpulmonary pressure, and lung volume. Airway closure and air trapping induced by immersion in the upright position may increase the risk of lung overstretching during ascent.[14] Once alveolar pressure becomes positive by about 100 cm H_2O to that at the mouth, the lung will rupture. During breath-holding at total lung capacity (TLC), the difference between alveolar and ambient pressure is approximately 50 cm H_2O. Thus, hydrostatic pressure outside the body during ascent must decrease another 50 cm H_2O for the lung to rupture. Assuming a compliance of the lung and chest wall at a TLC of 15 mL/cm H_2O, lung volume during ascent must increase by 15 mL $\times$ 50 cm H_2O, or 750 mL, before the lung ruptures. Using the Boyle law (see Table 112-1), an approximate depth can be determined from which a diver must ascend for pulmonary rupture during a breath-hold at TLC. At the surface, $P_1 =$ 1.0 ATA; suppose $V_1 = 7000$ mL. Then, $V_2 = 7000 - 750$, or 6250 mL. Therefore,

$$(1.0)\ (7000\ \text{mL}) = P_2\ (6250\ \text{mL}) \qquad (112\text{-}2)$$

and

$$P_2 = (1.0)\ (7000/6250) = 1.12\ \text{ATA, or } 4.0\ \text{ft} \qquad (112\text{-}3)$$

This calculation illustrates why pulmonary overinflation and AGE occur in shallow water during rapid ascent. The calculation also points out that relative volume changes are greatest at low hydrostatic pressures.

Venous and Arterial Gas Embolism

Venous gas emboli (VGE) occur fairly often in compressed gas diving and in diverse clinical settings (see Chap. 27). Asymptomatic venous bubbles occur often in divers during and after decompression. In clinical settings, even careful intravenous infusion of solutions or contrast materials may be accompanied by VGE. If a small volume of gas enters the circulation, such emboli are usually clinically silent. VGE thus create injurious consequences in four situations: (1) obstruction of the heart or major vessels by gas, (2) arterialization of bubbles across the pulmonary vasculature, (3) arterialization of bubbles across a PFO, and (4) physical interactions between air and blood. When venous gas bubbles enter the arterial system, even a small amount of gas can produce substantial morbidity or death.[15,16]

The lungs effectively filter VGE larger than about 20 μm in diameter;[17] this size barrier is not absolute because bubbles of 500 μm may cross the lung in some cases. VGE spillover through the pulmonary system has been demonstrated in animals such as dogs, in which spillover to the pulmonary veins occurred at an intravenous air bubbling rate of 0.3 mL/kg per minute.[15] The VGE crossover rate and passage size increases in the setting of a large difference between pulmonary arterial and pulmonary venous pressures. Pulmonary arterioles constrict in response to VGE and pulmonary arterial pressures increases.[18] As more VGE mechanically obstruct the vasculature, the gradient of pulmonary arterial versus venous pressure increases, thereby decreasing the filtering effectiveness of the pulmonary capillaries and allowing VGE to pass.[19] Anatomic intrapulmonary shunting also decreases the filtering efficiency of the lungs.

Paradoxical air embolism may occur when VGE are arterialized via a PFO in divers or patients.[11] Detection of PFO by echocardiography relies on gas microbubbles for ultrasonic contrast. Right-to-left atrial crossover of these bubbles is variable and may require Valsalva or other special maneuver to increase right atrial pressure. Bubble crossover also may occur spontaneously during some phases of the cardiac cycle.[20] The probability of paradoxical gas embolism increases in patients who develop pulmonary hypertension and vascular obstruction from VGE.

VGE also become physiologically significant when a large quantity of gas obstructs major vessels at the level of the pulmonary vasculature or the heart. In the heart, gas churned to foam obstructs inflow and outflow and diminishes cardiac output. In addition to obstructing the pulmonary vasculature, venous gas triggers pulmonary arterial constriction, bronchospasm, and dyspnea.[21]

Physical interactions at the blood-bubble interface complicate mechanical obstruction of the circulation and amplify the physiologic effects of small volumes of intravenous gas. The blood-bubble interface stimulates biochemical events associated with release of multiple inflammatory mediators with subsequent damage to the vascular endothelium. Noncardiogenic pulmonary edema may develop quickly as extravasated fluid floods alveoli and may progress to ARDS.[22] Compressed gas divers have long recognized a similar sequence of events as the syndrome of chokes.[23]

AGE may occur in diving by VGE that cross into the arterial circulation or by gas entering the left heart after pulmonary overpressurization. AGE is second to drowning as the leading cause of fatal accidents in SCUBA diving. The most common source of AGE in divers is pulmonary barotrauma. Similar events may occur in patients on mechanical ventilation who require high airway pressures for ventilation. Pulmonary overdistention, which produces AGE in divers or ventilated patients, may not produce other evidence of barotrauma such as pneumothorax, pneumomediastinum, or pneumopericardium. Gas in vessels is not detected reliably by radiography, and the diagnosis is suggested by clinical evidence of end-organ damage, primarily ischemia of the brain or heart.[24] Therefore, procedures to document the presence of

air may delay treatment of a critically ill patient. Appropriate management of AGE begins with heightened suspicion of the problem in an appropriate setting.

Like VGE, AGE obstruct, induce vasoconstriction, activate coagulation, complement, and neutrophils and aggregate platelets. This leads to release of mediators of inflammation that activate and may subsequently damage vascular endothelium. Even minor AGE have the potential for permanent injury and should never be regarded as benign, but the severity of injury in general appears to be related to the volume of intravascular gas. In the heart, the myocardial response to AGE is similar to coronary insufficiency of any etiology. Ventricular arrhythmias and ST-segment elevation or depression are common and may lead to infarction.[25,26] Cerebral manifestations of AGE are similar to those of thromboembolism and include focal neurologic deficits, loss of consciousness, seizures, and death. The distinction between AGE and VGE may become blurred clinically because the possibility of arterial spillover is difficult to exclude, and either event may be heralded by cardiovascular collapse.

Divers who have AGE are most often inexperienced and frequently arrive suddenly at the surface after diving. They may cry out, indicating a rapid ascent with a closed glottis, or they may surface unconscious. AGE are complicated occasionally by pneumothorax or pneumomediastinum and accompanied by clinical signs of pulmonary barotrauma, such as mediastinal crunch (Hamman sign), subcutaneous air, or tension pneumothorax. The onset of AGE is quite sudden, virtually always within 15 minutes of surfacing, and presents with symptoms of brain ischemia, which may be progressive. Initial symptoms of AGE appearing more than 1 hour after ascent should not be attributed to AGE but to serious DCS, ND, or stroke. Common clinical findings of AGE include headache, confusion, nausea, vomiting, blindness, hemiparesis, seizures, and unconsciousness. Chest pain, hemoptysis, and shortness of breath may also occur. Laboratory abnormalities may include elevated serum creatine kinase levels, signifying injury to skeletal and cardiac muscle.[27]

Therapy of Arterial Gas Embolism and Decompression Sickness

ADJUNCTIVE THERAPY

The management of VGE or AGE begins with identifying the problem and preventing additional emboli. In VGE of any etiology, a "mill wheel" murmur produced by air in the right ventricle may be audible with a stethoscope.[28] Positioning the patient in the left lateral decubitus and Trendelenburg position in an effort to avoid PFO crossover and brain emboli is traditional clinical practice for AGE and serious DCS.[28,29] The Trendelenburg position has been proposed to reduce cerebral bubble diameter by increasing hydrostatic pressure in the cranium; however, animal studies have suggested that positioning efforts are not efficacious because blood flow rather than buoyancy of the bubble determines the course of air emboli.[29,30] Further, Trendelenburg positioning has been associated in animals with increased cerebral edema. Ventilation with 100% O_2 helps correct hypoxemia and increases the diffusion gradient for nitrogen out of the bubbles, causing them to shrink.[31,32] Vasopressors and antiarrhythmic agents may be required for hypotension and ventricular arrhythmias associated with AGE. Lidocaine at 2 to 4 mg/min intravenously after a 1-mg/kg loading dose ameliorates cerebral injury after experimental cerebral AGE.[33]

Adjunctive therapy for AGE and serious DCS, other than oxygen and lidocaine, consists of correction of hemoconcentration with intravenous fluids and management of complications.[34,35] Parenteral corticosteroids such as dexamethasone, 4 mg every 6 hours, have been recommended to decrease cerebral or spinal cord edema after AGE and serious DCS, but evidence demonstrating efficacy in either situation is lacking. Stress ulceration may occur after AGE, and prophylaxis for this complication should be used routinely. Because of blood-bubble physical interactions discussed earlier, treatment of cerebral AGE with heparin was once recommended, but has not proved efficacious, and is associated with hemorrhage into areas of cerebral infarction induced by the air embolus.[33] However, heparin prophylaxis of deep venous thrombosis and pulmonary emboli should be given for spinal cord DCS because of immobility of the patient.

RECOMPRESSION THERAPY

Gas bubbles in tissue or circulation slowly resolve spontaneously, but the rate at which they are removed can be enhanced greatly by oxygen breathing and recompression. Recompression and hyperbaric oxygen (HBO) administration are primary therapy for DCS and AGE.[34] Bubble resolution is related to size and the partial pressure difference between the bubble and tissue. This partial pressure difference is due to the inherent unsaturation of venous blood that results from the difference in solubility of CO_2 and O_2 in body tissues. CO_2 is 20 times more soluble than is O_2 in tissues. As O_2 is consumed, it is replaced by CO_2 from substrate oxidation at a ratio of about 0.8 mol of CO_2 for each mole of O_2. Thus, O_2 entering tissue at an arterial P_{O_2} of 100 mm Hg leaves the venous capillary at a P_{O_2} of 40 mm Hg. In contrast, CO_2 enters at 40 mm Hg and leaves at only 46 mm Hg. The remaining gas pressure in tissues is primarily N_2, which is inert and has the same partial pressure at equilibrium, 573 mm Hg, on both sides of the circulation. Therefore, the sum of partial pressures in the venous system is 54 mm Hg less than in the arterial system. This "oxygen window" provides a pressure gradient to eliminate N_2. As a gas pocket or bubble collapses from removal of O_2 by metabolism, the internal partial pressure of N_2 (P_{N_2}) increases above tissue P_{N_2} because total pressure in the bubble remains in equilibrium with ambient pressure. In this way, N_2 is gradually absorbed. The oxygen window can be expanded during and after decompression and during recompression by administration of high values of P_{O_2}, which decreases tissue P_{N_2} and increases the partial pressure gradient for N_2 between bubble and tissue. Immediate O_2 administration at the scene of a diving accident before recompression therapy is clearly beneficial in the management of DCS and AGE.

Different recompression schedules are effective for AGE and DCS if treatment is begun promptly. Recompression tables that use HBO and minimal recompression are the treatment of choice. U.S. Navy Treatment (USNT) Table 6, which uses intermittent HBO at a maximum depth of 2.8 ATA (60 fsw), is a standard for primary DCS and for recurrent symptoms.[4] Recurrent or persisting symptoms should be retreated with USNT Table 6 once a day or with USNT

Table 5 twice a day; in general, a point of diminishing returns is reached after a small number (approximately six to eight) treatments. Persistent bladder and bowel dysfunction or neuromuscular weakness also may respond to saturation therapy (e.g., USNT Table 7), if resources and expertise are available for conducting prolonged treatments.[4] In some cases of DCS, oxygen recompression is not available, and air recompression tables must be used. Air treatment tables are longer and less effective than HBO tables and are more likely to produce DCS in the chamber attendants. Recompression presents several logistical challenges for the intensive care team.[36]

HBO is also used to treat AGE and clinically serious VGE on the basis of the following rationale. First, an increase in ambient pressure compresses the gas and increases the ratio of surface area to volume of the bubble, thus improving nitrogen diffusion from the bubble. Second, greater oxygen tension in the blood increases the nitrogen gradient across the blood-bubble interface. Third, the amount of O_2 physically dissolved in plasma during HBO (~6 mL O_2/dL of plasma at 2.8 ATA) may avert or reverse ischemia if plasma streaming occurs around emboli, which obstruct erythrocyte flow.

The optimal depth and duration of HBO treatment of AGE are still debatable. Experience by the U.S. Navy with air embolism after military diving accidents led to the development of USNT Table 6A, which uses initial recompression of the patient breathing air to an equivalent pressure of 165 fsw (6 ATA) followed by prompt decompression to 60 fsw (2.8 ATA), when the patient breathes 100% O_2. The chamber is then decompressed slowly to the surface while the patient breathes O_2 in cycles alternating with air. The intent of the initial, deep compression in USNT Table 6A is reduction of emboli size to 55% of their original diameter (assuming spherical geometry). This approach may be appropriate for very recent AGE or when the quantity of intravascular gas is very large. Deep compression on air, however, may actually allow nitrogen into the emboli so that they are larger after decompression than before compression. This problem can be circumvented in part by having the patient breathe a mixture of 50% O_2 and 50% N_2 during compression to decrease the driving force of N_2 into the emboli. Of note, recent experience using USNT Table 6 to treat air embolism suggests that equally good results are obtained when using USNT Table 6 at 2.8 ATA. This compresses the emboli to about 70% of their original diameter and expedites release of nitrogen. USNT Table 6, originally designed for the treatment of type II DCS, is more amenable to hospital-based chambers and is particularly well suited to critically ill patients with AGE at sea level pressure. Like DCS, recurrent or persisting symptoms of gas embolism may respond to daily USNT Table 6 treatments until no further improvement is noted.

Many hospitals may not have the experience or equipment to manage critically ill patients in a hyperbaric chamber. In that case, the patient may require transfer to a suitably equipped facility. This can be accomplished by ground or air transportation as long as the aircraft can be pressurized to 1 ATA or safely fly below 1000 ft of altitude to avoid further enlargement of gas emboli.

The best responses to therapy for AGE and serious DCS occur with prompt treatment. However, even recompression therapy delayed as long as 12 to 24 hours may be useful for both conditions.[37] Advice from a diving medicine physician concerning diving-related injuries is available 24 hours a day by calling the Divers Alert Network (919- 684-8111. The Divers Alert Network is a nonprofit organization that collects and disseminates information on diving safety and related injuries and is associated with the Center for Hyperbaric Medicine at Duke University Medical Center.

Near Drowning

PATHOPHYSIOLOGY

The consequences of ND are primarily those of asphyxia. When effective gas exchange ceases, the individual presents the consequences of hypoxia and hypercapnia. Excellent summaries of the demographics and emergency response to ND are available and are not covered here.[38–40] This section summarizes the pathogenesis of ND injury of the frequently injured systems supported in the intensive care unit (ICU): lungs, brain, heart, and kidneys.

LUNG

The pathogenesis of lung injury in ND is initiated by upper airway obstruction when fresh water (FW) or sea water (SW) contacts the respiratory tract mucosa and provokes laryngospasm. Laryngospasm is a protective response provided the duration of hypoxemia is limited by a brief immersion time. Approximately 10% to 15% of individuals with ND aspirate trivial amounts of water, but some of these individuals develop sufficient O_2 deprivation to produce hypoxic encephalopathy or ventricular arrhythmia due directly to laryngospasm.[41] Aspiration of SW and FW also induces mechanical airway obstruction with a small airway component. Small airway obstruction is aggravated by bronchoconstriction, mucosal edema, and plugging by water and suspended debris such as algae, diatoms, sand, mud or by teeth and gastric contents.[42]

Aspiration of even small quantities of water immediately decreases lung compliance and creates persistent areas of low ventilation-perfusion ratio and shunt.[42,43] Therefore, aspiration of water may produce a longer lasting hypoxemia than laryngospasm alone. Some of the mechanisms of the early changes in pulmonary gas exchange have been elucidated in animals and are attributable, in general, to loss of surfactant or its activity, damage to the alveolar epithelium and capillary endothelium, and alveolar flooding. In human beings, vomiting and aspiration of stomach contents during ND is common and aggravates mucosal and alveolar epithelial injury.

The combination of alveolar flooding, loss of surfactant or its function, atelectasis, and alveolar damage may give rise to progressive hypoxemia from intrapulmonary shunting, which in severe cases may reach 70% of the cardiac output.[42,44] In about 40% of individuals with ND, the injury culminates in ARDS hours to days after the episode.[45,46] Hypoxemia usually necessitates treatment with supplemental oxygen at high inspired O_2 fraction, which may superimpose pulmonary oxygen toxicity on ARDS. Fortunately, ARDS, which develops after ND, is more likely to be reversible than ARDS from other causes.[46]

BRAIN

ND is the second leading cause of brain death, after trauma, in children admitted to a pediatric ICU.[47] Brain injury pathogenesis in ND is that of global anoxia or severe hypoxia.

Prolonged anoxia or hypoxia produces diffuse neuronal damage that, if severe, compromises the function of the blood-brain barrier, leading to cerebral edema. As edema develops, intracranial pressure (ICP) may increase, further decreasing brain perfusion, exacerbating intracellular hypoxia, and, in severe cases, causing uncal herniation. Profound increases in ICP are infrequent after ND but tend to appear more than 24 hours after resuscitation of patients who already show evidence of neurologic dysfunction.[46] There is some evidence that the increase in ICP indicates severity of neuronal injury rather than being a major contributor to the insult.[46,48]

The difference between ND and anoxic brain injury of other etiologies involves the potential mitigating effects of the diving reflex and hypothermia.[49] In human beings, the diving reflex is not well developed and most apparent in young children exposed to cold water.[49,50] ND in cold water leading to rapid hypothermia slows cerebral metabolism, thereby postponing the deleterious effects of anoxia.[51] These factors are associated with a better prognosis after an apparently severe ND episode.[50–52]

HEART

The most important cardiac effects of ND are atrial and ventricular arrhythmias, in particular ventricular fibrillation.[53] Studies of drowning in animals have demonstrated hemolysis and rapid shifts in blood electrolyte composition after instillation of FW and SW into the lungs. These responses correlated with the occurrence of ventricular arrhythmias. However, human studies have not confirmed significant electrolyte changes even in patients with ventricular fibrillation,[54] except for drowning in Dead Sea waters, which have a much higher mineral content than other SW. Individuals with ND in the Dead Sea develop hypernatremia, hyperchloremia, hypermagnesemia, and hypercalcemia more than 24 hours after exposure because electrolytes are absorbed from the gastrointestinal tract after swallowing large amounts of water during the episode.[52]

ND in human beings differs from that in animal studies primarily because humans rarely aspirate enough water to produce significant electrolyte changes.[54] Human pathologic studies after SW or FW drowning have demonstrated cardiac myocyte hypercontraction and hypereosinophilic sarcomeres. These pathologic changes are characteristic of catecholamine excess and suggest that intense adrenergic stimulation contributes to the arrhythmias after ND.[55] Thus, the etiology of ventricular fibrillation in human beings is most likely related to hypoxia, respiratory and metabolic acidosis, and catecholamine excess. A review of cases of children with brain death has demonstrated myocardial infarction to be commonly associated with ND.[56]

KIDNEY

The incidence of renal insufficiency after ND is unknown but is reported far less frequently than lung, brain, or cardiac injury. The renal complication cited most often is oliguria attributable to acute tubular necrosis,[57] probably caused by hypoxemia and hypotension. Infrequently, ND may be complicated by rhabdomyolysis and hemolysis with disseminated intravascular coagulation.[58,59] Hemolysis and disseminated intravascular coagulation also may contribute to acute tubular necrosis. Although patients with acute renal failure after ND may require transient dialysis, recovery of adequate renal function can be expected in most patients.

MANAGEMENT

GENERAL MEASURES

ND in adults and adolescents is associated with several predisposing factors and complicating injuries, which are easily overlooked in the unconscious, critically ill ND patient. They must be considered in each case because they may affect the treatment and prognosis of the patient.

Alcohol and other drugs that alter the central nervous system are commonly implicated in adult ND.[60] Sedatives and alcohol in particular may complicate the patient's initial ICU course by exacerbating hypothermia and hypotension and impairing mental status and respiratory drive. Levels of toxic drugs and blood alcohol should be measured in complicated patients admitted to the ICU.

Other predispositions to ND include unrelated pathologic events in otherwise unimpaired adult swimmers. Myocardial infarction, cardiac arrhythmias, seizures, subarachnoid hemorrhage, and AGE in the SCUBA diver have been implicated in many ND episodes.[60] These events may require extraordinary diagnostic efforts in the immediate postresuscitation environment of the ICU. Electrocardiography should be obtained routinely because the heart is a target organ for hypoxemia in patients with ND. Serial measurements of cardiac enzymes in ND are useful for confirming the diagnosis of myocardial infarction when electrocardiographic changes are nondiagnostic. Acute intracranial hemorrhage or status epilepticus may need to be ruled out in patients whose course is complicated by neurologic dysfunction. Recompression and HBO therapy should be considered for ND in SCUBA divers with unexplained obtundation, coma, or other neurologic deficit (see section on VGE and AGE).

Injuries to the spine and skull are common in patients with ND. These occur most often when a swimmer dives into shallow water and strikes the head on the bottom or on a submerged object.[60] A common scenario involves a motor vehicle accident that leaves the passenger submerged in a body of water. Burst fractures of the cervical vertebrae resulting in tetraplegia have been reported in these settings. In addition, skin, middle ear, or sinus trauma sustained during ND may serve as portals of entry for infection.[61]

ICU MANAGEMENT

The ND patient should be placed in an ICU for respiratory insufficiency, after cardiac arrest or arrhythmia, and for altered mental status. Clinically, the patient may exhibit cyanosis, tachycardia, hypo- or hypertension, hypothermia, respiratory distress with frothy, blood-tinged sputum, diffuse crackles, and wheezing on examination. Initial laboratory evaluation often shows a metabolic acidosis (caused by lactic acid) and hypoxemia on arterial blood-gas analysis. Serum electrolytes, with the exception of a decreased bicarbonate concentration, are rarely perturbed significantly.[62] However, ND in industrial fluids or the Dead Sea can perturb serum electrolytes. As an example, a 28-year-old male developed severe hypercalcemia after a ND incident in an industrial vessel with oil-well drilling fluid that contained calcium salts.[63] Hypoglycemia is common.[64] Hemolysis and rhabdomyolysis, if seen, tend to occur early in the clinical course unless they are the result

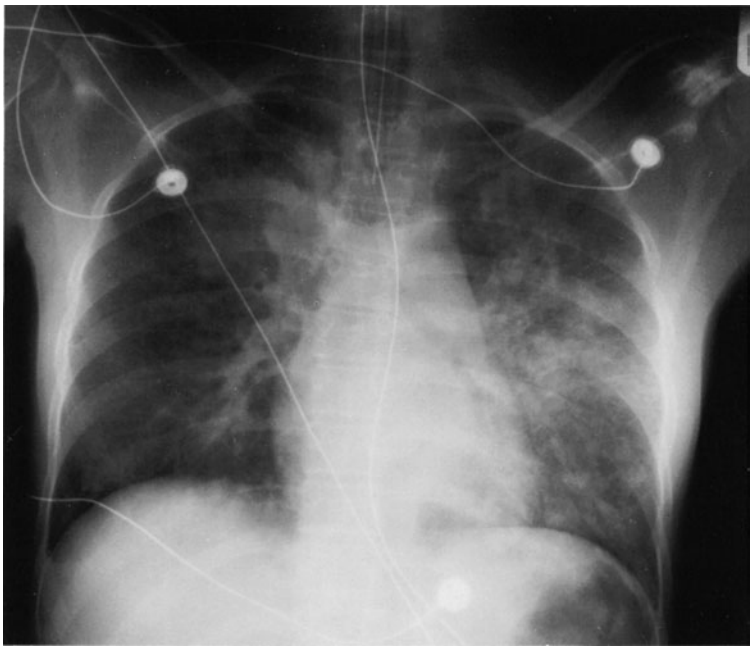

FIGURE 112-2 Chest radiograph 2 hours after an episode of near drowing shows typical patchy infiltrates.

of late sepsis. Electrocardiographic abnormalities include evidence of ischemia or injury and ventricular and atrial arrhythmias. Initial chest radiographic findings range from patchy infiltrates to diffuse airspace disease (Fig. 112-2). Progressive increase in parenchymal infiltrates over hours to days is not unusual.

RESPIRATORY CARE

Mechanical ventilation can be a challenge in the severely injured ND patient. Atelectasis and pulmonary edema with intrapulmonary shunting are encountered in all types of ND. ARDS can develop with poor lung compliance that should be treated, like all cases of ARDS, with normal tidal volume ventilation (6mL/kg ideal body weight; see Chap. 38). These conditions can be further complicated by the presence of foreign bodies in the airways. Heavy sedation or muscle relaxants are best avoided in ND patients because the drugs impair the clinician's ability to follow the neurologic examination. However, careful use of these agents may improve mechanical ventilation by synchronizing the patient with the ventilator or decreasing airway pressures and the risk of barotrauma. The advantages of positive end-expiratory pressure in decreasing intrapulmonary shunt can be dramatic in severe hypoxemia after ND. Treatment of children with ARDS after ND with artificial surfactant did not improve outcome but did improve pulmonary function modestly.[65]

Respiratory insufficiency in ND may be complicated by factors other than atelectasis and intrapulmonary shunt. Airway obstruction may occur as bronchospasm or from a foreign body. Bronchodilator therapy may benefit the patient with diffuse wheezing. Patients with localized atelectasis that fails to improve with effective ventilation or those who exhibit localized wheezing should undergo fiberoptic bronchoscopy to exclude or remove a foreign body.

Many ND accidents occur in water contaminated with human or animal waste or naturally containing pathogenic bacteria or fungi. The lung is the most common portal of entry for a wide variety of these organisms. Infection is heralded by fever 2 to 7 days after the event and should prompt sputum and blood cultures before initiation of antibiotic therapy.[66] Prophylactic antibiotic coverage has not improved outcome after ND, and routine use of antibiotics is not indicated. Reported infections are presented in Table 112-3. Awareness of infection by more unusual organisms is crucial because they may have specific culture requirements not offered routinely in many hospital microbiology laboratories.[61]

TABLE 112-3 Microbial Isolates Associated with Infection in Individuals After Near Drowning[a]

	Type of Water	Reference
Bacteria		
Klebsiella oxytoca	FW	64, 58
Herellea spp.	FW	55
Neiserria meningitidis	FW	55
Pseudomonas aeruginosa	FW	64
Listeria monocytogenes	FW	64
Plesiomonas shigelloides	FW	64
Edwardsiella tarda	FW	64
Chromobacterium violaceum	FW	81
Aeromonas hydrophila	SW, FW	64, 58
Escherichia coli	SW, FW	64, 58
Proteus mirabilis	SW, FW	58, 64
Staphylococcus aureus	SW, FW	64, 65
Neiserria mucosus	Brackish	66
Pseudomonas putrefaciens	SW	58, 65
Francisella philomiragia	SW	63
Vibrio parahemolyticus	SW	58
Fungus		
Pseudoallescheria boydii	FW	64
Aspergillus fumigatus	FW	67, 64

[a] Organisms isolated from sputum or blood of clinically infected ND victims soon after admission. This list does not include organisms recovered from infected wounds.

ABBREVIATIONS: FW, fresh water; SW, sea water.

TABLE 112-4 Classification of Individuals After Near Drowning and Initial Resuscitation

Category A	Awake, fully conscious
Category B	Blunted consciousness, stuporous but arousable
Category C	Comatose
C.1	Decorticate posturing
C.2	Decerebrate posturing
C.3	Flaccid

BRAIN RESUSCITATION

Brain resuscitation measurements after ND are controversial. The debate is complicated by the diverse parameters that influence brain injury and recovery, including age, water temperature and submersion time (or period of asphyxia), coexisting injuries, and preexisting disease.[67] The matter is complicated further by anecdotes of complete or nearly complete neurologic recovery in association with specific therapeutic modes after prolonged immersion. The initial prognostic uncertainties about brain recovery after ND mandate a full effort at cardiopulmonary resuscitation, including correction of hypothermia.[68]

Classification of neurologic status 1 to 2 hours after resuscitation allows assessment of prognosis. A system with reasonable discrimination for outcome in humans classifies patients after resuscitation into three categories, as listed in Table 112-4.[50,51]

The best discrimination for outcome using this system has been found in children in whom all category A and B patients (n = 57) recovered completely. Level C patients (n = 39) had 33.3% and 23.9% cerebral morbidity rates (mortality rate + morbidity rate = 56.2%), with the lowest survival rate in the C.3 group.[51] In another series of patients that included 52 adults, the category A patients recovered completely, and two adults and one child in level B eventually succumbed to barotrauma or other complications.[50] Eight of 11 (73%) adult and 8 of 18 (44%) child category C patients recovered completely in that series.

Use of a brain resuscitation regimen known as HYPER (hyperhydration, hyperpyrexia, hyperexcitability, and hyperrigidity) suggested that a larger fraction of seriously injured ND children had complete recovery.[51] The acronym addressed the overhydration, fever, excitability, and muscular rigidity noted in some patients. These findings were thought to affect outcome adversely, and aggressive therapy was recommended to minimize them.

HYPER therapy consists of systemic corticosteroids, osmotic diuretics, hyperventilation, barbiturate coma, and muscle relaxants administered to minimize cerebral edema and decrease ICP. Controlled hypothermia (32°C, 89.6°F) to decrease neuronal metabolism also was advocated.[52] ICP monitoring is necessary to guide such aggressive therapy. The rationale for HYPER therapy was based on the idea that control of ICP would minimize neuronal damage after diffuse anoxia. However, the increase in ICP that develops 24 to 48 hours after ND may be a result of severe neuronal injury rather than its cause.

Critical reviews and subsequent experience with HYPER therapy failed to confirm its efficacy and highlighted its potentially detrimental effects.[41,46,68] A retrospective review of 40 ND patients from the same institution that reported the original experience with HYPER found increased incidences of sepsis and multiple organ failure in patients treated with hypothermia.[67] This may result from cold-induced immune suppression (including neutropenia) complicated by cold-induced bronchorrhea and decreased mucociliary clearance.[67]

Corticosteroids have no proved benefit in decreasing brain edema associated with trauma, intracerebral hemorrhage, or stroke. In the absence of convincing evidence that corticosteroids increase edema and, hence, ICP and that decreased ICP improves neurologic outcome after ND, these agents should be avoided because they are immunosuppressive and predispose to infection and gastric ulceration.[69] Although hypothermia and barbiturates can decrease ICP in some circumstances, their use has not been demonstrated to improve neurologic outcome. Attempts to decrease ICP by use of osmotic agents also have not been shown to improve neurologic outcome after ND and may induce hyperosmolarity and renal insufficiency. Mild hyperventilation is a comparably benign intervention to decrease ICP temporarily, and ICP monitoring may help direct therapy in the subset of ND patients with increased ICP and poor prognosis. More recent experience with aggressive cerebral monitoring and resuscitation of the ND patient has shown no benefit.[70]

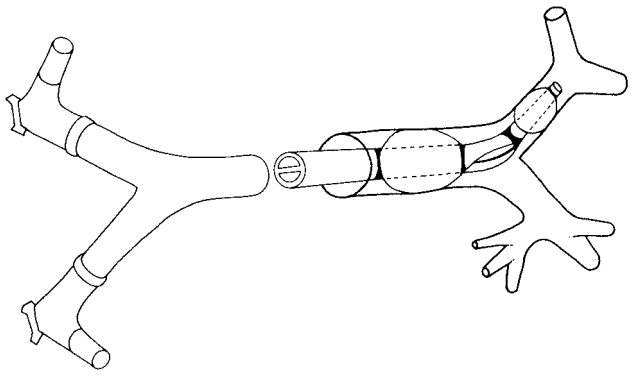
PROGNOSIS

Overall, about 80% of child and adult ND victims recover completely, 8% to 10% survive but with brain damage, and 10% to 12% die. About 90% of category A and B and approximately 50% of category C patients survive with full recovery, whereas 10% to 23% of the later group survive but have permanent neurologic sequelae.[45,46,50,54] Thus, respiratory insufficiency in the absence of sepsis or infection is seldom the cause of death in ND patients in hospitals with modern intensive care capabilities.

Many parameters such as serum electrolytes, arterial blood-gas and pH values, electroencephalographic findings or clinical features (body temperature, absence of pupillary response, cardiac arrest, duration of submersion, and resuscitative efforts), and cross-brain oxygen content differences[71] have been examined for use as indicators of prognosis. None is sufficiently discriminating to guide early therapy. Conversely, the presence of cardiac arrest and absence of spontaneous respirations after resuscitation are ominous signs associated with permanent neurologic impairment or death.[68] In a retrospective review of 44 ND children, all survivors who regained good neurologic function, were awake with purposeful motion 24 hours after the incident.[72]

Therapeutic Lung Lavage

Therapeutic flooding of the whole lung is a form of controlled ND used for many years to treat alveolar filling diseases including lipoid pneumonia, cystic fibrosis, and pulmonary alveolar proteinosis (PAP). Whole lung lavage is currently used primarily for PAP, a rare diffuse lung disease of unknown etiology.[73] In PAP, a combination of lipoproteins and noninflammatory cellular debris accumulates in the alveoli and creates a physiologic picture of low ventilation-perfusion ratio that may progress to severe shunting and refractory



hypoxemia. The disease affects men twice as often as women and begins commonly in the fourth to sixth decade of life. Occasional onset in childhood is also well documented. Approximately 33% of patients with PAP spontaneously remit, 33% do not progress, and 33% progress to pulmonary fibrosis that may be fatal.

Indications for whole lung lavage include resting hypoxemia, for instance, less than 90% hemoglobin oxygen saturation or arterial desaturation with routine activities. The frequency of need for lavage is variable; some patients require only one, whereas others require the procedure every few months for extended periods. Therapeutic whole lung lavage with warm saline is more effective for physical removal of the debris than segmental lavage via a bronchoscope in patients with PAP. The efficiency of protein clearance is increased by manual percussion of the chest during the emptying phases of the lavage but not by additives such as proteolytic enzymes or heparin in the lavage fluid.[74] Complications of the procedure include inadvertent flooding of the contralateral lung, hypoxemia, arrhythmias, hydropneumothorax (<5%), and bronchitis or pneumonia (<5%).[75,76]

TECHNIQUE

Whole lung lavage should be performed under general anesthesia by an experienced team. Standard monitoring during the procedure includes pulse oximetry, electrocardiography, blood pressure by indwelling radial artery catheter, core temperature, and volume of exchange in and out of the lung.[74,77] The trachea and left main bronchus are intubated with a dual-lumen endotracheal tube (Fig. 112-3). Although intubation of the left main bronchus is technically more difficult than that of the right main bronchus, the longer left mainstem before the first bifurcation provides better mechanical stability of the dual-lumen tube and less chance of bronchial obstruction. Proper placement of the tube is crucial for success in separating the lungs for independent lavage and ventilation. Tube placement is verified anatomically by fiberoptic bronchoscopy and functionally by auscultation and inflation of one lung to 50 cm H_2O to ensure that the contralateral main bronchus has been isolated. This is accomplished by connecting the appropriate bronchial tube to a connecting tube to a beaker of saline and observing for bubbles. Although a few bubbles are seen initially from compression by the pressurized lung, persisting bubbles indicate a leak and incomplete separation of the lungs.

FIGURE 112-3 Schematic drawing of left main bronchus intubation with a dual-lumen endotracheal tube (Broncho-Cath, Mallinckrodt).

Some patients with PAP are referred for lavage with advanced lung disease and severe hypoxemia despite supplemental O_2. In these cases, the procedure may be performed in a large hyperbaric chamber by a team composed of an anesthesiologist, a pulmonologist, a nurse and a physical therapist. This permits HBO to be used to maintain adequate arterial oxygenation during the procedure, if necessary.[78]

In many patients with PAP, hypoxemia worsens during the lavage procedure, particularly during the emptying phases of the lavage. This occurs because pulmonary blood flow to the lavaged lung increases when the hydrostatic compression of the pulmonary capillaries is alleviated by lung emptying. Therefore, it is useful to simulate the emptying phase of the lavage before the procedure by ventilating the lung to be lavaged with 6% O_2 (approximate mixed venous P_{O_2}) and the other lung with 100% O_2 for 5 minutes. Hemoglobin saturation is monitored by pulse oximetry, and an arterial P_{O_2} at the nadir of the response is used to confirm the level of hypoxemia. Hemoglobin saturations below 85% (P_{O_2} < 55 mm Hg) during this maneuver indicate that lavage will be more safely performed under hyperbaric conditions (1.2 to 2.8 ATA).

The first phase of the procedure is to wash N_2 out of the lungs by ventilating the patient with 100% O_2. This prevents relatively insoluble and non-metabolizable N_2 from creating an "air lock" in the lavaged lung. The lung is then flooded with normal saline at 37°C (98.6°F) at a rate based on one-half the patient's O_2 uptake (1 to 2 mL O_2/kg body weight per minute) through a tube connected to a reservoir of saline 45 to 50 cm above the mid-axillary line. Prior lung volume measurements are used to estimate the volume of fluid that the lung will hold. If HBO is required, compression begins during flooding as the hemoglobin saturation decreases. Compression of the chamber continues until hemoglobin saturation can be maintained at 90%.

After filling the lung, the hemithorax is percussed vigorously as 400 to 500 mL of fluid is drained by gravity into a graduated receiver 40 to 45 cm below the patient. Some investigators have advocated nearly complete emptying of the lung with each aliquot, but smaller tidal aliquots minimize the hypoxemia associated with the emptying phases of the lavage.[77,78] After emptying, repeated tidal aliquots of saline are instilled and emptied until the effluent is nearly clear to inspection. This usually requires 10 to 25 L of fluid per lung. The efficiency of this method with respect to yield of wet debris is comparable to that achieved with nearly complete emptying of the lung (Fig. 112-4). Afterward, the lung is drained and suctioned before reinflating with 100% O_2 and administration of positive end-expiration pressure. The availability of HBO allows the patient after one lung lavage to remain well oxygenated during the contralateral procedure. Hence, both lungs can be lavaged in sequence on the same day. This allows a single period of general anesthesia and a shorter hospitalization for the patient. Some institutions require a 2- to 4-day recovery period after one lavage before performing the procedure on the second lung. After the procedure, the patient is weaned rapidly from 10 cm H_2O positive end-expiration pressure and a high inspired O_2 fraction in the ICU and usually can be extubated within 12 hours.

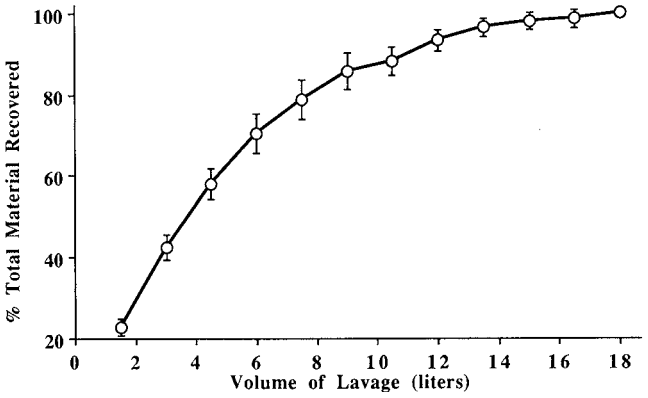


FIGURE 112-4 Cumulative recovery of wet debris in lavage fluid compared with lavage volume in six patients with alveolar proteinosis. Approximately 95% of the debris is recovered within 12 to 15 L of lavage. ***(Data courtesy Dr. Alexander Spock, Department of Pediatrics, Duke University Medical Center, Durham, North Carolina.)***

Aldosterone, 1219
in critically ill surgical patient, 1321
Alefacept, for psoriasis, 1639
Alkalemia, 1202, 1202t
Alkaline tide, 1202
Alkalosis
in acute-on-chronic respiratory failure, ventilated, 559
metabolic, 1202t. *See also* Acid-base disturbances, metabolic
in acute renal failure, 1155
in hypokalemia, 1171
respiratory, 1207–1208. *See also* Acid-base disturbances, respiratory
hypophosphatemia from, 1185
in pregnancy, 1594, 1611
Allergic, 1615
Allograft, 1355
Allopurinol
with azathioprine, 1586
with chemotherapy, 1175
for hyperuricemia and hyperuricosuria in leukemia, 1096
renal excreted active metabolites of, 1555t
for tumor lysis syndrome, 1106, 1175
Allostasis, 1219
All-*trans*-retinoic acid (ATRA, tretinoin)
for acute promyelocytic leukemia, 1097–1098, 1097t
for leukemia, 1091t
retinoic acid syndrome from, 1124, 1125t
toxicities of, 1097–1098, 1097t
Aloe, adverse effects of, 1633t
Alopecia, from chemotherapy, 1631
Alpha-adrenergic receptor blockers. *See also* specific agents
for cocaine-induced chest pain, 1525
Alpha-adrenergic toxidrome, 1507t
Alteplase, for pulmonary embolism, 360–362, 360t, 361t
Alveolar damage, diffuse, 523t, 585
in acute lung injury and ARDS, 519, 519f
Alveolar dead space fraction, 348, 349f
Alveolar distention, reduction of, 507
Alveolar edema clearance, in ARDS and acute lung injury, 521–522
Alveolar emptying, slow, 551
Alveolar fibrin, in acute lung injury, 705
Alveolar flooding, 1699
Alveolar gas equation, 1207
Alveolar gas exchange, in breath-hold diving, 1694, 1695f
Alveolar hypoventilation
perioperative, 1326–1328
in respiratory disease, 421
Alveolar pressure (Pa), 243f, 244
Alveolar-to-arterial gradient, for oxygen in pulmonary embolism, 348–349
Alveolar ventilation, 456
CNS maintenance of, 550
maternal, in pregnancy, 1594
Alvimapam, for intestinal pseudo-obstruction, 1251
Amantadine, 674–675
for neuroleptic malignant syndrome, 1692
neuroleptic malignant syndrome from withdrawal of, 1691
for pneumonia in pregnancy, 1609
Ambulance medical transport
fixed-wing air (airplane), 85–86, 85t, 86f
ground, 84
rotor-wing air (helicopter), 84–85, 86f
Ambulation, in chronic critical illness patients, 212
Ambulatory electrocardiographic monitoring, in preoperative assessment of high-risk patient, 1332–1333
Amebiasis, antimicrobial therapy for, 782t
American European Consensus Conference (AECC) for ALI and ARDS, 516–517, 517t
American Society of Anesthesiologists preoperative patient classification, 1331, 1331t
Amikacin, 653–656. *See also* Aminoglycoside antibiotics
acute renal failure from, 1142–1143
adverse drug reactions of, 656
clinical pharmacology of, 654–656
for febrile neutropenia, 744t, 745, 747–748
for lung infections in immunocompromised, 843t
mechanisms of action of, 654
mechanisms of resistance of, 654
for meningitis, 849, 849t
once-daily dosing of, 655–656
use of, 653–654
Amiloride
hyperkalemia from, 1175
on potassium, serum, 1173
ε-Aminocaproic acid (EACA), on pancreatic enzyme secretion, 1303
Aminoglycoside antibiotics, 653–656. *See also* specific agents
adverse drug reactions of, 656
for chemotherapy-related infection prophylaxis, 758
clinical pharmacology of, 654–656
elimination of, 1553
extracorporeal removal of, 1515t
for febrile neutropenia, 744t, 745
hypomagnesemia from, 1190
mechanisms of action of, 654
mechanisms of resistance of, 654
nephrotoxicity of, 1142–1143, 1143t
once-daily dosing of, 655–656
for Pseudomonas bacteremia, 1644
for pulmonary infiltrates in leukemia, 1092, 1092t
use of, 653–654
for *Vibrio vulnificus* bacteremia, 1644
Aminophylline
for acute-on-chronic respiratory failure, 557
for status asthmaticus, 570t, 572

Amiodarone
adverse effects and drug interactions of, 300t
for atrial fibrillation or atrial flutter, 306
for cardiac arrest, 189, 189t
on CYP2D6 activity, 1559t, 1562
for hypertrophic cardiomyopathy, 390
for myocardial infarction, 323
pharmacodynamics of, 297, 297t
pharmacokinetics of, 297, 298t
polymorphic ventricular tachycardia from, 1504
thyrotoxicosis from, 1240–1241, 1241f
torsades de pointes from, 1504
for ventricular fibrillation/tachyarrhythmias, 304, 304f
cardiac arrest from, 184
electrical storm from, 304
monomorphic, 302
polymorphic, 303f
for ventricular tachycardia with pulse, 183
Amitriptyline overdose/toxicity, 1527–1528
Amlodipine, for myocardial infarction, 322
Amnesia, in critical illness, 165
Amniotic fluid embolism, in pregnancy, 1606–1607
Amobarbital, for status epilepticus from overdose/toxin ingestion, 1506
Amoxapine overdose/toxicity, 1527–1528
Amoxicillin
for endocarditis prophylaxis, 644t
for *Salmonella* bacteremia with HIV/AIDS, 785t
Amoxicillin-clavulanate, for febrile neutropenia, 746
Amphetamines. *See also* specific drugs
overdose/toxicity of, 1507t, 1520–1521
ventricular arrhythmias from, 1503
Amphotericin B, 684–687
adverse effects of, 686–687, 754
for amebic meningoencephalitis, 875
antifungal prophylaxis with, 759
for *Aspergillus* infection, 756
after lung transplantation, 1360, 1362
pneumonia, after stem cell transplantation, 1119
for *Candida* infections
from chemotherapy, 751
esophagitis, 751, 915
oropharyngeal, 751
pneumonia, after stem cell transplantation, 1119
urinary tract, 909
for candidemia and candidiasis
from chemotherapy, 753–755
with HIV/AIDS, 783t, 793
esophageal, 783t
fluconazole-refractory, 783t
for chemotherapy-related infection prophylaxis, 758
clinical pharmacology of, 685–686
for coccidioidal infections
pneumonia, 835t
in pregnancy, 1609
for coccidioidomycosis with HIV/AIDS, 794
diffuse pneumonia, 783t
meningitis, 783t–784t
combinations with, 685
for cryptococcal meningitis with HIV/AIDS, 793
for cryptococcosis
in CNS, 874
pneumonia, 835t
for endocarditis, 805t
for febrile neutropenia, 744t, 748, 749
formulations of, 684–685
for fungal pneumonia, 835t
after stem cell transplantation, 1119
hypokalemia from, 1173
hypomagnesemia from, 1190
for intravascular access device infections, 820
for intravascular infections, 805t
for lung infections in immunocompromised, 843t
mechanism of action of, 685
mechanism of resistance of, 685
uses of, 684–685
Amphotericin B liposomal
for *Aspergillus* infection, 757
in lung transplant recipients, 1360
for *Candida* infections after liver transplantation, pre-emptive, 1361
for *Candida* pneumonia, after stem cell transplantation, 1119
for candidemia from chemotherapy, 753–755
for candidiasis with HIV/AIDS, 793
for cryptococcal meningitis with HIV/AIDS, 793
fluconazole-refractory, 783t
for febrile neutropenia, 744t, 749
for histoplasmosis with HIV/AIDS, 783t
toxicity of, 754
Ampicillin, 645. *See also* Penicillin
for acute-on-chronic respiratory failure, 558
for anthrax, 958
dosing of, IV, 646t
for endocarditis, 803, 805t
prophylaxis against, 644t
for *H. influenzae* pneumonia with HIV/AIDS, 785t
for intravascular infections, 803, 805t
for *Listeria* meningitis with HIV/AIDS, 785t
for meningitis, 848–850, 848t, 849t
for pneumonia, community-acquired, 834t
for pyelonephritis, 906
for *Salmonella* bacteremia with HIV/AIDS, 785t
for sepsis, severe, 716t
skin reactions to, 648
Ampicillin-sulbactam
for cervical fascial space infections, 886t
for epiglottitis, 890
for lateral pharyngeal or retropharyngeal space infections, 886t
for peritonsillar abscess, 886t
Amprenavir. *See also* Protease inhibitors (PIs)
adverse drug reactions of, 684
for AIDS, 773
clinical pharmacology of, 684
Amputation, limb, antibiotic prophylaxis for, 642t
Amrinone, for acute right heart syndromes, 342
Amyl nitrite, for cyanide poisoning, 1526
Amyloidosis of larynx, airway obstruction from, 461
Anabolic steroids
for acute-on-chronic respiratory failure, 558
for burn patients, 1476
Anaerobes. *See also* specific anaerobes
ventilator-associated pneumonia from, 602t, 603
Anaerobic cellulitis, 897, 898f, 899–900
Anaerobic metabolism, in acute respiratory failure, 417, 419–420
Anagen effluvium, from chemotherapy, 1631
Anakinra, 1588
Analgesia, 166–168. *See also* Pain; specific analgesics; specific disorders
epidural, 167
in high-risk surgical patient, 1338
indications for, 165–166
neuroaxial opiate, 167–168
opiate withdrawal in, 166
regional techniques for, 167–168
route of administration of, 166
Anaphylactic and anaphylactoid reactions, 1615–1624. *See also* specific allergens
from antibiotics, 1618
from blood products, 1619
clinical presentation of, 1616
from colloids, 1619, 1619t
definitions of, 1615
drug-induced, 1630. *See also* Adverse drug reactions (ADRs); specific drugs
follow-up in, 1624
from hypnotics, 1618–1619
identifying agent in, 1621
immunologic considerations in, other, 1624
incidence and prevalence of, 1615–1616
from latex, 1620
leukoagglutinins in, 1619
manifestations of, other, 1617
mediators of, 1617–1618
from neuromuscular blocking agents, 1618, 1618f
from opioids, 1619
pathophysiologic changes in, 1616f
prevention and recognition of, 1620–1621, 1621t
from protamine, 1619–1620
radioallergosorbent test for, 1622
skin testing for, 1621–1622
treatment of, 1620–1621, 1621t
initial, 1622–1623
secondary, 1623–1624
tryptase in, 1621, 1622f
from volume expanders, 1619, 1619t
Anaphylactic shock, 243, 262
Anaphylatoxin, in severe sepsis, 724
Anemia, 1055–1058
definition of, 1055
evaluation of, 1058
incidence of, 1055
in malaria, 930
microangiopathic hemolytic
from chemotherapy, 1131–1132
clinical presentation of, 1081–1082, 1082f
physiologic impact of, assessing, 1055–1056
red cell loss or destruction in, 1056–1057, 1056t
red cell loss underproduction in, 1056t, 1057–1058
sickle cell, 1655. *See also* Sickle cell disease
Anemia of chronic disease, 1057
evaluation for, 1058
Anesthesia. *See also* specific types and agents
in high-risk surgical patients, 1338
epidural, 1336
Anesthetics. *See also* specific agents
anaphylactic and anaphylactoid reactions to, 1615–1616, 1619
CYP2E1 metabolism of, 1563
cytochrome P450 clearance of, 1557t
for epidural anesthesia, 167
in high-risk surgical patients, 1336
malignant hyperthermia from, 1690

Anesthetics (*Cont.*)
neuroleptic malignant syndrome from, 1691
Aneurysms
dissecting. *See* Aortic dissection
mycotic. *See* Mycotic aneurysms
"Angel dust," 1533–1534
Angina, 313
management of, in MI, 317–319
stable and unstable, 313
Angiodysplasia
bleeding from, 1272–1273
small intestinal, 1275
Angioedema, 1630–1631
airway obstruction from, 461–462
Angiography
of aortic dissection, 404–405, 404f
of bronchial artery hemorrhage, 1490
coronary
for angina in myocardial ischemia, 319
for postinfarction ischemia, diagnostic, 325
for lower GI bleeding, 1486, 1487f
therapeutic, 1273–1274
for mesenteric ischemia, 1315
for peptic ulcer disease bleeding, 1270
for pulmonary embolism diagnosis, 355
Angioplasty, for right ventricular infarction, 327
Angiotensin-converting enzyme (ACE) inhibitors. *See also* specific agents
for angina in myocardial ischemia, 318
angioedema from, 461–462
for aortic insufficiency, 392
for aortic stenosis, 388
hyperkalemia from, 1175
for mitral regurgitation, 396
for myocardial infarction, 322
prerenal azotemia from, 1140
for renal crisis with scleroderma, 1576
Angiotensin receptor blockers (ARBs). *See also* specific agents
hyperkalemia from, 1175
prerenal azotemia from, 1140
Anion gap, 1203–1204, 1509
decreased, 1509, 1509t
elevated, 1509, 1509t
in toxicology, 1509, 1509t, 1510t
Anions, unmeasured, 1509
Ankylosing spondylitis
respiratory mechanics in, 569f
spine injuries in, 1414
Antacids
for stress ulcer prophylaxis in sepsis, 726–727
ventilator-associated pneumonia and, 605
Anterior cord syndrome, 1412
Anthracycline
cardiotoxicity of, 1126, 1126t, 1127
ECG changes from, 1126
extravasation from, antidote to, 1632t
for leukemia, 1091t
before stem cell transplantation, adverse effects of, 1112
stomatitis and diarrhea from, 1124, 1124t
Anthralin, for psoriasis, 1639
Anthrax, 955–960
clinical presentation of, 956
decontamination and transmission risk in, 958
diagnosis of, 956–958, 957f, 958f
differential diagnosis of, 958, 959t
etiologic agent in, 955
inhalation, 955–956
isolation guidelines for, 961, 962t
postexposure prophylaxis for, 958
prognosis in, 958–960
treatment of, 958
pneumonia from, 834, 834t
Anthrax meningoencephalitis, 873
Anthrax vaccine, 958
Antiangiogenic agents, 1133–1134. *See also* specific agents
Antiarrhythmic drug therapy. *See also* specific agents
adverse effects of, 299t–300t
classes of, 296, 297t
cytochrome P450 clearance of, 1557t
dosing of, 299t–300t
drug interactions of, 299t–300t
mechanisms of action of, 295–297, 297t. *See also* specific drugs
for myocardial infarction, 322–323
pharmacodynamics of, 297, 297t
pharmacokinetics of, 297, 298t
for ventricular tachyarrhythmias, monomorphic, 302–303
Antibacterial agents, 645–670. *See also* specific agents and infections
aminoglycoside antibiotics, 653–656
β-lactamase inhibitors, 651t, 653
carbapenems, 651–652, 651t
cephalosporins, 648–650, 650t
glycopeptide antibiotics, 657–660

Antibodies
to DNA, 1581, 1582t
Jo-1, 1583
to nRNP, 1581–1582, 1582t
in polymyositis/dermatomyositis, 1583
to SCL-70 (topoisomerase I), 1582, 1582t
to Sm, 1581, 1582t
to SS-A/Ro and SS-B/La, 1582, 1582t
Anticardiolipin (ACL) antibodies, 1582t, 1584
Anticentromere antibody, 1581, 1582t
Anticholinergic agents. *See also* specific agents
antidote for, 1516t
Anticholinergic toxidrome, 1507t
Anticholinesterase agents. *See also* specific agents
antidote for, 1516t
for myasthenia gravis, 1028
Anticoagulant agents. *See also* specific agents
cutaneous adverse drug reactions from, 1632–1633
cytochrome P450 clearance of, 1557t
for heart failure, acute, 286
invasive procedures with, 1077–1078
for myocardial infarction, 324
for pulmonary embolism, 357–359
for superior vena cava syndrome, 1100
for suppurative intracranial thrombophlebitis, 859–860
Anticoagulant-induced dermatoses, 1632–1633
Anticonvulsants. *See also* specific agents
cytochrome P450 clearance of, 1557t
overdose/toxicity of, 1507t
Antidepressants, cyclic. *See also* specific agents
arrhythmias from, 1504
overdose/toxicity of, 1500, 1504, 1507t, 1527–1528
hypertonic sodium bicarbonate for, 1504
polymorphic ventricular tachycardia from, 1504
torsades de pointes from, 1504
toxicology of, 1500, 1527–1528
Antidepressants, tricyclic. *See also* specific agents
overdose/toxicity of, 1527–1528
Antidiuretic hormone (ADH), 1161, 1162t. *See also* Vasopressin
in hyponatremia, 1166–1167
on sodium concentration, 1161, 1162t
in surgical patient, critically ill, 1321
syndrome of inappropriate secretion of, 1162t, 1166–1167
with malignancy, 1107, 1107t
Antidotes, 1516, 1516t
in chemotherapeutic agent extravasation, 1632, 1632t
Antifreeze poisoning, 1519–1520, 1519t
Antifungal agents, 684–692. *See also* specific agents and infections
amphotericin B, 684–687
caspofungin, 687–688
in critically ill, 684–692. *See also* specific agents
5-fluorocytosine, 688–689
imidazoles, 689–690
triazoles, 690–692
Anti-GBM disease, 1579
Antigen-presenting cells (APCs), in gut, 118–119, 119f
Antihistamines. *See also* specific agents
for anaphylactic and anaphylactoid reactions, 1623
overdose/toxicity of, 1507t
Antihypertensives. *See* specific agents
Anti–IL-2 receptor antibodies, for immunosuppression in transplant patient, 1358
Anti-inflammatory agents. *See also* Nonsteroidal antiinflammatory drugs (NSAIDs); specific agents
for rheumatologic diseases, 1587–1588
Antilymphocyte antibodies, for immunosuppression in transplant patient, 1358
Antilymphocyte globulin (ALG), for immunosuppression in transplant patient, 1358
Antimicrobial catheter treatment, 134
Antimicrobial prophylaxis, for medical and dental procedures, 397, 397t
Antimicrobial prophylaxis, in critically ill, 641
for commonly performed surgical procedures, 642t–643t
for endocarditis
with cardiac conditions, 643t
regimens of, 644t
in surgical procedures, 643t
Antimicrobial therapy, in critically ill, 641–645. *See also* specific agents, drug classes, and infections

for acute-on-chronic respiratory failure, 558
anaphylactic reactions from, 1618
antibacterial agents in, 645–670. *See also* Antibacterial agents
antifungal agents in, 684–692. *See also* Antifungal agents
antiviral agents in, 670–684. *See also* Antiviral agents
broad-spectrum, antibiotic resistance and, 45–46
coagulopathy from, 1075
for febrile neutropenia with chemotherapy, empiric, 744–750, 744t. *See also under* Febrile neutropenic episodes
identification of infectious disease in, 643
inference of infection in, 641–643
selection of agent in, 644–645
thrombocytopathy from, 1071
ventilator-associated pneumonia and, 611–613, 611t, 612t
nosocomial, 604–605
Antineutrophil cytoplasmic autoantibodies (ANCA), 1582–1583, 1582t
Antinuclear antibodies (ANA), 1581–1583, 1582t
antibodies in polymyositis/dermatomyositis, 1583
antibodies to DNA, 1581, 1582t
antibodies to nRNP, 1581–1582, 1582t
antibodies to SCL-70 (topoisomerase I), 1582, 1582t
antibodies to Sm, 1581, 1582t
antibodies to SS-A/Ro and SS-B/La, 1582, 1582t
anticentromere antibody, 1581, 1582t
antineutrophil cytoplasmic autoantibodies, 1582–1583, 1582t
Antioxidants. *See also* specific antioxidants
in enteral nutrition, 125–126
Antiphospholipid (APLA) antibodies, 1584
Antiphospholipid (APLA) antibody syndrome, 1584
Antiphospholipid syndrome, coronary thrombosis from, 1574
Antiplatelet therapy. *See also* specific agents
for myocardial infarction, 323–324
for thrombotic thrombocytopenic purpura/hemolytic uremia syndromes, 1085
thrombotic thrombocytopenic purpura syndromes from, 1081
Antiproliferative agents. *See also* specific agents
for acute right heart syndromes, 343
Antipseudomonal penicillins, 646. *See also* specific agents
IV dosing of, 646t
Antipsychotics. *See also* specific agents
for delirium in ICU, 981–982. *See also* specific agents
overdose/toxicity of, 1507t

Fluoroscopy, of percutaneous abscess drainage, 1481, 1482f
Fluorouracil (5-fluorouracil)
  acral erythema from, 1632
  acute cerebellar syndrome from, 1128t
  angina and MI from, 1126t
  diarrhea from, 1124, 1124t
  extravasation from, 1632
  hyperpigmentation from, 1632
  stomatitis from, 1124, 1124t, 1632
  as vesicant, 1632
Fluoxetine
  on CYP2D6 activity, 1559t, 1562
  overdose/toxicity of, 1507t
Fluphenazine, neuroleptic malignant syndrome from, 1691
Focal neurologic disease, with HIV/AIDS, 789t, 790–792, 791f, 792f
Focused surveillance, 41–42
Folate, for methanol poisoning, 1519t
Folinic acid
  for isosporiasis with HIV/AIDS, 782t
  for toxoplasmosis, 875
Folliculitis
  clinicoanatomy of, 898f
  Pityrosporum, 1649–1650
Fomepizole (4-methylpyrazole)
  for alcohol poisoning, 1519
  for ethylene glycol poisoning, 1519t, 1520
  for methanol poisoning, 1519t
Fondaparinux, for pulmonary embolism, 359
Foreign body
  aspirated, airway obstruction from, 460
  intravascular, percutaneous retrieval of, 1491
Foscarnet, 673–674
  for cytomegalovirus infection with HIV/AIDS, 784t
    encephalitis, 868
    pneumonitis, 781, 784t

Foscarnet (*Cont.*)
for herpes simplex infection with HIV/AIDS, 784t
for herpes zoster infection with HIV/AIDS, 784t
Fosphenytoin
for acute convulsive status epilepticus, 1002, 1002t
for seizures in children, 1004
Fournier syndrome, 897–898, 898f. *See also* Gangrene
Fractional excretion of sodium (FE_{Na}), 1147–1148
Fractional excretion of urea (FE_{Urea}), 1148
Fractional resorption of magnesium, 1191
Fractional resorption of phosphorus, 1187
Fractures
extremity
assessment of, 1448, 1448t
treatment of, 1448–1449
stabilization of, in multisystem trauma, 1391
Francisella tularensis
in biowarfare, 961–963, 962t
isolation guidelines for, 962t
pneumonia from
diagnosis of, 832, 961–963
treatment of, 834, 834t, 963
Frangula, adverse effects of, 1633t
Free radicals, oxygen, enteral nutrition and, 125
Free wall rupture. *See* Ventricular free wall rupture
Free water clearance, 1162
Fresh frozen plasma (FFP)
for coagulopathy of liver disease, 1076
for disseminated intravascular coagulation, in leukemia, 1096–1097
for factor II, V, and X deficiency, 1072
for factor VII deficiency, 1072
for factor XIII deficiency, 1073
for factor IX deficiency, 1072
for hypofibrinogenemia, 1072
for massive transfusion–induced coagulopathy, 1062, 1075
for typhlitis in leukemia, 1095
for variceal hemorrhage, 1265
Frozen red blood cells, transfusion of, 1059
Fulminant hepatic failure. *See* Hepatic failure, fulminant
Functional residual capacity (FRC), 1325
closing volume and
alveolar-arterial oxygen tension gradient and, 1325
body position, incisional pain, and age on, 1325, 1326f
maternal, in pregnancy, 1594
in obesity, 1673–1674
Fundus paraproteinaemicus, 1108
Fungal infections. *See also* specific infections
in AIDS, 782t–783t, 793–794
pneumonias, 787
in burn patients, 1477
with chemotherapy, 753–757
opportunistic filamentous, 755–757, 755f, 756f
opportunistic yeast, 753–755, 754f
prophylaxis against, 759–760
cutaneous, 1649–1650
febrile neutropenia from, 749–750
respiratory, in pregnancy, 1608
ventilator-associated pneumonia, 602t, 603
Fungi, 1649
Furazolidone, for giardiasis with HIV/AIDS, 782t
Furosemide
for acute hypoxemic respiratory failure, 246
for ascites with cirrhosis, 1292
for heart failure
acute, 286
acute on chronic, 280
for hypercalcemia, 1184t
for intracranial pressured, elevated, 1406
on renal failure, acute, 1152
on vascular resistance, in acute MI, 236
Furunculosis, clinicoanatomy of, 898f
Fusion inhibitors. *See also* specific agents
adverse effects of, 773, 774t
for AIDS, 773
Fusobacterium nucleatum, ventilator-associated pneumonia from, 603

G

Gaar equation, 153–154
GABA receptor, benzodiazepines on, 172
Gadolinium, for vascular imaging, 1480
Gallstones
calcium bilirubinate, in sickle cell disease, 1660
pancreatitis from, 1299, 1299t
γ-aminobutyric acid (GABA), in delirium, 975
γ-aminobutyric acid (GABA) receptor complex, benzodiazepines on, 172
Gamma hydroxybutyrate (GHB) intoxication/poisoning, 1500, 1528
Ganciclovir, 672–673
for cytomegalovirus
encephalitis from, 868
after lung transplantation, 1362
after organ transplantation, 1361
pneumonitis with HIV/AIDS from, 781, 784t
for Epstein-Barr virus encephalitis, 869
for febrile neutropenia, 744t
after heart transplantation, as prophylaxis, 1362
for lung infections in immunocompromised, 843t
for pneumonia
in transplant patients, 1369
viral, after stem cell transplantation, 1119
Gangrene
gas, 898, 902
progressive bacterial synergistic, 897, 898f
Gangrenous cellulitis, 897, 898f, 899–900. *See also* Gangrene
Gari, cyanide poisoning from, 1526
Garlic, drug interactions of, 1634t
Gas abscess, 899–900. *See also* Gangrene
Gas embolism, 364–366, 364t, 365t
Gas exchange
in acute respiratory failure, 420, 421f
in burn injury, 1459
in obesity, 1673
in pulmonary thromboembolism, 348–349, 349f
in status asthmaticus, 567–568
Gas flow rate, in ventilator-induced lung injury, 502
Gas gangrene, 898, 902. *See also* Myonecrosis
Gas insufflation, tracheal ventilator, in acute lung injury/ARDS, 535
Gas law, ideal, 1693
Gas laws, 1693, 1694t
Gas trapping
in mechanical ventilation, 500
permissive hypercapnia on, 507
Gastric acidity, on GI infections, 913–914
Gastric emptying, for drug and toxin removal, 1511–1512
Gastric entries. *See also* Stomach entries
Gastric lavage, for drug and toxin removal, 1511–1512
Gastric resection, antibiotic prophylaxis for, 642t
Gastric varices
endoscopic therapy for, 1265–1266, 1266f
transjugular intrahepatic portosystemic shunt (TIPS) for, 1489
Gastritis, 915
Gastroesophageal sphincter tone, in pregnancy, 1595
Gastrointestinal acidosis, 1206
Gastrointestinal dialysis, 1512
Gastrointestinal hemorrhage, 1261–1276
in acute renal failure, 1155
aortoenteric fistula in, 1276
epidemiology of, 1261
hemobilia in, 1275–1276
initial evaluation and management of, 1261–1262, 1262t
lower GI, 1272–1275
angiographic therapy for, 1273–1274
colonoscopy of, 1272
endoscopic therapy for, 1272–1273, 1274f
evaluation and management of, 1272, 1273f
radionuclide studies of, 1273
surgical therapy for, 1274–1275
Meckel's diverticulum in, 1276
in pregnancy, prevention of, 1611
prognostic factors in, 1261, 1261t
rebleeding in, 1263
small bowel evaluation in, 1275
small intestinal angiodysplasia in, 1275
upper GI, nonvariceal, 1267–1272
Dieulafoy's lesion in, 1270
Mallory-Weiss tear in, 1270
management of, 1267, 1268f
peptic ulcer disease in, 1267–1270. *See also* Peptic ulcer disease, hemorrhage from
stress-related mucosal damage in, 1271–1272
upper GI, variceal, 1263–1267
Childs-Pugh classification of, 1263, 1263t
management of
cardiopulmonary, 1264
endoscopic therapy in, 1265–1266, 1266f
hematologic and hemostatic, 1265
infection in, 1264–1265
neurologic, 1265
outline of, 1263–1264, 1264f
pharmacotherapy in, 1265
salvage therapy for endoscopically uncontrolled bleeding in, 1266–1267
Gastrointestinal infections, 913–920. *See also* specific infections
clinical manifestations of, 913t
Clostridium difficile, 918–920
colonizing flora on, normal, 914
diarrhea from, 915–918
evaluation of critically ill patient with, 917–918, 917t
hemorrhagic, 916t, 917
inflammatory, 916–917, 916t
noninflammatory, 916, 916t
treatment of, 918, 918t

esophagitis from, 914–915
gastric acidity on, 913–914
gastritis from, 915
host defenses in, 913–914
motility on, 913
Gastrointestinal integrity, importance of, 119–121
Gastrointestinal surgery. *See also* specific disorders and procedures
in critically ill, 1323
endocarditis prophylaxis for, 644t
gut use after, 1323
Gastrointestinal system. *See also* specific organs
in AIDS patients, 795, 795t
immune system in, ischemia/reperfusion injury and, 118–119, 119f, 120f
in organ failure pathogenesis, 117
in pregnancy, 1595
in severe sepsis, 706
systemic endotoxemia or bacteremia from, 1352
Gatifloxacin, 663–664. *See also* Quinolones
for head-and-neck infections, 886t
for *S. pneumoniae* with HIV/AIDS, 784t–785t
Gauer-Henry response, 1694
Gefitinib
interstitial lung disease from, 1124, 1125t
stomatitis and diarrhea from, 1124, 1124t
toxicities of, 1134
Gelatin sponge (Gelfoam)
for GI tract embolization, 1487–1488
for massive hemoptysis, 1491
Gell and Coombs classification, 1630
Gemcitabine, thrombotic thrombocytopenic purpura syndromes from, 1131
Gemfibrozil, for angina in myocardial ischemia, 319
Gemtuzumab ozogamicin, for leukemia, 1091t
Gender, on drug metabolism and clearance, 1561
Genitourinary injuries, traumatic, 1437–1438, 1438f
Genitourinary procedures. *See also* specific procedures
endocarditis prophylaxis for, 644t
Gentamicin, 653–656. *See also* Aminoglycoside antibiotics
acute renal failure from, 1142–1143
adverse drug reactions of, 656
for cellulitis, 899
anaerobic, 900
for chemotherapy-related infection prophylaxis, 758
clinical pharmacology of, 654–656
for craniotomy, 643t
for endocarditis, 803, 805t
prophylaxis against, 644t
for febrile neutropenia, 744t
for intravascular infections, 803, 805t
for *Listeria* meningitis with HIV/AIDS, 785t
mechanisms of action of, 654
mechanisms of resistance of, 654
for meningitis, 849, 849t
for myonecrosis, 904
for necrotizing fasciitis, 902
once-daily dosing of, 655–656
for pneumonia
community-acquired, 834t
nosocomial, 838t
for pneumonic plague, 961
for sepsis, severe, 716t
for surgery, 642t
for tularemia, 963
use of, 653–654
Germander, adverse effects of, 1633t
Giardiasis, with HIV/AIDS, antimicrobial therapy for, 782t
Ginger
adverse effects of, 1633t
drug interactions of, 1634t
Gingko biloba
adverse effects of, 1633t
drug interactions of, 1634t
Ginseng
adverse effects of, 1633t
drug interactions of, 1634t
Gitelman's syndrome, 1190
Glanders, isolation guidelines for, 962t
Glasgow Coma Scale (GCS), 1040, 1041t
changes in, 66
with head injury, 1395, 1395f, 1396f, 1400
Global cerebral hypoperfusion, 1019
Glomerular filtration, 1556
Glomerular filtration rate (GFR)
in acute renal failure, prerenal, 1139
creatine clearance and, 1556
on drug clearance, 1554–1555
in pregnancy, 1595
Glomerulonephritis
lung infiltrates and renal failure in, 1579
rapidly progressive, 1145
Glomerulosclerosis, cirrhotic, 1150
Glomerulotubular balance, 1140–1141
Glottis, 455
Glucagon
for beta blocker overdose, 1521, 1522
for calcium channel blocker overdose, 1522
response to injury of, 1321
Glucocorticoid receptor (GR), 1219
Glucocorticoid response elements (GREs), 1219
Glucocorticoids, 1219. *See also* Corticosteroids; Steroids; specific agents
in critically ill, 1584–1585
on HPA axis, 1224–1225
mechanism of action of, 1219, 1238t
physiologic actions of, major, 1220
preoperative coverage with, 1227
for sepsis, 1220
severe, 723–724
for sickle cell disease, 1668–1669
for spine injury, 1417
supplementation of, in high-risk surgical patient chronically using, 1340–1341
for thrombotic thrombocytopenic purpura/hemolytic uremia syndromes, 1085
Glucose
for coma, 1047
for hyperkalemia, 1176t, 1177
Glucose, blood, in sepsis, 725
Glucose-6-phosphate-dehydrogenase (G-6-PD) deficiency, 1562t, 1563
metabolic hemolysis from, 1057
Glucuronidation deficiency, 1562t, 1563, 1563t
Glutamine
in enteral nutrition, 125
in parenteral nutrition, 127
Glutathione transferase deficiency, 1562t, 1563
Glycemic control, in parenteral nutrition, 127
Glycerol, for meningitis, 850
Glycogen storage disease, decreased left ventricular contractility in, 272
Glycopeptide antibiotics, 657–660, 658f. *See also* specific agents
for febrile neutropenia, 744t, 747–748
Glycoprotein IIb/IIIa antagonists. *See also* specific agents
for myocardial infarction
non–ST-elevation, 324–325
ST-elevation, 321
thrombocytopathy from, 1070
Glycopyrrolate, for intubation, 468
Glycosaminoglycans, for severe sepsis, 722
Glycyrrhizin, drug interactions of, 1634t
Goal-directed therapy, early
for sepsis, severe, 714
for shock, 251–254, 252f. *See also under* Shock, resuscitation for
Goals, therapeutic, 4

  overuse of, morbid complications from, 111
Intestinal disorders. *See also* Gut; Large bowel; Small bowel; specific disorders
  in AIDS patients, 795
  infections. *See also* specific infections
    with chemotherapy, 751–753, 752f
  ischemia. *See* Mesenteric ischemia
  mucosal damage, with chemotherapy, 738
  traumatic injuries, 1433–1434
Intestinal motility, 1247–1249, 1248f, 1249f
  disordered
    acute intestinal obstruction in, 1249–1250, 1250f
    intestinal pseudo-obstruction in, 1250–1251, 1251t
    Ogilvie's syndrome in, 1251–1252, 1251f
Intestinal obstruction, 1249
  acute, 1249–1250, 1250f
Intestinal pseudo-obstruction, 1250–1251, 1251t
Intra-abdominal infections, after liver transplantation, 1364
Intra-abdominal sepsis. *See also* Abdomen, acute
  classification of, 1346, 1346t
  occult, 1351–1352, 1352t
  severe, initial treatment of, 715–716, 716t
Intra-amniotic infection, 1600–1601
Intraaortic balloon pump (IABP)
  for angina in myocardial ischemia, 319
  for cardiogenic shock, 328–329
  for heart failure, acute, 288
  for mitral regurgitation after acute MI, 326
  for right ventricular infarction, 326–327
Intracerebral hematoma, confluent traumatic, 1398, 1399f
Intracerebral hemorrhage, 985, 989–990
Intracranial aneurysm, ruptured, subarachnoid hemorrhage from, 990–994. *See also* Subarachnoid hemorrhage, from ruptured intracranial aneurysm
Intracranial compliance, 1007–1008, 1008f
Intracranial hematoma, operative management of, 1401–1402, 1402f
Intracranial hypertension. *See also* Intracranial pressure (ICP)
  management of, 1014–1017
    aggravating factors in, 1014
    barbiturate coma in, 1016–1017
    cerebrospinal fluid drainage in, 1015
    corticosteroids in, 1016
    in fulminant hepatic failure, 1283, 1283f
    hypertonic saline in, 1016
    hypothermia in, 1016
    loop diuretics in, 1016
    mannitol in, 1015–1016
    mechanical ventilation and hyperventilation in, 1014–1015
    surgical procedures in, 1017
  measurement of, 1399–1400
  medical manipulation of, 1405–1406
  monitor tracing of, 1007, 1008f
  after neurosurgery, 1323
  on outcome, 1403–1404
  waveforms for, 1008f, 1013
Intracranial infections, 886t, 891–893, 892t
Intracranial pressure (ICP), 1007–1021
  brain tissue displacement and herniations in, 1011–1012, 1011f
  cerebral edema in, 1010–1011, 1010t
  cerebral hemodynamics in, 1007–1010
    blood flow in, 1008–1009, 1009f, 1009t
    brain swelling in, 1007, 1008t
    ICP monitor tracing in, 1007, 1008f
    intracranial compliance in, 1007–1008, 1008f
    perfusion pressure in, 1009–1010, 1009t
    plateau waves in, 1010
  factors in, 1009t
  in fulminant hepatic failure, 1018–1019, 1018f
  in global cerebral hypoperfusion, 1019
  in head injury, 1323, 1399–1400
  in hypertensive encephalopathy and eclampsia, 1017–1018, 1017f
  increased, with intubation, 466
  management of, 1014–1017. *See also* Intracranial hypertension, management of
  in supratentorial hemispheric infarctions, 1019–1021, 1020f
Intracranial pressure (ICP) monitoring
  with head injury, 1403–1405, 1404f
  intracranial, 1012–1014, 1012f
Intracranial pressure (ICP) monitoring devices, 1012–1014, 1012f
  for brain abscess, 855
  for encephalitis, 876
  for head injury, 1404, 1404f
  infection control with, 44
  for meningitis, 850
Intracranial pressure-volume curve, 1007, 1008f

Intracranial suppuration, 893
Intracranial thrombophlebitis
  septic, 892t, 893, 894f
  suppurative, 858–860, 858f
Intradialytic hypotension, 1155–1156, 1156t
Intrahepatic cholestasis of pregnancy, 1609–1611, 1610t
Intrahospital transport, 89–90
Intravascular
  prosthetic valve endocarditis, 808–809, 809t–811t
  ventricular assist devices, 810, 810t, 811t
Intravascular access devices. *See also* Catheters, central venous (CVCs); specific devices
  infectious complications of, 815–821
    definitions and diagnosis of, 818–819
    epidemiology of, 815–816, 816t
    management of, 819–820
    microbiology of, 817–818, 818t
    pathogenesis of, 816–817, 817f
    prevention of, 820–821, 820t
    risk factors for, 815–816, 816t
Intravascular coagulation, disseminated. *See* Disseminated intravascular coagulation (DIC)
Intravascular infection, 801–812. *See also* specific infections and devices
  antimicrobial therapy for, 805t
  approach to patients with, 811–812
  arterial grafts, 810–811, 810t, 811t
  endocarditis from, 801–809. *See also* Endocarditis, infective
Intravenous gamma globulin
  for hemoptysis, massive, 584
  for immune thrombocytopenic purpura, 1068
  for posttransfusion purpura, 1069
  for toxic shock syndrome, 1643
Intravenous human anti-Rh_o (D) IgG, for immune thrombocytopenic purpura, 1068
Intravenous immune globulin (IVIg)
  for dermatomyositis and polymyositis, 1029
  for graft-*versus*-host disease, 1642
  for Guillain-Barré syndrome, 1027
  for myasthenia gravis, 1028
  for myonecrosis, 904
  for necrotizing fasciitis, 902
  for pemphigus vulgaris, 1638
  for respiratory failure in polymyositis/dermatomyositis, 1576
  for rheumatic disease, 1587
Intrinsic acute renal failure, 1141–1143
  acute tubular necrosis in, 1141–1144, 1142f. *See also* Tubular necrosis, acute
  acute tubulointerstitial nephritis in, 1144
  etiology of, 1140t
  rapidly progressive glomerulonephritis in, 1145
Intubation. *See also* specific types and indications
  in acute cardiopulmonary failure with kyphoscoliosis, 591
  in drug overdose/toxin ingestion, 1502
  in obese, morbidly, 1674
  in shock, indications for, 251, 251t
  in status asthmaticus, 573–576
    assessing lung inflation in, 575, 575f, 576f
    initial ventilator settings and dynamic hyperinflation in, 574–575, 574f
    postintubation hypotension in, 574
    sedation and paralysis in, 576
    ventilator adjustments in, 575–576
Intubation, endotracheal
  airway obstruction from, 459–460, 459t
  complications of, 626t
  for variceal hemorrhage, 1264
Intubation, tracheal, 455, 456f, 465–477
  assessing patient prior to, 466–467, 466t
  changing endotracheal tube in, 473–474
  with difficult airway, 471–473, 473f
  equipment for, 467–468, 467t
  fiberoptic, 470–471, 471f
  indications for, 465–466, 465t, 466t
  with laryngeal mask airway, 471, 472f
  nasotracheal, 470
  orotracheal, 469–470
  pharmacologic preparation and use in, 468–469, 468t
  physiologic changes with, 474
  practical rules of thumb for, 477t
  teaching skills for, 477
Inverse-ratio ventilation, 488–489, 488f
  in acute lung injury/ARDS, 536–537, 537f
Iodide-induced thyrotoxicosis, 1242
Iodoquinol, for amebiasis with HIV/AIDS, 782t
Ion difference, strong. *See* Strong ion difference (SID)
Ion gap, 1203–1204
  strong, 1204
Ionized hypocalcemia
  from citrate, 1179–1180
  decreased left ventricular systolic function in, 274
Iopanoic acid
  mechanism of action of, 1238t
  for thyrotoxicosis, 1238, 1238t
Ipecac, for drug and toxin removal, 1511–1512
Ipodate, for thyrotoxicosis, 1238, 1238t
Ipratropium, for acute-on-chronic respiratory failure, 557
Ipratropium bromide, for status asthmaticus, 570t, 571
Irinotecan (CPT-11), stomatitis and diarrhea from, 1124, 1124t
Iron, antidote for, 1516t
Iron metabolism, abnormal, 1057
Irrigation, heated, 1684
Ischemia
  cerebral, 985
  inferior mesenteric artery. *See* Mesenteric ischemia
  mesenteric. *See* Mesenteric ischemia
  myocardial. *See* Myocardial ischemia
  papillary muscle, v wave in, 151, 151f
  postinfarction, with acute MI, 325
  right ventricular, 336, 337t
    in cardiogenic shock, 260
  silent, in MI diagnosis, 315
  superior mesenteric artery. *See* Mesenteric ischemia
  weaning-related, 627, 627f
Ischemia-reperfusion injury
  GI tract, immune system and, 118–119, 119f, 120f
  after lung transplantation, 1365–1366
Ischemia-reperfusion model systems, 194
Ischemic edema, 1010, 1010t
Isoflurane, for refractory status epilepticus, 1004
Isoniazid
  antidote for, 1516t
  on CYP2E1 metabolism, 1563
  for *Mycobacterium* tuberculosis with HIV/AIDS, 780, 786t
  prophylactic, in transplant recipient, 1360
  for tuberculosis, 835, 836t
    in pregnancy, 1609
Isoprinosine, for measles subacute sclerosing panencephalitis, 872
Isopropanol (isopropyl alcohol)
  for anaphylactic and anaphylactoid reactions, 1623
  extracorporeal removal of, 1515t
  poisoning with, 1519–1520, 1519t
    diagnosis of, 1212
Isoproterenol
  ethnicity on sensitivity to, 1551
  for polymorphic ventricular tachyarrhythmias, 303f
Isosorbide dinitrate, 275t
Isosporiasis *(Isospora belli)* with HIV/AIDS, antimicrobial therapy for, 782t
Isosthenuria, in sickle cell disease, 1661
Itraconazole, 690–691
  adverse drug reactions of, 691
  antifungal prophylaxis with, 759–760
  for *Aspergillus* after lung transplantation, 1362
  for candidiasis with HIV/AIDS
    esophageal, 783t
    fluconazole-refractory, 783t
    oropharyngeal, 782t
  clinical pharmacology of, 690–691
  for coccidioidomycosis with HIV/AIDS
    meningitis, 783t
    pneumonia, 783t–784t
  for cryptococcal meningitis with HIV/AIDS, 783t, 793
  for febrile neutropenia, 744t
  for fungal pneumonia, after stem cell transplantation, 1119–1120
  for histoplasmosis with HIV/AIDS, 783t
  mechanism of action of, 690
  for mold infections, with chemotherapy, 757

J

Janeway lesions, 802, 803f
  in infective endocarditis, 1645, 1645f
Japanese B encephalitis, 869–870, 869t, 870t
Jaundice, in ICU patient, 1347
Jefferson's fracture, 1409, 1410f
Jet ventilation, with difficult airway, 472–473
Jin Bu Huan, adverse effects of, 1633t
Jo-1 antibody, 1583
Jodbasedow, 1242
j point, 145, 145f
Junin, 941t, 942t, 947–948. *See also* Hemorrhagic fevers, viral
J wave, 1681, 1681f

K

Kanamycin, 653–656. *See also* Aminoglycoside antibiotics
  adverse drug reactions of, 656
  clinical pharmacology of, 654–656
  mechanisms of action and resistance of, 654
  once-daily dosing of, 655–656
  use of, 653–654
Kaposi's sarcoma, with HIV/AIDS
  cutaneous, 1648–1649
  respiratory, 774, 787
Kappa receptors, for opiates, 171
Kava-kava, drug interactions of, 1634, 1634t
Kawasaki's disease, acute renal failure from, 1145
Keratoderma blenorrhagicum, 1648

Kerosene aspiration, pulmonary wedge pressure after, 246, 246f
Ketamine, for refractory status epilepticus, 1003t, 1004
Ketoacidosis, 1204–1205
  alcohol, 1204–1205, 1211
  diabetic. *See* Diabetic ketoacidosis (DKA)
Ketoconazole, 689–690
  on CYP3A4, 1563–1564
  for hypercalcemia, 1184
  hyperkalemia from, 1175
  for pseudomembranous candidiasis with chemotherapy, 751
  for skin fungal infections, 1649
Ketolide antibiotics, 668–669. *See also* specific agents
Ketone bodies, 1204
Ketorolac
  for sickle cell disease, 1666, 1666t
  thrombocytopathy from, 1070
Ketosis, starvation, 1211
Kidney-pancreas transplantation, 1368
Kidneys. *See* Renal entries
Kidney transplantation
  acute renal failure in, 1151
  donor criteria for, 1381, 1381t
  pancreatitis after, 1299t, 1300
Kinins
  in anaphylactoid reactions, 1617
  in anaphylaxis, 1615, 1616f, 1617
Klebsiella
  anaerobic cellulitis from, 899
  meningitis from, 846, 846t
  myonecrosis from, 903
  necrotizing fasciitis from, 900
  ventilator-associated pneumonia from, 602–603, 602t
Klebsiella pneumoniae pneumonia
  community-acquired, 824, 824t, 825f. *See also* Pneumonia, community-acquired
    treatment of, 834, 834t
  nosocomial, 837, 837t
Köbner phenomenon, 1638
Kombucha mushroom, adverse effects of, 1633t
Kupffer cells, in severe sepsis, 706
Kussmaul's sign
  right atrial pressure in, 144
  y descent in, 151, 152f
Kyphoscoliosis, 587–590
  acute respiratory failure with, 590–592
  causes of, 587–588, 588t
  gas exchange in, 588–589
  on pulmonary circulation, 589–590
  respiratory mechanics in, 588, 589f
  scoliotic angle determination in, 587, 588f
Kyphosis. *See* Kyphoscoliosis

L
Labetalol
  for alpha-adrenergic stimulation from drug overdose, 1504
  for aortic dissection, 407–408, 407t
  for cardiogenic shock, in pregnancy, 1599
  for hypertension
    from PCP intoxication, 1534
    in subarachnoid hemorrhage, 991
  for hypertensive crises in pregnancy, 1603, 1603t
Labor, with cardiac disease, 1599
La Crosse (California) encephalitis, 869–870, 869t, 870t
Lactate, 1204
Lactate dehydrogenase (LDH), in myocardial ischemia diagnosis, 315–316
Lactated Ringer's, with CPR, 183
Lactic acidosis, 1204
  in acute respiratory failure, 419–420
  on left ventricular systolic function, 273–274
  in leukemia, 1098
  in malaria, 930
  with malignancy, 1105
  in shock, 253t
Lactulose, for hepatic encephalopathy, 1293
Laminar airflow, 456
  adverse effects of, 773, 774t
Laminectomy, antibiotic prophylaxis for, 642t
Lamivudine (3TC). *See also* Nucleoside reverse transcriptase inhibitors (NRTIs)
  adverse drug reactions of, 679
  for AIDS, 773
  clinical pharmacology of, 678–679
  for hepatitis B suppression after liver transplantation, 1361
  for virus-induced fulminant hepatic failure, 1282
Large bowel. *See also* Gut
  traumatic injuries to, 1433–1434
Large supratentorial cerebral hemispheric infarctions, 1019–1021, 1020f
Laryngeal mask airways (LMAs)
  with difficult airways, 471, 472f, 473f
  intubation with, 471, 472f
Laryngeal nerve, 455
Laryngeal obstruction, 458–462
  amyloidosis in, 461
  angioedema in, 461–462
  arthritis in, 461
  aspirated foreign bodies in, 460
  endotracheal intubation in, 459–460, 459t
  iatrogenic causes of, 460
  infections in, 458–459
  neck injury in, 460
  neoplasms in, 461
  relapsing polychondritis in, 461
  sarcoidosis in, 461
  thermal injury in, 460
  toxic chemical inhalation in, 460
  vocal cord closure abnormality/paralysis in, 460–461
  Wegener granulomatosis in, 461
Laryngospasm, from fresh water or sea water, 1699
Laryngotracheitis, airway obstruction from, 459
Laryngotracheobronchitis (croup), 891
Larynx, anatomy of, 455–456, 456f
Lassa fever, 941t, 942t, 946–947. *See also* Hemorrhagic fevers, viral
Lateral pharyngeal space, 884
  anatomy of, 884–885, 887f
Lateral pharyngeal space infections, 884–888
  anatomy in, 884–885, 887f
  clinical features of, 885, 885t, 888f
  postanginal sepsis in, 885–886
  suppurative jugular thrombophlebitis in, 885t, 886–887, 888f
  treatment of, 886t, 887–888
Lateral transtentorial herniation, 1011, 1011f
Latex
  allergy and anaphylactic reactions to, 1620
  prevalence of sensitization to, 1615–1616
Layout, ICU, in infection control, 42
LD-HCA stimulation test, 1221, 1223f
Lead
  antidote for, 1516t
  in herbal remedies, 1633, 1634t
Lead-time bias, 74
Leaky gut, 119
Leapfrog Group, telemedicine recommendations of, 32, 94, 98
Learning, affirmation of, 8
Left atrial compliance, decreased, v wave in, 151
Left atrial pressure (Pla), 243–244, 243f
  measurement of, 145, 145f
Left heart failure. *See also* Heart failure
  pulmonary edema from, 523t
Left ventricle, pressure-volume (compliance) relationship of, 154, 154f
Left ventricular assist devices, after heart transplantation, 1367
Left ventricular contractility. *See also* Left ventricular systolic function
  decreased, management of, 274–275, 275t
Left ventricular diastolic chamber stiffness
  on cardiac function curve, 270, 273f
  in cardiogenic shock, 255f, 258
Left ventricular diastolic pressure-volume (PV) relationship, in pulmonary embolism, 350, 350f
Left ventricular dysfunction, in critical illness, 271–278
  afterload on, 277
  decreased LV contractility in, 274–275, 275t
  decreased LV systolic function in, 271–276, 273t. *See also* Left ventricular systolic function, decreased
  heart rate and rhythm abnormalities on, 277
  increased diastolic stiffness in, 275–277
  valvular dysfunction on, 277–278
Left-ventricular end-diastolic area (LVEDA), fluid responsiveness and, 155
Left ventricular end-diastolic pressure (LVEDP)
  left ventricular end-diastolic volume relation with, 373–374, 374f, 375f
  vs. LV end-systolic pressure, 234, 234f
  pulmonary artery wedge pressure and, 154, 154f
Left ventricular end-diastolic volume (LVEDV)
  in cardiogenic shock, 255f, 257, 258
  pulmonary artery wedge pressure and, 154, 154f
Left ventricular end-systolic pressure (LVESP), *vs.* LV end-diastolic pressure, 234, 234f
Left ventricular failure
  from acute myocardial infarction/ischemia, 258
  in cardiogenic shock, 257–259, 257t
    cardiac arrhythmias in, 259
    diastolic dysfunction in, 255f, 257t, 258
    systolic dysfunction in, 255f, 258
    treatment of, 259
    valvular dysfunction in, 258–259
Left ventricular hypertrophy (hypertrophic cardiomyopathy). *See* Hypertrophic cardiomyopathy
Left ventricular pressure (LVP). *See* Cardiac function curve
Left ventricular pressure-volume (compliance) relations, 154, 154f, 268–269, 269f
  in cardiac function curve, 268–269, 270f
Left ventricular systolic function, decreased, 271–276

acute causes of, 272–274, 273t
chronic causes of, 271–272, 273t
diastolic stiffness in, increased, 275–276
management of, 274–275, 275t
Legal issues, 53–60
decisional capacity and surrogate decision making in, 54–55, 60. *See also* Withholding/withdrawing life-sustaining therapy
decisions to limit treatment in, 55–56, 61–62

Metals, heavy, antidote for, 1516t
Metaproterenol
for acute-on-chronic respiratory failure, 557
in pregnancy, 1605–1606
"Meth," 1519–1520
Methadone, pharmacologic properties of, 171t
Methamphetamine poisoning, 1519–1520
Methanol poisoning, 1519–1520, 1519t
antidote for, 1516t
diagnosis of, 1212
metabolic acidoses + elevated anion gap and osmolal gap in, 1508
Methemoglobin, for cyanide poisoning, 1526
Methemoglobinemia, 1500, 1530–1531, 1531t
antidote for, 1516t
drugs and toxins in, 1530–1531, 1531t
hereditary, 1530
oxygen saturation gap in, 1510
Methicillin
hypokalemia from, 648
interstitial nephritis from, 647
neutropenia from, 648
for staphylococcal scalded skin syndrome, 1643
Methicillin-resistant *Staphylococcus aureus* (MRSA), 45–46
Methimazole
mechanism of action of, 1238t
for thyrotoxicosis, 1237, 1238t
Methodological rigor, of severity-of-illness scoring systems, 65
Methotrexate
adverse effects of, 1586–1587
for bullous pemphigoid, 1638
for carcinomatous meningitis, 1105
for CNS leukemia, 1094–1095
for dermatomyositis and polymyositis, 1029, 1586
diarrhea from, 1124, 1124t
for graft-*versus*-host disease, acute, 1117
hair hyperpigmentation from, 1632
hepatotoxicity of, 1132t
for leukemia, 1091t
neurotoxicity of, 1128t, 1129–1130
paraplegia from, acute, 1128t, 1130

Methotrexate (*Cont.*)
for psoriasis, 1639
pulmonary toxicity of, 1125t
renal and urinary toxicity of, 1130t, 1131
for respiratory failure in polymyositis/dermatomyositis, 1576
for rheumatic disease, 1586–1587
for rheumatoid arthritis, 1586
stomatitis from, 1124, 1124t, 1632
Methotrexate pneumonitis, 1576–1577
Methyl-CCNU, renal toxicity of, 1130t
Methylene blue, for methemoglobinemia, 1530
3,4-Methylenedioxymethamphetamine (MDMA), 1519–1520
Methylnaltrexone, for intestinal pseudo-obstruction, 1251
Methylparaben, anaphylactic reactions to, 1619
Methylphenidate overdose/toxicity, 1519–1520
Methylprednisolone
in critically ill, 1585
for graft-*versus*-host disease, 1117, 1642
for organ donors, 1384
properties of, 1225t
for respiratory failure
acute-on-chronic, 557–558
in polymyositis/dermatomyositis, 1576
for sickle cell disease, 1668–1669
for spine injury, 1417
for status asthmaticus, 570t, 572
Methylprednisone, in ventilator-induced lung injury, 504
4-Methylpyrazole (fomepizole)
for alcohol poisoning, 1519
for ethylene glycol poisoning, 1519t, 1520
for methanol poisoning, 1519t
Metoclopramide
in enteral nutrition, 123
neuroleptic malignant syndrome from, 1691
Metoprolol
for angina in myocardial ischemia, 318
for atrial fibrillation or atrial flutter, 305f, 306
dosing, adverse effects and drug interactions of, 300t
for heart failure, acute, 287
for myocardial infarction, 322
pharmacodynamics of, 297, 297t
pharmacokinetics of, 297, 298t
renal excreted active metabolites of, 1555t
for supraventricular tachyarrhythmias from theophylline overdose, 1536
for supraventricular tachycardia, regular narrow complex, 306, 307f
Metronidazole, 664–665
adverse effects of, 665
for amebiasis with HIV/AIDS, 782t
for appendectomy, 642t
for brain abscess, 853–854, 854t
for cervical fascial space infections, 886t
clinical pharmacology of, 665
Clostridium difficile diarrhea, 918t
for colon surgery, 642t
for febrile neutropenia, 744t
for giardiasis with HIV/AIDS, 782t
for gynecologic surgery, 642t
for hepatic encephalopathy, 1293
for HSV encephalitis, 867
for lateral pharyngeal or retropharyngeal space infections, 886t
mechanism of action of, 665
mechanism of resistance of, 665
for meningitis, 849, 849t
for myonecrosis, 904
for necrotizing fasciitis, 902
for necrotizing polymicrobial anaerobic mucositis with chemotherapy, 751
for peritonsillar abscess, 886t
for pneumonia, community-acquired, 835
for Pott's puffy tumor, 886t
for sepsis, severe, 716t
for subdural empyema and epidural abscess, 857, 857t
for suppurative intracranial thrombophlebitis, 857t, 859
for suppurative parotitis, 886t
for tetanus, 935t, 936
use of, 664–665
Mexiletine
dosing, adverse effects and drug interactions of, 299t
pharmacodynamics of, 297, 297t
pharmacokinetics of, 297, 298t
Mezlocillin, 646. *See also* Penicillin
for febrile neutropenia, 744t
IV dosing of, 646t
on platelet aggregation, 648
Micafungin, antifungal prophylaxis with, 760
Microangiopathic hemolytic anemia
from chemotherapy, 1131–1132
clinical presentation of, 1081–1082, 1082f
Microcirculatory obstruction, bleeding complications of, 1067
Micrococcus, in skin, 897
Microcoils, for GI tract embolization, 1487–1488
Microhematuria, 1437
Micro-occlusion, purpura fulminans from, 1641
Microscopic polyangiitis, lung infiltrates and renal failure in, 1579
Microvascular pressure, in perioperative pulmonary edema, 1323–1324
Midazolam
for intubation, 468, 468t
on opiate analgesic effects, 166, 169
pharmacokinetics and pharmacodynamics of, 172–173, 173t
for sedation, delirium from, 981
for seizures in children, 1004
for status epilepticus, 1003
acute convulsive, 1002t
refractory, 1003t, 1004
for tetanus, 935t, 936
Midbrain injuries, 1039
Midodrine, for hepatorenal syndrome, 1151, 1295
Migraine headache, with systemic lupus erythematosus, 1575
Migrating motor complex (MMC), 1249
Miliaria, 1650
Miliary tuberculosis, pneumonia from, 832, 833f. *See also* Pneumonia, community-acquired
Military antishock trousers (MAST), for pelvic ring injury, 1445
Milk-alkali syndrome, 1182
Milrinone
for cardiogenic shock, 328
for heart failure
acute, 287–288, 287t
acute on chronic, 280–281
for hypoxemic respiratory failure, acute, 246
for right heart syndromes, acute, 342
Minerals, trace, in enteral nutrition, 125–126
Minimal conscious state, 1038, 1038t
Minitracheostomy, 476
Minocycline
for brain abscess, 854t
catheter treatment with, 134
plus rifampin, catheter treatment with, 134
for *Vibrio vulnificus* bacteremia, 1644
Minoxidil, pharmacokinetics and cardiovascular effects of, 275t
Minute ventilation loads, in chronic obstructive pulmonary disease, 554
Minute volume, 628
Mithramycin
hepatotoxicity of, 1132t
for hypercalcemia, 1184t
Mitigation, 102
Mitochondrial disease, in respiratory failure, 1029–1030
Mitomycin
antidote to extravasation from, 1632t
hyperpigmentation from, 1632
as vesicant, 1632
Mitomycin C
hemolytic-uremic syndrome from, 1131–1132
myelosuppression from, 1123–1124, 1124t
pneumonitis/fibrosis from, 1125t
renal toxicity of, 1130t
thrombotic thrombocytopenic purpura from, 1081, 1131–1132
Mitotane, encephalopathy from, 1128t
Mitoxantrone
cardiomyopathy from, 1126t
for leukemia, 1091t
Mitral commissurotomy, 394
Mitral insufficiency, v wave in, 151
Mitral regurgitation, acute, 258
with acute MI, 290, 325–326
cardiogenic shock from, 258–259
v wave in, 151, 151f
Mitral stenosis, 392–394, 393f
Mitral valve incompetence, on LVEDV and stroke volume, 235f, 236
Mitral valve repair, for mitral regurgitation, 396
Mitral valve replacement
for hypertrophic cardiomyopathy, 390
for mitral regurgitation, 396–397, 397f, 397t
for mitral stenosis, 394
Mivacurium, for intubation, 468
Mixed connective tissue disease (MCTD), 1578
Mixed cryoglobulinemia, acute renal failure from, 1145
Mixed venous oxygen saturation ($S_{V_{O_2}}$)
clinical use of, 159
monitoring of, 158–159, 158f
Mixed venous oxyhemoglobin saturation, in pulmonary embolism, 349, 349f
Mixed ventilation modes, 486
Model for End-Stage Liver Disease (MELD), 1295–1296, 1295t
Moderating factors, 223
MODS, 24, 68
Momordica charantia, adverse effects of, 1633t
Monitor waveforms, bedside, real-time viewing of, 95
Monobactams, 652–653. *See also* specific agents
adverse drug reactions of, 653–654
anaphylactic reactions to, 1618
clinical pharmacology of, 653
IV dosing of, 651t
for pyelonephritis, 906

structure and mechanisms of action of, 653
for ventilator-associated pneumonia, 612t
Monoclonal antibodies. *See also* specific agents
for graft-*versus*-host disease, 1642
hypersensitivity reactions from, 1123
toxicities of, 1133
Mononeuritis multiplex, with HIV/AIDS, 790t, 792
Montelukast, for status asthmaticus, 570t, 572–573
Mood disorders. *See also* specific disorders
in ARDS survivors, 221
Moraxella catarrhalis pneumonia
community acquired, 834, 834t. *See also* Pneumonia, community-acquired
nosocomial, 837, 837t
ventilator-associated, 603
Morbidity. *See also* specific disorders
late, after ICU care, 217

Propafenone
  for atrial fibrillation or atrial flutter, 305f, 306
  dosing, adverse effects and drug interactions of, 299t
  pharmacodynamics of, 297, 297t
  pharmacokinetics of, 297, 298t
  renal excreted active metabolites of, 1555t
Propantheline overdose/toxicity, 1507t
Prophylaxis. *See also* specific agents and disorders
  antimicrobial
    for commonly performed surgical procedures, 642t–643t
    in critically ill, 641
    for endocarditis, 643t, 644t, 804, 806t
    for medical and dental procedures, 397, 397t
  with cytotoxic chemotherapy
    antibacterial, 758–759
    antifungal, 759–760
    antiviral, 760
  for intubation, 468, 468t
Propofol
  for intracranial pressure, elevated, 1405
  pharmacokinetics and pharmacodynamics of, 173–174, 175t
  rapid therapeutic effect of, 1553
  for sedation
    delirium from, 981
    of mechanically ventilated patients, 173–174
  for status epilepticus, refractory, 1003t, 1004
Proportional-assist ventilation, 450, 489
Propoxyphene
  overdose/toxicity of, 1507t
  renal excreted active metabolites of, 1555t
Propranolol
  for aortic dissection, 407t, 408
  for atrial fibrillation or atrial flutter, 305f, 306
  dosing, adverse effects and drug interactions of, 300t
  on end-systolic volume-pressure relation, 235
  ethnicity on sensitivity to, 1551
  mechanism of action of, 1238t
  overdose/toxicity of, 1522
  pharmacodynamics of, 297, 297t
  pharmacokinetics of, 297, 298t
  in thyroid storm, 1239
  for thyrotoxicosis, 1237, 1238t
Propylthiouracil
  mechanism of action of, 1238t
  for thyrotoxicosis, 1237, 1238t
Prostacyclin
  in acute lung injury/ARDS, 536
  for acute right heart syndromes, 342, 343
Prostaglandin E, for fulminant hepatic failure, 1285
Prostaglandin E_1, for acute right heart syndromes, 342
Prostaglandins, in anaphylaxis, 1615, 1616f, 1617
Prostatic infections, 910
Prosthetic heart valves, 396–397, 397f, 397t
  antibiotic prophylaxis with, 397, 397t
  for aortic stenosis, 388
  obstruction of, 396–397
Prosthetic valve endocarditis, 397, 397f, 808–809
  etiology of, 808–809, 809t
  microorganisms in, 811t
  treatment of, 805t, 809, 810t
Prosthetic valve thrombosis, acute heart failure from, 290
Protamine, anaphylactic reactions to, 1619–1620
Protease inhibitors (PIs), 682–684. *See also* specific agents
  adverse effects of, 773, 774t
  for AIDS, 773

Whole blood transfusion, 1059
Whole-bowel irrigation, for drug and toxin removal, 1513
Wide area network (WAN), in telemedicine, 96
Widow spider bite, 1537
Wintergreen oil, adverse effects of, 1633t
Wireless capsule endoscopy, 1275
Withdrawal syndromes. *See also* specific agents and therapies
treatment of, 981
Withholding/withdrawing life-sustaining therapy, 193–198, 201–206. *See also* Do not resuscitate (DNR) orders
clinical aspects of, 195–196, 203–204
definition of, 193, 201
ethical aspects of, 193–194, 201–202
legal aspects of, 194–195, 202–203
practical aspects of, 196–198, 204–206
Wolff Parkinson White syndrome, 304–306, 305f, 306t
Wound care
with burn injuries, 1469–1471, 1470f, 1470t
hypermetabolic-catabolic state on, 1474
muscle loss on wound healing rate in, 1474, 1475f
with electrical trauma, 1454–1455
with sepsis, 1471
Wound conversion, 1469

X
Xanthine oxidase, in sickle cell disease, 1658f
x descent
in constrictive pericarditis and restrictive cardiomyopathy, 152, 153f
in pericardial tamponade, 152, 153f
in right atrial pressure waveform, 143f, 144
x' descent, in right atrial pressure waveform, 143f, 144
Xerosis, 1650
"XG = TC," 1519–1520
Ximelagatran, for pulmonary embolism, 359
Xinjiang fever (Crimean Congo hemorrhagic fever), 941t–942t, 943–944. *See also* Hemorrhagic fevers, viral

Y
y descent
in constrictive pericarditis and restrictive cardiomyopathy, 152–153, 153f
in pericardial tamponade, 152, 153f
in right atrial pressure waveform, 143f, 144
in tricuspid regurgitation, 151, 152f
Yeast infection, with chemotherapy, 753–755, 754f
prophylaxis against, 760
Yeasts, 1649
Yellow fever, 941t, 950–951. *See also* Hemorrhagic fevers, viral
Yersinia enterocolitica diarrhea, 918, 918t
Yersinia pestis
in biowarfare, 960–961, 960f
pneumonia from, 834, 834t, 961
Young-Burgess classification, 1443–1444, 1445f

Z
Zafirlukast, for status asthmaticus, 570t, 572–573
Zalcitabine (ddC), 679, 773, 774t. *See also* Nucleoside reverse transcriptase inhibitors (NRTIs)
Zanamivir, 676
Zidovudine (AZT, ZDV). *See also* Nucleoside reverse transcriptase inhibitors (NRTIs)
adverse effects of, 678, 773, 774t
for AIDS, 773
on AIDS dementia complex, 790
clinical pharmacology of, 678
myopathy from, 792–793
Zinc, in enteral nutrition, 126
Zinc oxide, for erythroderma, 1640
Ziprasidone
for delirium, 981
neuroleptic malignant syndrome from, 1691
Zoledronic acid, for hypercalcemia of malignancy, 1106
Zolendronate, for hypercalcemia, 1184, 1184t
Zoster encephalitis, 868
z point, 154
